Aggression Psychiatric Assessment and Treatment, *edited by Emil F Coccaro*

Series Introduction

In the late 1950s and early 1960s many of the senior professors of psychiatry, including those who were psychoanalysts, also had extensive training in neurology. Some departments, including the one in which I trained, were departments of psychiatry and neurology. To be certified as a psychiatrist, one of the three patients you examined and were questioned about was a patient with primary neurological disease. We were expected to know how to recognize seizure spindles in an EEG, and to be able to point out the anatomy and pathology visible in brain slices. The neurology candidates were similarly examined and questioned in psychiatry. Many practitioners did a bit of both: for example, the senior neurologist in the department in which I trained made his own diagnoses of depression, and administered ECT to the patient in his office.

Outside the "black box" of the skull, our ties to the rest of medicine were not as strong. This was true despite the attempts to promote both concepts of "psychosomatic" medicine and humane care. Unfortunately, neither the concepts nor the data were strong enough to carry the day. More recently, however, the development of new technologies, such as imaging and explication of the genetic code, has resulted in an explosion of knowledge about human biology and pathology. Newer findings have begun to break down the barriers between psychiatry and neurology, and between our understanding of behavioral disorders and the rest of medicine. While I do not believe that we will ever be able to do without a psychology in psychiatry, it is also increasingly clear that psychiatry cannot function without understanding the biology of the brain.

Drs. Soares and Gershon have done an excellent job in bringing together a group of outstanding contributors who bring this new understanding to our field. They have presented the complex material clearly and comprehensively, making it easier to master—a necessary task if we are to continue to help our patients.

William A. Frosch

Foreword

With the publication of the *Handbook of Medical Psychiatry*, Drs. Soares and Gershon have recaptured the traditions of psychiatry over the past century, added the impressive technical capacities of the field in the last decade, and created an important educational resource for this new century. The deceptively simple title of the book belies the scope and depth of the volume. The chapters are organized, in part, by major diagnostic categories (e.g., mood disorders, schizophrenia, and related disorders, etc.), but also by significant crosscutting issues such as research methods and psychopharmacology.

Within this rich composite of important theoretical and practical information the editors have integrated critical themes of modern psychiatry such as:

Classification/nosology. DSM-III and -IV and ICD-10 are clearly interim steps in the development of disease-based classification systems for psychiatry. However, movement from phenomenology to etiolo-pathogenesis will have many steps along the way. This book examines fundamental issues in diagnosis across the range of psychiatric disorders and will help prepare psychiatrists to better understand strategies to move along that path.

Mechanisms. Ultimately, a disease-based classification will require the elucidation of the basic mechanisms underlying mental disorders. The book presents, in a provocative manner, current leads in neurochemistry, neurocircuitry, molecular biology, and genetics, among other fields.

Tools. Realizing that a more comprehensive understanding of basic mechanisms will evolve over decades, the authors have provided the reader with an understanding of the remarkable tools now available in imaging, molecular biology, and genetics. These new technologies enable researchers to open the "black boxes" of the brain, the cell, and the gene. Understanding how these tools are applied and getting a taste of current findings will enhance the reader's ability to become educated consumers of the barrage of information that is, and will be, emanating from the tremendous growth of research activity in psychiatry.

Evidence. Over the past decades, the values of psychiatry have become more and more closely aligned with the values of science. As such, the ability to interpret and evaluate scientific evidence and augment it with clinical insights is a critical skill. It is a skill that must be not only learned during medical school and

residency but also continuously exercised over the course of every psychiatrist's career. The authors have effectively captured the essence of that task in this volume. Readers who engage this important and challenging material will be revitalizing those skills and also preparing themselves for the future. Impressively, Drs. Soares and Gershon have enlisted the talents of many of the world's leading clinicians and scientists in this ambitious work. Even more importantly, they have tapped some of the most promising younger psy-

chiatrists who will be major contributors in expanding our understanding of psychiatric disorders in the future.

Harold Alan Pincus, M.D.
Professor and Executive Vice Chairman
Department of Psychiatry
Western Psychiatric Institute and Clinic

Pittsburgh, Pennsylvania

Preface

Over the past few decades, increasing emphasis has been given to the study of brain mechanisms that may be dysfunctional in neuropsychiatric illnesses. In recent years, new methodologies from various disciplines in the clinical neurosciences have made available substantially improved and more sophisticated tools for studies of causation of these severe illnesses. For instance, we have seen tremendous progress in knowledge from disciplines such as molecular genetics, neuropsychopharmacology, and brain imaging, which has provided unprecedented tools for studies of the human brain and neuropsychiatric illnesses. These efforts have begun to produce important findings and are beginning to contribute to a better understanding of the basic mechanisms involved in these disorders and the mechanisms of actions of treatments for these conditions, and lead to the development of new therapeutic possibilities.

The *Handbook of Medical Psychiatry* summarizes the main advances in the understanding of the basic mechanisms and therapeutics of the major psychiatric illnesses that have taken place in recent years. The format provides easy access to new information in these areas, making the book of significant interest to academicians, researchers, practitioners, students, residents, and trainees in psychiatry, clinical neuroscience, and the mental health professions. We believe this book will be a helpful, comprehensive, and important resource for individuals in psychiatry and related fields.

Animal Models of Neuropsychiatric Disorders
Challenges for the Future

WILLIAM T. McKINNEY

Northwestern University Medical School, Chicago, Illinois, U.S.A.

I. INTRODUCTION

The major challenges for future animal modeling research primarily involve conceptual and philosophical issues. Despite the fact that there are a variety of animal models available for many psychiatric disorders [1–3] there are still widespread perceptions that (1) one cannot reasonably study human psychiatric disorders in animals, because psychiatric illnesses are inherently human, and (2) there are no animal models of the various psychiatric disorders available.

In medicine in general, animal models are generally accepted as important for research directed at understanding the mechanisms underlying human disease as well as the development of new treatments. In contrast, modeling of mental disorders in experimental animals has often been regarded as "a highly controversial or outright heretical idea" [4]. There is widespread skepticism regarding animal models in psychiatry, with virtually no organized federal programs/initiatives for encouraging and supporting research in this field. When the active opposition of components of the animal rights movement to research with animals is coupled with the above-mentioned lack of understanding of the role of animal models by leaders in the field (who sometimes have backed off encouraging further developments in this field in the face of the animal rights movement), the stage is set for continuing major problems. This in summary represents the major future challenges for the field of animal modeling research.

The above situation is ironical given the role that research utilizing animal models has played in advancing the understanding of psychiatric disorders. As will be discussed in the historical section, the first data-based integrative theories of psychopathology grew largely out of animal research and/or improving treatment approaches. Since psychiatric disorders need to be understood by using a multivariate approach, animal studies, where variables can be controlled, have the potential for permitting the study of both the main effects of single variables and especially their interaction. Such approaches are highly relevant to what has recently been termed the "biopsychosocial" view of human psychopathology [5].

Research with animals has also been critical in broadening our understanding of human development and in providing empirical support for the importance of early experiences for behavioral and neurobiological development. Work with multiple species has documented the central importance of early social attachment systems and has clarified the behavioral and neurobiological variables mediating the development of these attachment systems [6–10]. Such concepts are

by now woven into the fabric of development theory in adult and child psychiatry, and it was experimental animal research that provided the fundamental basis for this knowledge. Furthermore, research with experimental animal systems has documented the devastating and long-term behavioral and neurobiological effects, including effects on brain cytoarchitecture, of never letting such attachment systems develop or of their intermittent disruption at certain developmental stages [11–14].

Studies utilizing animal models have also focused on the interaction between social functioning and neurobiological status and have documented the interactive and reciprocal nature of these relationships in paradigms that would be impossible to implement in human studies [15,16]. In addition, the impact of different types of stress has been extensively explored in animal models and in some instances genetic strains have also been identified or developed which exhibit similarities to clinical syndromes [17,18].

Though there is no perfect animal model with regard to predicting clinical efficacy of pharmacological agents, their use has been critical in the discovery and development of drug treatments [19–22]. There are always false positives and false negatives, but there are experimental paradigms with a high degree of empirical validity. Given a new era of drug discovery and development, there will likely continue to be many challenging issues in this context.

Despite these and many other contributions, acrimonious debates about the validity and/or usefulness of animal models for psychiatric disorders persist. The evaluation of animal models for psychiatric disorders is complex. Unfortunately, there is not yet any single laboratory finding or set of findings for any clinical psychiatric syndrome that one could insist upon as part of the validating criteria. Thus, one largely relies on a combination of behavioral measures and response to known clinically effective agents. Part of the challenge for the future may be to reconsider the validity measures of animal models and to reconceptualize expectations.

There is no "perfect," complete, or comprehensive single animal model for any specific psychiatric disorder. Indeed, there will likely never be an animal model in any field of medicine that is a perfect fit with the human condition; rather the emphasis in the development and study of disease models in animals needs to increasingly focus on specific components of the human illness.

Animal models of diseases in medicine, including psychiatry, need to be understood in a historical and evolutionary perspective and their advantages as well as limitations recognized. Neither overextended cross-species comparisons nor unjustified negativism about animal models seems defensible.

An especially critical challenge in the continuing development and utilization of biobehavioral animal models in psychiatry is their relationship to the molecular neurosciences, including genetics. Given recent advances in the molecular neurosciences relevant to mental disorders, the role of animal models in this context needs to be reconsidered. Failure to do so could lead to an excessively narrow view of animal models or a dismissal of the entire area. Danger signals already exist in this regard. Some contend that, given the new molecular techniques, animal models no longer have a place in psychiatric research. Others have taken the position that since psychiatric illnesses are so difficult to model in animals, we will need to do most of the research on mental disorders in clinical populations [23]. There is also tension between those who think that while one can, with high validity and reliability, measure, for example, receptor functioning in certain brain regions, the measure of behavior in animals lacks comparable scientific precision [24]. Unfortunately, the latter reflects a serious lack of communication between fields because the quantitative assessment of animal behavior is a well-developed science.

With the increasing advances in molecular biology and genetics, functional neuroimaging, and other methods for studying mental disorders, conceptualization of and research on behaviorally based animal models needs to be able to keep pace to maximally enrich psychiatric research. Despite several recent publications about the animal modeling field [25–28], there are many indications that the area remains poorly understood. This paper is an attempt to provide an overview of the past contributions of animal models and to propose some new perspectives that might be helpful in reevaluating the role of animal models in better understanding the major psychiatric illnesses. In an attempt to focus on some fundamental issues and challenges regarding animal models as they relate to neuropsychiatric disorders, a review of available models for each disorder becomes impossible. To attempt such a review would certainly shortchange many important areas, so, rather than attempt this, appropriate references will be provided to articles where such models are discussed.

II. HISTORICAL CONTEXT

Pavlov, often said to have been the originator of research relevant to animal modeling of human psychopathology in general, used clinical terms and experimental techniques that now seem foreign to most clinicians. However, the fact that his work represented one of the first moves away from a strictly correlational method of behavioral analysis to the experimental study of psychopathology is of central importance [29].

Considering Pavlov and other early scientists [30–33], it is difficult to know what conclusions to draw about the early history of the field of experimental psychopathology research. From one standpoint it was not a particularly noteworthy beginning. However, the early pioneers may have been more successful than it appears in developing certain principles that seem to be being rediscovered today, including:

1. Demonstration that psychopathology could be experimentally studied in animals as well as in the strictly correlational studies done previously in humans.

2. Demonstration of the importance of both careful behavioral observations and serendipity. Although most of the early workers did not use the more sophisticated and quantifiable behavioral scoring techniques now available, they were keen observers and literate in their descriptions.

3. The repeated proposal of an interactive model of psychopathology. The role of the temperament of the animals, along with a variety of social and neurobiological variables, was repeatedly stressed in the early literature. The concept of individual variability was part of the early work, and investigation of the sources of such variability continues to be an important area of research.

4. Recognition that there could be a persistent internal response, even after the inducing stimulus was no longer present, a discovery that remains a major contribution to the understanding of a number of forms of psychopathology.

5. Recognition of the importance of unpredictability and uncontrollability of which systematic investigations continue today [5].

III. ETHOLOGICAL CONTEXT

This section touches on some principles of ethology important in evaluating and understanding experimental animal research and a few selected research approaches. Avoidance of misleading clinical labeling based on superficial comparisons across species is critical. However, behavioral profiling in a given species can be done with a degree of precision comparable to other methods in neurobiology. Evolutionary biology principles then need to be understood and applied when it comes to interpretation of these phenomena. Ethology focuses on describing and understanding "animal behavior in the natural habitat and assumes operation of evolutionarily conserved basic plans encoded in the genome. Such basic plans determine behavioral patternings including flexible variants involving learning. Human ethology has emerged as a subdiscipline, including observations of psychiatric patients. The research involved has produced an enormous and varied literature" [34].

Gardner describes this interface as follows:

Sensitive observers have noted that relationshipless psychiatry seems the objective of much current psychiatric practice augmented by the cost-conscious managed care industry. Such a peculiar objective can stand almost unopposed in part because psychiatry has no basic science other than that limited to drug actions on the one hand and venerable, used but unproven and unphysiological theories of psychotherapy on the other hand. Adopting a perspective that shows human relatedness to other animals (near identity of genome) yet human uniqueness (with a massively larger brain) would underline the importance of people for other people that would augment the psychiatric enterprise. Human bonding and human competition shares much in common with other species, yet has its own flavor likely stemming from the human capacity to use stories in many ways. An important step towards psychiatry as a relationship-focused enterprise might come about if there was an explicit label for it. Sociophysiology could furnish that label to emphasize the importance of weighing the following as equally important while interactive: complex behaviors especially communicative ones, ancient reaction patterns, brain functions, cellular actions and genomic mechanisms [35].

Gardner described modeling as depending upon brain-body factors that the animal and humans possess in common. While behavior patterns may be species specific, "core components shared by related animals are typically embroidered through natural selection to produce modified methods of survival and reproduc-

tion" [34]. He cites the example of human brains which contrast in size to those of other animals, weighing three times more than brains of surviving large primates or those of human ancestors 3 million years ago. The contrast with other primates especially stems from a massively enlarged neocortex, especially the frontal lobes, with these increases likely stemming from advantages of social functions. Despite differences, the human brain and behavior also show comparability to those of other species through widely shared, conserved features. Gardner contends that this comparability makes continued use of animals important for the study of the pathogenesis, mechanisms, and treatment of mental disease. "Lack of a sufficient database as yet limits other modeling efforts such as computer simulations, mathematical models, and experimentally induced states in hums, and research on animals remains indispensable" [34].

Homology and convergence are important ethological concepts which can serve as frameworks for helping to understand comparative cross species behavior.

> Homology means that a common ancestor once possessed a trait now shared by two species. At points in the past, humans shared common ancestors with monkeys, mice, chickens, fish, insects, and single celled organisms, each such forebear more remote in biological history. In contrast, convergent traits are similar features that stem from environmental shaping through natural selection, although basic plan starting points vary. Wings of insects, bats and birds illustrate this. Ancestors of each animal group had not flown so airborne ability evolved separately and the three kinds of wings illustrate convergent evolution on the level of aerial locomotion. As vertebrate upper extremities, however, wings of bats and birds are homologous to each other but not to the wings of insects. If the starting point of the basic plan generalizes to contractile tissue, however, locomotory body extensions of all three achieve homology [34].

There is great excitement with genome projects of species at different phylogenetic levels and importance. The genome seems to contain at least a partial record of the organism's ancestry, and therefore genomic analysis may help determine evolutionary history (homology) which in turn may foster knowledge of proximal neuronal determinants of behavior. However, this is a very complicated area, and simplistic and overly optimistic expectations will likely fail. As Gardner says, at the behavioral level, redundant, multiply determined

brain-behavior adaptations complicate inference, and at the DNA level, genetic transformations such as chromosomal crossovers will reduce certainty about genomic hypotheses [34].

IV.   DEFINITIONAL/CONCEPTUAL ISSUES

Animal models are experimental paradigms developed in one species for the purpose of studying specific phenomena occurring in another species. By definition they are not the "real thing." There will always be differences and similarities between models and what is being modeled; otherwise it is not a model. Furthermore, there is no single comprehensive animal model for any mental disorder and probably not for any general medical illness. Thus, animal models should be judged primarily by their relevance to specific questions that they are being used to address rather than their scope. They permit the evaluation of selected aspects of human psychopathology in a systematic and controlled manner and represent simplified and abstracted versions of behavior and physiology, which can be used to develop hypotheses applicable to humans and/or to test hypotheses originating from clinical work [34].

V.   TYPES OF ANIMAL MODELS

The following overlapping categories of animal models [29,36–39] have been proposed.

A.   Behavioral Similarity Models

These types of models are designed to simulate specific symptoms of a human disorder in animals. The primary intent is to produce a particular set of behaviors that are similar to those shown by humans with a certain illness, rather than to evaluate any specific etiological theory or to study underlying mechanisms or even treatment responsiveness. The validity of these models is judged by how closely the model approximates the human disorder from a phenomenological standpoint [29]. Inducing conditions became secondary.

B.   Theory-Driven Models

In these approaches a theory drives the development of specific experimental paradigms. One does not assume the validity of the theory in order to proceed with the research. Rather, the goal is to operationalize the theory one wants to evaluate and study prospectively

the efforts of specific manipulations designed to represent putative causative factors.

C. Mechanistic Models

In these kinds of models, animals are used to study mechanisms. With the increasing array of methods for studying pathophysiology, there has been a preoccupation with the molecular and submolecular basis of altered behavior seen in many animal models. Some would consider that the only useful animal models are those which permit these types of studies.

While mechanistic studies can include evaluation of both neurobiological mechanisms as well as social, behavioral, and developmental mechanisms, one cannot necessarily transpose techniques of mechanism studies cross species, i.e., from humans to rodents to primates or vice versa from rodents to monkeys. The study of mechanisms needs to be specific for a particular species. A serious challenge for animal modeling research is the development and utilization of techniques for mechanism studies in socially behaving animals. Some compromises between invasiveness of neurobiological studies and assessment of social behavior may be necessary [29]. Insistence on cross-species mechanistic similarities is premature given that at present we have no mental disorders in humans uniquely linked with a specific mechanism.

D. Empirical Validity Models

Perhaps the best-known and widest use of animal models involves the use of animal preparations to develop and test potential clinically active drugs. In this context, an ideal animal model is one in which there are no false positives and no false negatives; that is, when a drug works in animals it is predictive of its clinical effects in humans, and when it is inactive in animal models it will not have clinical efficacy in humans. Although there are a number of models with high empirical validity, there is never 100% correspondence between the effects of a drug in an animal model and in a clinical condition. The establishment of an animal model as valid on empirical grounds (or on any other grounds) does not necessarily establish its validity on other parameters.

E. Genetic Models

Genetic models involve studying strains that exhibit spontaneous behaviors that mimic a given illness.

Through selective breeding, some investigators have developed animal strains that are especially sensitive on certain tests. This topic is discussed more extensively elsewhere in this chapter.

VI. VALIDATION CRITERIA FOR ANIMAL MODELS

In 1969 McKinney and Bunney [36] made explicit the concept of using animal models for studying human depression and proposed for the first time criteria to consider in developing and evaluating animal models in general. Subsequently, modified or expanded sets of criteria were presented [5].

Willner [39] has described three different concepts of validity:

1. *Predictive validity* primarily concerns the correspondence between drug actions in the animal model and in clinical situations. Manipulations which have certain effects in humans should have similar effects in the animal model for that model to be valid from this standpoint. Using this criterion, there will always be false positives and false negatives. Not all agents that work in an animal model will also work in humans, and not all drugs that work in humans will necessarily work in animal models. There is no animal model that has perfect concordance in this regard. In terms of evaluating animal models according to this criteria it is the pharmacological profiling that is critical rather than the response to just one drug.

2. *Face validity* means that there are phenomenological similarities between the model and the illness being studied. In any one model it is never possible to model all the composite patterns of behaviors shown rather than the presence or absence of any one behavior or symptom.

3. *Construct validity* refers to the theoretical rationale for the model, which in turn relates to the theoretical understanding of the clinical condition and its causation. Unfortunately, too many proposed animal models utilize single proposed etiologies rather than a concept involving multiple risk factors. One of the exciting challenges for future animal models is the evaluation of the relative contributions of various risk factors thought to be important in the human syndrome in question.

Geyer [1] makes the point that, before criteria can be considered, it is important to be explicit about the intended purpose of the model which will determine in part the criteria that should be utilized in evaluating its

validity. He contends that for a model to be of value in it must satisfy only two criteria: reliability and predictive validity. He does not think that construct validity is essential.

VII.   SIGNIFICANCE OF ANIMAL MODELS

As Willner has stated [37,39,40], animal models form an important interface between clinical psychiatry and basic research in behavioral neuroscience. In this context they represent major modalities by which developments at the basic level can be brought into a clinical perspective and clinical theories can be evaluated in a controlled manner. This viewpoint contrasts sharply with the position that animal models have no more use since, for example, we can now discover and design drugs that are very specific and can go directly to testing in humans.

The significance of animal models is also their role in the specification and study of focused components of a clinical syndrome. Experimental paradigms in animals permit evaluation of selected aspects of human psychopathology in a systematic and controlled manner. Their obvious advantage is in the ability to precisely control and alter inducing conditions and to permit the collection of prospective data on both a short- and a long-term basis and permit a broader range of mechanistic studies. For example, in relation to depression, prospective studies examining the effects of developmental events on behavior and on neurobiology can be done much more easily in animals. The timing and exact nature of certain alterations in development can be specified, and the short- and long-term consequences studied. That aspect of modeling research is relevant to the question of developmental vulnerability based on early experiences and the mediating mechanisms of vulnerability.

Animal models make possible the dissection of mechanisms in a more direct way than is possible in human clinical research, and they complement ongoing efforts in human protocols, although such procedures need to be suited to both the species and the overall purpose of the experimental paradigm. The research questions have to be clear and specific.

It is easier in animal studies to isolate and evaluate single variables in terms of their main effects and their interaction with each other. For example, the nature of the interactions among genetic, developmental, social, and biological variables can be studied in various combinations in different species. In human clinical research, multiple variables interact simultaneously, and it has been virtually impossible to sort them out in any quantifiable way.

Of course, animal models are most widely utilized in the preclinical evaluation of drugs. A related aspect is their contribution to a better understanding of the mechanism of the action of drugs in altering specific behavior patterns that goes beyond a mere prediction of whether drugs work or not [29].

Studies utilizing animal models can also help to understand the mechanisms of established treatment techniques, i.e., why do some treatment work in certain paradigms whereas others do not? A type of significance which is often not recognized is that animal modeling research has led to the development of improved behavioral, ethologically based rating methods that are now widely used in clinical research settings.

The following quote is focused on affective disorders but, when considering the significance of animal models for psychopathology in general, contains principles applicable to any psychiatric disorder:

> The traditional difficulties in accepting animal models for psychopathology stem from the argument that there is no evidence for what occurs in the brain of the animal that is equivalent to what occurs in the brain of a human. However, if one models any or some core aspects of affective disorder, this model can become an invaluable tool in the analysis of the multitude of causes, genetic, environmental or pharmacological, that can bring about symptoms homologous to those of patients with affective disorders. Animal models can also allow the study of the mechanisms of specific behaviors, their pathophysiology, and can aid to develop and predict therapeutic response to pharmacological agents.
>
> The use of animal models in the research of affective disorders is multifold. Firstly, these models offer experimental systems that may provide insights into the multitude of causes, genetic, environmental or pharmacological, that can bring about symptoms homologous to those of patients with affective disorders. Models also allow study of the development of specific behaviors and their underlying neuroanatomical substrates and neurochemical mechanisms. Finally, animal models can be utilized to develop and predict therapeutic response to pharmacological agents and investigate their putative mechanisms of action [41].

VIII. CHANGING ROLE OF ANIMAL MODELS

A. Neurosciences

Rapid developments in the basic and clinical neurosciences have presented and will continue to present opportunities yet also serious challenges for animal modeling research. On the positive side has been the general recognition of the importance of having experimental animal models if one is going to better understand the pathophysiology of psychiatric illness and move beyond correlative research. Indeed, some contend that the only useful animal models are those that permit molecular mechanistic studies to be done. However, as important as these types of models are, they are not the only useful types of animal models. There is also a role for more integrative models that will facilitate the study of vulnerability factors in a broader context. Conceptualizing animal models narrowly in a deterministic basic neuroscience context has had some unfortunate consequences in terms of the field's development in that attention to the development and study of new biobehavioral models has been diminished along with critical research on already existing models.

"Mechanisms" should not be viewed as synonymous with "molecular." There is far more involved in understanding mechanism of behavior than molecular genetics and molecular biology. Some animal models will lend themselves to molecular biological studies of mechanisms; others will allow other kinds of contributions. Many major discoveries that have significantly impacted clinical psychiatry have come from either behaviorally oriented studies in animals, e.g., the significant enhancement of our understanding of developmental theories and attachment systems, and/or have been based on empirical observations of animal behaviors in relation to drug treatment, e.g., the initial observations by Cade of lithium's calming effects in guinea pigs [42].

A major challenge/opportunity for the development of animal models in the future relates to alterations of circadian rhythms which remain among the most pervasive and consistent findings in several types of mental disorders, especially the mood disorders. A considerable amount of research needs to be done to understand the mechanisms that underlie this connection. One context to begin to understand these mechanisms is at the interface between development/early experience, social stress, and circadian rhythms. This approach could serve as the nexus of a new approach to animal models which incorporates genetic, developmental, and social stress issues. With the identification and characterization of the first mammalian circadian clock gene [43], some exciting cross-species approaches with high relevance to human disorders are going to become possible.

B. Stress Vulnerability

Early theories of the origins of human psychopathology focused on the importance of a variety of early life relationships and events. With the advent of a new era of neurosciences, interest in such developmental events has waned in many quarters. However, research utilizing animal models over the past 25 years has continued to steadily emphasize that these development stressors are important and can have long-term effects on brain and neurobiological development [44–47]. Obviously such events do not operate in a vacuum. The role of genetic vulnerability and how this interacts with developmental events and their consequences is an extremely important and newly emerging area of research in which experimental animal models can play an increasingly important role. Major theories have been proposed that provide an integrated developmental neurobiological perspective of depressive disorders [48–51] and of schizophrenia [52]. In terms of this approach, animal models have already contributed and have great potential for the future [13,53–59].

C. Clinical Disorders

At present, diagnostic criteria for most human clinical disorders involve both a time dimension and signs and symptoms. Since the defining criteria for animal models of psychiatric disorders rely heavily on observed behaviors, a research challenge is to operationalize in animals what in humans are reported as subjective symptoms. Of course, an animal cannot tell one whether it has a certain symptom or not; however, it is possible to measure in animals such things as motor activity, food and water intake, weight, sleep, a range of social activities, changes in self-rewarding activities, and cognitive behaviors. A collection of changes in such behaviors might be postulated to resemble the symptoms or behavioral changes shown by humans diagnosed as having a certain illness, and by working within proper ethological frameworks cross-species research can aid in the understanding of human illness.

Rather than trying to model an aggregate of symptoms, another approach is to focus on the experimental production of a more limited set of behaviors and to

use animal preparations to study these behaviors, e.g., anhedonia, uncontrollability, or changes in social and self-directed behaviors.

What induction techniques to use? There are two broad approaches in utilizing induction procedures. One approach is to use those for which there are data to suggest that they might be important in the etiology of human clinical disorders. An alternative approach is to not worry too much about the cross-species compatibility of inducing conditions, but to use procedures that will produce a set of behaviors in animals that bear some phenomenological similarity to a human illness.

IX.   GENETICS

Statements are beginning to appear that the best, or even only, approach to animal models is "genetic," though it is not totally clear what this means. However, with the established importance of genetic vulnerability, experimental paradigms to systematically study genetic variables in animal models are needed as part of an overall approach to the creation and development of animal models. Many techniques are possible. For example, two lines of work, both from the animal models of depression literature, can be summarized as illustrative of this approach. One involves selective breeding and the other study of a specified strain [5].

A.   Selective Breeding: Flinders–Sensitive Line (FSL) of Rats

The Flinders line rats [17,60,61] were developed by selective breeding for differences in effects of the anti-cholinesterase, di-isopropylfluorophosphate (DFP) on temperature, drinking, and body weight. The FSL line rats are more sensitive to DFP as well as cholinergic agonists and have more brain muscarinic receptors in comparison with the Flinders-resistant line (FRL). They were originally proposed as an animal model of depression because of reports that human depressives are also more sensitive to cholinergic agonists. The FSL rats also resemble depressed humans in some other ways: elevated REM sleep, appetite and weight changes, reduced activity and increased anhedonia after exposure to chronic mild stress, and exaggerated immobility in the forced swim test. Imipramine, desipramine, and sertraline have all been shown to reduce immobility in the forced swim test in the Flinders line rats. Lithium, bright lights, and DFP do not. Likewise,

amphetamine and scopolamine have no effect in the forced swim paradigm. The calcium channel blockers verapamil and nicardipine were effective in reducing immobility in the forced swim test. Overstreet [62] has also presented data that the FSL rats exhibit altered sensitivity to the locomotor suppressant effects of diazepam; however, anxiolytic effects of diazepam are similar in the FSL. They do not voluntarily drink much alcohol, unlike some depressed individuals. They also do not exhibit any model schizophrenic behavior. They found that swim test immobility cosegregates with serotonergic but not cholinergic sensitivity in cross breeds of Flinders line rats. In conclusion, they present the FSL rat as fulfilling the criteria of face, construct, and predictive validity for an animal model of depression.

B.   Specified Strain: Wistar Kyoto (WKY) Rats

Okamoto and Aoki [63] isolated a strain of Wistar rats with spontaneously developed hypertension, the SHR rat. Its normotensive inbred progenitor strain, the WKY rat not only differs from the SHR in respect to resting blood pressure, but also displays smaller stress-induced increases in plasma catecholamines [64], heart rate, and blood pressure [65–67]. In contrast, WKYs show larger endocrine and behavioral responses to stress than SHRs and a heightened susceptibility to stress ulcer. WKY rats [18,68,69] have been proposed as another animal model of depression based on the fact that they (1) exhibit hypoactivity in open field and defensive burying tests (2) readily acquire a learned helplessness task as well as a passive avoidance task; and (3) exhibit more depressive behavior in the Porsolt forced swim test of "behavioral despair" and desipramine reduces the immobility seen in this test. WKY rats also have a heightened susceptibility to stress ulcer and show evidence of heightened emotionality and an exaggerated stress response.

C.   Other Genetic Strategies

Another genetic approach would be to utilize targeted mutagenic strategies that rely on transgenic and recombinant DNA-based knockout technologies to create animal models in available biobehavioral tests, thus permitting, within the limitation of these strategies, better understanding of the role of various genes in the control of specific behaviors. A critical research challenge for the future is the question of what specific

strategies should be used to develop such models based on current knowledge of the pathophysiology of various mental disorders.

Other genetic approaches could involve genetic manipulation of candidate genes leading to knockout or transgenic mice, chance findings of altered behavioral phenotypes in other, not a priori designed, mouse mutants, or systematic behavioral screening of mutagenized mice to gain novel animal models [41]. A theoretical advantage of the transgenic or knockout approaches is that a specified behavioral alteration can be assigned to a single gene mutation. However, compensatory mechanisms and genetic background are always at work and sometimes obscure the role of a specific gene in a behavior.

> A method that will gain influence over the next years is genome-wide or directed mutagenesis followed by screens for relevant phenotypes. The forced swim test has already been used as a pilot behavioral assay in a random mutagenesis screen [70], but the identification of a series of well-defined and well characterized tests with high predictive validity would dramatically increase the efficacy of such an enterprise.

X. NEW THERAPIES

A. New Methods of Discovering and Developing Pharmacological Therapies

Drug discovery is a multidisciplinary effort requiring chemical, structural, and biological approaches. This last includes animal models.

Historically, one of the major uses of animal models has been for the preclinical screening of proposed pharmacological treatment agents. In this context, a variety of experimental animal models have been developed which have reasonable empirical validity. Unfortunately, the presence of false negatives and false positives has led some to sharply criticize animal models and even refuse to use them in drug discovery and development.

A related position is that animal models, in the context of drug discovery and development, are irrelevant given newer molecular techniques for discovering and developing drugs. Newer therapies can be discovered based on hypothesized molecular mechanisms of illness and then moved directly to clinical trials. However, one of the major problems with this approach is that not enough is yet known about the specific pathophysiology of psychiatric illnesses to let that alone drive

the therapeutic discovery and development process. Some in vivo testing in animals remains critical to complement drug discovery based on novel mechanisms. Also, since psychiatric disorders are still largely defined by behaviors, it does not intuitively make sense to bypass behavior in the drug discovery and development process [5].

XI. ANIMAL RIGHTS ISSUES

This is one of the foremost challenges with regard to animal modeling research [71,72]. The use of animals for biomedical research in general, and especially for neuropsychiatric disorders, continues under serious threat [73–80]. Detailed discussion of the various groups and strategies is beyond the scope of this chapter; however, the issue is not animal welfare organizations who, in so many invaluable ways, help look after the welfare of needy animals and deserve our enthusiastic support. Likewise, the problem is not the thoughtful groups that share our genuine concern about the welfare of all animals and work to establish reasonable regulations. The problem is with those organizations that are dedicated to stopping animal research at all costs, including violence to researchers and to physical property, and who advocate senseless bureaucracy to discourage researchers from pursuing animal research. We all support the humane treatment of all animals in research and careful and diligent review of all research by independent groups—as is done with human clinical research. However, with the escalating tempo of violence and intimidation in this area that has occurred over the last 10–20 years, some government agencies have hesitated to move ahead with programmatic initiatives in the animal modeling research area, and some universities have been, at best, ambivalent in backing faculty doing animal research. The field has lost productive people as a result, and new, junior people have sometimes hesitated to enter the field. This is a major challenge for the field in the future.

XII. SUMMARY

There are a variety of animal models available for many psychiatric disorders. Just as in any other field of medicine, none are perfect. Indeed, if they were, they would be replicas rather than models. Continuing efforts need to be made to further understand and utilize the models that are available as well as to develop new ones. However, major challenges for the

future will also include dealing with the conceptual and philosophical issues that surround animal modeling research in psychiatry. Many of these have been summarized in this chapter.

Methodological Advances in Psychiatric Genetics

YOAV KOHN and BERNARD LERER

Hadassah University Hospital and Hebrew University School of Medicine, Jerusalem, Israel

I. RATIONALE FOR GENETIC RESEARCH IN PSYCHIATRY

Genes play a major role in determining and controlling every phenomenon in life. The inherited potential of the new embryo is encoded in the genes transmitted to him by both his parents. The activation or deactivation of certain genes at certain times governs the differentiation of embryonic stem cells into different tissues and systems. This influence goes on after birth and throughought the life span when the production of enzymes and structural proteins is under genetic control. In this way genes control the activity of cells, tissues, and body systems, produce disorders, and determine programmed cell death. Genes also mediate the influence of the environment. Nutrition, toxins, infectious agents, and psychosocial stresses can all affect the organism by activating or deactivating certain genes. Also, genes may affect the environment that a subject is exposed to. For example, it was found that monkeys with an inborn tendency to have low levels of serotonin metabolite in the CSF were more likely to be subject to violent death in a younger age [1].

When we try to better understand the etiology and pathogenesis of complex phenomena such as behavior, personality traits, and psychiatric disorders, it seems almost impossible to disentangle the numerous factors involved in their development. The situation is very different from research on metabolic disorders, where a biochemical imbalance is obvious and allows rapid characterization of the enzymatic defect and its etiology. In the case of schizophrenia numerous changes probably occur, from the hypothesized maldevelopment of the embryonic central nervous system during the first trimester of pregnancy until the onset of disease at the age of 15–20 years. That psychotic symptoms improve after the administration of dopamine D2 receptor antagonists tells us very little about the beginning of the process two decades before, nor can it help us define the contribution of inherited and environmental factors to the development of the illness.

This complexity of mental phenomena makes genetic research crucial to their understanding. Genes have been implicated in the etiology of almost every psychiatric disorder. The etiological role of environmental and psychosocial factors is also well recognized and, as noted above, may be substantially mediated through genes. Unlike environment, which is constantly changing and always difficult to characterize, genes remain unchanged for the most part from conception until death. Although the level of activation of genes does change throughout life, the DNA sequence remains practically constant. Thus we can find in the adult person with schizophrenia the same inherited predisposing genes that started the process of the disorder in fetal life. Identifying these genes would allow

us to understand the unfolding of this process and characterize the relative contribution of environmental factors. Ultimately, this would lead to improvement not only of diagnosis and treatment, but also of prevention. The strategy of starting research on the etiology of disorders by first finding the contributing genes, and then revealing the pathogenesis, is opposite in direction from classical research in medicine and therefore is called "reverse genetics." This methodology will be described in the following sections and is summarized in Table 1.

II. DEFINITION OF PHENOTYPES

Before a search for a disease-causing gene begins, one should correctly define the phenotype—who has the disease and who does not. It is widely aknowledged that psychiatric diagnosis is limited to subjective measures. The identification of genes that cause psychiatric disorders should improve our diagnostic capabilities imensely. The circular problem is that in order to find these genes we should make the correct diagnosis. Broadening the diagnosis to include as many individuals as possible with similar symptoms is doomed to hamper our effort to find the gene. It was shown, for example, that the transmission of schizophrenia is independent of the transmission of bipolar disorder [2]. But even categories such as DSM-IV-defined schizophrenia might be too broad. It is concievable that what we define today as one disorder comprised dozens of different diseases with different etiologies and clinical pictures. Narrowing down the diagnosis is an important step in ensuring that a homogeneous sample with the same genetic etiology is studied. This process should be based not only on theoretical hypotheses but on empirical data. Thus, patients can be subdivided according to

clusters of specific symptoms (such as negative or positive ones), neuropsychological tests or imaging studies (e.g., enlarged or nonenlarged ventricles). On the other hand, too much narrowing could lead us to false-negative results and to missing a gene that is expressed differently in different individuals. For example, the genetic liability to develop schizophrenia can also lead to a spectrum of related disorders such as schizotypal and schizoid personality disorders [3].

III. ESTABLISHMENT OF GENETIC ETIOLOGY IN PSYCHIATRIC DISORDERS

A. Family Studies

The first step in genetic research on any disease is to establish its heritability. The most obvious way of doing so is by studying the recurrence rate of the disorder in relatives of affected individuals. This rate should not be measured simply against the rate in the general population. Rather, the comparison should come from the study of relatives of healthy controls, who should be diagnosed using the same instruments. Raters should be blind to the proband's diagnosis. Family studies have revealed increased risk in relatives of probands with schizophrenia [2,4], bipolar disorder [2], major depressive disorder [5], obsessive-compulsive disorder [6], autism [7], attention deficit hyperactivity disorder [8], and anorexia nervosa [9], among others. Increased risk for relatives would suggest that the disorder is familial. This is not equivalent to its being genetic since family members share more than genes. Environmental factors such as nutrition, infections, and psychosocial stressors are also common to family members.

Table 1 Methods of Identifying Genes for Medical Disorders

Establishment of Heritability	Localization of Genes
Family studies	Parametric Linkage Analysis
Adoption studies	Nonparametric methods
Twin studies	Association studies: case control and family based
Segregation analysis	Haplotype relative risk (HRR)
	Transmission disequilibrium test (TDT)
	Allele sharing methods (sibpairs and pedigrees)
	Linkage disequilibrium in genetic isolates
	Quantitative trait loci (QTL)

B.   Adoption Studies

Adoption studies are designed to try to disentangle inherited from environmental etiological factors. The rate of the studied disorder is compared between biological and adoptive parents of individuals with a certain disorder. Alternatively, the risk of the disorder can be compared between offspring of affected individuals who were given for adoption and offspring of healthy individuals who were also given for adoption. A third and obviously rare paradigm would be the comparison of offspring of healthy parents who were either adopted by affected individuals or by healthy ones. The last variation is the study of offspring of affected parents who were either reared by them or adopted or reared outside their families (as in foster homes). These methods have mainly been used for the study of schizophrenia [3,10], bipolar disorder, and major depressive disorder [11,12], and have shown the major role of genetics in their etiology.

C.   Twin Studies

Twin studies are the gold standard of research on the genetic etiology of disease. The recurrence risk or concordance of a disorder is compared between monozygotic (MZ) and dizygotic (DZ) twins. MZ twins share 100% of their genes while DZ twins share on average 50% of their genes, as do any other pair of siblings. Researchers assume that MZ and DZ twins are similar in the degree to which they share environmental influences. While it is probably true that twins are exposed to the same kind of environment more than nontwin siblings, it is obvious that MZ twins experience a more unique and shared environment than DZ twins.

   The only way to overcome this limitation is by comparing concordance rates of MZ twins who were reared together or apart. As this is a rare phenomenon, it is quite impractical for genetic research. Nevertheless, twin studies are considered the best estimate of the heritability of the disorder, which is calculated from the difference in concordance between MZ and DZ twins. Thus, autism is considered to be highly heritable with an MZ concordance rate of 92% compared to 10% for DZ twins [13]. Bipolar disorder has also a high heritabilty rate with MZ concordance of 67% against 20% for DZ twins [14]. In schizophrenia the rates are also suggestive of a strong genetic component in etiology: 48% concordance in MZ twins and 4% in DZ twins [15]. Concordance rates also teach us about the importance of environment in the etiology of disorders. The 48% concordance rate for schizophre-

nia between MZ twins is a striking example. While a strong genetic influence is suggested, it also means that a person with the genetic predisposition to develop the disorder has $> 50\%$ chance of avoiding it, perhaps by avoiding a noxious environment or by experiencing some as yet unknown, protective factors. The study of discordant sibs or preferably discordant MZ twins can thus teach us on the role of environment. For example, it was shown that MZ twins with Tourette syndrome (TS), a neuropsychiatric disorder characterized by motor and vocal tics, varied in the severity of symptoms. The twins with a more severe clinical course had a lower birth weight [16].

D.   Segregation Analysis

After establishing the role of genetic factors in the etiology of a disorder, the next step is to try to define its mode of inheritance. This is done by studying large pedigrees with multiple affected individuals. The observed inheritance is compared with expected inheritance under various genetic models. The goodness of fit is calculated and certain solutions are rejected. Those that are not rejected are considered consistent with the data, which supports this solution as a possible mode of inheritance (although it does not prove it to be the right one). Using this method, most psychiatric disorders show a complex mode of inheritance. None of them is consistent with simple Mendelian inheritance (i.e., autosomal dominant or recessive, X-linked). Even models of oligogenic or polygenic inheritance (few or many genes with small contribution of each of them) must take into account the role of environment to fit the data. Thus, the model consistent with the inheritance of psychiatric disorders is usually termed multifactorial [17]. The impact of this on the choice of methods for genetic analysis is discussed below.

IV.   LOCALIZATION OF GENES THAT PREDISPOSE TO PSYCHIATRIC DISORDERS

A.   Parametric Methods

Until a decade ago the most widely used method employed to detect genes for inherited disorders was parametric linkage analysis. In this method large pedigrees with multiple affected members are studied. In each pedigree the inheritance of the studied disorder is compared with the inheritance of DNA markers with a known location on the human genome. The marker

can be chosen because of an a priori idea regarding the genetic location of the disease gene. This idea might stem from the study of affected individuals with chromosomal aberrations. This was the case in Douchene muscular dystrophy (DMD). The gene for this X-linked disorder was localized after the study of two females who had the disorder were found to have a deletion and a translocation in a certain region on chromosome X [18]. More frequently there is no idea about the putative location of the disease gene. In this case DNA markers spanning the whole genome are used in what is called a genome scan. These markers are usually DNA sequences with no genetic function known to us, but with slight variations from person to person. These variations, or polymorphisms, serve to mark a specific location on the human genome. Depending on the number of markers (usually in the order of hundreds), some gaps are left unchecked. Nevertheless, as nearby genes and markers are usually transmitted together from parent to offspring, we can compare the inheritance of the marker and of the disease in a certain pedigree. If the studied disease is inherited together with a specific marker, we have a clue about the location of the disease gene.

Take for example the hypothetical pedigree in Figure 1. From looking at the pedigree it seems that the inheritance of the disorder is indeed linked to the inheritance of the studied marker. The affected grandfather (#400) has transmitted the disease coupled with allele 1 of the marker to some of his offspring. The

possibility that true linkage exists between the two phenomena is compared with the possibility of observing this by chance. The ratio between these two probabilities is calculated. A ratio of 1000 in favor of linkage is traditionally considered significant. For practical reasons the ratio logarithm is used and called the LOD (logarithm of the odds) score. The LOD scores of different pedigrees can be summed together. Tight linkage (LOD score of >3) implies that the disease gene is located close to the studied marker. LOD score of -2 excludes the region as the possible location for the disease gene. When a genome scan is carried out, multiple testing for hundreds of markers is being done and thus a higher level of significance is needed. A LOD score of 3.3 was shown to correlate to a P value of .05 in this situation and is thus considered significant evidence for linkage in a genome scan [19]. LOD scores of 1.9, the magnitude of most positive findings in psychiatry, are considered only suggestive of linkage.

Recombination, the exchange of DNA between a pair of chromosomes during meiosis, can decrease the evidence for linkage by separating the disease gene from the linked allele. Thus, in our hypothetical pedigree the disease gene can be transmitted by individual #400 to one of his offspring with allele 2 instead of allele 1. This might decrease the evidence for linkage in the pedigree. To overcome the problem, the recombination rate is allowed for in the calculation of the LOD score in relation to the estimated distance between the disease gene and the marker. The recombination rate (or fraction) can vary from 0% if they are in exactly the same location to 50% (or 0.5) if they are on different chromosomes.

As stated above, parametric linkage analysis was the main method of genetic analysis employed until recently. It led to the discovery of genes causing disorders with simple Mendelian inheritance such cystic fibrosis [20] and Huntington's disease [21]. In disorders with a more complex inheritance, such as diabetes, hypertension, and psychiatric disorders, it has not proved to be as useful. The main limitation of this method is that in order to correctly calculate the probability of linkage, certain parameters regarding the inheritance of the disease have to be taken into account. First of all, the mode of inheritance has to be specified. As noted before, in psychiatric disorders, mode of inheritance is probably polygenic with a considerable environmental contribution.

For many years the genes for psychiatric disorders were sought under the incorrect assumption of simple Mendelian inheritance, which yielded mainly negative results or some unreplicable positive results. For exam-

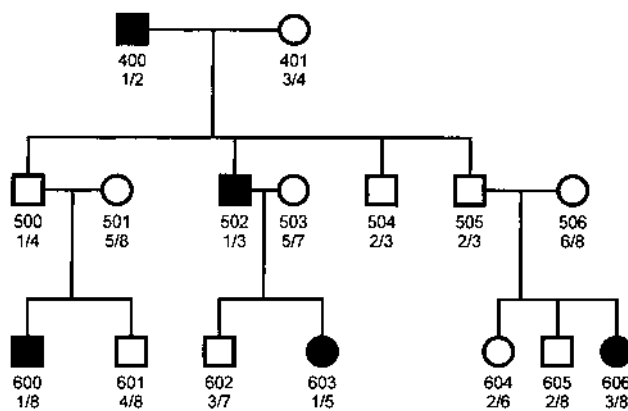

Figure 1 A hypothetical pedigree for linkage analysis. Affected individuals are marked by a dark symbol. Individuals are given identifying numbers from 400 to 606. Genotypes for a certain marker are shown for each individual by the two alleles found in this individual.

ple, researchers who studied Tourette syndrome, were very optimistic at first regarding the chances of finding the gene causing the disorder. It seemed that the inheritance of the disorder was autosomal dominant. It took many years and a great deal of effort with no significant results of parametric linkage analysis to realize that even in TS the inheritance is probably more complex [22,23]. As the exact number of genes that act together to cause psychiatric disorders and the relative role of environment are not known, it is very hard to define the right model for linkage calculations. Unfortunately, the only way to overcome this problem is by finding these genes and isolating their etiological influence from that of environment.

Mode of inheritance is only one of the parameters that linkage analysis is dependent upon. Other parameters are also not known for psychiatric disorders and have to be guessed. Gene frequency, for example, is estimated from disease frequency and the number of implicated genes. The rate of genetic heterogeneity is also estimated. This is the proportion of pedigrees in the studied sample where the disease is caused by different genes. Penetrance has to be taken into account as well. This is the probability that a certain person who carries the disease gene will actually express the disorder. Correct definition of the phenotype is a serious problem that limits the use of parametric linkage in psychiatric genetics, and has been already discussed. But even if we had an accurate diagnostic measure, we would probably still encounter people who carry the gene but for some reason, such as protective factors, do not express the disorder. This might be the case of the person in Figure 1 (#500) who transmitted the disease gene with the linked allele to his affected son from his affected father. Thus, with no correction for penetrance, true linkage can be missed.

Another related parameter that has to be specified in linkage analysis is the rate of phenocopies. These are affected members in the pedigree who acquired their disease because of another, nongenetic factor. This might be the explanation for the occurrence of the disease in individual #606 in the hypothetical pedigree in Figure 1. She has the disease but not the 1 allele. Another possible explanation is that this woman inherited the disease gene or another gene causing the disorder from her mother who is unrelated genetically to the affected grandfather. This phenomenon of disease genes coming from different founders of the pedigree is called bilineality. It is common in pedigrees with psychiatric disorders where assortative mating (between two affected individuals, or between relatives of affected individuals) is common. Bilineality is another parameter that has to be considered to calculate linkage. Usually, researchers attempt to exclude bilineal families from their samples, but absence of bilineality is very difficult to establish with certainty.

Thus, most of the parameters needed for the calculation of linkage are not known for psychiatric disorders and will be known only after the genes for the disorders have been found. When running parametric linkage analyses, many estimates and guesses are made. For each analysis, a specific model composed of the estimated parameters is being used. The many parameters and the numerous different options for each of them make endless numbers of combinations. Examining all of them is impractical and carries the risk of obtaining false-positive results because of multiple testing. Examining only a limited number of models, as is usually done in linkage analysis, is unlikely to include the correct one. This is probably the reason why parametric linkage analysis has been unable as yet to identify a gene for any of the major psychiatric disorders.

Notwithstanding the limitations of parametric linkage analysis in the study of psychiatric disorders, there might be rare instances where its application can be fruitful. Some rare neuropsychiatric disorders such as Rett's disorder, a severe autisticlike X-linked disease, have a more simple Mendelian inheritance. The gene for Rett's disorder was cloned after linkage analysis had been localized to a certain location on chromosome X [24]. The identification of such disease genes, even if rare, could shed light on the pathogenesis of other more common disorders.

B. Nonparametric Methods

Unlike parametric linkage analysis, nonparametric methods are not dependent upon the specification of parameters regarding inheritance. Thus, their use is more suitable for the study of disorders with complex inheritance. Nonparametric methods have been used extensively in the past decade and have shed light on the genetics of disorders such as diabetes, hypertension, Alzheimer's disease, and psychiatric disorders.

1. Association Studies

Case control association studies overcome the problems encountered in genetic analyses of complex disorders by studying a sample of unrelated affected individuals. In this group the frequency of alleles of certain genes is determined and compared to the frequency of the same alleles in a control group of un-

affected individuals. Because the affected individuals are not related, increased frequency of a certain allele in them does not usually imply linkage with the disease gene. Rather, it points to a direct role of the studied allele in the etiology of the disorder. Because of that, different alleles or DNA polymorphisms of genes must be studied instead of merely studying DNA markers. This means that the DNA variations that can be used in association studies must occur in the regions of the genome that code for proteins. The variations can occur in an exon, which is the coding region of the gene, meaning that sequence encodes the sequence of amino acids in the product protein. In other cases the polymorphism occurs in a noncoding region of the gene, or intron. As noted above, if a polymorphism occurs in a noncoding region between genes, it is not useful for association studies, as linkage to a nearby gene cannot be studied in a group of unrelated subjects.

Polymorphism can also occur in a regulatory region of the gene, which is a sequence of DNA where certain molecules bind and affect the rate of transcription. A functional DNA polymorphism occurs in a coding region of a gene and affects the function of the product protein. Functional polymorphisms, or those occurring in the regulatory region of the gene, are usually preferred in association studies, as genes with a suspected role in etiology of disorders are investigated in this paradigm.

It was thought until recently that association studies were not suitable for a genome scan because they cannot detect linkage. Now, with the completion of the Human Genome Project, almost the entire DNA sequence of the human genome is known. Thus, theoretically, association can be studied in polymorphism in each and every gene. Practical, technical, and computation limitations make this option not feasible yet.

Many association studies of psychiatric disorders have been performed using candidate genes. These are genes for proteins with a hypothetical function in the pathogenesis of the disorder. In psychiatric genetics these candidate genes are usually genes involved in the production, metabolism, and signal transduction of neurotransmitters. For example, a repeat polymorphism in the gene for the dopamine receptor D4 was found to be associated with ADHD [25] and with the novelty-seeking personality trait [26], and a certain allele of the serotonin transporter gene was associated with anxious personality [27]. These associations were significant but of small magnitude. They explained only a small part of the variance of the studied traits. This means that these genes might have a small con-

tribution to the etiology of the studied phenomena. Combinations of alleles for two different genes were studied and shown to be associated with tardive dyskinesia, for example [28]. Looking at larger numbers of genes simultaneously would yield a greater number of combinations that might be too numerous to study without enormous samples.

The relatively small role of each gene found to be associated with disorders is only one limitation of this study design. As the Human Genome Project has revealed, there are ~30,000 genes (many fewer than once thought, but still an enormous number). A third of these genes are estimated to be expressed in the brain. Most of them are still not known. Moreover, our understanding of the pathogenesis of psychiatric disorders is limited to current processes in the brain of the affected individual. These may be very different from the genetic vulnerability that started the disease many years before. A genomewide association scan might overcome these obstacles but, as stated above, is not feasible yet.

Notwithstanding the above-mentioned difficulties of association studies, their main limitation is the need to find a perfectly matched control group. Controls should resemble affected individuals in every measure that might be related to the studied genes, apart from disease status. The most problematic confounding factor in this regard is ethnicity. Variations of allelic distribution are highly dependent on ethnicity. Significant variations of allelic distribution are found even among ethnic subgroups of a relatively homogeneous population such as Jews [29]. The choice of an ethnically unmatched control group might be the reason for the failure to replicate some of the positive associations reported between psychiatric disorders and certain alleles. Indeed, some of these nonreplications were in studies in which the patient and control group came from a homogeneous population [30]. It is hard to say whether the positive results or the nonreplications were spurious. To overcome this problem researchers are turning more and more to methods that employ unaffected family members as controls. Two widely used family based methods are haplotype relative risk (HRR) and the transmission disequilibrium test (TDT).

2. Haplotype Relative Risk (HRR)

In HRR allele frequencies are studied in a group of affected individuals. The comparison group is made up of hypothetical sibs of these individuals. These made up sibs are presumably healthy and have inher-

ited from their parents the alleles that were not transmitted to the affected sib (Fig. 2). To be able to make up the control group, both parents of the affected individual must be studied for the same alleles. Thus, HRR requires the ascertainment of "trios" of affected individual and both parents, alive and willing to participate in the study. This makes the research design more complicated. On the other hand, the hypothetical control group in this design is perfectly matched for ethnicity to the patient group.

3. Transmission Disequilibrium Test (TDT)

In TDT, as in HRR, trios are needed for the analysis. In this research design, affected individuals with a parent heterozygous for the allele of interest are studied. In each such case it is determined whether the studied allele was transmitted to the affected offspring or not (Fig. 2). A transmission rate that is significantly higher than the random rate of 50% is considered as evidence for a role of the allele in the etiology of the disorder. The inheritance of multiple genes or haplotypes can be investigated as TDT is studied in families.

Although addressing the issue of ethnicity, both HRR and TDT are limited, as association studies in populations, to the study of candidate genes. Nevertheless, both methods are useful for the attempts to further establish findings from population-based association studies. For example, HRR was used to both replicate and (in other populations) not replicate the association of DRD4 with ADHD [31,32].
Figure 2 Family based association studies using two different methods. The first method is haplotype relative risk (HRR). Two parents and one offspring (a trio) are studied. The nontransmitted alleles (2 and 4 in this pedigree) comprise the control group of hypothetical healthy sibs made up from many trios. Allele frequencies are compared between groups. The second method is transmission disequilibrium test (TDT). Trios are studied in which one of the parents is heterozygous for a certain allele of the studied marker (1, for example). Transmission of the allele is counted for each trio. The rate of transmission is compared with random rate of transmission, which is 50%.

C. Allele Sharing Methods

1. General Principles

In allele sharing methods of genetic analysis, the degree of sharing of alleles of certain genes or markers is examined in related individuals with the investigated disorder. This can be done either in affected sibs, which is called sibpair analysis, or in affected individuals with a more distant relationship (grandfather and grandson, cousins, etc.). Sharing of alleles can be incidental or can be secondary to inheritance of the same allele from a common ancestor (parent, grandparent, etc.). When the reason for the sharing is not known, it is called "identity by state." When it can be shown that both individuals inherited the same allele from a common source, we use the term "identity by descent." Identity by descent allele sharing is a more powerful tool in genetic analysis. If related individuals with the disorder share the same alleles, identical by descent, more often than expected by chance, an association between the allele and the disease is implied. Alternatively, as the individuals are related, increased sharing can stem from linkage of the marker to the disease gene. Thus a genome scan can be performed with these methods, as well as the study of candidate genes.

When allele sharing is studied, no assumption has to be made about mode of inheritance, genetic heterogeneity, gene frequency, penetrance, rate of phenocopies, and so on. This nonparametric method is model free. This is its great advantage over parametric linkage analysis. On the other hand, parametric linkage under the correct model is much more powerful in the detection of linkage. In order to compare their power to that of parametric linkage, allele sharing methods need to use very large samples of the order of hundreds of sibpairs or dozens of multiplex pedigrees. These are hard to ascertain in one population. Researchers usually combine samples from different populations, which increases the risk of genetic heterogeneity and decreases the chance of finding significant linkage. For this reason allele sharing methods are used in combination with parametric linkage analysis, which means that in the same pedigrees both parametric and nonparametric methods are used. For example, the addition of sibpair analysis to parametric linkage analysis was helpful in supporting suggestive linkage to a locus on chromosome 22q in schizophrenia [33]. Significant linkage between two forms of dyslexia and markers on chromosome 6p and 15p were found using parametric linkage for one form and allele sharing methods for the other [34].

2. Sibpair Analysis

Take for example the sibpair in Figure 3. Affected sibs can either inherit the same two alleles from their parents, one shared allele and one nonshared allele, or two different alleles. If there is no relation between affection status and the studied allele, we expect the probabilities for each of the three cases to be 0.25, 0.5, 0.25, respectively.

The actual allele sharing is studied in many sibpairs, and the observed frequency of sharing of one, two, or zero alleles is compared with the theoretical random frequencies. Any deviance from random distribution is considered evidence for increased allele sharing.

3. Allele Sharing in Pedigrees

In this paradigm allele sharing is compared between affected pedigree members with any degree of relationship apart from parent and offspring (as the allele sharing will always be 0.50 in this case). Observed sharing is compared with expected sharing under no association or linkage. As for parametric linkage analysis, large pedigrees with many affected members are ascertained. But unlike traditional linkage analysis, only allele sharing between affected individuals is studied. Take Figure 1 for example. In allele sharing analysis, only the affected individuals (#400, #502, #600, #603, and #606) will be studied, and allele sharing will be examined in every possible combination of two out of these individuals (apart from parent and child). The other unaffected pedigree members do not contribute to the calculation, apart from verifying that identity between individuals is indeed by descent and not by chance. Thus it is clear that this paradigm is model free, as it is not dependent on the parameters required by parametric linkage. The most widely used software that employs this paradigm is called Genehunter [35], which can also calculate parametric linkage in the same pedigree.

D. Linkage Disequilibrium in Isolated Populations

One of the main limitations of both parametric and nonparametric methods of genetic analysis is the problem of genetic heterogeneity. Researchers use large samples to increase power, and thus run the risk of mixing subpopulations with different genetic etiologies. Studying small populations that are genetically isolated can overcome this obstacle. In such a population, affected individuals are more likely to represent a homogeneous sample, in terms of etiology. It is plausible that most of the affected individuals in a genetic isolate, who have a certain disorder, carry the same disease-causing mutation, which they inherited from a common ancestor. If the mutation process is relatively new, or more possibly if the genetic isolate is relatively young (and the mutation was introduced to it relatively late), we expect that affected individuals share more than the mutation itself. Large regions of DNA on both sides of the mutation should be identical in these individuals, as the short time that elapsed since the isolate was founded did not allow recombination to change them considerably. Thus, these individuals share not merely alleles but large haplotypes identically by descent. The aggregation of certain alleles into haplotypes that are more frequent than what is expected by chance is called "linkage disequilibrium," and is evidence for the presence of a shared mutation in this region.

The main advantage of this paradigm is that only a few affected individuals (as few three or four) need to be examined. These people do not have to be related (apart from being part of the same isolate), and their relatives are not needed for the study. The disadvantages are that these genetic isolates are not easy to find, and are even more difficult to study. Also, genes responsible for psychiatric disorders in these unique populations might be very well specific to them only. Nevertheless, finding one gene for one psychiatric disorder in one population has not yet been achieved by any other method. Linkage disequilibrium in genetic isolates has been used to locate genes for rare medical disorders with simple Mendelian inheritance [36], and

Figure 3 Sibpair analysis: two affected sibs and their parents are studied. In this example one daughter received alleles 1 and 3 from her parents. Her sister can either receive the same two alleles, only one of them (1/4 or 2/3), or the two that were not transmitted to her sister (2/4). The probabilties for each case are equal, and thus for sharing the same two alleles are 0.25, only one allele 0.5, and no sharing 0.25. Actual sharing in many sibpairs is compared to these random probabilities. Significant deviance implies association or linkage.

also for a common disorder with a more complex inheritance such as Hirschprung's disease [37]. Lately, it is being applied to the study of psychiatric disorders as well.

E. Quantitative Trait Loci (QTL)

As implied by its name, QTL is suited for the study of quantitative traits, such as height and weight. It allows the study of many genes, each with a small contribution, to the expression of one continuous variable. QTL is easily applied in laboratory animals, where pure strains can be inbred and the change in the studied trait can be measured under different genetic conditions. Obviously this cannot be done with human beings. Rather, sibs or unrelated subjects with extremely different values of the studied trait are studied and their genotypes compared. It is also debatable whether most psychiatric disorders can be perceived as quantitative traits. Medical psychiatry assumes in most cases a more categorical approach to psychiatric disorders. On the other hand QTL might prove beneficial to the study of personality traits and intelligence [38].

V. ADVANCES IN THE LABORATORY

The significant expansion of DNA marker maps enables the performance of better genome scans. More and more polymorphisms of the human DNA are known. These include single nucleotide polymorphisms (SNP) and certain sequences (from two or three to several dozen nucletodies) that vary in the number in which they are repeated in different individuals. This improved map increases the chances of finding association or linkage with a studied disorder. Data are shared through the Internet and are freely available to any researcher. Technology is improving from day to day. Methods that identify different DNA sequences are much easier to perform and are less time-consuming.

The recent completion of the Human Genome Project opens new and endless horizons for the study of psychiatric genetics. One aspect is the further improvement of marker maps. Moreover, in a short while we should be able (with sufficient computation power) to study association of disorders with each and every of the human genes. Thus we will be able to desert the study of candidate genes that were chosen merely because of our limited knowledge. In this way association studies (both case control and family-based

paradigms) will be used for the purpose of hunting genes in genome scans.

When the location of a gene for a psychiatric disorder is eventually found, the new map of the human genome will enable its rapid identification and cloning. The mutations that cause the disorders will be characterized shortly thereafter, and shorten the way to the study of pathogenesis and the application to diagnosis, prevention, and treatment.

VI. SUMMARY AND FUTURE DIRECTIONS

Finding a significant linkage between a psychiatric disorder and a DNA marker, which is replicated consistently, is an objective that has not yet been accomplished. The further objectives of mapping actual disease genes, cloning them, and determining their protein structure and function, are more distant.

The inherent obstacles have been described in this chapter, as well as newer methods of genetic analysis that aim to overcome them. Advances in molecular technology constantly improve our technical tools. Eventually one gene for one psychiatric disorder in (at least) one population will be found. And then? The journey just begins.

The gene for Huntington's disease (HD) was discovered a decade ago [21]. No dramatic change has occurred in the treatment and prognosis of HD patients since then, even though diagnosis is now possible before the onset of the disorder. This has raised painful ethical questions. Is it justified to test young healthy individuals for a dreadful, incurable disease? When we finally find genes for schizophrenia won't we be in the same position? We will have to deal with difficult ethical questions regarding prenatal diagnosis of susceptibility to a disorder with a variable clinical course that has its onset 15–20 years later.

We will also be at the very beginning of the long road which will need to be traversed in order to understand how genes start the process that eventually culminates in psychiatric disorder. Apart from the complexities inherent to the field of psychiatric genetics, there are additional ones. These are related to the fact that interposed between the gene and the protein for which it codes are variations in transcription, translation, and posttranslational modifications that prevent us from being able to assume a simple relationship between gene and disease. Also, epigenetic factors modify expression of genes in ways that can be time specific and tissue specific. Thus, even when a gene for a psychiatric disease is eventually found, a

long route will have to be traversed before we under-
tand how it affects the disease process.

I. INTRODUCTION

The process of synaptic transmission is the key target for all psychoactive drugs. Transmission may be influenced by drugs affecting the synthesis, storage, release, inactivation, and postsynaptic effects of transmitter substances. Further, drugs effective in major psychiatric illnesses such as depression and schizophrenia have prominent effects on transmission mediated by biogenic amines such as dopamine (DA), norepinephrine (NE), and 5-hydroxytryptamine (5HT; serotonin). The past decade has seen marked advances in our understanding of key features of the transmission process mediated by these amines. Of particular importance is the emerging concept that transmission mediated by these substances appears, at least in part, to occur through diffusion-mediated signaling, termed extrasynaptic or volume transmission (VT). Also, it is now recognized that the inactivation process of reuptake,

mediated by specific transporters located in the plasma membrane, plays the key role in regulating the concentration of these amines in the extracellular fluid (ECF). Furthermore, these protein transporters are not merely constitutive membrane components but undergo a variety of regulatory processes. Finally, in the past decade it has become more accepted, even if still not completely understood, that effects of released amines can be influenced by other peptide transmitters colocalized in the same neurons. Our emerging concepts of the functioning of transporters and the processes of cotransmission and VT have not been well integrated into current views of psychoactive drug action. Yet it is likely that they influence profoundly the effects produced by such drugs. Because of this, it is appropriate to view such processes from the perspective of their potential neuropsychopharmacologic impact.

II. HARD-WIRED VS. PARACRINE OR VOLUME TRANSMISSION

The most widely accepted model for synaptic transmission, including that which occurs in brain, was devel-

---

*Some of the material in this chapter was presented in a review article by Frazer A, Gerhardt GA, and Daws LC: New views of biogenic amine transporter function: implications for neuropsychopharmacology. Int J Neuropsychopharmacol 2:305–320, 1999.

oped from studies involving cholinergic transmission through nicotinic receptors, particularly at the neuromuscular junction. This model was derived in part from the morphological characteristics of such synapses, involving a presynaptic knob with specialized features, a cleft of $\sim$ 40–60 nm, and the postsynaptic membrane containing both receptors and invaginations. Such specialized features within the synapse pose barriers to transmitter diffusion and help to ensure that the transmitter acts only within the strict confines of such conventional synapses. Further contributing to acetylcholine (ACh) having only synaptic effects is the presence of its degradative enzyme acetylcholinesterase within the synapse. This type of transmitter process has been termed "hard-wired."

However, in the mid-1970s, anatomic studies on brain tissue generated data that were interpreted as favoring a different model of synaptic transmission. This model has been referred to as extrasynaptic communication or paracrine transmission (which, historically, relates to a hormone affecting the function of cells at a distance from its site of release) or volume transmission (VT). The essence of such transmission is the passage of chemical messages along multiple, largely unpredictable channels such that transmitters may pervade the extracellular space to act at distant receptors outside the strict confines of conventional synapses. Although there are attractive features of this concept, it has been elusive and difficult to prove. It is outside the scope of this chapter to review this subject in detail. The interested reader is referred to comprehensive reviews of this topic in a recent volume [1]. Since the mid-1970s, anatomic, physiologic, and pharmacologic data have been generated that are consistent with VT, although not proving it. If such transmission does occur in the brain, it could have profound neuropsychopharmacologic implications.

The original observation that there may be nontraditional types of transmission in brain was that of Descarries et al. [2]. These investigators, using [3]H-5HT autoradiography in the neocortex of rats, claimed that serotonergic terminals were rarely engaged in morphologically differentiated synapses and speculated about "nonsynaptic" release of 5HT in this brain area. Subsequently, Beaudet and Descarries [3] suggested that 5HT acted on a large number of cortical cells rather than just a restricted number of postsynaptic targets. Their notion was of a predominantly nonjunctional serotonergic innervation of the cortex having paracrine-like properties. Although this work has

been criticized [4] and others have found much higher percentages of typical synaptic specializations for 5HT [5,6], there does seem to be a body of data showing a reasonable percentage of nonsynaptic varicosities for biogenic amines in brain [7–9]. The presence of nontraditional synapses may be specific to certain brain regions [10], indicating that these biogenic amines may function both at conventional synapses and nontraditional ones. Further, in different brain regions the extent to which VT is involved in, for example, dopaminergic transmission may vary [11].

Consistent with the view of diffusion of transmitter to act at distant, nonsynaptic receptors is the realization that channels between cells are of sufficient width to allow the passage by diffusion of neuroactive compounds [12]. Although fraught with a variety of assumptions, it has been estimated that DA can diffuse at least 10 μm and 5HT 20 μm from its release site in brain tissue within one half-life [13,14], distances that would permit action at extrasynaptic receptors. Also, in a series of elegant investigations, Wightman and his colleagues [13–15] showed the concentration of either DA or 5HT in ECF to be directly proportional to the number of electrical pulses in an electrical train, a result not consistent with the buffered diffusion that occurs with hard-wired transmission. Further, peak extracellular concentration of either transmitter after a single stimulus was not altered by uptake inhibitors, suggesting that the uptake process is not altering the efflux of these transmitters into the extrasynaptic space. As is discussed in the section on transporters, one explanation for such data is that the uptake sites are extrasynaptic.

If DA or 5HT can "escape" from the synapse and diffuse in ECF some distance from the synapse, is there any evidence that they will encounter appropriate receptors outside the synapse? There appears to be. Although certainly not conclusive, much has been made of, and considerable controversy has been generated by, the many observations showing a "mismatch" in brain between areas receiving very little innervation by a specific type of neuron yet having a high density of receptors for the particular transmitter [16]. For example, in rat cerebral cortex, only the $5HT_2$ receptor has a distribution that appears to match the regional and laminar density of serotonergic innervation [17]. More convincing, though, are studies carried out with electron microscopy which reveal receptor immunoreactivity outside of synapses. This has been found for both D_1 and D_2 dopamine receptors [18,19], $5HT_{1A}$ [20] and $5HT_{2A}$ [21] receptors.

The foregoing lends credence to the view that DA, 5HT, and perhaps NE can spill out from synapses to diffuse to distal sites in concentrations that may be sufficient to activate extrasynaptic receptors [13,14]. This issue and its neuropsychopharmacologic implications are highlighted in the sections dealing with the localization of transporters and their regulation.

III. BIOGENIC AMINE REUPTAKE AND TRANSPORTERS

It has been 40 years since the initial observation that tritiated NE could be taken up from blood into organs containing sympathetic nerves [22], due to an active transport process contained in these nerves. Further research revealed that the primary means of terminating synaptic activity of NE, DA, or 5HT was by these active transport processes. Key neuropsychopharmacological discoveries were that many antidepressants inhibited the uptake of NE and 5HT [23,24], whereas psychostimulants, such as cocaine and methylenedioxymethamphetamine (MDMA; "Ectasy"), blocked the uptake of DA as well as that of 5HT, and, for some of the drugs in this class, uptake of NE was also inhibited [25–27]. The inhibition of uptake was thought to be responsible for the efficacy of antidepressants, whereas the inhibition of DA uptake was linked to the euphoric and reinforcing properties of psychostimulants.

Although the uptake processes for these three amines had similar characteristics, the uptake of each amine is mediated by a specific protein termed a transporter. Furthermore, the transporter proteins were presumed to have a synaptic localization to account for the enhancement of synaptic transmission thought to occur when pharmacological agents inhibited the uptake process. In other words, reuptake (and diffusion) altered the magnitude, duration, and spatial domain of transmitter-induced receptor activation and, in so doing, modified neurotransmission. More recent work [28] has substantiated the idea that these transporters are the *key* cellular elements regulating the concentrations of biogenic amines in ECF. The cloning of biogenic amine transporters in the early 1990s [29–32] and the development of selective radioligands for them at about the same time permitted a range of studies not possible previously. These studies have begun to provide important information about transporter function and regulation that in some cases expands and amplifies our previously held concepts, but in other ways, fundamentally changes them.

A. Structure of Monoamine Transporters

The dopamine transporter (DAT), norepinephrine transporter (NET), and 5-hydroxytryptamine transporter (5HTT) are part of a family of neuronal plasma membrane transporters that include the monoamines and certain amino acids such as gamma-aminobutyric acid (GABA), glycine, and proline [33]. These three transporters share considerable structural homology. They are all Na^+ and Cl^- dependent, have 12 membrane-spanning domains, N- and C-termini located intracellularly and a large extracellular loop with glycosylation sites which may alter trafficking and/or function of the transporters. The extracellular and intracellular portions of the proteins have phosphorylation sites that likely contribute to the functional properties of the transporters. The DAT, NET and 5HTT are each believed to represent a single gene product [33]. Since they represent single gene products, this means that posttranslational or other intracellular regulatory mechanisms must play a role in regulation of the function of these transporters. Data, reviewed below, are starting to appear that support the theory that phosphorylation of transporters through a variety of protein kinases and phosphatases causes changes in their function and plays a role in the trafficking and incorporation of transporters into the plasma membrane.

B. Models of Transporter Function

Current ideas about the function of monoamine transporters have led to proposals that transporters may operate in at least two modes: (1) as an alternating access carrier [34], or (2) in a channel mode [35]. In the more standard alternating access carrier mode (Fig. 1) [36], the protein is first in a conformation such that the cotransported ions, Na^+ and Cl^-, and the substrate (e.g., DA, NE, or 5HT) bind to a cleft in the transporter that is open to the extracellular space. The transporter then converts to a form that is accessible to the intracellular space, allowing the cotransported ions and the substrate access to the cytoplasm. This internal-facing form releases the transported substances into the cytoplasm and then interconverts so as to expose the now empty binding sites to the extracellular environment. This is the transport cycle. In the case of the 5HTT [34], K^+ ion binds to the transporter protein when it is open to the cytoplasm and may facilitate the interconversion of the protein to the form that exposes binding sites to the extracellular space to reinitiate the transport process. According to this model, the rate of

influx of extracellular solute determines the rate of efflux of intracellular solute; i.e., influx and efflux rates are modulated equivalently. Data have been obtained recently with the 5HTT and the DAT showing independent modulation of inward and outward transport [38–40]. Thus, some features of transport seem inconsistent with the classical alternating access carrier model.

By contrast, in the channel mode, which is thought to be a low probability event, the transporter protein functions as an ion channel (Fig. 1). Evidence in support of the channel mode of conductance is that the 5HTT and NET have transmitter-activated currents that are not linked stoichiometrically to substrate movement [35, 36, 41–45]. For example, if charge movement were merely linked to coupled transport for the NET, then one would predict one charge/NE molecule. What has been found for the human NET expressed in cultured cells is 200 charges/NE molecule. Such data have been interpreted to mean that these charges are carried by the positively charged NE molecules and cotransported ions [41]. Moreover, when the transporter is in the channel mode, a single transport event carries many more NE molecules than would be predicted by the classic alternating access model [46]. One way this could occur would be if the transporter

acted as a channel permitting bulk flow of substrate through the open pore. This behavior of the transporter may be explained by the existence of two gates, one directed intracellularly and one extracellularly. In the case of the alternating access model, the two gates open sequentially during the transport cycle to allow the exchange of ions and substrate between ECF and cytosol by alternating access to the cleft of the transporter [36]. On occasion, the "gates" on both the extracellular and cytoplasmic sides of the transporter open simultaneously, permitting bulk flow of substrate and associated ions through an "ion" channel. It seems possible that transporters are really combined carriers and channels.

One implication of transporters acting as ion channels is that it should be possible to develop drugs that change the probability of the transporter acting in the channel mode, akin to the effect of benzodiazepines at the $GABA_A$ receptor. Such drugs should markedly influence the effect of synaptically released transmitter. If, for example, some psychotic states are linked to excessive dopaminergic transmission, drugs that change the probability of the DAT acting in the channel mode might be effective in these states. Another interesting aspect of the realization of transport-associated currents is that it permits analysis of the effects
Figure 1 Schematic for biogenic amine transport in the alternating access and channel mode. In the alternating access model, the carrier has an aqueous lumen or cleft that exposes alternatively to the extracellular or intracellular environments. This transition state (A) ⇔ (B) results in transport of the substrate (S) and co-transported ions (empty circles) that is coupled stoichiometrically. The channel mode (C) is a low probability event, in which the ions and substrate move through the channel pore down their electrochemical gradients. The constrictions indicated on the cytoplasmic (A) or extracellular (B) domains of the transporter may be viewed as "gates", both of which are open simultaneously to form a pore (C). (Diagram courtesy of Dr. Aurelio Galli, Department of Pharmacology, University of Texas Health Science Center, San Antonio TX.).

of psychoactive drugs on such currents. These analyses may provide some explanation for differences in the pharmacological properties of "similar" drugs. For example, amphetaminelike compounds (including the neurotoxin 1-methyl-4-phenylpyridinium (MPP$^+$) acted like DA and caused transport-associated currents at DATs whereas cocainelike drugs (including methylphenidate) blocked such currents [47].

C. Electrogenic Processes

The DA, NE, and 5HT transport cycles involve cotransport of ions and therefore the processes are potentially electrogenic. One or two Na$^+$ ions and one Cl$^-$ ion are cotransported, resulting in a net inward flux of positive charge [45,48]. In general, the electrogenic processes involved in transport may contribute substantially to the resting membrane potential of a given nerve terminal and affect not only the relative activity of the transporters but also other processes such as transmitter release. Flux of charges associated with substrate uptake has been demonstrated for all of the monoamine transporters [41,44,46,49]. Consistent with this is the finding that depolarization decreased whereas hyperpolarization enhanced DA uptake in xenopus oocytes [47]. It seems that the DAT is regulated similarly in a voltage-dependent fashion in the mammalian CNS [48,50–53].

The implication of this is that when DA neurons are depolarized, DAT will decrease its transporter activity, allowing for greater diffusion of DA to its receptors [54,55], perhaps distant from a synapse or varicosity (see above). By contrast, hyperpolarization of DA neurons would enhance uptake of DA so as to decrease its receptor-mediated effects. This scheme makes sense physiologically since, for example, situations that would call for depolarization-induced release of DA would "turn off" its inactivation mechanism (i.e., the DAT) in order to facilitate dopaminergic transmission. This regulatory process now appears likely for DA-containing neurons, and may also occur for the NET and 5HTT as well [41,46,56].

D. Anatomical Localization of Transporters

Although transporters were presumed to have a localization within the synapse, results of studies visualizing either the DAT or 5HTT by electron microscopy have revealed the presence of these transporters outside the synapse. For example, Zhou et al. [57] found the majority of 5HTTs to exist in small unmyelinated axons, suggesting 5HT uptake to be mainly extrasynaptic;

they found also that 5HTTs on axons outside synapses were engaged in high-affinity uptake of 5HT. They speculated that 5HT can spill out from the synaptic cleft and that the 5HTT located just outside the synapse can take up 5HT near the synapse whereas axonal 5HTT takes up 5HT that has diffused to more distal sites. Evidence for extrasynaptic localization of 5HTTs has also been found in both the shell and core of the nucleus accumbens [21]. Similarly, Nirenberg et al. [58,59] visualized the DAT under electron microscopy in the substantia nigra, the dorsolateral striatum, and the nucleus accumbens, and found evidence in all areas for the DAT being outside of synapses.

The extrasynaptic localization of transporters, coupled with the idea of VT, means, for example, that DA may come into contact with NETs. This is of importance as it has been shown that the NET transports DA even better than NE [60]. By contrast, the DAT does not transport NE, but it has been demonstrated that 5HT can be taken up by the DAT in the striatum [61]. Much earlier work of Shaskan and Snyder [62] showed, using rat brain slices, that noradrenergic nerves could take up 5HT, albeit much less potently than they transported NE; however, their capacity to take up 5HT was much greater than that for NE.

Thus, transporter "promiscuity" coupled with VT could result, for example, in DA reaching NETs in sufficient concentrations so as to be taken up into noradrenergic nerves, or 5HT reaching DATs or NETs so as to be removed by these transporters. There is evidence in support of this concept. For example, in the ventral mesencephalon ^{3}H-DA can be taken up by serotonergic neurons and this effect is partially blocked by fluoxetine [63]. Results with in vivo microdialysis have shown that systemic administration of selective inhibitors of the NET raise DA in the prefrontal cortex [64], and local application into the nucleus accumbens of selective inhibitors of the NET raised extracellular levels of 5HT and DA in addition to NE [65]. Using in vivo voltametry, we also obtained evidence for the uptake of 5HT into noradrenergic nerves [66]. In the dentate gyrus of the hippocampus, where the density of NETs outnumbers 5HTTs by roughly 2:1 (unpublished observations), exogenously administered 5HT was taken up by both serotonergic and noradrenergic nerves. By contrast, in the CA$_3$ region, where 5HTTs outnumber NETs about fourfold (unpublished observations) no evidence of 5HT uptake into noradrenergic nerves was obtained.

Relevant to this issue is an interesting result of Bel and Artigas [67]. These investigators measured the con-

centration of 5HT in the ECF of the frontal cortex, obtained by microdialysis. Systemic administration of desipramine alone did not raise the concentration of 5HT whereas administration of fluoxetine did. However, when the concentration of 5HT was elevated by a dose of fluoxetine that produced a maximal effect, administration of desipramine was able to raise further the concentration of 5HT. One explanation for this result is that blockade of the 5HTT permitted 5HT to reach noradrenergic nerves where it was taken up by NETs located on them.

All the results cited above have certain limitations which make their extrapolation to the clinical situation problematic. Nevertheless, such results are consistent with data showing that depressed patients treated with selective inhibitors of the 5HTT show decreases not only in the concentration of 5-hydroxyindoleacetic acid (5HIAA) in spinal fluid but in the norepinephrine metabolite 3,4,dehydroxyphenylglycol (MHPG) as well; similarly, treatment of patients with selective noradrenergic uptake inhibitors results in decreases in both MHPG and 5HIAA in spinal fluid [68]. One implication, then, of VT and extrasynaptic localization of transporters is that administration of selective uptake inhibitors could facilitate the uptake of a specific transmitter into other types of nerves producing as yet unknown effects. Another implication is that administration of dual uptake inhibitors (e.g., imipramine, which inhibits the uptake of both NE and 5HT) could result in even greater diffusion of NE or 5HT from their release sites so as to reach receptors on targets that they would not if only one transporter was inhibited. The consequences of this are not clear, but this could be an important area for future research.

Thus, even though uptake inhibitors were developed for clinical use because of the idea that they would prolong "synaptic" transmission (and they may do so by inhibiting perisynaptic transporters), they may produce many other effects as well, both on the membrane potential and intracellular processes of the nerves containing the transporter that they inhibit and on other nerves at a distance from the site of transmitter release.

E. Regulation of Transporter Function

Because transporters for the biogenic amines both are critical in regulating the extracellular concentrations of these amines, and are key targets for a number of psychotherapeutic drugs, understanding how their function is regulated has come under intense scrutiny in recent years. Once the mechanisms for regulation of the biogenic amine transporters are understood, there

is great potential for developing new classes of drugs for the treatment of disorders such as depression, mania, anxiety, schizophrenia, and drug abuse. It is becoming clear that transport of biogenic amines is not simply a constitutive property of synaptic membranes but a dynamically regulated component of aminergic signaling.

1. Acute Regulation of Transporter Function

Acute changes in transporter function can occur rapidly (within minutes). Consequently, it is unlikely that such changes are mediated via alterations in gene expression given that at least several hours are required for increases in transporter mRNA to translate into increased transporter expression in the plasma membrane [69]. Commensurate with the finding that transporters for the biogenic amines contain sites for protein phosphorylation by a number of kinases [33], several groups reported rapid changes in transport capacity following activation of cellular kinases. The most common observation was that activation of protein kinase C (PKC) led to a reduction in amine transport capacity [70–72]. There are also considerable data implicating a role for calcium, calmodulin, and other kinase-dependent as well as kinase-independent pathways in the acute regulation of transporter function [73–78]. The decrease in transport capacity ensuing PKC activation is due to a reduction in V_{max} with K_m remaining largely unaltered. The reduction in V_{max} is associated with a decline in the number of transport proteins in the cell membrane [75,79]. This seems to result from sequestration of the transporter for recycling rather than degradation [77,79–81].

New techniques have enabled researchers to track changes in the distribution of transporters within cells. The most extensive studies to date have been carried out in cell lines transfected with the DAT and have consistently demonstrated PKC activation to evoke internalization of this transporter [82–85]. The fate of internalized DATs remains under debate, with evidence for both recycling [85] and degradation [82]. Nevertheless, it is apparent that cell surface redistribution of biogenic amine transporters is a mechanism that contributes to regulation of extracellular levels of transmitter. Such cell surface redistribution has pharmacological significance. For example, Saunders et al. [86] showed that amphetamine, a substrate for the DAT, caused trafficking of the human DAT (hDAT) from the plasma membrane to the cytosol of cultured cells. Callaghan and coworkers [87] subsequently showed that cocaine exerted the opposite

effect, that is, mobilization of the *h*DAT from the cytosol to plasma membrane of cultured cells. Determining the pathways through which such psychotropic drugs are able to alter the distribution of transporters on the plasma membrane will have important ramifications for the development of new drug therapies for the treatment of numerous psychiatric disease states and drug abuse.

2. Mechanisms for Trafficking of Biogenic Amine Transporters

One way in which protein kinases can be activated is via presynaptic receptors. Apparsundaram and coworkers [79,81] demonstrated that activation of muscarinic acetylcholine receptors linked to PKC rapidly and selectively decreased the transport capacity (V_{max}) of the NET. In another study, Miller and Hoffman [88] reported that activation of A_3 adenosine receptors in cells increased 5HT uptake. This increase could be blocked by inhibitors of nitric oxide synthase and cGMP-dependent kinases, providing evidence for a nitric oxide–cGMP pathway in the acute regulation of the 5HTT.

In vivo studies have also provided evidence for receptor-mediated pathways in acute transporter regulation. For example, using high-speed chronoamperometry, Daws et al. [89,90] reported that antagonism of the $5HT_{1B}$ autoreceptor prolonged clearance of 5HT in rat hippocampus. Importantly, antagonism of the $5HT_{1B}$ autoreceptor in 5HTT knockout mice failed to alter clearance of 5HT, indicating that the presence of both proteins is required for this effect [91]. These observations are consistent with the idea that activation of $5HT_{1B}$ autoreceptors enhances 5HTT function. Similarly, blockade of the dopamine D2 receptor has been shown to inhibit clearance of DA from extracellular fluid [50,51], an effect that was absent in mice lacking the D2 receptor [52]. Whether autoreceptor regulation of transporter activity leads to transporter trafficking is unknown, as are the signal transduction pathways linking receptor to transporter.

Many signaling proteins, including receptors and ion channels, are modulated via direct protein phosphorylation, and there is evidence that this is also true for biogenic amine transporters [for a recent review, 72]. Blakely and colleagues [92] demonstrated that 5HT reduced phosphorylation of the 5HTT both under basal conditions and following PKC activation. These effects could be blocked by paroxetine, a selective serotonin reuptake inhibitor (SSRI), suggesting that the effects of 5HT were mediated by an action

on the transporter and not on 5HT receptors. Ramamoorthy and Blakely [77] later showed that PKC-induced transporter internalization was reduced in the presence of 5HT [77]. The inhibitory effect of 5HT on phosphorylation of the 5HTT is due to its binding to the 5HTT and/or its translocation by it. This indicates that phosphorylation of the 5HTT occurs when it is in the plasma membrane, and further suggests that such phosphorylation serves as a signal for its trafficking and internalization. The ability of 5HT to suppress phosphorylation may be a mechanism to maintain high transporter function when extracellular levels of 5HT are elevated [71]. In contrast to the 5HTT, direct phosphorylation of the DAT does not appear to be involved in PKC-mediated regulation of DAT function [93]. Further, it now appears that phosphatases are also involved in regulating the state of phosphorylation of amine transporters [72,94], providing yet another approach to regulating the function of transporters in vivo.

3. Long-Term Regulation of Transporter Function

Several lines of evidence, including changes in transporter activity and/or expression in response to environmental perturbations (e.g., altered photoperiods) [73], fluctuations in hormone levels (e.g. corticosteroids, estrogen) [95–97], and as a consequence of aging [98,99], suggest that biogenic amine transporters also undergo long-term regulation.

Most relevant to the present review are the changes in transporter activity/expression observed in certain disease states and as a consequence of therapeutic intervention. For example, reductions in both 5HTT and NET binding have been reported in patients with depression [100–102], and significant reductions of 5HTT binding and DAT immunoreactivity have been observed in patients with Parkinson's disease [reviewed in 103]. Depressive disorders are commonly treated with selective inhibitors of 5HT and/or NE uptake. Pharmacologic inhibition of transporters occurs rapidly. However, maximal therapeutic benefit takes weeks to occur, so adaptive changes induced by such drugs on biogenic amine systems have been investigated extensively. Although much of this work focused on receptors and receptor-mediated responses [104], data on transporter function have also been obtained. Numerous studies have assessed the effect of chronic antidepressant treatment on the density of binding sites for the 5HTT and NET. The results have not been consistent [reviewed in 73,105]. Similarly, although

several studies have shown no effect of chronic treatment with antidepressants on mRNAs for the 5HTT and NET, others have reported increases and still others, no change [101,105,106]. Obviously, differences in the duration of chronic drug dosage and route of drug delivery, which inevitably exist in such in vivo studies, make firm conclusions regarding alterations in gene expression by chronic drug treatment difficult.

Using high-speed chronoamperometry, we [107] measured the ability of an SSRI, fluvoxamine, applied locally to the hippocampus, to inhibit uptake of exogenously applied 5HT in rats treated for 21 days by osmotic minipump with the SSRI paroxetine. The more constant level of drug in plasma obtained by administration via minipump may better model clinical administration of uptake inhibitors. Acute local administration of fluvoxamine did not inhibit uptake of 5HT in chronically treated rats (as it did in non-treated rats). This lack of an inhibitory effect of fluvoxamine may be due to a robust decrease in 5HTT-binding sites in paroxetine-treated rats [107]. Pineyro et al. [108] also found chronic administration of paroxetine by minipump to cause a decrease in 5HTT function and density. More recently, we [109] showed that the time course for decreased 5HTT function following chronic treatment of rats with an SSRI was gradual. This functional decrease was paralleled by a decrease in 5HTT density but not by mRNA levels for the 5HTT. These data suggest that posttranscriptional events mediate changes in 5HTT function caused by long-term administration of SSRIs. One implication of these data for the clinical setting is that antidepressant-induced decreases in 5HTT density may need to reach a "critical" level before therapeutic benefits are seen. In keeping with this, Alvarez et al. [102] reported that platelet 5HTTs were decreased in patients treated with fluoxetine. Thus, if transporter density can be reduced more rapidly, perhaps clinical improvement can be accomplished in a shorter time frame.

F. Genetic Knockout and Polymorphisms of Biogenic Amine Transporters

Perhaps the most striking demonstration of the importance of transporters in regulating extracellular fluid concentrations of biogenic amines comes from studies using transporter deficient mice. In vivo studies using voltametric recording techniques show that homozygous 5HTT knockout (KO) [91], DAT KO [110], and NET KO [111] mice have a profoundly reduced ability to clear 5HT, DA and NE, respectively, from ECF. However, in most cases, clearance remains more

rapid than simple diffusion would predict. This implies that other mechanisms must compensate, at least to some extent, for the loss of transporter. One possibility is that transporters other than the specific transport protein for a given biogenic amine are able to compensate. As has been discussed, transporters for the biogenic amines exhibit some "promiscuity" for transmitters. In addition, the presence of nonneuronal monoamine transporters, such as the extraneuronal monoamine transporter and organic cation transporter 2 (OCT2), in brain [112] may also account for clearance of biogenic amines from ECF in 5HTT-, DAT- and NET-deficient mice. Indeed, OCT2 is reportedly increased in the brains of 5HTT KO mice [113] and may represent an adaptive response to the loss of 5HTT.

The advent of transporter-deficient mice and their altered responses to drugs as well as inherent differences in amine levels, receptors, and behavior [28,111,114], prompted researchers to look for genetic variants in transporter proteins that may predispose to psychiatric disorders. Variants have now been uncovered in the promoter region of the gene encoding the 5HTT that alter mRNA and protein expression both in vitro and in vivo. An association between these variants and a number of disorders, including anxiety, affective disorder, autism, and alcoholism, have been reported. Such associations include a predisposition for the disorder and altered sensitivity to drugs used to treat the disorder [115–118]. Clearly, this is an area for active research which should lend important insights into the underlying etiology of such disorders and improved treatments for them.

G. Implications for Neuropsychopharmacology

Our changing views on modes of neurotransmission (hard-wired vs. VT) and on transporter function (carrier vs. channel mode), together with the marked advances in our understanding of transporter regulation, have paved the way for the development of new drugs. For example, drugs that cause immediate activation of certain protein kinases (or inhibition of certain phosphatases) may speed or enhance the therapeutic efficacy of current antidepressant treatments by either (1) causing a rapid reduction in the number of active transporters at the plasma membrane (e.g., through sequestration) and/or (2) bringing about more rapid changes in transporter gene expression. Likewise, the development of drugs that alter the probability of transporters acting in channel mode, or of drugs that

allow greater diffusion of transmitter from their release sites, is also an area for active research because of their therapeutic potential. In addition, understanding the regulation of transporters and the consequences of VT may result in determination of the mechanisms that underlie the reinforcing properties of cocaine, amphetamine, and other drugs of abuse.

Although our understanding of the role of transporters and of diffusion in regulating monoaminergic neurotransmission has increased tremendously in recent years, these remain more "classical" concepts. More recently the idea of peptidergic regulation of monoaminergic neurotransmission has emerged. In particular, there is new evidence that neuropeptide receptors may be novel targets for antidepressant and anxiolytic drugs. Therapeutic efficacy induced by antagonists of certain neuropeptide receptors is thought to be due to changes in noradrenergic and serotonergic activity. Because of this it is timely to review our current understanding of neuropeptide regulation of monoaminergic neurotransmission.

IV. NEUROPEPTIDE MODULATION OF MONOAMINERGIC NEUROTRANSMISSION

In the late 1970s and early 1980s, much fanfare hailed the emergence of a "new" class of brain neurotransmitter, the neuropeptides. Every year, more peptides were isolated, identified, quantified, and mapped anatomically in the brain. There was much excitement and anticipation that this era would generate a new understanding of neurotransmission and regulation of brain function. A noteworthy feature of neuropeptides that emerged from this period of research is that they seem invariably to be colocalized in the same nerve terminals with other neurotransmitters, including the monoamines [119], essentially forcing an obligatory inteaction between the two transmitter classes. Nonetheless, the nature of this interaction and the contexts in which it occurs must be determined by the complement of receptor subtypes expressed by the postsynaptic target neuron, and also by the differential release characteristics of the colocalized peptidergic and monoaminergic neurotransmitters.

A. Neuropeptides Are "Slow" Modulatory Transmitters

The general characteristics of peptide neurotransmission differ in many important respects from those of

monoamines [see 120]. Unlike monoamine transmitters, which are derived from a single amino acid by enzymatic synthesis, neuropeptides are small proteins comprising a chain of several amino acids. As such, they are synthesized in the cell body by ribosomal translation of messenger RNA. Like other proteins, they are usually synthesized first in the form of a precursor protein, which is then further cleaved and modified before the peptide is shipped via axonal transport to the nerve terminal. There it is incorporated into large dense-core synaptic vesicles [121]. Thus, unlike the relatively rapid changes that can be induced in the rate of enzymatic synthesis of monoamines directly in the nerve terminal, regulatory induction of neuropeptide synthesis is a slow process, requiring hours or even days for the activation of gene expression, *de novo* protein synthesis, and axonal transport before any change in releasable peptide becomes available to the nerve terminal.

The localization of peptide transmitters in large, dense-core synaptic vesicles, as opposed to the small, clear vesicles in which monoamines are found, also confers unique release characteristics on peptides. These large vesicles are situated father from the so-called active zones [122], than are the small clear vesicles. Thus, they are farther from vesicle docking and release sites, and farther from calcium entry sites, rendering them less sensitive to low levels of electrical activity in the nerve terminal. The practical implication of this is that monoamines show a fairly graded relationship between firing rate in the presynaptic fiber and the amount of neurotransmitter released into the synapse, whereas neuropeptides are preferentially released under conditions of intense activation or burst firing [123]. Thus, whatever regulatory interactions the peptides may have with monoamines, they are likely to occur preferentially under conditions of intense activation of the neuron in which the two transmitters are colocalized.

Unlike the monoamines, for which reuptake by specific transporters is so important to the regulation of synaptic effects, no such reuptake transporters have been identified for neuropeptides in the brain. Rather, termination of the synaptic action of peptides appears to depend upon bulk diffusion and extracellular enzymatic degradation by general peptidases, which can be located at some distance from the synapse [124]. Thus, not only is the synthesis and release of neuropeptides slower than that of monoamines, but the termination of action is slower as well. Moreover, the lack of transporter-mediated reuptake means that peptides are likely to engage in VT, as defined earlier in this

chapter. This is supported, perhaps even more strongly than with monoamines, by frequent "mismatches" between the distribution of peptide-containing nerve terminals and appropriate postsynaptic receptors in the brain [reviewed in 125]. These characteristics have all led to the general view that neuropeptides function primarily as neuromodulators, altering effects exerted by other neurotransmitters on the activity of target brain circuits.

The monoamines have themselves been described as serving neuromodulatory functions in the brain [126]. Thus, the corelease of neuropeptides and monoamines during stress, arousal, reward, etc., confers a much higher level of complexity on this modulatory process. With increasing neuronal activity, proportionately more monoaminergic transmitter is released, and its modulatory effect is presumably increased accordingly. However, at some threshold level of activity, the release of a neuropeptide cotransmitter may be progressively recruited. The peptide may itself have modulatory effects on the same target, or it may modify the presynaptic release or the postsynaptic effects of the monoamine with which it has been coreleased.

B. Potential Modes of Interaction Between Neuropeptides and Monoamines in the Brain

There are several ways that neuropeptides and monoamines may interact in the brain. They can be colocalized and coreleased onto common targets, whereby they may exert their respective postsynaptic modulatory effects independently, cooperatively, synergistically, or in opposition, depending on the physiological context and the complement of receptors expressed by the post-synaptic target neuron (see reviews [120,127] for general discussions of colocalized transmitter interactions). Alternatively, they may originate in different afferents that converge onto a common target. In this case, the possibilities for postsynaptic interaction are the same, though independent activation of the different afferent pathways allows for more context specificity in the modulatory interaction. Finally, peptidergic neurons may innervate monoaminergic neurons or terminals, thereby affecting the firing rate or release of the monoamine transmitter in its target region.

The recent development of new tools and techniques, together with the novel application of established approaches, is just now providing both the means and the mindset for making substantive progress in understanding the functional interaction between brain neu-

ropeptides and monoamine transmitters [128]. As this understanding progresses, we are forging a richer understanding of the potential contribution of neuropeptides, and their interaction with monoamine transmitters, in the development or treatment of affective disorders, including depression and anxiety [see reviews 129–133].

C. Substance P Antagonists as Novel Antidepressant/Anxiolytic Drugs

Substance P (SP) and its receptors are present in high concentrations in many forebrain limbic areas that have been implicated in affect and anxiety, including the hypothalamus, septal region, amygdala, and bed nucleus of the stria terminalis, as well as the periaqueductal gray, locus coeruleus, and raphe nuclei [134]. As for its relationship with NE and 5HT, the monoamines most implicated in the etiology and treatment of affective disorders, the substrates exist for many potential modes of interaction between these transmitters. Substance P terminals and receptors overlap those of both NE and 5HT. Likewise, SP fibers innervate serotonergic neurons of the dorsal raphe and noradrenergic neurons of the locus coeruleus. Finally, SP is colocalized with 5HT in ascending projections innervating the limbic forebrain in humans, other primates, and certain other species such as guinea pigs, though apparently not in rats or mice [135].

Surprisingly, whereas SP itself exerts primarily excitatory effects, blockade of SP receptors enhances both noradrenergic and serotonergic activity, most likely through a process of multisynaptic disinhibition [136]. Thus, SP antagonists may have an effect on monoaminergic transmission that is similar, at least acutely, to the effect of classical antidepressants that block monoamine reuptake. In preclinical behavioral assays, systemic or intraventricular administration of a SP antagonist attenuated anxietylike behaviors [137]. In animal models of anxiety- or depressive-like behavior, SP antagonist administration had effects similar to those of established antidepressant and antianxiety compounds [138]. These experiments on the affective response to SP antagonist administration culminated in a clinical study of the antidepressant and antianxiety efficacy of a centrally active SP antagonist in depressed patients [137]. The results of this study showed that the SP antagonist exerted both antidepressant and antianxiety effects, comparable to those of the SSRI paroxetine. This study showed great promise for the establishment of a novel antidepressant agent. Caution is necessary, though, until these clinical results

can be replicated. Nonetheless, should SP antagonists ultimately prove useful and efficacious against depression, their targeting a specific neuropeptide that interacts in a novel way with monoamines opens a new possibility for more widely effective, more efficient, or faster treatment of affective disorders.

D. Interaction of Neuropeptide Y and Galanin with Norepinephrine in Modulating Behavioral Reactivity to Stress

Two neuropeptides are prominently colocalized with NE in the locus coeruleus (LC)—neuropeptide Y (NPY) and galanin (GAL). Galanin is expressed in nearly all noradrenergic neurons in the locus coeruleus [139]; thus it likely serves as a cotransmitter in the many limbic forebrain sites innervated by the LC. By contrast, NPY is found in a much smaller proportion of noradrenergic neurons in the LC, but is extensively colocalized with NE in medullary noradrenergic neurons [140].

The central nucleus of the amygdala and the bed nucleus of the stria terminalis, two closely related components of the extended amygdala, are targets of dense noradrenergic innervation, and both have been implicated in fear and anxiety [141]. In a recent series of experiments, we demonstrated that the stress-induced release of NE in these regions facilitates the expression of anxietylike behavioral responses to acute stress [142,143]. This is consistent with the role proposed for NE in modulating affective components of the stress response, including vigilance, arousal, and anxiety [144–146]. By contrast, administration of NPY into the central nucleus exerts distinct anxiolytic effects [147–148], while local administration of NPY antagonist drugs into LC target regions can be anxiogenic [149].

Much like the autoinhibitory effects of NE acting on presynaptic alpha-2 adrenergic autoreceptors, it has been shown that NPY also acts on presynaptic NPY autoreceptors, reducing the release of both NE and NPY [150,151]. In addition, NPY receptors located on noradrenergic cell bodies inhibit the activity of these cells [152,153]. Thus, corelease of NPY with NE invoked when high levels of activity have been stimulated in noradrenergic neurons, may attenuate the anxiogenic effects of NE released in the limbic forebrain, exerting direct anxiolytic effects postsynaptically while at the same time acting presynaptically to inhibit the further release of NE.

Even more than NPY, galanin is extensively co-expressed with NE in the LC [139]. Like NPY, NE neuronal activity is also inhibited by galanin [154,155], and galanin receptors located on NE terminals, which may function either as postsynaptic heteroreceptors or as inhibitory autoreceptors that limit the release of galanin from those terminals, also inhibit the release of NE [151]. In a recent series of studies, we have shown that galanin exerts an anxiety-buffering effect in the central amygdala, attenuating the anxiogenic effects of acute stress that we showed were attributable to NE [156]. In this case, however, the galanin-mediated anxiolytic effect was elicited specifically when stress-induced activation of the noradrenergic system had been accentuated by prior administration of the autoreceptor antagonist yohimbine [158,159].

Along with this context specificity in the CeA related to the level of activation of the noradrenergic system, additional studies revealed that the functional interaction between NE and galanin in other regions of the limbic forebrain during stress were more complicated. In the bed nucleus, acute stress also induced NE release to facilitate anxietylike behavioral responses, but in this region, galanin facilitated these same behavioral responses [156,157], thus acting in the same direction as NE. Moreover, this facilitatory effect of galanin in the BST did not require prior treatment with yohimbine, as did the anxiolytic NE-buffering effects of galanin in the CeA. This is perhaps due to the fact that the major source of noradrenergic innervation in the bed nucleus arises from caudal medullary noradrenergic cell groups rather than the LC. Unlike the LC, these other noradrenergic cell groups do not show a high degree of galanin colocalization [139]. Thus, anxiolytic effects in the CeA may have originated from the corelease of galanin and NE from noradrenergic terminals, while anxiogenic effects in the bed nucleus may have originated from the activation of galanin-synthesizing neurons within the nucleus itself.

These neurons may themselves be targets of noradrenergic innervation [160], which would explain why their activity was elicited specifically in response to stress. Thus, depending on the level of activation of the noradrenergic system, the specific physiological context in which that activation occurred, and the specific brain region involved, galanin could either act in concert with or oppose the stress-induced behavioral effects of NE. Likewise, any drug that mimicked or blocked the effects of galanin in the brain could have anxiogenic, anxiolytic, or mixed effects depending on the context and the circumstance by which the behavioral response had been elicited.

Such complex interactions between transmitters of different classes may be subject to modification by a number of factors, including prior exposure to stress, chronic drug treatment, or genetic predisposition. Given the nature of this interaction, it is clear that drugs that affect monoaminergic neurotransmission could induce regulatory changes in both neuropeptide and monoaminergic functions, disrupting or resetting the delicate balance between these modulatory transmitters, either contributing to or interfering with their clinical effects.

In summary, then, the past decade has witnessed tremendous increases in our understanding of the complexity of the process of monoaminergic transmission and its regulation. This increased understanding has not yet been translated into substantial therapeutic advances but clearly has the potential to do so.

I. INTRODUCTION

The scientific inquiry into the human mind seeks to decode how brain structure and activity result in the vast range of cognitive and emotional processes each of us experiences. It also attempts to identify the anatomical and functional correlates of abnormal mental activity, as represented in the neurological and psychiatric disorders. In this perspective, neuroimaging has effected a radical change on the study of the connection between brain and mind.

Early investigations of brain function had to depend on indirect approaches. Lesion experiments on animals and postmortem clinicopathological correlations were the usual methods to investigate cerebral function, with obvious limitations. It was only at the end of the 18th century that the idea that different structures of the nervous system could perform distinct functions began to predominate. During the 19th century, the notion of functionally distinct cortical areas became well established, initially with the controversial works of Gall and the Phrenology school, and later with the discovery of the association of frontal cortex lesion and aphasia by Paul Broca [1]. Afterward, the conceptualization of the neuron, the discovery of specific

cytoarchitectonics of different cortical areas, and the electrophysiological experiments on animal and later human cortex have set up the theory of cortical localization of mental functions as the mainstream scientific framework for brain investigation. Event-related potentials and single-neuron recording, 50 years ago, provided further experimental support for cortical localization. But it was only in the early 1970s, with the advent of X-ray computed axial tomography (CT), that it was possible to visualize the brain parenchyma in vivo [2]. Since then, the field of neuroimaging has undergone astonishing developments, and these new methods have rapidly become the most powerful tools to contribute to the understanding of neural organization and mechanisms underlying the mental phenomenon.

The present chapter does not intend to be an exhaustive review of the various neuroimaging techniques currently in use. The specific findings of neuroimaging studies in various psychiatric disorders will be presented in other sections of this book. In this chapter, we have focused on the imaging methods of highest relevance for investigations of the neural basis of behavior, providing an overview of the physiological rationale underlying each method. Each available method

assesses a specific feature of the intricate cerebral machinery, with its typical resolution on the spatial and temporal domains, and characteristic methodological limitations. For didactical reasons, we grouped the various techniques into three groups: structural neuroimaging, including the methods designed to explore brain anatomy and structure; chemical neuroimaging, for the methods dedicated to evaluate cell metabolites, neurotransmitters, and receptors in the brain; and functional neuroimaging, encompassing the techniques that evaluate cerebral perfusion, metabolism, and neuronal activation.

II. STRUCTURAL NEUROIMAGING

Before the first CT studies, only highly invasive radiological approaches could be utilized to evaluate brain structural abnormalities in human subjects. Pneumoencephalography, which consisted of an X-ray after air injection into the encephalon through a lumbar puncture, was utilized during the first half of the 20th century to examine the ventricular system. This technique has provided the first in vivo indications of enlarged ventricles and cortical atrophy on schizophrenic patients [3]. The advent of CT yielded a booming interest on structural neuroimaging of psychiatric disorders. Measurements of ventricular dilatation and cortical and cerebellar atrophy could then be performed in several psychiatric disorders [4]. But the evaluation of specific brain structures was still challenging, due to the limited contrast between gray and white matter observed in the CT images. Also, artifacts on the posterior fossa were relatively common owing to dense bone structures surrounding this region, which made brainstem and cerebellum more difficult to evaluate with CT scans. Most of the shortcomings in the earlier structural brain imaging studies were overcome with the advent of magnetic resonance imaging (MRI).

The first commercially available MRI scans appeared in the early 1980s, but the phenomenon of nuclear magnetic resonance has been under study since the 1930s, through the landmark works of the American physicist Isaac Rabi [5], who received the Nobel Prize in physics in 1944. Structural MRI is one of the several brain-imaging technologies that explore the magnetic properties of the atomic nucleus. The MR method is based on the property of some atoms, whose nuclei present an odd number of either protons or neurons, to posses "spin"—i.e., a net magnetic charge, like a small bar magnet. Only the atoms

that have this property will be "visible" through nuclear magnetic resonance (NMR). Some biologically relevant examples include ^1H, ^{31}P, and ^{23}Na. Also, ^7Li and ^{19}F can be detected using NMR. Although present in negligible concentrations in the human brain, these atoms have important pharmacological relevance. On the other hand, atoms such as ^{12}C and ^{16}O are invisible to NMR.

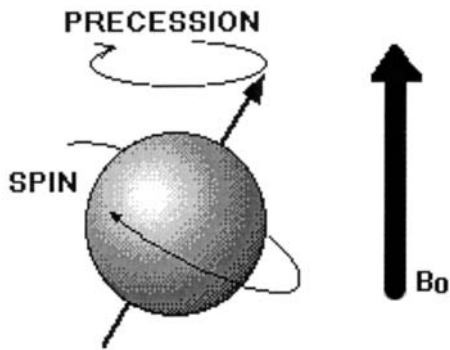
The atoms visible to NMR present a random distribution of the orientation of their nuclear magnetic moment when no external magnetic field is applied. However, when under an external magnetic field (B_0), the nuclei of these atoms tend to align with this field, in the same (lower energy) or the opposite direction (higher energy) (see **Fig. 1**). This is the first step in the acquisition of MR images: to immerse the brain in a strong magnetic field, usually $\sim$ 0.5–3 Tesla. For comparison, 1 Tesla is $\sim$ 20,000 times the Earth's magnetic field. Under the action of the magnetic field, the nuclei will spin and generate a movement of precession (see **Fig. 2**), whose frequency is characteristic for each
Figure 1 The nuclei of the individual atoms have a random distribution of their magnetic moment (A), with no net direction. When an external magnetic field B_0 is applied (B), all spins align either against or on the same direction of the field.


Figure 2 Spinning and precession.

atomic nucleus, and is proportional to B_0 strength. The next step is to expose these nuclei to a short-duration electromagnetic field (B_1, orthogonal to B_0), usually in the radio frequency range. This pulse excites the nuclei, disturbing the previous equilibrium state and inducing a transient phase coherence among the nuclei. This resonance can then be detected as a radio signal through a receiver coil. After turning off B_1, all nuclei return to equilibrium, i.e., from high-energy (excited) to low-energy (equilibrium) state. This process is associated with exponential loss of energy to surrounding nuclei; the time required for the magnetization to return to 63% of its original value is called T1. Since the process is exponential, the spins are usually completely relaxed after 3–5 T1 times. When returning to equilibrium, spins with high and low energy can also exchange energy without loosing it to surrounding nuclei. This phenomenon is termed spin-spin relaxation, and it is related to exponential loss in the transverse magnetization. Similarly, the time required for 63% of transverse magnetization to subside is called T2. For pure water, T1 and T2 are practically the same, around 2–3 secs. However, for most biological materials T2 is far shorter than T1. By varying parameters such as the repetition time or echo time of the radio-frequency signal, it is possible to acquire T1- or T2-weighted images, and consequently obtain distinct information from the biological tissues under analysis. Of course, this is a very simplified explanation of the mechanisms underlying the NMR phenomenon. Nonetheless, it is important to keep in mind that NMR can provide a varied range of information in a noninvasive fashion, from hemodynamics to cell chemistry. In the case of MRI, the resonance of large amounts of ^1H in the brain provides high-quality structural image, with spatial resolution of < 1 mm^3, allowing the identification of small brain structures.

Most morphometric studies with MRI utilize an approach known as region of interest (ROI). Basically, the area of a specific brain structure is manually "traced" directly in the image, and the final volume is estimated from the number of slices that intersect the structure under study (see **Fig. 3**). Usually this is done in a blind fashion; i.e., the researcher is not aware of the diagnosis of the subject whose brain MRI is being evaluated. Standardized protocols defining the boundaries of the structure are utilized, which enables reliable reproduction of these methods among different researchers. In some cases, semiautomated procedures can be used to detect the border of particular brain structures, or to derive three-dimensional volumes from the tracings. Also, algorithms are used to segment the brain into gray and white matter and CSF, allowing more specific measurements. ROI-based morphometry has provided extremely important contributions over the past several years, allowing the study of relationship between structural anatomy and psychopathology.

However, this method presents some limitations. Certain arbitrariness is necessary to set the boundaries of structures that do not have well-defined edges. Another limitation of ROI-based analysis is that struc-
Figure 3 Example of a structural MRI, with the hippocampus traced bilaterally in a coronal slice. In the region-of-interest analysis, an anatomical structure is usually traced in several slices, and the volume is derived from the sum of the areas multiplied by the slice thickness. For the hippocampus, semiautomated procedures are utilized to include in the analysis only the pixels identified as gray matter.

tures with different shapes can have the same volume. Thus, if the shape of an anatomical structure is different between patients and controls, but with similar final volumes, no differences between the groups will be detected. As an attempt to minimize these shortcomings, new experimental designs have been developed. For instance, it is possible to compare the content of gray matter between two groups of subjects in a voxel-by-voxel basis. Voxel is the three-dimensional graphic unit of an MR image, and through a specific mathematical approach, it is possible to examine the whole brain and identify areas that present a lower density of gray matter (voxel-based morphometry), or to compare the relative position (deformation-based morphometry), or local shape (tensor-based morphometry) of certain brain structures among different groups [6]. These statistical parametric methods have been used for functional data, and now are being validated for structural neuroimaging studies.

Nonetheless, a basic shortcoming underlies most of these morphometric methods: the links between the volume of a specific structure and the pathophysiology are still tentative. Data from other neuroimaging methodologies should be considered together to provide a better insight into the relevance of a volumetric finding. The cellular abnormalities underlying an atrophic cortex, for instance, can only be assessed directly through postmortem studies, or indirectly with MR spectroscopy (see below). Also, brain areas that are dysfunctional, but that maintain the same final volume and gray matter density of a healthy structure, will not be identified with morphometric studies, only with functional neuroimaging approaches. Moreover, typical MR images have a limited capacity to discriminate distinct white matter tracts. A very interesting and complementary morphometric approach, diffusion tensor imaging (DTI), has provided new possibilities to examine white-matter fibers. This MR methodology is based on the fact that water molecules inside axons have restricted diffusion; i.e., they diffuse faster in the direction of the axonal fibers than perpendicular to them. This property can be used to map white-matter tracts in vivo, and study the integrity of the connections among different brain areas [7].

The clinical application of MRI in psychiatry is limited, in most cases, to rule out neurologic abnormalities that might be responsible for the psychiatric symptoms, such as stroke or brain tumors. Even with the vast advances in structural neuroimaging observed in recent decades, it is still not possible to individually identify subjects with psychiatric disorders based on brain imaging. Typically, there is a considerable over-lap among the structural measurements of patients and healthy controls, even when the patients, as a group, present a statistically significant difference from the control group. Nevertheless, anatomical abnormalities identified with structural neuroimaging studies are helping to develop, in parallel with other neuroimaging approaches, integrated models of pathophysiology of mental disorders.

III. CHEMICAL NEUROIMAGING

Abnormalities in the signaling among neurons have been implied in virtually every neurobiological model for psychiatric disorders. The mechanism of action of drugs with profound effects on behavior, such as antidepressants and antipsychotics, has supported the idea of an imbalance in specific neurotransmitter systems in mental illnesses, e.g., the dopamine hypothesis in schizophrenia, and the monoaminergic theories in depression. However, most of the studies on neurotransmitter functioning were restricted to postmortem brain tissue or peripheral blood cells. This picture has changed drastically with the advent of positron emission tomography (PET) and single-photon emission computed tomography (SPECT). These techniques can provide in vivo anatomically localized information about several parameters of neural transmission, metabolism, and pharmacology.

PET and SPECT are imaging techniques that can quantify and localize biologically relevant molecules, marked with a radionuclide. The brain uptake of the molecule of interest can be ascertained by measuring the amount of the radiotracer in each specific brain region. PET and SPECT are based on different properties of radioactive decay. Basically, in PET the radiotracer decays emitting a positron, which collides with an adjacent electron. This leads to the annihilation of both particles and to the release of two gamma rays (photons) which exact opposite directions [8]. The radiation detector surrounding the brain can detect this coincident emission (see **Fig. 4**). A computer registers that the marked molecule was present at some point along this imaginary line, and later rebuilt a three-dimensional map of the amount of radiotracer for the whole brain. On the other hand, in SPECT, the radiotracer absorbs an electron when decaying, which results in an unstable nucleus that emits a single gamma-photon in this process [8]. The detector, also called *collimator*, rotates 360° around the subject's head, and later translates this information into a picture of the distribution of the radionuclide in the brain
Figure 4 Schematic representation of a PET scanner.
Figure 5 Schematic representation of a SPECT scanner.

(**Fig. 5**). Owing to these differences in the physical principles, PET and SPECT utilize radiotracers with distinct intrinsic properties, with PET usually providing better spatial resolution than SPECT.

Several aspects of in vivo neurochemical functioning can be assessed with either PET or SPECT. Numerous radiotracers have been developed to identify specific targets in the brain, including neurotransmitter synthesis and release, receptor occupancy and density, monoamine transporters and metabolism [9–11]. Dopaminergic, serotonergic, GABAergic (see **Fig. 6**), opioid, and cholinergic pathways have been studied through PET and SPECT radiotracers in several neuropsychiatric disorders; extensive reviews of available findings can be found elsewhere [12]. Also, PET and SPECT receptor studies have proven informative about the in vivo brain actions of several medications during clinical treatment. For instance, typical and atypical antipsychotics present a distinct pattern of occupancy of dopaminergic and serotonergic receptor subtypes [13,14]. These studies are particularly relevant to the investigation of links between side effects and response to treatment and receptor occupancy, and can aid in the development of new drugs.

Although the amount of radiation in the radiotracers currently utilized for research is minimal, the utilization of radioactivity represents a disadvantage of PET and SPECT techniques, since it limits the number of sessions in which a subject can participate. Better

spatial resolution and a greater diversity of available radiotracers make PET a more attractive methodology than SPECT for in vivo brain investigations in neuropsychiatry. However, PET radioligands typically have very short half-lives, so a cyclotron located near the PET scanner is required to the production of these tracers. This makes PET scan a very expensive technology: about US$5 million is necessary to install a PET center, not including the costs related to the extremely specialized and multidisciplinary staff [15]. Since SPECT costs a fraction of PET, and is more widely available, it is expected that improvements in tracer development and technical complexity will result in further advances of SPECT studies in psychiatry.

Measures of brain chemistry can also be obtained through the phenomenon of nuclear magnetic resonance. As stated in the previous section, several different atoms have nuclei with magnetic moment and can therefore be visualized through NMR. For instance, in MRI the images are formed through the resonance of huge amounts of ^{1}H atoms in water and fat. However, ^{1}H is also present in several other metabolites, and the resonance frequency of hydrogen is different depending on the molecule it is found. This occurs because nuclear resonance frequency is influenced by the magnetic fields of the nearby electrons and nuclei; i.e., the molecular environment of a certain nucleus produces a resonance frequency for this nucleus that is slightly different than the resonance of the nucleus alone.
Figure 6 PET scan image showing the brain distribution of GABA A / benzodiazepine receptors using the radiotracer [11C]-Flumazenil. Brighter areas indicate higher concentration of the tracer, and higher receptor densities.

This resonance is characteristic of each molecule, and can be represented in a scale called *chemical shift*, expressed in parts per million (ppm). For instance, the protons in water and fat exhibit two different frequencies, separated by approximately 3.5 ppm [16].

Several different ^{1}H-containing molecules will result in a spectrum of frequencies. This is the principle of magnetic resonance spectroscopy (MRS), a technique that has been used for decades in chemistry and physics to provide information about molecular structure and dynamics [17], and more recently has been employed in the study of in vivo brain chemistry. Given that different nuclei such as ^{1}H, ^{31}P, ^{23}Na, ^{13}C, ^{7}Li, and ^{19}F can be visualized in MRS, this technique allows measurements of molecules containing these nuclei in a noninvasive fashion, and without using radiation.

Since the concentration of most metabolites of interest in the brain is $\sim 10,000$ times smaller than the concentration of water, the signal of these metabolites is much weaker. Therefore, MRS studies usually exchange spatial resolution for chemical information. Although MRS procedures are evolving toward improvements on spatial resolution, most studies still utilize a volume-of-interest (VOI) approach; i.e., voxels usually ranging from 1 to 8 mL are placed in relevant

anatomical locations, and a spectrum is acquired from each VOI. A spectrum is a plot of intensity versus frequency, with each peak representing a different resonance frequency, i.e., different metabolites, whose concentrations can be estimated from the area under the peaks (see **Fig. 7**).

A varied range of chemical information relevant to research in psychiatry can be acquired from the in vivo brain with MRS [18]:

1. ^{31}P MRS studies enable measurement of pH, inorganic P, adenosine diphosphate (ADP) and triphosphate (ATP), phosphocreatine (PCr), phosphomonoesters, and phosphodiesters. Thus, information on cell membrane integrity and high-energy phosphate metabolism can be obtained.

2. ^{1}H MRS can quantify metabolites involved in neurotransmission (glutamate and choline), energy metabolism (PCr, creatine, lactate, and acetate), second messenger systems (myoinositol), membrane metabolism (phosphocholine and phosphoethanolamine), and neuronal viability (N-acetyl aspartate).

3. Pharmacokinetic and pharmacodynamic data can be obtained through ^{7}Li (brain lithium concentra-
Figure 7 After the processing of the raw MRS data, a mathematical model allows the identification of the peaks corresponding to the ^{1}H resonance frequencies in each distinct molecule. The concentration of each metabolite is then derived from the area under the respective peak. In ^{1}H MRS, the resonance signal of water is suppressed to permit the quantification of other ^{1}H-containing metabolites. The most important metabolites assessed with ^{1}H-MRS are: N-acetyl aspartate (NAA), phosphocreatine + creatine (PCr + Cr), trimethylamines (TMA; commonly referred to as choline containing molecules, which mainly includes phosphorylcholine and glycerophosphocholine), myoinositol (INO), glutamate (Glu), and glutamine (Gln).

tion and distribution, and its correlation with outcome/side effects) and ^{19}F MRS (measurement of the brain concentration of fluorinated compounds, such as fluoxetine and fluphenazine).

4. Glucose metabolism and its relation with the glutamate/GABA cycle can be assessed with ^{13}C MRS [19].

Thus, MRS provides noninvasive measurements of a variety of chemical species *in vivo*, and has the potential to bring important contributions for the investigation of brain chemistry in neuropsychiatric disorders. However, the current MRS methodology still presents significant limitations. MRS signals are weaker than those used by MRI, and the proper acquisition of the spectrum generally requires relatively large voxel sizes (poor spatial resolution) and long acquisition times (poor temporal resolution). Also, several compounds are not MRS visible, even when containing MRS-visible nuclei, owing to intrinsic molecular dynamics. Nonetheless, the ability to provide unique neurochemical information not accessible through other brain-imaging methodologies makes MRS an important tool in psychiatric research, and it is expected that future technical improvements will likely overcome some of the current shortcomings.

Another technique that makes use of the phenomenon of NMR to obtain neurochemical information is the magnetization transfer imaging (MTI). As MRS, this novel MR methodology utilizes the same magnets used to obtain structural MR images. While MRI explores the resonance of ^{1}H in free water to produce brain images, MTI identifies the resonance of protons that are bound to macromolecular structures, such as myelin, and therefore less mobile. The integrity of these macromolecular structures can be assessed through the exchange of magnetization between bounded protons and free water, denominated magnetization transfer ratio (MTR). MTR appears to be a sensitive methodology to identify subtle white-matter abnormalities that do not involve gross loss of volume, or an obvious focal lesion, and therefore are not detected on structural MRI [20]. Reductions in MTR have been reported in neurological conditions that involve white-matter lesions such as multiple sclerosis, and more recently this technique has also been applied to investigations in schizophrenia [21].

IV. FUNCTIONAL NEUROIMAGING

While structural and chemical brain imaging methodologies have remarkably bolstered our knowledge on the pathophysiological process involved in neuropsychiatric disorders, only functional neuroimaging can fully explore the temporal dynamics and regional neural activation underlying specific cognitive functions. Functional neuroimaging is at the forefront of scientific efforts to understand the mental phenomenon. Currently, this is the best method to evaluate the relationship between brain activation and a vast range of mental processes, from problem solving to consciousness. Based on the physiological rationale underlying the methods, we can divide the functional imaging technologies in two groups: those that evaluate an indirect measure of brain activation, such as regional blood flow and energy consumption, and those that directly assess the electrical and magnetical components of neural activity.

The connection between brain functioning and regional increases in blood flow was first proposed in the 19th century, but the scientific attention to this phenomenon had waxed and waned up to the 1950s, when the first measurements of regional blood flow with a diffusible radioactive tracer were made in animals (for a historical perspective of functional brain imaging, see Raichle [22]). Although the relationship of blood flow and neuronal activation is not fully understood, it is postulated that synaptic firing of a group of neurons results in a transient increase in the energetic demands of these cells, and in the local production of some metabolites that, eventually, will lead to local blood vessel response and consequent increased flow [23]. The spatial correlation between neural activation and hemodynamic changes is relatively precise, but the hemodynamic response is somewhat sluggish compared to the actual neuronal firing: blood flow begins to increase ~ 2 seconds after neuronal activation, reaching its peak ~ 5–7 sec [24]. Nonetheless, this robust physiological relationship was successfully explored initially through PET and SPECT methods, and more recently with functional MRI (fMRI).

Regional cerebral blood flow (rCBF) can be accurately and quickly measured with PET. Several radiotracers are available for these measurements, and $H_2^{15}O$ is the most widely used owing to, among other reasons, its short half-life (123 sec), which allows multiple repeat measurements in the same subject [15]. On the other hand, SPECT tracers only allow steady-state assessment of rCBF due to longer half-lives, with a relatively poorer spatial resolution when compared to PET [25]. However, the high costs involved in these procedures (particularly with PET) and the use of radioactive tracers represent relevant limitations to

their use. These shortcomings are helping to establish fMRI as the favored technique for rCBF measurements. fMRI is based on the fact that the hemodynamic response to neural activation usually surpasses the local oxygen needs, resulting in higher amounts of oxygenated and lower amounts of deoxygenated hemoglobin when compared with other surrounding areas. Since deoxygenated hemoglobin has more distinct magnetic properties than oxygenated hemoglobin, it may be unambiguously identified through NMR. Thus, neural activation leads to an increased rCBF, which results in a decrease in the content of deoxyhemoglobin in this specific brain region that can be quickly measured by the MRI scanner. This effect is termed BOLD (blood oxygen level dependent), and represents the most common fMRI approach to study brain activation [26]. Like PET, fMRI has the ability to map brain activation in the order of a few seconds, but with the advantages of having better spatial resolution, and being less expensive, noninvasive, and safer (no radiation involved).

fMRI has extended the work initiated with PET, due to its unique qualities, and has now a pivotal role in the functional mapping of the brain. Currently, the most important framework for the design of functional studies and interpretation of data is derived from cognitive neuroscience. In particular, the most widely used strategy consists of dissecting a simple cognitive task to its basic subunits, and to subtract the pattern of brain activation observed during the task of interest from a control task. For instance, one can subtract the map of activation after seeing a happy face from the activation after seeing a neutral face, in order to exclude brain activation related to the visual system, representation of human faces, etc., thus obtaining the activation correlated only with the identification of the emotion of happiness [27]. This methodology permits one to outline, either spatially and/or temporally, neural circuits that are active during specific cognitive processes. Cognitive subtraction is a powerful tool to examine the living brain, but is subject to some criticism, and more integrative and connectionist methodological approaches are now being utilized to address aspects of the mental phenomena that theoretically present less functional segregation [28]. A large number of studies have reported abnormal rCBF at rest or task-related for a variety of psychiatric syndromes and symptoms. An examination of all these findings is beyond the scope of this chapter; reviews of rCBF studies in mental disorders can be found elsewhere [12,29].

Increase in regional blood flow to the brain is not the only indirect physiological measurement of neuronal activation. Increased consumption of glucose is usually bound to increased rCBF in discrete neuronal areas. In fact, the first studies with PET utilized labeled glucose (^{18}F-2-fluoro-2-deoxy-D-glucose, or FDG) to map neural activation. It soon became clear, however, that the long half-life of FDG (110 min) would not allow quick and repeated measurements of discrete cognitive tasks. Nonetheless, interesting task-related regional changes in brain glucose metabolism could be identified with PET studies [30]. The increased blood flow in active brain areas is also correlated with localized tiny increases in temperature. A noninvasive methodology to record thermal information of cortical areas (thermoencephaloscopy; TES) is under investigation, and can potentially be a useful tool for functional neuroimaging [31].

Nonetheless, all methodologies assessing secondary physiological responses to neural activation, such as blood flow or glucose consumption, experience a critical weakness: these methods are not able to unambiguously track the time course of neural events. Neuronal activation occurs within milliseconds, while secondary increases in blood flow and energy consumption happen within a few seconds. Only direct recordings of the electric currents and magnetic fields that accompany the synaptic firing can provide such precise temporal resolution. Neuroelectrical brain measurements are based on the fact that synchronous activation of anatomically localized neurons results in electrical current strong enough to be detected at the surface of the head. Noninvasive recording of this effect is done by placing electrodes on the scalp surface; the more electrodes, the better spatial resolution. In essence, two basic types of neuroelectrical recordings can be performed: electroencephalography (EEG), comprising the examination of brain spontaneous electrical activity, and event-related potentials (ERP), which involves techniques to extract the characteristics of electrical events that are time-related to specific sensory, motor, or cognitive events [32]. ERP studies represent an essential methodology to evaluate functional integrity of sensory systems; moreover, this methodology allowed the identification of electrical potentials that are not directly related to sensory stimuli. These ''endogenous'' ERPs, such as P300 [33], have played a critical role in the examination of temporal and anatomical sequencing of neural activation related to cognitive processes such as attention, stimuli perception, and memory [34,35].

However, EEG and ERP can not be considered imaging methods in the same way that PET and

MRI. Although exhibiting superb temporal resolution, traditional electrophysiological methods provide poor spatial detail, which limits substantially the anatomical localization of neural activation. The distortion of the electrical signal caused by surrounding brain tissue, skull, and scalp is one of the reasons that account for the lack of detailed anatomical information of EEG/ERPs. On the other hand, the recording of the tiny magnetic fields that result from neuronal electrical activity can potentially provide better spatial resolution, since magnetic fields are not affected by the tissues and fluids they need to cross over.

This technique, named magnetoencephalography (MEG), requires more specialized facilities than EEG, such as a magnetically shielded room, and superconducting technology to record the in vivo brain magnetic fields, but offers similar temporal resolution with improved spatial definition. However, even with MEG, the anatomical resolution of electromagnetical technologies is strikingly inferior to PET or fMRI. Also, electrical or magnetic activities from structures below the surface of the cerebral cortex are difficult to register. Recent methodological strategies have been developed to combine the outstanding anatomical resolution of MRI with the unrivaled temporal definition of EEG/MEG. Brain electrical activity mapping (BEAM), quantitative EEG, and high-density electrical mapping (involving even 256 electrodes) are some of the methodologies utilized to provide a topographical analysis of the EEG/ERP signal. Multichannel MEG and magnetic-evoked field (the magnetic representation of the ERPs) studies have focused in source localization of neural activity by deriving coordinate transformations that permit one to locate magnetic fields in three-dimensional MR images; this technique is called magnetic source imaging (MSI).

These combined functional imaging techniques have been utilized to establish presurgical functional maps for the treatment of pathologies such as brain neoplasms and epilepsy, and more recently have been applied to the characterization of information processing in psychiatric disorders [36,37].

A novel and promising functional technique that may potentially provide insight on both hemodynamic and electrophysiological components of neural response is known as optical imaging. Initially utilized only on exposed living brain cortex [38], optical imaging has evolved into a noninvasive technique capable of mapping brain activity in vivo by way of measuring changes in the properties of light as it crosses different brain tissues. A basic assumption in this approach is that neuronal firing leads to rapid changes in the optical

characteristics of the brain region under activation [39]. Malonek and Grinvald have shown that localized changes in light *scattering* have a strong temporal association with cortical activation [40], whereas localized changes in light *absorption* appear to follow a temporal pattern strikingly similar to the slow hemodynamic response of neural activity [41]. Although the physiological mechanisms underlying these phenomena are not completely clear, it is believed that hemoglobin is the major factor responsible for photon absorption [42], while changes in light scattering may be directly related with alterations on the neural membrane potential [43].

Near-infrared spectroscopy (NIRS) is currently the most common form of noninvasive functional optical imaging [44], employing light of long wavelength that characteristically crosses farther through brain tissue than visible light. Investigations combining NIRS with fMRI, PET, and evoked-potential methodologies [39,45] have been validating NIRS and demonstrating its ability to evaluate in vivo changes in rCBF and neuronal activation in humans. Although the spatial resolution of NIRS is still limited [44], it is expected that technical advances will bring further improvements for this promising neuroimaging methodology.

V. DISCUSSION

The elucidation of brain mechanisms involved in formation of the human mind, and how it emerges from the activation of billions of neural cells, is one of the most interesting and challenging scientific endeavors of our day. Currently, in vivo neuroimaging methods have allowed unprecedented studies of the living human brain in health and disease. Available imaging methods can provide a vast range of information, such as detailed anatomical resolution, accurate studies of distribution and function of neurotransmitter systems and intracellular metabolites, and functional activation maps describing the temporal and spatial features of information processing in the brain in virtually real time.

Nonetheless, significant questions still remain to be addressed in the understanding of brain functioning. Conceptual theories on how the brain works are extremely important in the interpretation of neurobiological data. Substantial evidence of functional segregation of several brain functions has been provided from lesion deficit studies, and the identification of "hot spots"—i.e., brain regions unambiguously activated during specific cognitive processes—seems to provide support to theoretical approaches that try to localize mental tasks

to discrete anatomical regions. However, the brain is a massively interconnected structure, with reciprocal communications linking practically every anatomical region. A connectionist view of human brain function proposes that several brain regions must be integrated to perform elaborate cognitive functions such as thinking and emotion. Although not excluding modular processing, an integrative framework may be more promising to raise the most critical hypotheses to be examined with neuroimaging studies in psychiatric disorders [28].

Another major challenge in designing neuroimaging studies is the precise definition of the mental processes being tested. Concepts such as emotion, attention, and perception are clearly broad and complex terms, based on psychological models that have been debated over the years. This point is of crucial interest for neuroimaging studies in mental illness, since most psychiatric syndromes present myriad symptoms that may be potentially related to distinct neuropathological processes. Also, the blurred boundaries between some psychiatric diagnoses represent another thorny issue when conceiving an experimental imaging approach. In this sense, brain imaging studies can play a formidable role by helping to dissect the neural processes involved in each component of cognitive processing. This knowledge may eventually allow the development of more precise definitions of mental functions and psychiatric symptoms. Moreover, neuroimaging can potentially provide very important contributions to the development of new models to explain the pathophysiology of mental disorders, and ultimately characterize, for instance, neurobiological markers of illness vulnerability or psychopathology severity. These developments could eventually result in more effective treatments for psychiatric illnesses.

It is essential to understand the weakness and strengths of imaging methodologies, though. Significant efforts are being directed to the improvement of the spatial and temporal resolution of these techniques, and also to be able to examine various neurotransmitter and intracellular signaling systems. Techniques that blend different methodologies, such as MEG + MRI (MSI), seem especially promising. Furthermore, the appreciation of pathological brain functioning will not be complete without a thorough investigation of the healthy brain. In this direction, the development of detailed brain atlases comprising different imaging modalities (anatomical, neurochemical, and functional) is crucial. However, most brain measurements are continuous instead of categorical, and there is an enormous interindividual variability,

and consequent overlap of these measurements among psychiatric patients and healthy controls. To consider these issues, population-specific, diagnostic-specific, and developmental probabilistic atlases are in progress [46]. Moreover, the systematic brain mapping of nonhuman primates, and even other species, plays a vital role in setting the findings into an evolutionary perspective, providing a relevant theoretical framework for the identification of specialized neural systems in the human brain [47].

In summary, neuroimaging studies are helping to narrow the gap between clinical psychiatric manifestations and the underlying neuronal pathology. Numerous investigations have confirmed the presence of identifiable brain pathology in mental illness, from gross anatomical abnormalities to dysfunctional task-induced activation of cortical areas. Although no pathognomonic lesions have been identified so far, neuroimaging represents one of the most powerful and versatile methodologies for the study of the living human brain, and has started to provide significant advances in our knowledge of the neurobiology of mental illnesses.

Classification of Childhood and Adolescent Psychiatric Disorders

NORAH C. FEENY and ROBERT L. FINDLING

University Hospitals of Cleveland and Case Western Reserve University, Cleveland, Ohio, U.S.A.

I. INTRODUCTION

In the past 20 years, the classification and diagnosis of psychiatric disorders in children and adolescents have undergone substantial change. For example, though long disputed, we now know that depressive disorders can and do occur in youths, as well as in adults [e.g., 1–3]. In general, we use classification systems to reduce complexity, to create order, and, in psychiatry and psychology, to inform treatment. They are heuristic systems that assume general similarities across individuals in particular groups (e.g., depressed vs. not; anxious vs. not) who show similar symptoms. For a psychiatric classification system to be optimally useful, it must reliably differentiate between groups based on established criteria, serve a practical function, predict future behavior, and adequately capture the construct it was intended to. In short, it must be reliable and valid. The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) [4] is the most commonly used diagnostic system in the United States. It utilizes a categorical (as opposed to dimensional) classification system organized by symptom clusters and grounded in empirical findings. In this paper, the DSM-IV disorders will be reviewed as they relate to children and adolescents. First, we will discuss disorders typically diagnosed in infancy and childhood. Second, we will

review syndromes that are generally diagnosed in adulthood and how they manifest in children. Specifically, for each diagnostic category, we will review information related to the definition and prevalence of the disorder, comorbidity with other psychiatric disorders, course and developmental considerations relevant to the disorder.

II. DISORDERS TYPICALLY DIAGNOSED IN CHILDHOOD

A. Disruptive Behavior Disorders

In DSM-IIIR [5], attention, conduct, and oppositional behaviors were newly grouped together under the rubric of disruptive behavior disorders. This diagnostic reorganization was partly due to accumulating evidence that the separation of attention and behavior problems was not empirically supported (e.g., 6). DSM-IV maintained this overall organization, but made some major changes to the classification of these disorders: (1) the creation of an overarching category for patients who experience difficulties with restlessness, impulsivity, and inattention: attention deficit hyperactivity disorder (ADHD) with three resultant subtypes; and (2) the creation of two subtypes for conduct disorder based on age of onset.

1. Attention Deficit Hyperactivity Disorder (ADHD)

ADHD is characterized by a persistent and developmentally inappropriate pattern of inattention and/or hyperactivity-impulsivity that is present before age 7 and causes functional impairment in at least two settings (e.g., school and home). Symptoms must be present for at least 6 months. In the DSM-IV, there are three ADHD subtypes: predominantly hyperactive-impulsive, predominantly inattentive, and combined type. Diagnosis of the subtypes should be based on the predominant symptoms for the last 6 months. These subtypes were developed empirically from the DSM-IV field trials, but little is known regarding how valid and valuable they are clinically. In support of their usefulness, in the field trials the subtypes were shown to have differing clinical pictures: inattentive patients were more likely to be female, and were older than the combined types. Combined-type youths were older than the hyperactive impulsive patients and showed greater clinical impairment than the other two types.

The prevalence of ADHD is estimated to be 3–5% in school-age children [4,7]. With the new DSM-IV criteria, preliminary studies suggest that rates have increased owing to the definition of the three subtypes. While much is unknown about the etiology of ADHD, there is now a fair amount of evidence from twin and family-genetic studies that suggest that this disorder runs in families [e.g., 8,9].

Comorbidity is very common among youths with ADHD, most commonly with conduct disorder [10,11,12] and oppositional defiant disorder [13]. Conduct disorder is characterized by serious and pervasive aggressive and antisocial behavior. The overlap between ADHD and conduct disorder has been found consistently in studies of children with both disorders and estimates suggest that 40%–60% of teens with ADHD meet criteria for conduct disorder. The prognosis is worse for those youths who have both ADHD and conduct disorder; these youths are at increased risk for substance abuse, school failure, and future occupational failure.

In regard to the course of the disorder, ADHD is most typically diagnosed in children and adolescents, and symptoms usually decrease in later adolescent and adult years. Although ADHD severity decreases on average with age, symptoms are persistent for many children; in one study, 4 years after initial diagnosis 80% of youths continued to meet criteria for ADHD [14]. Although ADHD is usually diagnosed in child-

hood, the disorder can be diagnosed in adults as long as symptoms were present before the age of 7. The concept of adult ADHD is not without controversy, however; some claim that adult ADHD is very rare [e.g., 15], while a growing body of evidence suggests that ADHD often persist in adulthood [16]. Some data that support the validity of ADHD in adulthood come from studies that show the children of ADHD adults to have increased prevalence of the disorder [17]. Other support comes from studies showing parents of youths with "persistent" ADHD being much more likely to have ADHD than parents of youths with remitted ADHD [18]. As noted in DSM-IV [4], ADHD's symptom pattern changes with development, often making diagnosis more difficult in adults. For example, disorganization and inattention rather than hyperactivity, are often prominent in adults. Predictors of a good outcome for adulthood include: mild initial severity of ADHD, a supportive family environment, higher intelligence, and a lack of comorbid conduct disorder.

2. Oppositional Defiant Disorder (ODD) and Conduct Disorder (CD)

ODD and CD are childhood disorders characterized by a stable pattern of defiant and/or aggressive behavior that causes functional impairment at home, at school, or in both settings. The diagnosis of CD requires that at least three characteristic behaviors (e.g., stealing, threatening, fighting, cruelty to animals or people) be present in the last 12 months, with at least one symptom present in the last 6 months. Children with this disorder often violate the rights of others, break serious rules, and are destructive and deceitful. DSM-IV criteria specify two subtypes of CD: childhood onset and adolescent onset.

Children with ODD are characteristically negativistic, defiant, and hostile toward authority figures. For a diagnosis of ODD, four defiant behaviors (e.g., temper outbursts, talking back, breaking rules) must be present frequently over a period of 6 months. There are no identified subtypes for ODD.

Prevalence rates for CD appear to be on the rise in the recent decades and may be higher in urban than in rural settings [4]. However, prevalence rates differ dramatically depending on the sample being studied and the assessment method used: for males younger than 18, rates range from 6% to 16%; for females, rates range from 2% to 9%. Similarly, depending on the sample and assessment method, rates of ODD from 2% to 16% have been found [4]. Rates for both behavior disorders are higher in boys than in

girls, though after puberty, rates for ODD become roughly equal.

As discussed above, comorbidity between CD and ADHD is quite common. CD and ODD are also commonly comorbid. Indeed, there is significant diagnostic overlap among the disruptive behavior disorders (particularly among very young children) as well as genuine cooccurrence of these conditions [19,20]. It has been suggested by some that hyperactivity is a necessary part of CD [21]. Thus, to appropriately guide treatment, thorough, multimethod, multi-informant evaluations are necessary to attempt to determine which children meet criteria for CD, ODD, and/or ADHD.

In terms of the course of these disorders, there is a good amount of support for the continuity between externalizing problems in preschoolers and CD in children who are school aged and older [e.g., 19,22]. In a review of longitudinal studies examining preschoolers with behavior problems, Campbell [23] showed that at least 50% with moderate to severe behavior problems continued to manifest such problems when they were school aged. Similarly, Richman, et al. [24] showed that almost 70% of preschoolers with disruptive behavior problems continued to have aggression problems when assessed 5 years later.

However, studies of young adults suggest that CD symptoms decline with age; in a longitudinal study of children with ADHD, Manuzza et al. [25] reported that the prevalence of CD dropped from 25% at age 18 to 15% at age 25. In a similar study of youths (6–17 years) with ADHD, Biederman et al. [14] found that CD symptoms persisted in only 42% of those originally diagnosed with subthreshold or full CD. Consistent with these findings are those of CD samples documenting similar decreases in CD symptoms over time [e.g., 26,27]. It may be that significant conduct problems still remain for most, but that previously obvious and overt behaviors become more covert with age and thus are less readily discerned using standard assessment procedures. When looking at the course of ODD, symptoms appear to be stable over time [28]. Importantly, ODD does appear to be validly distinct from CD: the developmental profile, sex distribution, and factor analytically derived behavioral dimensions differ between the two disorders [29–31].

B. Mental Retardation

Many definitions of mental retardation (MR) have been utilized over the years, differing primarily in emphasis, rather than specific content. According to the DSM-IV, MR is defined by intellectual functioning that is significantly below average (IQ of 70 or below) existing prior to age 18, with associated deficits in adaptive functioning. This definition incorporates all of the elements of the widely accepted description of MR developed by the American Association of Mental Retardation (AAMR). In the DSM-IV, MR is further classified according to severity: mild (IQ of 50–55 to 70), moderate (IQ of 35–40 to 50–55) severe (IQ of 20–25 to 35–40), and profound (IQ below 20–25). The AAMR recently abandoned such severity classifications in favor of classification based on the specific needs of individuals with MR. Despite such classification differences, it is widely accepted that the core features of MR are low intelligence and deficits in developmentally appropriate life skills.

Mental retardation occurs in $\sim 1\%$ of children and adolescents. However, prevalence estimates vary significantly depending on how mental retardation is defined, the sample selected, and the assessment tools used. Early research suggests that MR is more common with increasing age [32], in males [33], and in minority groups [34], though this last finding may be related to bias in assessment tools. Additionally, research indicates that the prevalence of MR decreases with age as functional impairment due to low cognition reduces with age [4]. Recent reviews of the literature related to the prevalence of MR have suggested that large gaps remain in our knowledge and have called for standardization of MR definitions and research methodologies [e.g., 35].

Comorbidity of psychiatric disorders among individuals with MR is significantly more common than in the general population [4]. For example, a recent study of > 6000 children identified 1.5% as having some sort of intellectual deficiency; of these, 32% were also identified as having a comorbid psychiatric disturbance [36]. The rates of comorbidity were significantly higher among those with intellectual deficiencies than among those who were not intellectually disabled [32% vs. 13.5%). Similarly, in an investigation of all children identified with MR in a Norwegian county, 37% were diagnosed with a comorbid psychiatric disorder, most commonly a pervasive developmental disorder [37]. Rates obtained were higher for those with severe MR than with those with mild MR: 42% and 33%, respectively. This pattern is consistent with the adult literature where those with more severe MR have significantly higher rates of comorbidity as well [e.g., 38].

The course of MR varies somewhat depending on the severity of the disorder, associated medical conditions, and environmental opportunities. As mentioned above, a diagnosis of MR necessitates that the disorder

be present prior to 18 years of age. More severe retardation tends to be diagnosed at younger ages, especially when associated with a characteristic, syndromal presentation (e.g., trisomy 21) [4]. MR is only diagnosed when clear deficits in adaptive behavior, judged within a developmental context, are present (assessed using standardized tools such as the Vineland Adaptive Behavior Scales). Such deficits can include impaired self-help skills, communication, academics, safety, and work performance. Less severe cases are often not diagnosed until children are old enough to have noticeable difficulties in school. Academic deficits are among the most easily documented and measured, perhaps accounting for the relatively high prevalence of MR during the school years [39]. Indeed, in adulthood, many individuals previously diagnosed with MR may be able to function adaptively enough outside of the academic arena that they are no longer classifiable as MR. That is to say, MR is not necessarily a lifelong disorder; for those adults who can develop good adaptive life skills in various domains (e.g., self-care and work), their level of functioning precludes an MR diagnosis [4].

C. Learning, Communication, and Motor Disorders

This group of disorders is characterized by academic, motor, or communication skills that are below developmental and intellectual expectations. Learning disorders are a fairly heterogeneous group of difficulties distinguished by academic achievement that is substantially below that expected for one's age, intellect, and/or schooling [4]. As a group they include: reading disorder, mathematics disorder, disorder of written expression, and learning disorder not otherwise specified. In the DSM-IV [4], it is specified that achievement deficits be measured by a standardized, individualized test and that they significantly interfere with academic performance or daily life.

Developmental coordination disorder, the only motor skills disorder, is characterized by a significant impairment in motor coordination that causes functional impairment; the specific manifestations of this disorder vary with age and development. The communication disorders include expressive language disorder, mixed expressive-receptive language disorder, phonological disorder, stuttering, and communication disorder not otherwise specified (NOS). Those diagnosed with expressive language disorder have deficient expressive language skills, including small vocabul-

aries, few multiple-word combinations, and idiosyncratic word ordering. Mixed expressive-receptive disorder is characterized by delays in both expressive language and receptive language (i.e., comprehension). Phonological disorder is defined as the failure to develop typical speech sounds (e.g., ch, bu) at the expected age, and stuttering is characterized by speech dysfluency, syllable and sound repetition, and disrupted speech timing.

The prevalence of these disorders is thought to be relatively high, but estimates vary according to sample characteristics and measures used. According to most estimates, 5–15% of school-age children have learning disabilities [40], and these are diagnosed more commonly in boys than in girls [41]. Approximately 6% of young children have developmental coordination disorder [42], and 5–10% of children are estimated to have communication disorders [4,43]. Among the communications disorders, expressive language delays have been found to be the most common. Stuttering, in particular, is much more common in boys than in girls [3:1].

Many children with learning disorders also have associated comorbidities. Conversely, 10–15% of those with conduct disorder, oppositional defiant disorder, ADHD, and depressive disorder also have learning disorders [4]. Although developmental coordination disorder has not been well researched yet, associated difficulties are thought to include other developmental delays, in particular language delays [4]. More research has focused on communication disorders, and at this point, it is fairly well established that young children with communication difficulties are at increased risk for continued language problems, learning disorders, and psychiatric difficulties [e.g., 44–46].

Learning disorders as a group are thought to have a similar course over time. They are most commonly diagnosed in the elementary school years when academic challenges begin to go unmet. The school dropout rate for children with learning disabilities is 40%, significantly higher than the rate for those without such disorders [4]. Higher IQ is associated with better outcome for those with learning disorders. Depending on severity, learning disabilities may persist until adulthood and cause impaired occupational functioning [47].

Among the communication disorders, the course is more variable. Age of identification is predictive of language disorder severity, with later-identified children typically having more severe and persistent

delays. Phonological difficulties that are not severe are the most likely to resolve. Among those with expressive language difficulties, ∼ 50% will "recover" and the rest will continue to manifest significant language difficulties [e.g., 48–50]. We know very little about the course of developmental coordination disorder; future research should examine the longitudinal course of significant motor skills deficits.

D. Pervasive Developmental Disorders

The pervasive developmental disorders (PDDs) are characterized by severe impairment in several crucial areas of development: communication, social interaction skills, and/or the presence of stereotyped behavior, play, or interests. These disorders are often diagnosed in the first years of life and are typified by behaviors and skills that are grossly developmentally delayed and/or inappropriate. PDDs as defined by the DSM-IV include autistic disorder (autism), Rett's disorder, childhood disintegrative disorder, Asperger's disorder, and pervasive developmental disorder not otherwise specified (PDD NOS) [4].

Autism's essential features include abnormal or impaired social interaction and communication and a severely restricted inventory of interests and activities. Delays or abnormalities must be present before the age of 3 in at least one of the following areas: social interaction, language in social communications, or symbolic/imaginative play. Most children with autism are also mentally retarded [4]. Rett's disorder, which has only been seen in girls, is distinguished by a period of typical functioning followed by the development of multiple specific deficits. For these children, head growth decelerates between 5 and 48 months, previously acquired hands skills are lost between 5 and 30 months, and subsequently, stereotyped hand movements similar to hand-wringing or hand-washing appear. In addition, interest in social interaction diminishes, expressive and receptive language are impaired, psychomotor retardation develops, and poorly coordinated gait or trunk movements appear. Childhood disintegrative disorder (CDD) is similar to Rett's disorder in that severe regression occurs after a period of typical development, but normal development must have lasted at least 2 years. A diagnosis of CDD requires that after the age of 2 (but before 10) there is a clinically significant loss of previously acquired skills in at least two of the following areas: expressive and receptive language, social skills or adaptive behavior, bowel or bladder control, and/or play or

motor skills. Children with CDD exhibit social and communication deficits that are similar to those observed in children with autism. Asperger's disorder like autism, is characterized by persistent and severe impairments in social interaction and restricted, repetitive behavior, interests, and activities. However, with Asperger's disorder there are no characteristic language delays or deficits, nor are there cognitive impairments or deficits in age-appropriate adaptive behavior. PDD NOS is a diagnosis for those children who exhibit many, but not all, of the specific features required for a diagnosis of a specific PDD.

In terms of prevalence, PDDs are quite rare. Epidemiological studies suggest a rates of autism to be two to five cases per 10,000 individuals [4]. Data specific to prevalence for the other PDDs are very limited. Rett's disorder has only been discussed in limited case studies and only seen in females. Childhood disintegrative disorder (CDD) is thought to be very rare (much less common than autism) and more common in males than females. Asperger's disorder is also thought to be very rare, and also appears to be more common in males than in females.

PDDs are typically lifelong disorders with characteristic developmental shifts in symptom patterns. However, with early, intensive behavioral treatment some children with autism, Asperger's, or PDD NOS may benefit significantly enough that they lose their PDD diagnosis [51]. Unfortunately, this is not the case for most children; this sort of treatment is not widely available, and is variable in its success depending on factors such as severity of initial symptoms, comorbid mental retardation, and other individual differences that we do not yet well understand. Children with autism typically develop better functioning with age and often show some improvements in language and social interaction. For children with Rett's disorder there are characteristic developmental changes: between 1 and 3 years symptoms are very similar to those of autism, between 2 and 10 years of age, social interest increases somewhat, and after age 10, there are worsening motor problems [52]. For children with CDD, the long-term outcome is typically not very good, with little improvement in specific skills over time. Across the PDDs the prognosis is typically best for those with Asperger's, as they have communicative and cognitive skills that enable them to function well despite substantial social skill deficits. In adulthood, Asperger's (or mild autism) might be confused with schizoid or schizotypal personality disorders because of the overlapping social deficits [4].

III. PSYCHIATRIC DISORDERS USUALLY DIAGNOSED IN ADULTHOOD

A. Mood Disorders

1. *Major Depressive Disorder (MDD) and Dysthymia*

Although depression was not officially recognized as a disorder of childhood until 1980, at this point it is relatively well established that the clinical presentation of depressive disorders in children is similar to that seen in adults [4,53]. The DSM-IV uses adult criteria to diagnose depressive disorders in children, but places a greater emphasis on the developmental course of the disorder than DSM-III or DSM-III-R. Documented developmental differences in the presentation of MDD include increased suicide attempts and impairment in functioning with age, and decreased somatic complaints, phobias, and behavioral problems, which occur more in childhood than adulthood [e.g., 54].

In the DSM-IV [4], a diagnosis of MDD is made in individuals who demonstrate at least one major depressive episode (MDE) without previous experience of a manic, mixed, or hypomanic episode. Two weeks of a depressed mood or the loss of interest or pleasure in nearly all activities characterizes an MDE. In children, irritability rather than sadness can be the predominant emotion. In addition to a mood disturbance, at least four other symptoms from the following list must be present: changes in sleep, appetite/weight, or psychomotor activity; reduced energy; feelings of worthlessness or guilt; difficulty thinking concentrating or making decisions; and thoughts of death or suicidal ideation, intent, or plan. To be considered symptoms of MDD, these difficulties must represent a clear change from previous functioning.

Dysthymia is a more chronic depressive disorder characterized by similar symptoms of a lessor severity and longer duration (at least 2 years). In the following sections, we will focus primarily on MDD, as the majority of research data pertains to this diagnosis rather than dysthymia.

Depressive disorders in youths are not rare: population studies estimate that between 0.04% and 2.5% of children and 0.04% and 8.3% of adolescents have MDD [54] and ~3% have dysthymia. In a large-scale study of adolescent psychopathology, MDD had the highest lifetime prevalence rate (20%) of all disorders surveyed, and a point prevalence rate of 2.92 [55]. These findings are consistent with other studies of adolescent depression, and with lifetime rates of MDD found among adults [e.g., 56,57]. In childhood, rates of depression are similar for girls and boys; in adolescence, however, the female-to-male ratio jumps to 2:1, which is comparable with ratios found in adult depression [e.g., 3,58].

MDD in youths is often comorbid with other psychiatric disorders. Rates of comorbidity in youths are comparable with, or slightly higher than, rates seen among adults with depression [59]. Epidemiological studies have shown that 40–70% of depressed children and adolescents have a comorbid psychiatric disorder, and that approximately 20–50% have more than one comorbid condition [e.g., 60–62]. Dysthymia cooccurs with depression in ~ 30% of youths and adults [59]. Diagnoses that are most commonly comorbid with depression in youths include anxiety disorders (30–80%), disruptive behavior disorders (10–80%), and substance abuse (20–30%) [63]. Indeed, anxiety disorders so commonly co-occur with depression that some have argued that they are manifestation of the same, not distinct disorders [64]. Others have cogently argued that although anxiety and depression do share some overlapping symptoms, the absence of positive affect is characteristic of depression, not anxiety [see 65].

Depression in youths is disabling and chronic, though perhaps somewhat less so than among adults. In a large, randomly selected sample of high school students, those who were identified as depressed were likely to have moderate to severe depression (88.6%) and to be judged in need of treatment (93.2%) [55]. The average length of a depressive episode is 9 months in youths [66], while on average 12 months for adults. Relapse rates are disturbingly high for children and adolescents with depression; ~ 70% will relapse with in 5 years [55,59]. Moreover, follow-up studies of depressed youths indicate that 20–40% will go on to develop bipolar disorder within 5 years of the onset of their depression [e.g., 67,68].

2. *Bipolar Disorders*

Though not without controversy, in recent years it has become more recognized that children can manifest symptomatology that is consistent with a diagnosis of mania, or bipolar disorder (BPD). Indeed, several exhaustive reviews of the literature have supported the validity of this diagnosis in youths [69–71]. According to DSM-IV, the occurrence of one or more manic or mixed episodes determines BPD. A manic episode is characterized by a distinct period of an abnormally elevated, irritable, or expansive mood that lasts at least a week. In addition to this mood

disturbance, three symptoms from the following list must be present: inflated self-esteem or grandiosity, decreased need for sleep, pressured speech, increased activity or psychomotor agitation, distractibility, flight of ideas or racing thoughts, or involvement in pleasurable activities with a high potential for negative consequences (e.g., buying sprees or indiscriminant sexual encounters). A mixed episode is defined as a period of at least 1 week during which criteria for both a manic and depressed episode are met. Often there is also a history of depressive episodes in these individuals. As classified in DSM-IV, bipolar disorders include: bipolar I, bipolar II, cyclothymic disorder, and bipolar disorder not otherwise specified. These disorders are differentiated based on the duration of symptoms and presence or absence of a full-blown manic or mixed episode.

Empirical work suggests that while bipolar disorder is difficult to diagnose in children, in part because it differs from adult mania in presentation, prevalence rates are higher than previously thought in youths, particularly among inpatients. However, few well-done studies of the prevalence of BPD exist. In one recent study of > 250 consecutively referred preadolescent children, Wozniak and colleagues [72] found that a surprising 16% met diagnostic criteria (DSM-III-R) for mania. In light of such high rates of mania documented by some researchers in specialty mood clinics and low rates seen in epidemiological studies (lifetime prevalence rate of 0.58) [73], the "real" prevalence of BPD in youths and how to best diagnose the disorder is still a hotly debated topic [see, 74–76]. To resolve this debate, more well-designed research needs to be conducted in the area of diagnosis and prevalence of pediatric bipolarity.

Comorbidity with childhood mania is the rule rather than the exception. However, the exact nature of the relationship between childhood mania and other disorders, in particular, attention deficit hyperactivity disorder (ADHD), is still being debated [77]. Indeed, symptom overlap with ADHD (e.g., impulsivity, concentration problems) is one of the most challenging aspects of accurately assessing and diagnosing bipolar disorder in children. Studies have shown rates of ADHD ranging from 60% to up to 90% among children with mania [72,78,79]. Studies involving children with bipolar disorder have also documented a high degree of overlap with conduct disorder [72,80,81]. For example, Kovacs and Pollack [81] reported that among children with BPD, an astonishing 69% also had conduct disorder. A recent epidemiological study also documented high rates of cooccurrence between

these disorders [73]. Such complicating comorbidities, as is typical with other disorders, predict a worse course for these youths [e.g., 81].

Age of onset for a first manic episode is typically during late adolescence, but, as alluded to above, some cases start in early adolescence or childhood [4]. The course and presentation of pediatric mania is often atypical when compared to adult mania. Adult and adolescent mania is typically episodic with an acute onset, and is characterized by the presence of euphoric mood. With children, on the other hand, some have asserted that mania during childhood is characterized by a chronic, mixed mood state [72,76] and that the mood disturbance often manifests as irritability rather than euphoria [82,83]. In a recent review of the empirical literature related to pediatric bipolar disorder, it was concluded that, "pre-pubertal BPD is a nonepisodic, chronic, rapid cycling, mixed manic state." [70]. This suggests that BPD in youths is indeed atypical when compared to adult BPD, but that it is predictably atypical.

B. Anxiety Disorders

Excessive fear, distress, and/or avoidance of particular situations or objects, thoughts/memories, or physical sensations characterize anxiety disorders. In the DSM-III-R, three anxiety disorders were listed in the child section: overanxious disorder (OAD), separation anxiety disorder, and avoidant anxiety disorder. In DSM-IV, questions regarding the validity of these diagnostic categories led to a reorganization so that only separation anxiety disorder currently remains in the childhood disorders section (in the category "other disorders of childhood"). In addition, the criteria for social phobia and generalized anxiety disorder were modified so that they incorporated the symptoms of children who would have been previously diagnosed with avoidant or overanxious disorder. As such, according to DSM-IV, the general anxiety disorders include: panic disorder with and without agoraphobia, specific phobia, social phobia, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), acute stress disorder (ASD), generalized anxiety disorder (GAD), anxiety disorder due to a general medical condition, substance-induced anxiety disorder, and anxiety disorder NOS. After describing each disorder, we will focus on those that are most relevant to children and adolescents and for which the most research exists: social phobia (previously avoidant disorder in children), generalized anxiety disorder (formerly overanxious disorder in children), and

separation anxiety disorder. Although, as previously mentioned, separation anxiety disorder is not formally classified with the anxiety disorders, we will discuss it in this section because of the considerable theoretical and clinical overlap it shares with the anxiety disorders as listed in DSM-IV.

In terms of the features that are specific to each disorder, panic disorder with and without agoraphobia is characterized by panic attacks (sudden onset of intense fear and physical symptoms such as racing heart, shortness of breath, feeling dizzy or faint) about which there is persistent concern. Avoidance of or anxiety about places from which escape would be difficult or embarrassing in the event of panic characterizes agoraphobia. Specific phobias are defined by significant anxiety related to a specific object (e.g., insects or needles) or situation (e.g., elevators or flying) which often leads to avoidance. Social phobia is characterized by anxiety and resultant avoidance related to social or performance situations. OCD is defined by the presence of intrusive, upsetting thoughts (obsessions) and compulsions (repetitive or ritualized behaviors or mental acts) designed to reduce anxiety. PTSD is characterized by reexperiencing (e.g., in nightmares or intrusive thoughts) a traumatic event accompanied by avoidance of trauma-related stimuli and increased arousal (e.g., sleep and concentration difficulties). Acute stress disorder is defined by symptoms that are similar to those of PTSD (with an emphasis on dissociative symptoms) that occur very soon after the traumatic event. GAD is typified by persistent worry and anxiety that is difficult to control that lasts at least 6 months. Separation anxiety disorder is characterized by developmentally inappropriate anxiety (lasting at least 4 weeks) regarding separation from the home or people to whom the child is attached.

Anxiety disorders are among the most commonly diagnosed psychiatric disorders in both children and adults [84]. Epidemiological studies show rates of anxiety disorders ranging from 5.7% to 17.7% in children and adolescents [e.g., 57,61,85,86]. Additionally, these studies show a trend for rates of anxiety disorders to increase with age. Looking at specific disorders, epidemiological studies show prevalence rates as follows: social phobia, 0.06%–7.9%; GAD/OAD, 2.9–10.8%; and separation anxiety disorder, 2.0–4.7%. Though there is a good deal of variability in these estimates, GAD appears to be most common in youths, followed by social phobia, which is also very common.

Anxiety disorders in children (specifically social phobia, GAD, and separation anxiety disorder) are often comorbid with other psychiatric disorders.

Indeed, for most children with significant anxiety, comorbidity is the rule rather than the exception. As mentioned previously, depression and anxiety in particular very commonly cooccur; anxiety disorders are three to four times as likely to occur in youths with depressive disorders as in youths without such disorders [e.g., 85,86]. Anxiety disorders are also often comorbid with disruptive behavior disorders. Several studies have found them to be two to three times more common among children with ODD and CD [e.g., 85–87].

Data regarding the course of anxiety disorders in youths are scarce. In a recent study, children diagnosed with an anxiety disorder were followed up 3–4 years later [88]. Eighty percent of the children had recovered from the originally diagnosed disorder, and only a small percentage (8%) experienced a relapse of their disorder. However, these children were likely to develop new disorders. These results are consistent with findings from a 5-year follow-up study of children and adolescents initially diagnosed with anxiety disorders; at follow-up, most of the children had either recovered from the initial diagnosis or had developed a different disorder—most typically, a different anxiety disorder [28]. To date, two studies have found that continuity of anxiety disorders is more common among girls than among boys [85,89].

C. Psychotic Disorders

Psychotic disorders are characterized by the presence of hallucinations or delusions, and grossly disorganized behavior or speech. As with affective disorders, the assumption in DSM-IV is that adult criteria for psychotic disorders should be extended downward to apply to children. However, it has been suggested that the lack of specific attention to developmental issues and the focus in DSM-IV on disorganized speech may lead to errors of overdiagnosis in children [90,91]. In DSM-IV, the psychotic disorders include schizophrenia, schizophreniform disorder, schizoaffective disorder, delusional disorder, brief psychotic disorder, shared psychotic disorder, psychotic disorder due to a medical condition, substance-induced psychotic disorder, and psychotic disorder NOS.

The psychotic syndromes are differentiated based on duration and pattern of presenting symptoms. Schizophrenia is characterized by the presence of at least two of the following symptoms present for at least 1 month: hallucinations, delusions, disorganized speech or behavior, and negative symptoms (e.g., anhedonia, avolition). The disturbance must last at least 6

months overall and cause significant clinical impairment. In terms of symptoms, schizophreniform disorder is the same as schizophrenia, but does not last as long (1–6 months) and need not cause functional impairment. Schizoaffective disorder is typified by a mood disturbance that occurs simultaneously with the positive symptoms of schizophrenia, and is preceded by at least 2 weeks of delusions or hallucinations without concomitant mood disturbance. Delusional disorder is characterized by at least 1 month of delusions that are not bizarre in content. Shared psychotic disorder is a disturbance that develops in one person owing to the influence of another person with a similar delusion.

Psychotic disorders in children are considered rare, but few studies have been conducted in this area, and most focus exclusively on schizophrenia. The prevalence of schizophrenia in very young children (12 years old and younger) has been estimated at rates of 1.6–1.9 per 100,000 [92,93]. Among adolescents, rates of schizophrenia are estimated at 0.23% in the general population, 1% among outpatients [94], and 5% among inpatients [95]. Among adults, estimates of schizophrenia prevalence rates range from 0.2% to 2% [4]. Schizophrenia with onset at a very young age is about twice as likely in males as in females [96].

In youths with psychotic disorders it is thought that comorbidity is fairly common, particularly with disorders of behavior, attention, and motor skills. However, little empirical work exists in this area. Histories that are suggestive of premorbid pervasive developmental disorders are common [97,98], as are comorbid behavior and attention problems [99]. Results of one study indicated that among youths diagnosed with schizophrenia, $\sim 13\%$ had a history suggesting preexisting attention or motor skills deficits [100].

Psychotic disorders are typically first diagnosed in the late teens through early 30s, with onset before the teen years being uncommon [4]. Age of onset has been found to be prognostic: children with very early onset schizophrenia tend to have a very poor prognosis [91,101]. In general, studies of adult schizophrenia show a variable course of the disorder, with some individuals remaining chronically ill, and others experiencing periods of remission and exacerbation [4]. There are some common developmental variations in symptoms: in children, visual hallucinations may be more common than in adults, and hallucinations/delusions may be less elaborate. Delusions are only seen in $\sim 50\%$ of cases of childhood schizophrenia [102,103]. Additionally, disorganized speech is common to several disorders typically seen in children (e.g., pervasive

developmental disorders, communication disorders), so this symptom is less indicative of a psychotic disorder in this group then when seen in adults. Acute onset of the disorder is more likely the older the age of the child [96].

IV. CONCLUSIONS

This chapter has reviewed many of the major diagnostic classifications as listed in DSM-IV and highlighted diagnostic issues that pertain to children and adolescents. Overall, psychiatric disorders are common in youths and typically increase in prevalence with age. Comorbidity is also quite common in children and adolescents, and is associated with poor outcome. The course of the various psychiatric disorders is variable, but on average, early age of identification predicts a more chronic course, and as such, may serve as a proxy for severity. In terms of developmental sensitivity, in the DSM-IV, there are very few diagnostic criteria differences across the life cycle, but the presentation of symptoms is modified and mediated by developmental influences. As such, we have attempted to outline characteristic developmental symptom patterns for each disorder.

As we noted at the start of this chapter, the classification and diagnosis of psychiatric disorders in children and adolescents have undergone substantial change and progress in the past 20 or so years. We, as a field, have begun to accumulate empirical work that to varying degrees support or make us question our diagnostic categories as they now stand. More research that examines the presentation, course, and outcome of various psychiatric disorders in youth is needed, particularly in the area of bipolar disorders, pervasive developmental disorders, and psychotic disorders.

Classification of Schizophrenia and Related Psychotic Disorders

TONMOY SHARMA and PRIYA BAJAJ

Clinical Neuroscience Research Centre, Stonehouse Hospital, Dartford, Kent, England

I. INTRODUCTION

The need for a classification of mental disorders has been clear throughout the history of medicine, but there has been little agreement on which disorders should be included and the optimal method for their organization. The many nomenclatures that have been developed during the past two millennia have differed in their relative emphasis on phenomenology, etiology, and course as defining features. Some systems have included only a handful of diagnostic categories whereas others have included thousands. Moreover, the various systems for categorizing mental disorders have differed with respect to whether their principal objective was for use in clinical, research, or statistical settings [1].

Attitudes to psychiatric classification have also undergone a revolution in the last generation. In the 1950s and 1960s, psychiatric diagnoses did not occupy center stage in clinical practice. Their reliability was known to be low; it was known that key diagnostic terms like schizophrenia had different meanings in different parts of the world. On the other extreme, there were some who argued that diagnostic categories should be abandoned and they believed that all patients require the same treatment—the "moral regime" of the asylum for Neumann and Prichard in the 19th century, and psychotherapy of Rogers and Menninger in the 20th century [2].

However, a clear definition and accurate classification of a disorder are the first steps in any systematic attempt to understand the pathophysiology and etiology of the disorder. The revolution in biological psychiatry can, in part, be attributed to advances in nosology [3].

II. EVOLUTION OF CLASSIFICATION SYSTEMS

Ethnographic studies have demonstrated that schizophrenia is present in all existing cultures, from the preliterate to the most advanced. Psychotic symptomatology and schizophrenialike syndromes were clearly present in ancient civilizations. However, more accurate and systematized classifications of psychological disturbances began to evolve only in the 1st and 2nd centuries AD. The physician Aretaeus of Cappadocia defined a state of melancholy, which included depression as well as schizophrenialike withdrawal. In the 1700s there was an increasing emphasis on detailed and accurate descriptions of abnormal mental processes and states. Philippe Pinel, a French physician, considered to be one of the founders of modern psychiatry, argued for an objective medicophilosophical approach to psychological disorders. Jean Etienne Esquirol, a student of Pinel, defined hallucinations

and identified "monomania", a clinical syndrome similar to modern descriptions of paranoid schizophrenia.

Attempts were also being made to divide the clinical landscape into syndromes sharing both clinical features and course. Benedict Augustin Morel was the first to use the term dementia praecox (*dementia precoce*). Other symptom complexes identified included delusional states (France) and paranoid states, as described by the German physician Vogel in 1764. Johann Christian Augusts Heinroth outlined 48 distinct disease entities and thereby epitomized the general inability to develop straightforward, reliable criteria. These theoretical controversies and confusion led Heinrich Neumann to reject all systems of classifications and suggest that it was necessary to "throw overboard the whole business of classifications" to bring order to the field. He suggested that "there is but one type of mental disturbance, and we call it insanity." Nevertheless, despite the intermittent sense of frustration and confusion, classificatory efforts continued unabated [4].

III. 20TH CENTURY CLASSIFICATORY SCHEMAS OF KRAEPLIN AND BLEULER

It was in the latter part of the 19th century that Emil Kraeplin was able to integrate the diverse clinical phenomena into a coherent and far-reaching classificatory system. His synthetic formulation included the identification of "dementia praecox" to refer to the clinical entity we now call schizophrenia. "Dementia" referred to the progressive deteriorating course of both emotional and cognitive processes; "praecox" indicated the early age of onset in previously healthy individuals. Thus, fundamental to the diagnosis were both cross-sectional and longitudinal components. Importantly, he differentiated the generally deteriorating course of dementia praecox from the more episodic and customarily better outcome seen in manic-depressive disorder. He furthermore divided it into four subtypes: paranoid, hebephrenic, catatonic, and simple.

Eugen Bleuler used Kraeplin's systematic classification of psychoses and a theoretical model of etiological processes to reformulate dementia praecox as "schizophrenia," derived from the Greek words for "split" and "mind" [5]. He asserted that there were four cardinal features almost invariably present in schizophrenia patients, the "four A's": blunted affect, loosening of association, ambivalence, and autism.

He viewed schizophrenia as being composed of several different entities rather than a single disease state as Kraeplin conceptualized. Other symptoms of schizophrenia include delusions, catatonia, negativism, and stupor. These were thought to be "secondary" symptoms and to present in reaction to the individual's intentions, drives, psychotic state, and environmental conditions. Bleuler noted that these secondary symptoms were present in schizophrenia as well as in other disorders. He also asserted that despite the secondary nature of these symptoms, they formed the basis of Kraeplin's classificatory system.

It is noteworthy that two psychotic features emphasised by today's Diagnostic and Statistical Manual (DSM)—hallucinations and delusions—were not crucial for Bleuler's diagnosis of schizophrenia. His emphasis on theory as a means for determining the diagnostic relevance of signs and symptoms contrasted sharply with Kraeplin's reliance on empirical observations. Bleuler's approach was also notable for three other reasons. First, his reformulation of dementia praecox as "the group of schizophrenia" foreshadowed the contemporary view that schizophrenia is a heterogeneous group of disorders with similar clinical presentations. Second, he included defects in affect as a core feature of the disorder. Third, his view of schizophrenia allowed for the possibility of recovery.

Other clinicians also advocated a hierarchical system of symptom classification like Bleuler. In 1959, Kurt Schneider termed the core features "first-rank symptoms". These symptoms included: hearing one's thoughts spoken aloud; auditory hallucinations commenting on one's behavior; thought withdrawal, insertion, and broadcasting; and somatic hallucinations, or the experience of one's thoughts as being controlled or influenced from the outside.

Manifestations of first-rank symptoms in the absence of organic disease, persistent affective disorder, or drug intoxication, were sufficient for a diagnosis of schizophrenia. Second-rank symptoms included other forms of hallucinations, depressive or euphoric mood changes, emotional blunting, perplexity, and sudden delusional ideas. When first-rank symptoms were absent, schizophrenia might still be diagnosed if a sufficient number of second-rank symptoms were present. Although the schneiderian criteria have been criticized as being nonspecific, they have been incorporated into clinical diagnostic tools such as the Research Diagnostic Criteria (RDC) and Diagnostic and Statistical Manual of Mental Disorders (DSM) classificatory systems [4].

IV. CLASSIFICATION ON THE BASIS OF SYMPTOMS

It is widely believed that classification of diseases should, wherever possible, be based on etiology. Unfortunately, the same principle does not apply to psychiatric disorders, since the etiology of most is still unknown or all that is known for certain is that both genetic and environmental factors are involved. For this reason, most contemporary classifications of psychiatric disorders are largely based on clinical symptoms. This state of affairs has a number of important consequences. Decisions about the presence or absence of symptoms are relatively unreliable; and because few psychiatric conditions have pathognomonic symptoms, most conditions have to be defined by the presence of some or most of a group of symptoms rather than the presence of one key symptom. In the jargon of nosology, they are polythetic rather than monothetic. This invites ambiguity and lowers reliability still further, unless operational definitions are adopted. Another important consequence is that most psychiatric diagnoses can never be confirmed or refuted, for there is no external criterion to appeal to.

For these and other reasons it has often been suggested that symptoms should be ignored and a new classification developed on an entirely different basis. Psychoanalysts have frequently advocated a classification based on psychodynamic defense mechanisms and stages of libidinal development. In the 1950s, clinical psychologists extolled the advantages of a classification based on scores on batteries of cognitive and projective tests. More recently, learning theorists have argued that we should classify patients on the basis of a comprehensive analysis of their total behavioral repertoire. In principle, all of these approaches are perfectly legitimate. In practice, however, none of them has ever progressed beyond the stage of advocacy. Two other alternatives proposed are (1) classification on the basis of treatment response, and (2) classification on the basis of the course or outcome of the illness. Unfortunately, neither is feasible since there are few if any specific treatments available in psychiatry, and most disorders can have a wide range of outcomes. It is sometimes assumed that Kraeplin's classification or at least his distinction between dementia praecox and manic-depressive insanity, was based on long term outcome, but this is a misunderstanding. Kraeplin certainly emphasized the difference in the lifetime course of his two great rubrics, and perhaps subdivided the functional psychosis in the way he did to maximize the difference in outcome between them. But he used outcome as a validating criterion (i.e., as evidence that his two rubrics were fundamentally different disorders), not as a defining characteristic. Thus, when patients with dementia praecox recovered completely, he would automatically have changed their diagnosis [2].

As things stand, we have no choice but to use a classification, which is largely based on symptoms, despite its shortcomings and imperfections, because no practical alternative has yet been developed. Kraeplin's and Bleuler's observations evolved into today's psychiatric classification: the International Classification of Diseases (ICD) and the American Psychiatric Association's Diagnostic and Statistical Manual (DSM) [5].

V. DIAGNOSTIC CRITERIA: DIAGNOSTIC AND STATISTICAL MANUAL OF MENTAL DISORDERS (DSM)

In this chapter we shall discuss the evolution of the different classification systems over time using the diagnosis of schizophrenia as an example. We will first address the reliability and validity of DSM and then address how ICD later synchronized with the DSM system.

A. DSM-I

In 1949, the American Psychiatric Association in collaboration with the New York Academy of Medicine began an initiative to standardize the diagnostic system throughout the United States. The result was the Diagnostic and Statistical Manual of Mental Disorders-1 (DSM-I), published in 1952. It was influenced by the theories of Adolf Meyer, and psychiatric disorders were viewed as reactions of the personality to psychological, social, and biological factors [4]. In addition to its use of Kraeplin's and Bleuler's views on the signs and symptoms of schizophrenia, the first DSM defined schizophrenia in a way that at least implied environmental causes. For example, all schizophrenic (and other psychiatric) diagnoses included the term "reaction" (as in "schizophrenic reaction, simple type"). Moreover, definitions were vague and did not discuss differential diagnosis. Such imprecise definitions allowed clinicians much discretion in making a diagnosis. As a result, in the United States, schizophrenia became the diagnosis of choice for psychotic conditions that lacked a clear "organic aetiology" [5].

B. DSM-II

The manual had gone through several major revisions. The DSM-II was published in 1968, but did not differ significantly from its predecessors [4]. It dropped the term "reaction" from its diagnoses and added some discussion of differential diagnoses, but continued the DSM-I tradition of brief, vague descriptions of schizophrenia disorders, without specific operational criteria. Interestingly, both of these early systems viewed psychosis as the key feature of the disorder. DSM-II did not contain a category ("schizophrenia latent type") to describe people with "clear symptoms of schizophrenia but no history of a psychotic schizophrenia episode." This category was intended to encompass individuals with a variety of conditions (e.g., "incipient," "pre-psychotic," and "borderline schizophrenia," as well as "schizophrenic reaction, chronic undifferentiated type," from DSM-I). This did not reflect an important attempt to clarify the role of psychosis in schizophrenia illness [5]. Thus, the diagnosis, with schizophrenia as an example, lacked validity and was too vague in its description.

C. DSM-III

DSM-III was radically different from any previous classification. Published in 1980, it brought about a sea change in psychiatric classification, spearheaded by the "neo-Kraeplinian" movement in the 1960s and 1970s and by investigators in psychiatry and clinical psychology who emphasized the importance of empirical, psychometric validation of psychiatric syndromes. Its innovations were a response to the evidence that had accumulated over the previous 20 years that psychiatric diagnoses were generally unreliable, that there were systematic differences in the usage of key terms like "schizophrenia" between the United States and other parts of the world [2]. It contained several innovations, including field tests of diagnostic reliability, specific inclusion and exclusion criteria for diagnoses, multiaxial diagnosis, and a focus on the description of syndromes and course of disorders rather than inferences about their etiology. This last point made psychiatric diagnosis more explicitly consistent with the diagnosis of other medical disorders of unknown etiology.

The traditional distinction between neuroses and psychoses was abandoned to allow all affective disorders to be brought together. Also, in the absence of data to support diagnostic hierarchies, the system encourages comorbidity. DSM-III's use of clearly defined criteria limited the clinician's discretion and narrowed the construct of schizophrenia. This development improved the clinical homogeneity of the disorder, better delimited it from other serious mental illnesses, and raised diagnostic reliability to respectable levels. Nevertheless, DSM-III retained the view that psychosis was fundamental to the definition of schizophrenia. Fewer patients now had the diagnosis of schizophrenia, and more were diagnosed as having unipolar or bipolar affective disorder.

However, many senior American psychiatrists criticized this classification and its principal architect Robert Spitzer for introducing what they regarded as a crude "Chinese menu" approach to diagnoses, with a theoretical bias and phenomenology being favored over mental processes.

D. DSM-III-R

DSM-III was replaced by an extensive revision DSM-III-R (revised) in 1987. In this classification schizoaffective disorders were given an operational definition for the first time; the definition of paranoid disorders was enlarged to include patients with grandiose, somatic, and erotomanic delusions as well as with delusions of persecution and jealousy, and the inappropriate stipulation that schizophrenia must start before the age of 45 years was dropped. Being introduced only 7 years after DSM-III, this classification was criticized for disrupting research and practice because of the evolution of new definitions [2].

E. DSM-IV and DSM-IV-TR

The primacy of psychosis defining schizophrenia also survived DSM-III's revision and its evolution into DSM-IV (published in 1994) and DSM-TR (text revision published in 2000) [6]. DSM-IV was published in 1987 with the following goals [3]:

1. To develop criteria that are more constant with ICD-10, with regard to schizophrenia. Primarily, this had to do with changing the required duration of the psychotic symptoms from 1 week (as in DSM-III-R) to 1 month (as in ICD-9 and ICD-10)
2. To provide a simplified criterion of symptoms by reducing redundancy in the items of criterion A.
3. To include symptoms with proven reliability.
4. To include symptoms only with acceptable prevalence.
5. To provide maximum coverage (sensitivity) for existing cases, thus reducing the reclassification rate.

These goals were met by adopting a "thorough process" by the Psychotic Disorders Work Group, which consisted of comprehensive reviews of literature, reanalyses of previously collected data, input from the field, and issue-focused field trials that included testing of alternative sets of diagnostic criteria. Changes proposed ranged from minor modifications in the DSM-III-R criteria to more weightage for negative symptoms, expansion of the minimum duration of symptoms to 2 weeks or 4 weeks, to the introduction of a concept of "schizophrenia spectrum disorders."

Psychosis was deemphasized in DSM-IV, in that a patient could receive a diagnosis of schizophrenia according to DSM-IV criteria without having delusions or hallucinations. In that case, however, gross disorganization of speech and/or behavior, which are also psychotic symptoms, would still be required because criterion A (i.e., characteristic symptoms) requires at least two of the five symptoms in the category. Thus, four of the five symptoms are still related to psychosis (negative symptoms are the fifth symptom in the category). Moreover, delusions alone can satisfy the criterion if they are bizarre, and hallucinations alone can satisfy the criterion if they involve one or more voices engaging in running commentary or ongoing conversation. Diagnostic changes in DSM-IV thus expanded the nature of the required psychotic symptoms more than they deemphasized psychosis itself [5]. In the DSM-IV "Schizophrenia and other related disorders" include schizophrenia, delusional disorder, and schizoaffective disorder. Schizophrenia is divided into five subtypes including paranoid, disorganized, catatonic, undifferentiated, and residual [4]. The criteria for schizoaffective disorder has been changed to focus on an uninterrupted period of illness rather than on the lifetime pattern of symptoms. In Brief Psychotic Disorder, eliminating the requirement for a sever stressor has broadened the DSM-III-R construct of Brief Reactive Psychosis, and the minimum duration of the psychotic symptoms has been increased from a few hours to 1 day.

The importance of psychotic symptoms in diagnosis extends to other diagnostic systems. Schneider's first-rank symptoms, which form the basis of "nuclear schizophrenia," are types of hallucinations and delusions that have come (more than other, "second-rank" symptoms) to characterize the nature of psychosis in the disorder. More important, they have helped to define the disorder itself, although Schneider himself reviewed them more as diagnostic tools than as theoretical constructs about the etiology of the disorder. First-rank symptoms heavily influenced the develop-

ment of Research Diagnostic Criteria for schizophrenia, which in turn formed the basis of DSM-III criteria for schizophrenia. These criteria, particularly, continue to influence ICD-10 in the first three symptom groups "that have special importance for the diagnosis" for schizophrenia [5].

VI. DIAGNOSTIC CRITERIA: INTERNATIONAL CLASSIFICATION OF DISEASES (ICD)

The Mental Disorders section of ICD-6 was primarily a classification of "psychoses and mental deficiency." The eighth revision of the International Classification of Diseases, Injuries and Causes of Death (ICD-8) came into use in 1969, owing to strenuous efforts by the World Health Organization. It was replaced by ICD-9 a decade later, in 1979. However, the definitions provided in ICD-8 and ICD-9 were not operational definitions [2].

A. Preparation of ICD-10

The process of drafting ICD-10 started in 1983 but it came into use in United Kingdom and most other countries in 1993. It had a new title, the International Statistical Classification of Diseases and Related Health Problems, and a new alphanumeric format. The main purpose of the latter is to provide more categories and so leave space for future expansion without the whole classification having to be changed. It incorporates many of the radical innovations introduced in DSM-III. Most categories are provided with both diagnostic guidelines for everyday clinical use and separate "diagnostic criteria for research," providing unambiguous rules of application. There is also provision for multiple axes, as in DSM-III and its predecessors.

Field trials of the 1986 draft text were held in 194 different centers in 55 different countries, and the final text benefited greatly from the comments of users in these varied settings and the evidence they provided of the acceptability, coverage, and interrater reliability of the provisional categories and definitions of the draft [2].

B. Differences between ICD-9 and ICD-10

F20–F29, which included schizophrenia, schizotypal states, and delusional disorders have been expanded by the introduction of new categories such as undiffer-

entiated schizophrenia, postschizophrenic depression, and schizotypal disorder. The classification of acute short-lived psychoses, which are commonly seen in most developing countries, is considerably expanded compared with that in the ICD-9 [7].

VII. OTHER PSYCHOTIC DISORDERS: DSM AND ICD DEFINITIONS

A. Schizoaffective Disorder

The study of Schizoaffective Disorder, since it has generally been ill defined, has always presented unique problems due to the lack of producing comparable populations. Several conceptual models of schizoaffective disorder exist, e.g., the episode-based versus the course-based co-occurrence of mood and psychotic symptoms. Both the ICD and the DSM use a common definition of episode-based coexistence of symptoms and are very similar in the other criteria. A rare, small subgroup of patients may, however, be diagnosed as Schizophrenia by the DSM-IV, and Schizoaffective Disorder by the ICD-10. This occurs because the ICD requires that at least 2 weeks of psychosis precede any concurrent psychotic and mood symptoms of schizophrenia, whereas the DSM does not. A patient presenting with concurrent psychotic and mood symptoms from the onset of the episode could be diagnosed Schizophrenia by DSM-IV if satisfying all the other criteria, but might be diagnosed Schizoaffective by ICD-10.

B. Delusional Disorder

For delusional disorder it is likely that some difference in subject selection will persist between the two major symptoms because of differing requirement in duration, i.e., 1 month in DSM versus 3 months in ICD.

C. Acute/Brief Psychotic Disorder

Although termed differently, acute psychotic disorders provide substantially the same coverage in the two systems. In DSM, the terms brief psychotic disorder and schizophreniform disorder are used, while the ICD uses the terms acute and transient disorder with and without schizophrenialike symptoms [3].

VIII. INTERNATIONAL DIFFERENCES IN DIAGNOSTIC CRITERIA

A. Diagnostic Hierarchies

In ICD-10, schizophrenia and affective disorders are at the same level. A diagnosis of schizophrenia cannot be made if the full depressive/manic syndrome is also present "unless it is clear" that schizophrenic symptoms antedated the affective disturbance.

However, in the DSM classification, schizophrenia traditionally follows the "organic psychosis," and the third place in the hierarchy is occupied by the affective disorders. A very similar sequence is involved in the decision pathway of computer programs like Catego [2].

B. Threshold for Diagnosis

Comparative studies carried out by the US/UK diagnostic project in 1960s established that, in comparable series of patients, psychiatrists in New York diagnosed schizophrenia twice as frequently as their counterparts in London. The International Pilot Study of Schizophrenia confirmed that American psychiatrists had an unusually broad concept of schizophrenia, and also showed that the same was true of Russian psychiatrists. The very broad American concept of schizophrenia was psychoanalytic in origin, and the decline of psychoanalytic influence in the 1970s, together with a renewed interest in descriptive psychopathology and classification, led to rapid change. The widespread adoption of the operational definitions of DSM-III and DSM-III-R by research workers in many different parts of the world has also played an important role in reducing the international differences in usage [2].

IX. RELIABILITY AND VALIDITY: THE PREREQUISITES OF A CLINICAL DIAGNOSES

The introduction of structured interviews and operational definitions has improved the reliability and validity of psychiatric diagnosis over the years. But the existing evidence for the validity of most psychiatric diagnoses is rather meager. It is considerably better for the major syndromes like schizophrenia in comparison to sub-categories of major syndromes such as catatonic schizophrenia [2].

A. Reliability and Field Trials

Modern classification schemes such as ICD-10 and DSM-IV have made it possible to assign psychiatric patients reliably to different diagnostic categories [8]. A classificatory system, which has little reliability, has little practical utility [9]. Field trials have been conducted at seven USA sites (each of which contributed 50 subjects) to assess the concordance and symptom reliability within different systems, namely, DSM-III, DSM-III-R, and ICD-10 [1]. Some of the major highlights of the results were:

1. Concordance between diagnostic systems.
2. Symptom reliability.
3. Reliability of diagnostic criteria.
4. Agreement between ICD and DSM-III-R was high (87.6%) for schizophrenia, but 13% of DSM-III-R schizophrenia was classified by ICD as schizoaffective, acute and transient psychotic disorder, schizotypal, or none of the above.
5. Reliability of schneiderian symptoms was similar to that of other symptoms. Likewise, bizarre delusions were as reliably rated as nonbizarre, and even negative symptoms had good reliability in the trial.
6. The length of symptoms is a principal difference in criteria between ICD and DSM. The field trial demonstrated that ∼ 5% of DSM-III-R schizophrenia and > 30% of schizophreniform disorder would have to be reclassified to psychosis not otherwise specified (NOS) when the required duration of symptoms is changed to 1 month.

B. Validity of Classification Systems

As yet no clinical or pathological gold standard exists for the diagnosis of schizophrenia. The uncertain validity of the diagnostic categories assigned to the patients is a matter of serious concern because the usefulness of a particular diagnostic construct is greatly reduced if it carries no therapeutic implications.

The validity of diagnostic classification rests to some extent on its ability to predict outcome. In a study by Mason et al. [10], it was found that DSM-III-R and ICD-10 diagnosis of schizophrenia had high predictive validity and were superior to ICD-9. ICD-10, however, had superior sensitivity to DSM-III-R. This study thus suggests that ICD-10 should be preferred for studies needing high sensitivity as well as specificity for the diagnosis of schizophrenia in the acute phase, such as studies of incidence. It also sug-

gests that dropping the 6-month duration criterion should be considered for a future DSM-V [10].

In another study, by Van Os et al. [8], the introduction of a "treatment-relevant" classification of psychiatric disorders such as the functional psychoses was explored. In a sample of 706 patients aged 16–65 years with chronic psychosis, psychopathology was measured using the Comprehensive Psychopathological Rating Scale (CPRS). The principal component factor analysis of the 65 CPRS items on cross-sectional psychopathology yielded four dimensions of positive, negative, depressive, and manic symptoms. The authors concluded that although it was possible to reliably label combinations of psychopathological phenomena, the resulting diagnostic entities reveal very little about the patients. In patients with chronic psychosis, the dimensional approach constitutes a treatment-relevant alternative or complementary strategy. Its use in clinical practice, research, and service evaluation was in need of further investigation [8].

C. International Pilot Study of Schizophrenia: Symptom Frequencies in Cross-Cultural Groups

Computerized statistics have often been used to select diagnostic criteria. Such an approach will seek to select a set of symptoms that are relevant and distinct. The symptoms selected would be required to satisfy the following conditions: They should be common in a representative sample of the population under investigation. Thus, catatonia is not useful, although it's quite a striking symptom, because it is relatively infrequent; they require a high interrater reliability, and this eliminates symptoms that are difficult to identify consistently to serve well as diagnostic criteria the symptoms should be nonredundant; that is, they should be fairly independent of each other but necessary for the diagnosis (this means that they should not have high mutual intercorrelation to avoid tautology); and symptoms to be preferred should have discriminant value for the purpose of differential diagnoses, occurring quite often in concordant cases and rarely, if at all, in discordant cases with an alternative diagnosis. All these conditions define the following statistical criteria for the evaluation of symptoms characteristic of the illness: an adequate rate of occurrence, good interrater reliability, low intercorrelation of symptoms, and a high frequency ratio for concordant versus discordant groups.

Symptom frequencies in concordant and discordant groups from large-scale cross-cultural investigations

were published in the International Pilot Study of Schizophrenia (IPSS). Those data can be used to explore the potential for establishing the new diagnostic rules or criteria for schizophrenia.

The IPSS teams found that >40% of patients in concordant and <10% of patients in discordant groups had "experiences of control" (delusions of uncommon mental or physical external influences on the patients). "Auditory hallucinations" met the same conditions. If a less stringent criterion is used (at least 40% of members of concordant groups), flatness (flat affect) appears as a relevant marker. Some other symptoms (e.g., lack of insight, patient-related cooperation difficulties) appeared equally promising on the basis of their high incidence in the concordant group, but were too frequently observed in the discordant group [11].

X. FUTURE RESEARCH AND NEWER CLASSIFICATIONS

A. Reactive Psychosis: A Classical Category Revisited

Reactive psychosis was a category included in ICD-8 and ICD-9 as "reactive depression, reactive excitation, reactive confusion, acute paranoid reaction and unspecified reactive psychosis," and as "brief reactive psychosis" in DSM-III and DSM-III-R. However, in ICD-10 and DSM-IV it no longer occupies a separate category; instead it is subsumed as a subcategory in "acute and transient psychotic disorders" and "brief psychotic disorder," respectively, as "acute and transient psychotic disorder with marked stressor." ICD-10 and DSM-IV only require specifying the presence of a stressor prior to the outbreak of a usually brief, acute psychosis. However, Ungvari et al. [12] have reviewed the diagnostic concept and felt that the classical psychopathological concept of reactive psychosis goes beyond this by stipulating the temporal and contextual continuity between the stressful situation and the ensuing psychosis, taking into account the patient's personality and life history including individual vulnerability to psychological trauma. This diagnostic category featured in the psychiatric literature for several decades mostly on the basis of clinical experience. However, the original form of reactive psychosis had faded away before serious attempts were made to validate this diagnostic category. Currently the concept is not acknowledged or used in clinical practice outside Scandinavia. The wider recognition of reactive psychosis and its delimitation from other acute psychotic dis-

orders would be important for providing clinically more homogenous samples of subjects for psychiatric research [12].

B. Refining ''Acute Brief Psychoses''

One of the proposals for ICD-11 and DSM-V has been focused on the diagnostic classification of nonaffective acute remitting psychosis (NARP), also termed acute brief psychosis. The authors have suggested that this category can be delineated from both schizophrenia and the affective psychosis and be considered as a single diagnosis. They have proposed that four criteria be considered central to the diagnosis:

1. Nonaffective
2. Acute onset (over <2 weeks)
3. Recovery within a brief duration (<6 months)
4. Psychosis broadly defined.

The authors felt that both the ICD-10 and the DSM-IV lacked a firm empirical grounding in their classification of acute psychosis. Studies have indicated that the model duration of acute psychoses in the developing country setting is 2–4 months, whereas both ICD-10 and DSM-IV offered diagnoses that excluded psychoses of >1 month's duration. Furthermore, NARP is a highly distinct entity, as evidenced by studies on its demographic distribution, incidence, duration, and long-term course. The clinical characteristics are atypical for schizophrenia and affective psychoses, and it has a stable long-term course. Following recovery from the initial psychotic episodes, the cases rarely evolve into chronic disorders. Even on relapse, the subsequent psychotic episodes tend to be acute in onset and brief in duration. The diagnosis of NARP rests upon criteria, which could be reliably and comparably rated across diverse settings, and offer to bring the nosology of acute psychoses into far closer accord with current empirical data [13].

In summary, diagnostic criteria have evolved over the past five decades from vague concepts based on ideological viewpoints to field trials tested criteria which have high reliability across cultures. We have used schizophrenia as an example to illustrate the evolution of the changes in the DSM and ICD systems, but these evolutionary changes are true to a large extent of other diagnoses as well. Unfortunately, we still have to rely on signs and symptoms assessed clinically to come to a diagnosis. The lack (as yet) of biological markers in assisting clinicians to make a diagnosis can be seen as a drawback in psychiatry today. However, the rapid advances being made in

the neurobiology of psychiatric disorders may, one day, lead us to the Holy Grail and establish biological markers as anchors on which psychiatric diagnoses can be made.

1. INTRODUCTION

Several attempts to categorize the various mental disorders have been reported over the years. The first efforts to develop systematic diagnostic classifications were initially put forth by the so-called alienists, during the 19th century [1]. During the first half of the 20th century, psychiatry was strongly influenced by psychoanalysis. While psychoanalytic-oriented thinking initially brought advances to clinical practice by stressing the importance of an individual's personal history and reducing the social stigma of mental illnesses [2], important advances in neuropsychiatry were neglected, and communication among psychiatrists became difficult due to a lack of diagnostic uniformity.

The return of psychiatry to the mainstream of academic medicine, initiated after the early psychopharmacological advances in the 1960s, generated a crucial need for development of a valid and reliable diagnostic classification system that would serve clinical and research purposes [3]. In fact, the relative lack of a medical framework for psychiatry, when compared to other medical specialties, probably had its origins, at least in part, in a delay to have valid and reliable diag-

nostic classification systems [4]. After several individual attempts to categorize the various mental conditions in the 19th and 20th centuries, the DSM-III classification [5], published in 1980, constituted an important milestone, as it marked a definitive return of psychiatry to the medical model. The DSM-III was a landmark in operational psychiatric classifications, and also had important impact in research financing in the United States, as the absence of operational criteria and the resulting difficulty to accumulate reliable information on the major mental illnesses discouraged potential sponsors of research on this field [6,7]. A lot has changed since that time, with the development and widespread use of well-accepted diagnostic systems, which have substantially contributed to foster psychiatric research and improve clinical practice in this area, as reflected in subsequent revisions of the DSM and ICD classifications.

The phenomenological paradigm utilized for psychiatric diagnosis, which had been initiated in the asylum settings, is still hegemonic in currently available classifications, and therefore is very influential on research and clinical practice. The two most commonly utilized international diagnostic schemes (ICD-10 [8]

and DSM-IV [9]) are largely based on Kraepelinian classifications of mental disorders, relying on the observed symptoms, course of illness, and outcome [10]. Although of unquestionable value to psychiatric practice and research, these classifications still have important weaknesses for taking into account only the presence and variation of symptoms over time to define a diagnostic category, without contribution from research findings on biological mechanisms or treatment response. Obviously, because the pathophysiological mechanisms underlying these disorders are largely unknown, those important dimensions are therefore excluded from currently available diagnostic formulations. This lack of mechanistic evidence to support currently available classifications presents a very substantial difficulty for psychiatric research and clinical practice, and is clearly a very important area for future development.

Mood disorders have been included as a diagnostic category in eventually all major psychiatric classifications, as a reflection of their prevalence and significance as major mental illnesses [11]. Nevertheless, the diagnostic criteria utilized for mood disorders has evolved substantially through various diagnostic classifications. This chapter will present a brief historical overview of diagnostic classifications of mood disorders, critically review the available classification systems, and discuss prospects for new diagnostic classifications that would incorporate information on neurobiological mechanisms and treatment response, and possibly be of more assistance to research and clinical efforts.

II. DIAGNOSIS OF MOOD DISORDERS

In 1970, Robins and Guze [12] proposed specific criteria to establish the validity of a psychiatric diagnosis. According to these authors, in order to be valid, a psychiatric diagnosis should: (1) provide an adequate clinical description of the disorder; (2) be consistent with research findings; (3) be well delimited, excluding other disorders; (4) be reasonably related to prognosis; and (5) identify a family pattern, if applicable. Validity refers to the capacity to achieve the correct diagnosis, and reliability refers to the agreement on a specific diagnosis by two or more raters, or by one rater at distinct times [13].

As happened with other psychiatric diagnoses, the reliability of the diagnosis of mood disorders has significantly increased with the availability of operational diagnostic classifications, and with the utilization of structured diagnostic interviews. Since DSM-III was published in 1980, the reported reliability for mood disorders as a diagnostic entity has varied from 0.59 to 0.93. However, when assessing "other affective disorders"—i.e., dysthymia and cyclothymia—lower reliability rates are generally reported [14–16]. When analyzed separately, a classic manic episode presents the highest test-retest reliability among all axis I psychiatric disorders, probably because the behavioral abnormalities and symptoms of this syndrome are unique [17]. On the other hand, major depression presented only moderately high reliability in DSM-IV field trials accross distinct clinical sites. Possibly, the differences in reliability between a full manic episode and depressive disorders are a consequence of the various nonspecific symptoms that are part of the depressive syndrome, and also a reflection of the fact that depression or subthreshold depressive syndromes are largely present as comorbid conditions in many axis I diagnoses. Moreover, in spite of the moderate to high reliability rates achieved for the diagnoses included under "mood disorders," the particular syndromes (mania, depression, dysthymia, cyclothymia, and especially "other mood disorders") included under this large category have significant heterogeneity, with substantial variability on illness course, prognosis, treatment response, and biological abnormalities [18–23]. Furthermore, there are several minor clinical syndromes classified within the "mood disorders" category that are substantially distinct among themselves, even though they do not constitute at this point a separate diagnostic entity. Mixed mania, rapid-cycling bipolar disorder, atypical depression, melancholic depression, late-life depression, seasonal affective disorder, and psychotic depression are examples of subcategories of mood disorders with blurred diagnostic boundaries. Even the classic distinction between unipolar and bipolar depression may not be trivial in clinical settings, since the two syndromes are not easily differentiated if there is no clear history of a manic or hypomanic episode. At the outset of these illnesses, since most bipolar patients present initially with a depressive episode [24,25], a precise clinical distinction between unipolar and bipolar depression may be difficult. However, such a differentiation would be very relevant, from a clinical standpoint, since the administration of antidepressants as monotherapy to bipolar patients may induce a manic episode, or even be related to a rapid-cycling course [26–28].

There is a clear need to develop a diagnostic classification in psychiatry that would provide more homogeneous groups and subcategories that could assist

with both clinical and research purposes. Even though there are useful diagnostic research instruments in this field, such as the Schedule of Affective Disorders and Schizophrenia (SADS) [11], Structured Clinical Interview for DSM (SCID) [29], and Composite International Diagnostic Interview (CIDI) [30], all of them have the particular caveat of not including any information from biological research and pathophysiological mechanisms. With recent advances in methods for clinical neuroscience investigations, including developments in genetics, neuroimaging, and neuropsycho- pharmacology, promising new avenues to investigate the pathophysiology of these illnesses have become available and are now leading to studies that attempt to unravel the neurobiological underpinnings of these various conditions. As an example of a recent advance in this field, Steffens and Krishnan [31] proposed the term "vascular depression," based largely on neuroimaging findings, to describe a specific subtype of depression that includes the signs and symptoms of apathy, psychomotor retardation, cognitive impairment, functional disability, and lack of family history as the core clinical manifestations of vascular brain changes. According to the authors, this new proposed diagnostic sub-type is clinically distinguishable from other clinical presentations of depression, besides carrying an etiologic significance. Such advances are very timely and constitute a very welcome new development, and our hope is that, as research in this area continues to evolve, these diagnostic formulations will become increasingly more common.

III. INTEGRATING BASIC RESEARCH AND CLINICAL PROPOSALS

Various biological treatments have been established as effective modalities in the clinical management of mood disorders [32,33]. Furthermore, some preliminary studies have suggested the presence of specific biological markers that could possibly be useful in predicting outcome in a subset of mood disorder patients [34,35]. Nonetheless, despite promising advances in clinical neurosciences research applied to mental illnesses, current psychiatric classifications have had to rely exclusively on psychopathologic features, with no contribution from available findings from clinical neurosciences research or treatment response. This is a reflection of the fact that the pathophysiological mechanisms involved in these various conditions are largely unknown, and that none of the available neurobiological findings as of yet have been proven to

have diagnostic or prognostic value. Additionally, another difficulty relates to the fact that basic and clinical research in this area utilize currently available clinical psychopathology definitions and classifications to attempt to address pathophysiological mechanisms. This constitutes a potentially significant problem, as there are reasons to suggest that currently available classifications based only on psychopathological categories may not be fully adequate.

Nonetheless, the current psychiatric diagnostic paradigm brought on with DSM-III represented a real revolution in the field of mental disorders, and resulted on important advances in classification, epidemiology, and treatment, as it established a "common language" absolutely necessary for psychiatry as a medical specialty. However, classifications solely based on psychopathology may have been a limiting factor to further advances in our understanding of pathophysiology of various psychiatric conditions. Even though the main goal of biological psychiatry is to elucidate the pathophysiological mechanisms involved in the major psychiatric illnesses, the establishment of the diagnosis of these illnesses has been an important deterrent to further advances in this field. Although psychiatry can now offer effective pharmacological treatments for several diseases, it has clearly lagged behind other medical specialties concerning the understanding of the etiology and pathophysiology of its most prevalent illnesses, and considerable amount of additional research in this field and related areas is clearly needed.

As proposed by Van Praag [36], it is possible to improve the biological relevance of diagnostic classifications by: (1) using more accurate phenomenological definitions; (2) being cautious in incorporating new diagnoses; (3) establishing landmarks between normal and pathological; (4) not ignoring major domains of psychopathology; and (5) eliminating hierarchical elements from diagnostic process. Still, these measures represent only palliative remedies, since the diagnostic paradigm that focuses exclusively on clinical presentation, and does not include information on pathophysiological mechanisms, has not changed.

IV. A POSSIBLE NEW PARADIGM BASED PRIMARILY ON PATHOPHYSIOLOGY

Othmer et al. [37] proposed that a diagnostic model evolves through four sequential phases. In phase 1, diagnosis is made based on the presence or absence

of a key symptom, and its presence confirms, and absence discards, the disease in question. In phase 2 diagnosis is described as a group of associated symptoms constituting a syndrome, which has a known natural history; in phase 3 there is a detectable underlying pathophysiology of the disorder, and in phase 4, beyond a simple understanding about pathophysiology, etiology is also known. Given the complexity of mental disorders, psychiatry still faces tremendous challenges in diagnostic development, despite improvements in knowledge of neurobiological mechanisms involved in some of these disorders in the last decades. Although most psychiatric disorders are still on phase 2 of diagnostic achievement, there is a considerable amount of emerging evidence linking major psychiatric diagnosis, e.g., mood disorders, to identifiable underlying pathophysiological changes. Even though the etiology of these disorders is far from clear, recent neurobiological investigations are beginning to bring the field of psychiatry closer to the possibility of phase 4 diagnoses [37].

In the past three decades, clinical and basic research in the field of mood disorders has allowed important developments in the understanding of pathophysiology and treatment. Not surprisingly, available findings suggest that the pathophysiology of these illnesses is probably multifactorial. In fact, in less than five decades, pharmacological research on antidepressants has advanced from accidental discoveries of nonselective agents to specifically designed drugs that act selectively in target receptors potentially implicated in the pathophysiology of depression [38]. It is relevant to recognize that antidepressant drugs have their mechanisms of action dependent on modulation of specific neurotransmitter systems [38,39]. This fact has led several investigators to hypothesize a central role of neurotransmitter regulation in mood disorders, such as the pioneer works of Kety et al. in the 1950s and Schildkraut in the 1960s [40–42]. The documented therapeutic efficacy of these medications on depression generated a multitude of basic and clinical neurobiological studies attempting to investigate the postulated role of neurotransmitters on mood regulation. Over the past several years, research conducted in this field has indicated that at least three major neurotransmitter systems are likely to be involved in the pathophysiology of mood disorders, and in mechanisms involved in some of the symptomatic dimensions present in these illnesses:

1. Serotonin. There is evidence that serotonin depletion is associated with depression in people pre-

disposed to it, in accordance with the catecholamine theory of depression [42]. Serotonin is a neurotransmitter involved in processes as distinct as cardiovascular and respiratory activities, sleep, sexual and aggressive behaviors, eating, anxiety, mood, motor behavior, hormonal secretion, nociception, and analgesia [43]. The strongest evidence linking depression and serotonergic dysfunction resulted from the introduction of the new antidepressant class, serotonin-selective reuptake inhibitors (SSRIs). SSRIs have demonstrated efficacy in a wide range of psychiatric disorders like depression, obsessive-compulsive disorder, panic disorder, social phobia, eating disorders, and premenstrual dysphoric disorders [38]. Besides this important clinical confirmation, most investigations that addressed the concentration of serotonin, its major metabolites, and different receptors also suggested a serotonergic dysfunction in mood disorders [44–49].

2. Norepinephrine. There is compelling evidence implicating norepinephrine dysfunction in mood disorders, largely originated from depletion studies [41,50–52], and studies of noradrenergic metabolites [53,54] and receptors [55–57]. The strongest evidence linking noradrenergic dysfunction to mood disorders also came from clinical studies with nonspecific antidepressants like the heterocyclic agents [58–60], the partially selective agent venlafaxine (serotonin and norepinephrine reuptake inhibitor) [61,62], bupropion (noradrenergic and dopaminergic effects) [63,64], mirtazapine [65–67], and the most selective norepinephrine reuptake inhibitor, reboxetine [68,69].

3. Dopamine. Although less robust than the findings indicating abnormalities in the serotonin and noradrenergic systems, the possible implication of dopaminergic mechanisms in mood disorders is supported by some evidence. In depression, the theory was initially supported by observation of subcortical brain dopamine reduction in animals exposed to unpredictable stressful situations (animal model of depression). Subsequent studies confirmed this initial finding [70]: clinical effects of dopamine agonists (improving depressive symptoms, e.g., bromocriptine) and antagonists (worsening depressive symptomatology, e.g., classical antipsychotics) in a subgroup of patients [23,71]; measurement of the dopamine metabolite, homovanillic acid (HVA) [72,73]; and the therapeutic effects of bupropion, which possibly has dopamine reuptake blockade as one of its most important mechanisms of action [64]. The evidence for dopaminergic dysfunction in mania originated mainly from clinical studies that demonstrated the efficacy of neuroleptics (potent dopamine antagonists) in the treat-

ment of mania [23,74]. Additional evidence came from measurements of the dopamine metabolite HVA, which appears to be increased in manic states [75].

Despite important limitations, the monoamine theory of mood disorders is still the most accepted theory to attempt to explain pathophysiology of these disorders. It is largely based on the proven clinical efficacy of medications that modulate serotonergic, noradrenergic, or dopaminergic systems, separately or concomitantly, in treating either depression or mania.

Based on available research findings, Petty et al. [76] proposed a "neurotransmitter balance" theory, where psychiatric diagnosis would be determined not only by symptomatology, but also by its relation with neurotransmitter dysfunction. In this way, for instance, thought disorder would be associated with dopaminergic dysfunction, anxiety with noradrenergic dysfunction, and depressive symptoms with both. All systems would be integrated, with the serotonergic system as the most important in the maintenance and reestablishment of "brain homeostasis." In this way, a depressive disorder could therefore be classified as presenting either serotonergic, noradrenergic, or dopaminergic dysfunction, or a combination of them (it would be referred to as a depressive disorder with highlighted serotonergic, noradrenergic, or dopaminergic dysfunction, or a combination of them). Disruption of biological homeostasis could be triggered by environmental factors, which could be secondarily normalized by administration of serotonergic agents. In fact, given the broad efficacy of SSRIs in a wide range of psychiatric disorders—e.g., depression, social phobia, panic disorder, eating disorders, and obsessive-compulsive disorder—serotonin is probably a key neurotransmitter system possibly involved in the pathophysiology of various related mental illnesses. Nonetheless, such propositions still fail to capture the instances where dysfunction in several interrelated neurotransmitter systems and intracellular signal transduction pathways may be involved.

Basic research and clinical studies have provided important new insights about the behavioral manifestations of specific neurotransmitter dysfunction. There have been over the past several years proposals that specific behavioral dimensions would be linked to specific neurotransmitter dysfunction:

1. "Serotonergic syndromes." Although there is a well-described and clinically serious serotonergic syndrome that may be induced by potent serotonin reuptake inhibitors, we here use the term serotonergic syndromes only to refer to possible behavioral representations of a serotonergic dysfunction in the brain. Mood regulation, appetite regulation, anxiety, and sexual functioning are among the specific behavioral dimensions shown to be heavily modulated by serotonergic mechanisms [77–80].

2. "Noradrenergic syndromes." In vitro and in vivo studies have demonstrated an important role of norepinephrine in specific behavioral dimensions such as sleep-wake cycle, attention, learning, memory, and anxiety [81,82].

3. "Dopaminergic syndromes." Dopaminergic dysfunction has been proposed to be associated with some specific core behavioral symptoms, including motor symptoms/signs, motivation, thought abnormalities, and sexual and feeding behavior [83,84].

Obviously, the separation of behavioral manifestations among the distinct neurotransmitter systems discussed above is presented this way for didactical reasons, since it is impossible to isolate the functioning of a single neurotransmitter in human brain, as these various systems are interrelated. It is not possible to act in any neurotransmitter system without a repercussion in virtually all others; thus, a set of symptoms may be more related to a certain neurotransmitter system, but at the same time such abnormalities are generally not specific. Also, research conducted over the past decades has increasingly revealed the complexities of intracellular signaling and signal transduction processes, as well as related transcription mechanisms and gene expression, which are later events in the cascade triggered after a neurotransmitter couples to a receptor system. Therefore, the examination of specific neurotransmitter systems with an aim at improving diagnosis, as research in this area currently stands, may not necessarily result in substantial advances in diagnostics or therapeutics. Additional effects in intracellular processes and downstream mechanisms are being investigated, and their potential clinical relevance should also be examined as specific knowledge in this area continues to accumulate.

Despite all these provisions, it is expected that a dimensional approach to psychiatric diagnoses that takes into account other sources of information like neurochemical disturbances and neuroimaging findings, may become feasible in the next few years. By that time, we would have reached the third phase of evolution of psychiatric diagnoses, as proposed by Othmer et al. [37], and would then be able to treat mood disorders in a more complete manner, perhaps not only treating symptoms but also addressing the

real underlying pathophysiology. In this paradigm change, we would have incorporation of new diagnostic criteria that will hopefully be more meaningful and better reflect core aspects of the neurobiology of these illnesses. As a matter of fact, one could have a progressive incorporation of the most relevant research findings as they become available, and this gradual approach would constitute a more rational and productive way to try to integrate new information and foster future developments in this field.

With recent advances in clinical neurosciences, including advances in genetics, neuroimaging, and neuropsychopharmacology, we now have a formidable arsenal of powerful tools that are being applied to investigations in these specific areas, with very encouraging indications that substantial advances are very likely to be forthcoming in the next few years. Because of the probable insufficiency or inadequacy of the current diagnostic constructs for neurobiological investigations in this area, we have seen over recent years proposals to utilize new constructs related to a mood/anxiety disorder continuum of manifestations, or a continuum of psychotic disorders. Such proposals will generate newer and more specific phenotypes that may eventually be elucidative to the understanding of specific neurobiological mechanisms underlying psychiatric symptoms and clinical conditions. These new approches to neurobiological investigations of symptoms and syndromes in psychiatry constitute a significant departure from prevailing diagnostic thinking, and we will see in future years whether such approaches will result in significant contributions to our field.

V.   CONCLUSIONS

The achievement of high diagnostic validity and reliability in psychiatry has allowed significant advances in clinical and research endeavors in this field. In this sense, the DSM-III was a crucial milestone by providing a common language to psychiatric clinical care and research. Moreover, it allowed unquestionable advance by defining relatively homogeneous patient subgroups, a fundamental first step for both research and clinical initiatives. According to the model of "diagnostic evolution" proposed by Othmer et al. [37], the process of establishing a psychiatric diagnosis utilized nowadays is in the "second phase", i.e., the phase where we can identify "syndromic status," with a known natural history but without any specific information on underlying mechanisms or etiology.

Certainly, the progress in psychiatric classifications over the past few decades has allowed extremely relevant achievements, especially important advances in psychopharmacology. However, the currently utilized paradigm in this area is insufficient to assist contemporary clinical and research demands, since it leaves pathophysiology and etiology largely and intentionally neglected in the conceptualization of all currently valid psychiatric diagnoses. Very substantial advances are likely to result when a paradigm change that would incorporate meaningful information about pathophysiology and etiology of these illnesses in current diagnostic classifications becomes feasible. Nonetheless, there are not yet enough available findings that could have diagnostic or prognostic relevance, which hinders possible attempts to develop newer classification models. Because research in this area is advancing at a very fast pace, continued advances that would result in more meaningful psychiatric classifications are clearly expected in the near future. Because of the impossibility of changing immediately to the "next phase" of diagnostic evolution, our field could benefit largely from a "transitional phase," where a gradual incorporation of the most robust research findings into diagnostic classifications would become feasible.

Classification of Anxiety Disorders
Implications for Psychiatric Research

KERRIE L. POSEY, SUSAN G. BALL, and ANANTHA SHEKHAR

Indiana University School of Medicine, Indianapolis, Indiana U.S.A.

I. INTRODUCTION

From the momentary stage fright to the everyday worry, fear and anxiety are universally shared phenomena. Fear is experienced as the subjective emotion whereas anxiety refers to the construct of physiological symptoms, behaviors, and thoughts that occur in the context of fear. In this chapter, the adaptive and maladaptive features of anxiety will be presented along with a description of the most common anxiety disorders. The research base that has been used to design the current classification will be reviewed as well as the challenges that remain for the DSM diagnostic system. Finally, future directions for conceptualizing anxiety based on a neurobiological framework will be suggested for further consideration in this evolving area of psychiatry.

To understand anxiety as a disorder, one needs to consider the development and purpose of anxiety. The bioevolutionary theory of anxiety proposes that anxiety has developed as an alarm system that occurs in response to danger or threat [1]. The original types of threat that occurred within the natural environment were predominantly physical, e.g., the wild animal, or social challenges, e.g., group and interpersonal dynamics. Confronted with these types of threat, survival depended on the development of effective defensive responses to counter these dangers—defenses such as escape behaviors, avoidance, aggression, and submission [2]. For each type of defensive behavior, there is a corresponding physiological substrate to support the activation and mobilization of resources. The sympathetic activity that is characterized as the "fight-or-flight" mode is neither dangerous nor harmful, but is intended to be aversive, so that a response will be initiated, resulting in a defensive maneuver.

As an alarm system then, three components become necessary for successful functioning: the ability to detect a threat, the ability to identify the threat as a danger, and the ability to respond appropriately to the danger. An optimal alarm system will have a sensitivity that is balanced between the costs of false alarms, e.g., an escape response when there is not a danger, versus the cost of missing a true alarm, failure to respond to an actual danger. Given the relatively low costs of false versus true alarms in the context of danger, a biological alarm system will therefore be biased toward a "better safe than sorry" mechanism for both detection and response components [2]. In addition, the strength of the response should be associated directly with the strength of the perceived threat. The system may maintain a constant level of "hypervigilance" when the environment is generally perceived to be hostile and danger cues are considered to be probable. When the

actual danger cues are detected as present, the system then intensifies into a "response" status, whereupon the body is mobilized for a direct action. The "response" is expressed as the panic attack where each symptom either supports the escape behavior (e.g., increases in respiratory rate to support oxygen to muscles) or conserves physical resources (e.g., slowing down salivation and digestion).

Anxiety as an illness or disorder develops when there is a dysregulation in any of the three components of threat detection, threat interpretation, or threat response. A state of persistent hypervigilance will result in overdetection of threats; catastrophic thinking patterns can result in false perceptions of threat; and avoidance and escape behaviors may become over-utilized, resulting in maintenance of fears. The Diagnostic and Statistical Manual for Mental Disorders, 4th edition (DSM-IV) [3], for anxiety disorders classifies seven major areas of illness: generalized anxiety disorder, panic disorder, social phobia, specific phobia, obsessive-compulsive disorder, posttraumatic stress disorder, and acute stress disorder [4]. In the alarm system analogy, these syndromes can be viewed as a predominant disturbance in one or more of the components of threat detection, interpretation, or response. For example, generalized anxiety disorder is a perturbed alarm system, whose threshold for threat detection is set too low. Sharing a low threshold for threat detection, individuals with obsessive-compulsive disorder are also likely to perceive harm with a greater sensitivity than others. Once a stimulus has been detected, threat interpretation becomes problematic in the cases of panic disorder, social phobia, specific phobias, and obsessive-compulsive disorder wherein information is misperceived or processed erroneously (e.g., panic attack symptoms are interpreted as an impending heart attack). Panic disorder, acute stress disorder, and posttraumatic stress disorder develop from the response component of the alarm system, where the response either occurs in the absence of danger (i.e., spontaneous panic attacks) or continues to be triggered despite the cessation of the true danger.

II. CURRENT CLASSIFICATION OF ANXIETY DISORDERS

In the following section, each of the DSM-IV anxiety disorders will be reviewed for their conceptual and defining features. Similar to the other DSM-IV categories, the anxiety disorders diagnostic criteria are empirically descriptive rather than etiologically deter-

mined. However, the diagnostic criteria have been strongly influenced by bioevolutionary and cognitive models for anxiety that were developed during the 1980s and 1990s, which have served as the predominant research basis for anxiety disorders.

A.   Generalized Anxiety Disorder

Often characterized as the "basic anxiety disorder," generalized anxiety disorder is defined by worry that is pervasive and uncontrollable to the extent that it interferes with daily functioning or causes marked distress. The development of criteria for generalized anxiety disorder was mainly concerned with discriminating pathological worry from the normal adaptive process of worry, which alerts the individual to potential, probable threats. Some of the key findings from research studies were that pathological worry and normal worry could be differentiated on the basis of the difficulty with controlling worry as well as by the accompanying physiological symptoms [5].

Excessive worry was best discriminated from other anxiety disorders by being associated with at least three of the following symptoms: feeling keyed up/on edge, restlessness, easy fatigability, difficulty concentrating, irritability, and difficulty sleeping [6]. Again, consistent with a model of hypervigilance or "heightened threat detection," generalized anxiety disorder criteria require at least 6 months' duration, as "normal worry" typically resolves with the cessation of an episode of stress, but pathological worry persists despite stress resolution. More recent studies, however, such as one conducted by Bienvenu et al. [7], have suggested that the severity of associated symptoms rather than the duration of worry is a better discriminator along the continuum of nonclinical to clinical worry.

B.   Panic Disorder

Panic disorder has been a complicated diagnosis that has undergone numerous changes in the DSM classification system. In DSM-III-R, the definition of a panic attack was first defined as the acute onset of at least four cognitive or sympathetic symptoms with a peak onset of 10 min. Although it was useful to have a definition to discriminate the "panic response" from the anxiety pattern of generalized and other anxiety disorders, the exclusive inclusion of the definition of panic attacks within the diagnosis proved problematic. Many of the individuals meeting criteria for other types of anxiety disorders also present with panic

attacks, approximately 80% of those with different disorders [8].

Further, panic attacks have different functional significance within different anxiety disorders. Spontaneous attacks (no apparent trigger) may be driven by an underlying false alarm mechanism whereas situationally predisposed (attacks likely in the presence of the trigger) or situationally bound (attack always occurs in the presence of the trigger) are derived from learning or conditioning [9]. In addition, some people experience panic attacks but are not unduly distressed or impaired by them. In recognition of these limitations, the DSM-IV system separated the definition of panic attack from the definition of panic disorder. The panic attack criteria remained the same in requiring that four of 13 symptoms must occur and peak within 10 min to denote the acute intensity and sympathetic activity. The defining symptoms of a panic attacks are heart palpitations/pounding, sweating, trembling/shaking, shortness of breath, feeling of choking, chest pain/discomfort, nausea/abdominal distress, dizziness/unsteadiness, derealization, fear of losing control/going crazy, fear of dying, paresthesias, and chills/hot flushes. With this separate definition, panic attacks were now viewed as simply the "defensive response" that can occur in the context of a perceived imminent, severe threat and thus be diagnosed as occurring within any anxiety disorder [10].

Panic disorder, on the other hand, has been conceptualized to develop as a two-part process [11,12]. Initially, panic disorder may result from the occurrence of "false alarms"; the alarm system becomes triggered in the absence of any objective danger. This false alarm may arise from genetic, biological, and life stress vulnerabilities. For the person who is experiencing the false alarm, however, the phenomenon is inexplicable. The absence of an external source of danger to associate with the alarm results in an internal scanning for the threat. The person then misperceives the occurrence of the alarm as an indication of an internal danger, such as heart attack, loss of control, or fainting. Further focus on the perception that the attacks themselves are dangerous results in a secondary process that maintains the panic attacks. Fear of the attack triggers the alarm system, which then perpetuates further fear, i.e., " the fear of fear." In recognition of the necessity for both initial attacks and the developed fear of the attacks, the DSM-IV criteria for panic disorder requires the occurrence of recurrent panic attacks followed by either worry about the attacks, worry about the implications or consequences of the attacks, or a significant behavioral change due to the attacks.

A common complication of panic disorder is agoraphobia, which is avoidance of situations associated with the fear of having a panic attack and/or being unable to obtain assistance or to escape. Most common types of agoraphobia include situations associated with restriction of movement, e.g., standing in line, being in a barber's chair, or with travel, e.g., driving. One diagnostic controversy has been whether agoraphobia occurs only secondary to panic disorder or whether it can occur without a history of panic. Research that has fueled this controversy has focused on the findings that clinical samples of patients who report agoraphobia typically have an onset of panic disorder prior to the avoidance behavior [13]. However, in the Epidemiological Catchment Study survey, community respondents did meet agoraphobia without having panic disorder [14]. Although this study has been criticized for confounding the diagnoses between agoraphobia and specific phobias [15], the DSM-IV allows the diagnosis of agoraphobia independently of the presence of panic disorder. Clinical studies of patients meeting criteria for agoraphobia without panic disorder typically show that the agoraphobia develops in the context of limited symptom attacks, usually with a predominant gastrointestinal focus [16]. For example, nausea and diarrhea may provoke avoidance of public situations for fear of being unable to leave a place or to get to bathroom facilities adequately. Again, the avoidance strategies become a defensive response for the perception that the symptoms themselves are dangerous and the trigger point for the alarm.

C. Social Phobia

In DSM-IV, social phobia is defined by the cognitive component of an excessive fear of social or performance situations in which the person may be evaluated or the focus of attention [17]. Typical social situations that trigger this anxiety include performance types of situations, such as speaking in front of groups, or interactional types of situations, such as initiating and maintaining conversations. Most individuals (2/3) who have lifetime social phobia report having multiple situations associated with their anxiety [18]. Within these situations, the predominant trigger is a perception that one is going to be evaluated negatively because of one's own failings, which can include the demonstration of anxiety signs, e.g., blushing or sweating. Similarly to panic disorder, the anxiety symptoms themselves may become a focus of the fear. However, while the patient with panic disorder fears the anxiety

symptoms for its potential physical (stroke) or psycho-
logical (going crazy) consequences, the person with
social phobia fears the symptoms for their potential
for public embarrassment, as the person often believes
that these symptoms are detectable and that others will
view them as a sign of weakness or peculiarity.

Social phobia is often viewed by the person as being
related to shyness. Although shyness is a common
development process that occurs within children and
adolescents, it is typically transient and less severe [19].
Similar to generalized anxiety disorder, pathological
shyness is differentiated from "normal" shyness by its
interference and duration [20]. Situations that trigger
the fear must be sufficiently anxiety provoking and/or
interfering to warrant the clinical diagnosis. Social
phobia is commonly being renamed in the literature
as social anxiety disorder to emphasize that it is not
the external situation per se that triggers the alarm, as
in phobic illness, but rather the internal cognitive pro-
cesses of perceived negative evaluation [21].

D. Specific Phobias

Most individuals can easily identify specific situations
or objects that they associate with danger. The fears
that are common to all of us are usually dealt with by
simple avoidance. For the person who has an alarm
reaction to the stimulus of a dog, the easiest defense is
avoidance of dogs. When avoidance strategies fail as a
defense, e.g., the person is not able to avoid the situa-
tion because of occupational or social factors, the fears
then typically meet criteria for a specific phobia. The
essential diagnostic defining feature is an alarm
response to the object or situation that is excessive or
unreasonable, resulting in distress and/or impairment.
Often, it is the presence of multiple specific phobias
that prompts a person to seek out clinical treatment
[22] as the aggregation of several fears begin to impact
daily functioning or social relationships.

Interestingly, although the names of various pho-
bias range into the hundreds, most common specific
phobias fall into four categories: animal type; natural
environment, such as heights; blood/injection/injury
type; and situational (claustrophobia). Biological pre-
paredness theory propose that these situations and
objects are more easily predisposed to become a con-
ditioned fear object owing to their evolutionary signif-
icance to the species, but the empirical support for this
theory has been limited [23]. More recently, the devel-
opment of specific phobias has been associated with a
greater underlying fear of anxiety as well as the situa-
tion [24].

E. Obsessive-Compulsive Disorder

Although the diagnosis of obsessive-compulsive disor-
der can be made by meeting the diagnostic criteria for
obsessions or compulsions, research supporting the
DSM-IV criteria have found that most individuals
will meet criteria for both components of the illness
[25]. The definition of obsessions recognizes that
these may not only be thoughts, but can also be
other types of mental phenomenon, including imagery
or impulses. For the person who experiences this phe-
nomenon, the thoughts or impulses are perceived as
dangerous, thus triggering the alarm system. Unlike
an external situation that has been labeled as threaten-
ing, when a person is faced with a thought, he or she
cannot rely on a simple avoidance. In fact, attempts at
thought suppression are likely to increase the fre-
quency of a specific thought. Wegner et al. [26] demon-
strated that subjects asked to suppress thoughts about
a neutral stimulus, "white bear," actually experienced
more intrusions than subjects who were given the
directive to think about white bears. Exacerbating
the problem of thought suppression, most patients
with obsessive-compulsive disorder also have an overly
developed perception of responsibility, especially with
regard for being able to control one's thoughts [27,28].

Given the inability to suppress the thought and their
sense of responsibility for having the thought, the per-
son will then develop a neutralization strategy that will
defend against the thought. Compulsions are defined
as physical or mental acts that are designed to escape
or avoid a thought. Initially, most compulsions have a
logical connection with the thought, e.g., washing to
neutralize contamination fears, but for some thoughts,
the neutralization strategy may simply rely on a magi-
cal or superstitious connection, e.g., if I touch some-
thing three times, then nothing bad will happen.
Mental rituals can also serve this same function. For
example, for intrusive unwanted religious thoughts,
such as blasphemy, compulsive praying may be viewed
as a way to escape the consequence of having these
thoughts.

The DSM-IV criteria for OCD highlight these
essential features of this illness. The obsessions must
be perceived as repetitive/recurrent, anxiety provoking,
and ego-dystonic at some point, e.g., an intrusive
thought that the person does not want. The person
must then also make some effort to neutralize or
avoid the thought. To differentiate from psychotic
spectrum illness, the person has to recognize that
these are his or her own thoughts. Further, the amount
of time spent in response to these thoughts, either wor-

rying or compulsing to rid oneself of them, must be sufficiently distressing or interfering. To discriminate between worries that are also anxiety provoking and repetitive, the obsession criterion also includes recognition that the person's thoughts are not simply real-life concerns, but rather are viewed as being inappropriate content, e.g., thoughts of harming someone, or very low probability, e.g., getting contaminated from objects on the floor [29].

F. Acute Stress/Posttraumatic Stress Disorder

Unlike the above DSM anxiety disorders, where the triggers associated with anxiety are typically false signals or misperceptions of threat, acute and posttraumatic stress disorders occur following the experience of a "true alarm", e.g., actual physical threat or danger. Although physically traumatic events, such as assaults or accidents, are commonly considered to be the type of stressor that may result in difficulties with recovery, several studies have also shown that subjective or perceived threat can be as anxiety provoking as objective threat [30].

Most persons who experience a threat of serious physical injury will experience transient emotional and behavioral responses as they adjust to the recognition that they have survived the threat. However, in some cases, a person may experience an alarm reaction that causes significant distress or impairment in functioning, especially with regard to mobilizing resources to respond to the aftermath of the trauma. In recognizing that these types of alarm responses may require direct intervention, acute stress disorder was introduced in DSM-IV [4].

The main diagnostic criteria for acute stress disorder are the experience of a traumatic stressor of both objective or subjective threat; the experience of fear, helplessness, and horror; at least three dissociative symptoms (numbing of emotion, reduction in awareness, derealization, depersonalization, and amnesia), usually some form of reoccurrence of the trauma (images, thoughts, dreams, flashbacks); increased arousal (difficulty sleeping, irritability, exaggerated startles response, motor restlessness, poor concentration); and avoidance of stimuli associated with the trauma.

Posttraumatic stress disorder criteria share several of the same features as acute stress disorder, but there are a couple of key differences. Acute stress disorder requires at least three dissociative symptoms whereas PTSD allows, but does not require, the presence of dissociation. In addition, the PTSD criteria specify that more than one symptom must occur in the areas of reexperiencing, avoidance, and arousal, whereas acute stress disorder does not dictate the number of symptoms but rather focuses on severity as defined by the term "marked." A further difference is the time course, with acute stress disorder occurring between 2 days posttrauma and no longer than 4 weeks, whereas posttraumatic stress is diagnosed 4 weeks following a trauma to denote the chronic alarm response as a disorder.

In developing diagnostic criteria for classifying traumatic responses, several dilemmas have occurred concerning pathologizing normal responses to stressful events as well as whether there is a quantitative or qualitative continuum from the nonclinical to the clinical state. [31]. Although acute stress disorder may be a precursor to posttraumatic stress disorder [32], the emphasis on dissociation within the acute stress criteria makes it a qualitatively different disorder from PTSD [33]. Many individuals who meet criteria for PTSD do not necessarily experience the dissociative symptoms at the time of the trauma, but nonetheless experience impairment from the other symptom clusters [34]. Given these conceptual considerations, further empirical work needs to clarify as to whether the difficulty to integrate a traumatic experience resulting in posttraumatic stress disorder is actually a disorder of magnitude or severity of the alarm response, e.g., a stronger response due to individual vulnerabilities [35], or it is a disorder of the alarm response failing to cease in a normative time course.

III. CHALLENGES TO THE DSM DIAGNOSTIC SYSTEM

One of the primary missions of the DSM-IV task force was to develop a classification system that was supported by an empirical base and that also could be utilized widely to produce reliable diagnoses. Using structured clinical interviews, such as the Anxiety Disorders Interview Schedule for the DSM-IV, researchers have demonstrated good reliability for most of the DSM-IV anxiety disorders [36]. However, another important objective for a classification system is the utility of the diagnoses in predicting clinical profiles, treatment response, or identifying a shared etiology [37] Considering these functions of a diagnostic system, the DSM-IV classification system is challenged by the issues of high degree of comorbidity among the different disorders, a lack of good discrimi-

nation by available treatments, and an overlap in neurobiological and genetic diatheses.

A. Comorbidity Among the Different Disorders

In studies utilizing structured clinical interviews, most patients who meet criteria for one anxiety disorder are also likely to meet criteria for a second or third anxiety disorder [38]. Given the DSM-IV emphasis on the diagnosis by the type of threatening stimuli, it is not surprising that comorbidity occurs as a person who overperceives threat in one domain may also be likely to have misperceptions of threat in other domains. For example, a person with panic attacks may fear not only the physical consequences of the panic symptoms, but also the social/evaluative component and therefore meet criteria for panic disorder and social phobia. Similarly, generalized anxiety disorder in which hypervigilance is the primary mode may lead one to worry about physical consequences of symptoms, social performance, and daily responsibilities, resulting in diagnoses of generalized anxiety, panic disorder, and social phobia. Further, across the life span the focus of fear may change from one domain to another resulting in even higher comorbidity when examining lifetime prevalence.

Similarly, the comorbidity of anxiety and depressive illness is also quite high. Several studies have found that the cooccurrence of the diagnostic syndromes of anxiety and depression within clinical samples occurs in the majority of patients, especially when considering lifetime prevalence. Estimates have shown that this cooccurrence is present in both primary anxiety populations as well as primary depressive populations. Thirty percent to 60% of patients with anxiety disorders meet criteria for a current depressive disorder with lifetime estimates ranging to 80% [39,40]. The cooccurrence and risk for comorbidity is not limited solely to clinical populations. In the National Comorbidity Sample, 8000 community respondents were assessed by lay interviewers using the Composite Interview based on DSM-III-R criteria. The odds ratio for having panic attacks with the presence of a depression was 6.2 whereas the odds ratio for having panic disorder with depression, was 6.8. From the patterns found in this study, the presence of a primary panic disorder appeared to be a marker for a secondary depression, whereas primary depression is a risk factor for secondary panic attacks, but not panic disorder [41].

In considering the problem of anxiety and depression comorbidity, the focus of the literature has been on three possibilities: anxiety and depression are viewed as being two distinct illnesses, they are different expressions of a common underlying pathophysiology, or the comorbid condition is its own unique disorder. Further complicating these issues are the diagnostic criteria as defined by the DSM. Many of the symptoms that are included for the anxiety disorder diagnoses are also incorporated into the depressive disorder diagnoses. For example, generalized anxiety disorder and major depressive episode criteria share the symptoms of sleep disturbance, fatigability, and difficulty concentrating. Clinically, irritability has long been associated with depression as has rumination, making the distinction between these disorders more difficult [6].

One of the more influential models in recent years has tried to sort out the symptoms that are shared between the anxiety disorders and depression as well as the unique components. In the tripartite model, anxiety and depression share a common dimension, described as general negative affectivity, representing negative valence emotions and general distress [42]. Symptoms consistent with general negative affectivity include fear, sadness, and tension. Anxiety is proposed to have the unique component of the physiological hyperarousal of the "fight-or-flight" response whereas depressive disorders are suggested to be distinct by the dimension of low positive affectivity, described as the ability to experience pleasure and/or engage in the environment. Patients with anxiety disorders are described as having high levels of general negative affectivity accompanied by physiological hyperarousal; patients with depressive disorders have high general negative affectivity; and low positive affectivity; and those with the comorbid condition would have high general negative affectivity, low positive affectivity, and hyperarousal symptoms.

In the initial presentation of the model, Clark and Watson [42] demonstrated the dimensions of general and positive affectivity through administering multiple questionnaires to 483 outpatients seeking treatment for anxiety or depression, 516 college students, and 453 patients seeking treatment for substance abuse. They argued through the use of structured equation modeling that the responses were consistent with the tripartite model. However, different authors have countered that that the appropriate analyses for this data should be confirmatory factor analyses rather than structured equation modeling [43]. Using the same dataset, Burns and Eidelson [43] found that the responses supported a two-factor model because the nonspecific symptoms of anxiety and depression did not load onto a single general distress factor. Although the tripartite model has

provoked an intriguing line of research and discussion, the relationship between anxiety and depression models continues to remain complex and controversial.

B. Lack of Discrimination by Pharmacological Treatment/Biological Challenges

A second challenge to the DSM classification system includes the lack of discrimination in selecting effective treatment modalities based on the diagnoses. Both pharmacotherapy and cognitive-behavioral psychotherapy have been demonstrated to be efficacious for the treatment of anxiety disorders [44]. Within the spectrum of pharmacotherapy, the treatment options can be broadly categorized into two major classes of drugs: antidepressants and the benzodiazepines. The antidepressants can be further subclassified into serotonergic and nonserotonergic groups. As a first line of treatment, the serotonergic reuptake inhibitor (SRI) antidepressants appear to have a broad range of efficacy across the anxiety disorders, including OCD, panic disorder, GAD, social anxiety, and PTSD [45]. Thus, the specific anxiety diagnosis as defined by the current DSM system provides little utility for influencing the decision of SRI treatment. Similarly, benzodiazepines have also demonstrated a ubiquitous positive effect of the pharmacotherapy for anxiety. Initially, benzodiazepines were considered to be differentially more effective in reducing the hypervigilance "threat detection" associated with generalized anxiety than in reducing the "defensive response" of the panic attack. However, the development of high-potency benzodiazepines that were effective in ameliorating panic attacks suggested that this distinction was not as germane [46].

In considering the interaction between the DSM system and lack of treatment differentiation, part of the problem is clearly related to the broad nature of the neurochemical systems that are targeted by these drugs. The serotonin system is a global modulator pathway that affects almost every central nervous system function. Similarly, the benzodiazepines receptors are associated with the gamma-aminobutyric acid (GABA), another pervasive neurotransmitter. Some noradrenergic agents have shown some differential efficacy between panic disorder and obsessive-compulsive disorders, but these agents, too, demonstrate a broad base of efficacy for anxiety [47]. Given the pervasiveness of these neurotransmitter systems, it is not surprising that drugs that work through these neurotransmitters have a broad range of effects across multi-

ple diagnostic categories. Novel treatments based on less global systems, such as peptides, GABA receptor partial agonists and NMDA receptor antagonists may have a better ability to discriminate between diagnostic categories [48].

Not only have pharmacological treatments been nonspecific to different anxiety disorders, but biological challenges that have been used to elicit panic responses in patients have also failed to discriminate among the different disorders. Intravenous sodium lactate and other provocative agents (e.g., carbon dioxide, caffeine, yohimbine) elicit panic attacks in patients with panic disorder but not in normal controls [49]. These agents were thought to be initially be fairly selective for triggering symptoms in panic disorder. However, recent studies suggest that lactate infusions may provoke symptoms in patients with posttraumatic stress disorder [50] as well as premenstrual dysphoric disorder [51]. Therefore, the specificity of these challenges to panic disorder alone has been questioned. While these provocation agents have been of great help in elucidating some of the underlying neurobiology of anxiety symptoms, they have not exhibited adequate selectivity to be of assistance in the classification of the different anxiety disorders.

IV. FUTURE DIRECTIONS

A. Impact of Neuroimaging on Classification

Over the past decade, a number of seminal neuroimaging studies have been conducted in patients with anxiety disorders. Neuroimaging has considerable potential for reorganizing the classifications of psychiatric disorders [52]. Structural and functional imaging studies using psychiatric patients are beginning to identify neuroanatomical systems and neurotransmitters that are disrupted in the anxiety disorders. Studies in normal subjects continue to identify brain regions where activity is modified during presentation of fearful stimuli. For example, results of a recent functional imaging study examining amygdala activation during exposure to neutral or fearful faces revealed greater activation of the amygdala in normal adults during fearful face exposures. In contrast, children demonstrated amygdala activation to both neutral and fearful faces [53]. Furthermore, amygdala activation of male but not female children was decreased with repeated face presentations. These imaging studies clearly indicate that age and sex are both important factors in

determining anxious responses in the brain, and these findings are consistent with epidemiological data on anxiety disorders, in which prevalence rates tend to favor women [14]. Eventually, similar neuroimaging approaches may be used to identify individuals at risk for developing disorders.

Some general outlines of the central nervous system pathways involved in the different anxiety states are emerging based on neuroimaging studies of clinical populations, demonstrating specific anxiety symptoms [54,55]. For example, several reports have implicated the orbitofrontal cortex–striatum–thalamic pathway as being a critical component of the pathophysiology in OCD [56,57]. This pathway is quite distinct from areas often implicated in panic disorder, such as the para-hippocampal and amygdala regions. However, these areas implicated in panic disorder, especially the amygdala, may also be implicated in phobias, PTSD, and GAD. For example, studies have implicated the amygdala and anterior cingulate cortex in PTSD [58,59]. Some brain regions are consistently activated across several anxiety disorders. For example, symptom provocation paradigms have consistently been shown to activate the amygdala and the right side of the prefrontal cortex across anxiety patient populations [55]. Thus, once again, OCD separates out as a much different pathophysiological entity compared to the other anxiety disorders. With more refined imaging methodologies, it is hoped that greater discriminations can be made within the other anxiety disorders.

B. Impact of Genetic Studies on Classification

Genetic studies are another important approach to elucidating the pathophysiology of psychiatric disorders. Ideally, distinct disorders would be predicted to cluster separately in population genetic studies and eventually be linked to one or more susceptibility genes. There is clear evidence that the major anxiety disorders do exhibit familial patterns with significant genetic components in their etiology [60]. However, the ability to discriminate between the different anxiety disorders based on genetic predisposition has proven to be elusive. For example, there is considerable evidence that generalized anxiety disorder and major depression have common genetic risk factors [61]. Similarly, there are significant overlapping genetic factors between generalized anxiety and panic disorders [62]. Studies have also suggested that perhaps there are several common genetic susceptibility factors for anxiety disorders, some of which are common to anxiety

susceptibility in general and others more specific to individual anxiety syndromes [63,62]. Others have suggested that rather than try to find genetic factors for complex syndromes like the anxiety disorders, which are likely to involve a large number of genes, it may be better to define specific markers and endophenotypes (e.g., hypothalamic-pituitary response in posttraumatic stress disorder, respiratory reactivity in panic disorder) as better targets for genetic analysis. [64,65]. Thus, more sophisticated genetic studies are likely to provide other approaches to classification of anxiety syndromes.

C. Impact of Neurobiological Insights

Better elucidation of the underlying neurobiological mechanisms of emotions will undoubtedly have a major impact on our future classification of psychiatric disorders. With regard to the anxiety disorders, determining the neural basis of key components of anxiety disorders, such as threat detection, threat evaluation and defensive responses, will shed new light on classification. For example, the response system to a threatening stimulus involves a series of interconnected pathways extending from the medial amygdala, medial hypothalamus, periaqueductal gray, and the brainstem autonomic centers. Disorders that are clearly related to a disturbed response system such as panic and posttraumatic stress disorders would be expected to show pathological changes in these pathways. Current neuroimaging studies, in fact, suggest that it is indeed the case. Similarly, the functions of threat detection and assessment are likely to involve prefrontal, cingulated, and other cortical areas, the striatum and thalamus, as the key components. Disorders of these functions, such as obsessive-compulsive disorder and generalized anxiety disorder are likely to involve abnormalities in these circuits, which is again supported by current neuroimaging studies. Thus, such informed neurobiological approaches will in the future help to categorizing anxiety disorders at a pathophysiological level rather than at a symptomatic level.

In conclusion, like most psychiatric diagnoses, anxiety disorders are currently classified according to the symptom clusters and the primary focus or source of the anxiety. This empirical system has been extremely helpful in providing uniformity of clinical definition of syndromes, enabling us begin a systematic study of these syndromes. However, such a descriptive system will eventually need to be refined by information gathered from genetic, neurobiological, and treatment outcome studies. Such efforts will perhaps lead in the

future to better-defined syndromes that are grouped according to pathophysiological processes rather than purely descriptive similarities.

Classification of Dementias and Cognitive Disorders

FRÉDÉRIC ASSAL and JEFFREY L. CUMMINGS
David Geffen School of Medicine at UCLA, Los Angeles, California, U.S.A.

I. INTRODUCTION

There are multiple ways to classify dementias and cognitive disorders. Both may result from a variety of disorders according to their etiology, genetic features, pathophysiology, or clinical signs. Following these different classifications, this chapter will focus on clinically relevant disorders for clinicians or basic scientists who want an overview of current clinical knowledge of this evolving field of clinical neuroscience.

Multidimensional cognitive disorders include delirium and dementia. Single-dimensional cognitive disorder includes focal neuropsychological symptoms like aphasia, apraxia, or agnosia. For didactic reasons, this chapter will focus on dementia and include cognitive disorders related to dementia when they bear as differential diagnosis as augment understanding of dementia.

The term dementia refers to a clinical syndrome of acquired intellectual disturbance meeting criteria defined by the Diagnostic and Statistical Manual of Mental Disorders, 4th edition, Text Revision (DSM-IV-TR) [1] or the International Classification of Disease (ICD)-10 [2]. The essential diagnostic features include impairment in social and occupational functioning and disturbance of memory and one or more other domain (aphasia, apraxia, agnosia, executive functions). Alternative criteria were suggested by Cummings and Benson [3], where they define dementia as an acquired persistent disturbance in neuropsycho-

logical function involving at least three of the following spheres of mental activity: language, memory, visuospatial functions, executive functions, personality, and emotion. This definition allows for the possibility that memory disturbance may not be the presenting feature of a dementia. Most definitions identify similar patient groups with shared cognitive features

II. ETIOLOGY

Dementias can be classified into degenerative and nondegenerative etiologies. This classification is relevant in the differential diagnosis and is summarized in Table 1. The nondegenerative dementias encompass almost any neurological disease (vascular, traumatic, demyelinating, neoplastic, infectious, inflammatory, hydrocephalic, systemic and toxic conditions) and are often referred as secondary causes of dementia, some of which may be reversible. Secondary causes are relatively rare. In a cohort of 2915 community inhabitants aged 65 years and over, Alzheimer's disease (AD), vascular dementia (VaD), and mixed dementias encompassed 90.4% of all cases of dementia [4]. Reversible dementia may be even less frequent and account for < 1% of causes in the most recent studies [5]. Nevertheless, these disorders should be recognized and treated. For that reason, the American Academy of Neurology (AAN) has stated that workup of dementia should include structural neuroimaging,

Table 1 Classification of Dementias and Related Cognitive Disorders According to Their Etiology

Degenerative	Nondegenerative
Alzheimer's disease	Vascular dementias
Dementia with Lewy Bodies	Multi-infarct dementia
Frontotemporal dementia	Strategic infarct
Primary progressive aphasia	Lacunar state
Parkinson's disease	Binswanger's disease
Progressive supranuclear palsy	CADASIL
Corticobasal degeneration	Infectious dementias
Multiple system atrophy	AIDS dementia complex
Huntington's disease	Whipple's disease
Wilson's disease	Neurosyphillis
Neuroacanthocytosis	Creutzfeldt-Jakob disease
Idiopathic basal ganglia calcification	Demyelinating dementia
Neurodegeneration with brain iron accumulation type 1	Multiple sclerosis
Spinocerebellar ataxias	Neoplastic conditions
Leukodystrophies	Brain tumors (primary or secondary)
Neuronal ceroid lipofuscinosis	Meningeal carcinomatosis
Amyotrophic lateral sclerosis	Paraneoplastic limbic encephalitis
Cerebral amyloid angiopathy	Miscellaneous
	Nutritional deficiencies (vitamin B_{12}, thiamine, niacin)
	Toxic-metabolic disorders (thyroid, medication, alcohol, polysubstance abuse, heavy metal)
	Normal pressure hydrocephalus

screening for depression, B_{12} deficiency, and hypothyroidism [6].

A. Degenerative Dementia

1. Alzheimer's Disease

Alzheimer's disease is a progressive degenerative disorder that afflicts an estimated 4 million Americans. The sporadic form of AD is the leading cause of dementia among those over age 65. Common diagnostic criteria include those of the National Institute of Neurological and Communication Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA) [7] and the DSM-IV-TR [1]. Both sets of clinical criteria specify that the deficits must be gradually progressive, must not be limited to a period of delirium, and cannot have an alternative explanation. The core clinical syndrome of AD is relatively stereotyped and includes severe impairments in recent memory, mild to moderate language deficits, and visuospatial disturbances including environmental disorientation. Nevertheless,

there is substantial variation in the degree of impairment in these domains in individual patients. Cognitive impairment occurs first. Behavioral symptoms including delusions often related to theft or infidelity, misidentification syndromes such as Capgras syndrome, or agitation occur frequently during the middle stages and become more common as the disease progresses. Hallucinations are unusual. Motor problems occur only in the latter stage of the disease; these impair movement, and eventually the inability to swallow leads to aspiration pneumonia, and death.

Besides neuronal loss, senile plaques (SPs) and neurofibrillary tangles (NFTs) constitute the two major neuropathological lesions in AD. Their distribution can be really contrasted. SPs are found in the isocortex, the hippocampus being relatively spared, and their density increases with the severity of the disease. NFTs involve an increasing number of areas in a stereotyped order: entorhinal area, hippocampus-subiculum, isocortex. The occurrence of these two lesions explains why two systems of neuropathological criteria may be used with similar outcomes: the counting of plaques in the isocortex (Consortium to Establish a

Registry for Alzheimer's Disease, or CERAD, criteria) [8] or the mapping of the areas involved by the neuro-fibrillary pathology (Braak and Braak stages) [9]. These neuropathological lesions explain the progression of the clinical symptoms: entorhinal area and hippocampus causing the episodic memory loss and the associative posterior parietal isocortex, causing the visuospatial and language impairments. They also correlate with the structural and functional neuroimaging findings (medial temporal lobe atrophy, hypoperfusion, or hypometabolism in multimodal association parietal cortex).

2. Dementia with Lewy Bodies

Dementia, parkinsonism, hallucinations, and fluctuations in cognition are part of the Consensus Criteria of Dementia with Lewy Bodies (DLB) [10]. Cognitive deficits of DLB are characterized by prominent deficits in visuospatial skills, and relative sparing of memory. However, neuropsychological tests do not reliably differentiate DLB from either AD or VaD [11], and hallucinations and delusions occur in AD as well. This explains the low sensitivities of the diagnostic criteria when applied against neuropathological findings [12]. Promising tools for the diagnosis of DLB are MRI showing less temporal atrophy than patients with AD [13], functional neuroimaging disclosing more hypoperfusion in the occipital lobes [14,15], and a good response to cholineesterase inhibitors [16].

The neuropathologic hallmarks of DLB are intracytoplasmic inclusions (Lewy bodies; LBs) which are widely distributed throughout paralimbic and neocortical regions as well as the brainstem. Pure LB pathology may occur, but in most cases of DLB they coexist with a plaque-predominant AD (17). High NFT densities sufficient to meet AD pathological criteria are not frequent.

3. Frontotemporal Dementia

Frontotemporal dementia (FTD) is a clinical syndrome with a younger age of onset than AD, and a family history often suggests a dominantly inherited illness [18]. The consensus diagnostic criteria for FTD [19] include both behavioral and cognitive features. Using an earlier version of the consensus criteria [20], behavioral features such as early loss of personal awareness, early loss of social awareness, hyperorality, and stereotyped, perseverative behavior were found to be sensitive (63–73%) and highly specific (97–100%) for differentiating FTD and AD [21], although the study was without autopsy confirmation. Cognitive

functions such as speech and language, executive functions, and preserved posterior functions were less useful for differentiating FTD and AD. An autopsy-based class II study (using retrospective clinical diagnosis determined from review of medical records) showed that most patients with FTD fulfilled diagnostic criteria for AD [22]. One study found that the FAS word fluency test was the best neuropsychological test to differentiate the two conditions, and was more altered in FTD [23].

Functional brain imaging, showing decreased frontotemporal perfusion or metabolism, is a promising diagnostic tool which requires rigorous validation. Pathological findings are heterogeneous and complex, and include positive tau and ubiquitin inclusions [24,25]. Grossly, the brain has frontal and/or frontal and anterotemporal atrophy often associated with atrophy of the basal ganglia, substantia nigra, and amygdala. Histologically, neuronal loss, gliosis, and spongiform changes are found primarily in the top three layers of the cortex. Plaques and tangles do not occur beyond what is seen in normal elderly. Pick bodies or argentophilic cytoplasmic inclusions that fill inflated neurons and swollen achromatic cells are found in Pick's disease per se but are not required for the diagnosis of FTD since FTD may occur in the absence of these inclusion types. There are no clinical features that are useful for establishing histologic subtypes.

4. Parkinson's Disease

Parkinson's disease (PD) includes tremor, bradykinesia, rigidity, and postural abnormalities. Evidence of disease progression, parkinsonism, asymmetry of signs and of onset, marked response to levodopa, and absence of clinical feature of alternative diagnosis and of an etiology known to cause similar features have been proposed as research criteria for idiopathic PD [26]. Their validity and reliability remain to be assessed. Besides behavioral symptoms like hallucinations, delusions, mania, anxiety, depression, and obsessive-compulsive features, some of which may be secondary to drug treatment, patients with PD show a prevalence of dementia of $\sim 40\%$ [27]. The risk for developing dementia in patients with PD relative to controls, according to DSM-II-R criteria, after adjusting for age, sex, and education, was 5.9 (95% CI, 3.9–9.1) in a recent prospective study [28].

Several types of dementia have been identified in PD. A frequent pattern of dementia corresponds to a frontosubcortical profile of dysfunctions, characterized

by bradyphrenia (mental slowing), executive deficits, memory disturbance with retrieval deficit, and visuospatial deficits [29,30]. Significant disorientation, impairment of memory with an encoding deficit, or naming difficulties that develop in the course of PD are indicative of other degenerative pathology, most commonly of the Alzheimer's type [31].

Characteristic pathologic findings of PD include loss of pigmented neurons and LB in the pars compacta of the substantia nigra, and various other subcortical nuclei. Cortical LB are better correlated with cognitive impairment in patients with PD than AD-type histological findings [32,33]. The contributions of cortical LB, AD-type pathology, and the PD pathology to the dementia of PD are uncertain.

B. Nondegenerative

1. *Vascular Dementia*

Vascular dementia is a group of disorders resulting from the effects of vascular disease on the brain. The various location, type, and extension of the lesions express heterogeneous clinical symptoms. Recent criteria for VaD are the National Institute of Neurologic Disorders and Stroke and the Association Internationale pour la Recherche et l'Enseignement en Neurosciences (NINDS-AIREN) [34] criteria, and the DSM-IV criteria [1]. Diagnostic criteria typically require the presence of dementia, the demonstration of cerebrovascular disease, and onset of dementias following stroke or with a stepwise pattern of progression. In studies that compared clinical diagnosis and neuropathologic findings, these criteria had low sensitivities and high specificities [35,36].

Most of the autopsy data showed that vascular pathology was rarely sufficient to account for all cognitive symptoms and was frequently accompanied by AD pathology [37,38]. On the other hand, recent studies focus on the additive or even synergistic effect of vascular burden on AD [39].

Lacunar state and Binswanger's disease are both small-vessel diseases. Lacunar state has been defined as the presence of numerous lacunes in the basal ganglia, pons, and white matter of the centrum semiovale. The number of lacunes, the extent of periventricular luency, and the severity of ventricular enlargement were associated with cognitive deficits dependant on frontal executive function [40]. Frontal lobe hypometabolism on functional neuroimaging predicted cognitive decline in patients with lacunar state [41]. Binswanger's disease (BD) is a gradually progressive

dementia [42] caused by ischemic injury to the deep periventricular white matter of the cerebral hemispheres. Other usual clinical findings include pseudobulbar palsy, small-stepped gait, and urinary urgency.

Multi-infarct dementia (MID) [42] is the consequence of multiple large cortical infarctions throughout the distributions of the anterior, middle, or posterior artery circulations, usually secondary to atheroscerotic thrombosis or cardiac embolization. Abrupt onset, patchiness of cognitive deficits, associated focal neurological signs, and stepwise progression are the hallmarks of the dementia, and as the disease progresses, most intellectual functions become affected. Modern studies combining these neuropsychological aspects and recent neuroimaging techniques (MRI and functional imaging) are lacking.

Strategic infarcts include small infarctions located so as to disrupt multiple cognitive domains [42]. Angular gyrus syndrome exhibits fluent aphasia, alexia with agraphia, and Gerstmann syndrome (acalculia, right-left disorientation, dysgraphia, finger agnosia). Caudate infarcts produce executive deficits and behavioral symptoms (either disinterest or disinhibition). Executive deficits also occur with pallidum infarctions. When they are bilateral, the infarcts result in profound inertia and loss of psychic self-activation often with obsessive-compulsive features [43].

2. *Normal Pressure Hydrocephalus*

Normal pressure hydrocephalus (NPH) results from impaired absorption of cerebrospinal fluid at the level of the arachnoid granulations and causes dementia (often with bradyphrenia and executive dysfunctions), gait instability, and urinary incontinence [44]. NPH is a rare cause of dementia, accounting for < 2% of cases [45]. Diagnostic procedures (MRI, radioisotope cisternography, spinal fluid removal, and pressure monitoring) are nonstandardized, and predictive tests for surgical outcomes are still lacking. Recent data showed that AD pathology at biopsy was a frequent finding, contributed to the clinical impairment associated with NPH, and did not seem to strongly influence the clinical response to shunt surgery [46]. These findings require confirmation.

3. *Infectious and Prion Diseases*

AIDS Dementia Complex (ADC), or HIV dementia, reflects injury induced by HIV-1 viral proteins and the subsequent release of chemokines, cytokines, and toxins, predominantly in the frontal lobe and the basal ganglia [47]. The topography of those lesions explains

the clinical features of ADC (slowed mentation, apathy, and absence of aphasia, alexia, or agraphia). ADC occurs most often at moderate and advanced degrees of immunodeficiency. However, with the advent of highly active antiretroviral tharapy, ADC may occur at higher CD4 cell counts than previously [48].

Creutzfeldt-Jakob disease (CJD) is the most common human transmissible subacute spongiform encephalopathy or prion disease (49). Approximately 85% of cases are sporadic. The remaining 15% consist of genetic forms (familial CJD, Gerstmann-Sträussler-Scheinker disease, fatal familial insomnia) and acquired forms (iatrogenic forms transmitted by human growth hormone therapy, surgical procedures, and ingestion of contaminated material—Kuru, and new-variant CJD). New-variant CJD (vCJD) is caused by the same agent as bovine spongiform encephalopathy and was described in 1996 [50].

CJD results in a rapidly progressive dementia with frontal features evolving rapidly into profound aphasia then akinetic mutism. Most patients develop myoclonic jerks, ataxia, visual impairment, and frequent nonspecific symptoms such as anorexia, insomnia, mood changes, and malaise. During the disease course, patients have a characteristic electroencephalogram with periodic or pseudo-periodic complexes. Detection of the 14-3-3 protein in the CSF may be helpful in the diagnosis [51]. Spongiosis, neuronal loss and marked gliosis, and positive PrP immunostaining at autopsy make the diagnosis definite.

4. Neoplastic

Almost any brain tumor can cause simple or multiple cognitive signs such as dementia, but frequently the evolution is acute or subacute and signs of increased intracranial pressure may occur. One study of 119 cases referred for memory loss found that only one patient with significant structrural lesion had no features in the history or examination that would have predicted the lesions [52]. The AAN recommends structural nonconstrast neuroimaging examination at the time of the initial dementia assessment, to identify uncommon causes of dementias such as tumors as well as more common conditions that may cause dementia or coexist with AD such as cerebrovascular disease [6].

Seizures, personality changes, irritability, memory changes, and dementia preceding the diagnosis of the cancer are the most frequent signs of paraneoplastic limbic encephalitis. Although this is a rare condition, the combination of these symptoms, MRI abnormalities in the medial temporal lobes, and paraneoplastic antibodies establish the diagnosis in 78% of patients [53].

5. Metabolic and Toxic

Any kind of systemic illness, nutritional deficiency, and toxin exposure may affect cognitive functions and cause dementia if their effects persist for an extended period of time. Cyanocobalamin or vitamin B_{12} deficiency and hypothyroidism are common in the elderly but are rarely associated with dementia [54,55]. Elevated TSH levels carry an increased risk for dementia [56]. These findings suggest that the presence of these conditions could exaggerate cognitive deficits, rather than cause dementia per se. Treatment may partially reverse the cognitive symptoms [57].

Thiamine deficiency associated with chronic alcoholism or other nutritional deficiency leads to Wernicke-Korsakoff syndrome [58]. After a period of confusional state with ataxia and oculomotor abnormalities, such patients show a profound inability to learn new information (anterograde amnesia) with confabulations. This rare syndrome has been a valuable model for the neuropsychology and the neuropathology of medial diencephalic amnestic syndromes, showing lesions in the mammillary bodies and dorsomedial nucleus of the thalamus.

Marchiafava-Bignami (disconnexion syndrome secondary to corpus callosum pathology) and alcoholic dementia (prominent executive deficits due to frontal involvement) are other alcohol-related cognitive disorders [58].

6. Traumatic Brain Injury

Traumatic brain injury (TBI) is a leading cause of death and cognitive dysfunction among individuals under the age of 50 in the United States [59]. Focal and/or diffuse damage may occur, depending on the mechanisms of the injury. The clinical presentation is therefore heterogeneous, but slowed information processing and impaired concentration and memory, often with impulsivity and disinhibition, are typical [60]. Even in the absence of focal structural lesions of the brain, functional neuroimaging showed decreased metabolism in prefrontal and cingulate cortex [61]. TBI increases the risk for AD in later life [62].

7. Demyelinating disorders

Multiple sclerosis (MS) is the most common demyelinating disorder of the central nervous system. Its etiol-

ogy is still unknown. The clinical course of MS has three forms: relapsing-remitting, acute progressive, and chronic progressive. Cognitive dysfunction occurs in > 40% of patients with MS, and manifests primarily executive deficits [63,64], correlated with the lesion burden in the frontal lobe [65].

III. GENETICS

Defects in various genes have long been speculated to be the cause of several neurodegenerative diseases, mainly in autosomal-dominant inherited diseases. In the example of Huntington's disease (HD), discovery of the causative mutations helped the clinician in the diagnosis of familial choreiform movements as well as in genetic counseling. In the example of a subset of familial FTD, the discovery of the gene defect was rapidly linked to the protein aggregates that were involved in the disease, and this is helping substantially basic neuroscientists understand the pathophysiology of the disorder. The bulk of neurodegenerative diseases are sporadic and cannot be explained by single gene defects, but causative mutations and risk genes have been discovered for several dementing illnesses.

A. Alzheimer's Disease

Much of the progress in elucidating the genetics and the biology of AD derives from analysis of the two major neuropathological hallmarks of AD (SPs and NFTs). SP contain extracellular deposits of the amyloid-beta protein (A-beta), mainly of A-beta42 peptide, as opposed to A-beta40 peptide. The amyloid precursor protein (APP) is processed into several peptides through select cellular proteases (alpha, beta, and gamma secretases). While some products of this cleavage (A-beta42) form aggregates and eventually give rise to SPs, what other products (A-beta40) do is unclear. The A-beta42 peptide probably initiates a complex cellular response that results in neuronal cell death through calcium-mediated excitotoxicity, free radical–induced oxidative stress, and inflammation [66].

The NFTs are composed of insoluble forms of the microtubule-associated protein tau which are abnormally phosphorylated. This insoluble tau aggregates in the NFTs, and as tau phosphrylation increases, the density and number of NFTs increase.

It has been known for several decades that AD can occur in a familial form that appears to be transmitted as an autosomal-dominant trait. In these families, the symptomatology tends to appear much earlier than sporadic AD (typically in the 40s or 50s, but sometimes earlier). Estimates of the proportion of genetically based AD are < 5%, but may increase with disclosure of additional mutations. There are three well- confirmed genes in which mutations result in AD.

Several missense mutations in the APP gene (chromosome 21) have been described: they account for < 0.1% of all AD cases [67,68] but have been very informative in terms of AD pathogenesis. Most of these mutations are clustered at the beta or gamma secretase site. Inducing cleavage by these secretases leads to increased A-beta42 production.

Many mutations have been identified in presenilin 1 (PS1) on chromosome 14q24.3 [67,68]. PSs are membrane proteins, expressed in all cell types. PS1 mutations alter the processing of APP toward the release of the amyloidogenic A-beta42 peptides, through regulation of the gamma-secretase and other complex mechanisms [69]. PS1 mutations are the most genetic causes of AD and account for more than half of the cases of early-onset familial AD.

A few mutations have been described in the presenilin 2 (PS2) gene on chromosome 1q42.1. In contrast to the frequency of PS1 mutations, screening of large datasets reveal that PS2 mutations are likely to be rare and their phenotype much more variable [70].

Inheritance of one or two epsilon4 alleles of apolipoprotein E (APOE4) on chromosome 19 increases the risk of AD. APOE4 lowers the typical age of onset of sporadic late-life AD to approximately age 65 [71]. APOE4 is considered a risk factor for AD since some subjects who are homozygous for this isoform still show no symptoms in their ninth decade of life. The AAN does not recommend APOE testing as a diagnostic test for AD [6].

Another AD locus was identified in chromosome 12 [72] and 10 [73,74] whose identity at the moment is unclear.

B. Frontotemporal Dementias

In 1994, the first autosomal-dominant inherited FTD, associated with parkinsonism and amyotrophy, was described [75]. A genetic linkage was demonstrated between this pathology and a mutation on chromosome 17q21-22. Several additional families sharing a mutation on 17q21-22 have been reported and been included in a group of pathologies referred to as FTD with parkinsonism linked to chromosome 17 (FTDP-17). Finally, FTDP-17 has been related to

mutations in the tau gene [76]. Several mutations have been found in the tau gene among the different families with members diagnosed as FTDP-17 [77]. There are major differences in the phenotype and age of onset within families having the same mutations [78]. Mutations of the tau gene and their involvement in FTDP-17 indicate that abnormal tau protein plays a central role in the etiopathogenesis of neurodegenerative disorders, without the presence of the amyloid cascade.

Tau mutations on chromosome 17 explain only a small proportion of FTD, and alternate genetic loci have also been reported on chromosome 3 [79] and chromosome 9 [80]. These findings suggest that the pathology observed in these tau-negative FTD cases results from mechanisms unrelated to tau or alternative tau functions by different mechanisms [81,82].

Accumulating data suggest that the tau gene on chromosome 17q21-22 is associated with progressive supranuclear palsy (PSP) and corticobasal degeneration (CBD) [83,84]. Different phenotypes have been described within a family with the same tau mutation [85]. In this family one member presented with FTD and another one with CBD.

C. Huntington's Disease

Huntington's disease (HD) is a progressive, autosomal-dominant neurodegenerative disorder with 100% penetrance, caused by an increased number of CAG trinucleotide repeats affecting the IT15 gene at chromosome 4p16.3 [86]. Normal alleles contain 34 or fewer CAG repeats, whereas repeats of 37–150 or more occur in affected individuals. A negative correlation has been observed between the number of repeats and the age of onset of disease. Chorea and cognitive and behavioral changes are the main clinical features [87]. A large survey including 1238 individuals with symptomatic HD revealed that involuntary movements were the earliest reported symptoms, then respectively mental and emotional symptoms. As the disease progressed, behavioral and cognitive symptoms were experienced [88].

D. Wilson's Disease

Wilson's disease (WD), or hepatolenticular degeneration, is an inherited disorder of copper metabolism. Mutations of the gene ATP7B on chromosome 13q14 alter a copper-transporting protein resulting in copper accumulation leading to cellular toxicity [89]. WD is characterized clinically by liver, ocular (Kayser-

Fleischer ring), and neurological signs. The latter include extrapyramidal features due to putaminal changes and mainly executive deficits with personality and mood disturbances [90,91].

E. Cerebral Autosomal-Dominant Angiopathy with Subcortical Infarcts and Leucoencephalopathy

Cerebral autosomal-dominant angiopathy with subcortical infarcts and leucoencephalopathy (CADASIL) is an autosomal-dominant disorder due to severe alterations of vascular smooth muscle cells secondary to mutations of the Notch3 gene on chromosome 19q12 [92]. The patients usually present with migraine and recurrent ischemic episodes leading to gait disturbances, urinary urgency, pseudo-bulbar palsy, and psychiatric disturbances without other vascular risk factors [93]. Extensive white matter changes are evident on MRI. The main diseases according to their genetic basis are listed in Table 2.

IV. PATHOPHYSIOLOGY

Most of neurodegenerative diseases that manifest dementia or cognitive disorders are characterized by neuronal loss; intracellular inclusions such as LBs, Pick bodies, or NFTs; or extracellular deposits forming SPs. Intracellular inclusions (in neurons and sometimes in glial cells) and extracellular material are made of different insoluble fibrillar proteins that normally exist in soluble form. These tau, alpha- synuclein, or A-beta protein aggregates differentiate the most common neurodegenerative diseases and subserve this classification. These diseases thus share the deposition of insoluble fibrillar proteins that play an important role in the pathophysiology of neurodegeneration and the expression of the clinical symptoms. The main protein accumulations and their relationships with principal neurodegenerative diseases are summarized in Table 3.

A. Tauopathies

Tauopathies include neuropathological disorders composed of insoluble forms of microtubule-associated protein tau which are abnormally phosphorylated. This insoluble tau aggregates in the filamentous tau lesions, and as tau phosphorylation increases, so do the density and number of tau lesions. In normal brain, tau plays a role in the

Table 2 Classification of Dementias and Related Cognitive Disorders According to Their Genetic Basis

	Chromosome	Gene defect	Comment
Familial AD	14	PS1	Many mutations
	1	PS2	Few mutations
	21	APP	Several mutations
	12	?	
	10	?	
Sporadic AD	19	ApoE	E4 allele as a risk factor
Familial FTD	17	Tau	Several mutations
	3, 9	?	
Huntington's disease	4	IT15	Increase CAG repeats
Parkinson's disease	4	alphaS	Several mutations
	2, 1	?	
Wilson's disease	13	ATP7B	Several mutations
Idiopathic basal ganglia calcification	14	?	
CADASIL	19	Notch 3	Several mutations
Cerebral amyloid angiopathy	21	APP, CST3	Few mutations
Leukodystrophies	X, 22, 10	various	Several mutations
Neuronal ceroid lipofuscinosis type 3	16	CLN3	Several mutations
Mitochondrial encephalomyopathy			Several mutations in mitochondrial DNA
Prion diseases		PRNP	Several mutations

stabilization of neuronal microtubules by interacting with tubulin. Microtubules maintain the cell shape and serve as tracks for axonal transport. Six tau isoforms are produced from a single gene located on chromosome 17q21 by alternative mRNA splicing. The spliced products give rise to three tau isoforms with three repeats (3R) and three other tau isoforms having four repeats (4R). These repeats and their adjacent domains constitute the microtubule-binding domains of tau [94].

Major tauopathies include AD, Pick's disease, FTDP-17, PSP, and CBD, whereas the morphology

Table 3 Protein Aggregations in Major Dementias and Related Cognitive Disorders

Disease	Protein
Alzheimer's disease	A-beta, tau
Frontotemporal dementia, Pick's disease	Tau
Progressive supranuclear palsy	Tau
Corticobasal degeneration	Tau
Parkinson's disease	Alpha-synuclein
Multiple system atrophy	Alpha-synuclein
Huntington's disease	Huntingtin
Prion disease	Prion protein
Spinocerebellar ataxias	Ataxin

and isoform composition of the filamentous tau lesions and their regional brain distribution differ. Most common tauopathies are listed in Table 4.

In Pick's disease, intraneuronal tau aggregates assemble into characteristic spherical Pick bodies in nonpyramidal neurons of layers 2, 3, and 6 of the cerebral cortex and in the dentate granule cells [95]. They consist of paired and straight filaments and are formed of only 3R-tau isoforms [96].

In FTDP-17 (see Sec. III.B), the morphology and isoform composition of tau lesions varies in the different families [97]. In some families, they consist of paired helical filaments or straight filaments, and contain all six major isoforms, similarly to AD. In other families, the lesions resemble twisted ribbons and consist mainly of 4R-tau isoforms.

Although the accumulation of abnormal tau is the hallmark of major tauopathies like Pick's disease and FTDP-17, aggregates of tau are uncommon in sporadic FTD. Loss or reduction of tau has been described recently in sporadic FTD and in a familial form known as hereditary dysphasic dementia 2 [98]. This "tauless" tauopathy is characterized by loss or reduction of all six tau isoforms, but not tau mRNA, suggesting that the level of tau protein is controlled posttranscriptionally, at the level of either translation or mRNA stability. The mechanisms by which reduced levels of brain tau cause neurodegeneration remain unknown, but it is

Table 4 Classification of Dementias and Relative Cognitive Disorders According to Their Pathophysiology

Tauopathies	Alpha-synucleinopathies	A-Beta
FTDP-17	Sporadic Parkinson's disease (PD)	Sporadic AD
ALS/parkinsonism-dementia complex	Familial PD	Down syndrome
Pick's disease	Dementia with Lewy bodies	Cerebral amyloid angiopathy (familial and
Corticobasal degeneration	Sporadic AD (about 60%)	sporadic)
Alzheimer's disease (AD)	Familial AD	Prion disease
Dementia pugilistica	Down syndrome	
Down syndrome	Multiple system atrophy	
Multiple system atrophy	Shy-Drager syndrome	
Progressive supranuclear palsy	Striatonigral degeneration	
Gerstmann-Sträussler-Scheinker disease	Olivopontocerebellar atrophy	
Creutzfeldt-Jakob disease	Neurodegeneration with brain iron accumulation, type 1	

likely that loss of functional tau protein leads to death of affected neurons.

In PSP, tau lesions form NFTs and consist of straight and paired helical filaments. They are localized in subcortical regions [99], and in the cortex as well [100]. In contrast to AD, they contain the 4R-tau isoforms [101].

In CBD, neuropathological examination reveals severe glial and neuronal lesions predominantly in the frontoparietal regions and often in basal ganglia and substantia migra [102]. The glial pathology is constituted of astrocytic plaque or conglomerations of tau-positive astrocytes and tau-positive inclusions in oligodendrocytes. Abnormal achromatic ballooned neurons are composed of tau positive filaments. These filaments contain the 4R-tau isoforms [101].

The clinical presentation of CBD is characterized by asymmetric and progressive parkinsonism, alien limb phenomena, ideomotor apraxia, and myoclonus, followed by cognitive impairment (executive deficits and memory disturbance with retrieval deficit) [103,104]. Dementia is not infrequent [104,105]. The clinical diagnosis is often difficult because of overlapping features with PSP, FTD, and cerebrovascular disorder, and clinical findings considered characteristic of CBD are associated with heterogeneous pathologies (AD, PSP, Pick's disease, nonspecific changes, CJD) [106].

In AD, abnormally phosphorylated tau proteins form NFTs, which are composed predominantly of aggregated paired helical filaments and contain all six tau isoforms [96]. Despite these prominent tau accumulations, the tau gene has not been found to be the site of mutations in familial AD. Therefore AD is not considered a primary tauopathy. In this respect, many tauopathies listed in Table 4 may be related to second-

ary disturbances of tau metabolism rather than primary genetic defects.

B. Alpha-Synucleinopathies

Alpha-synucleinopathies are disorders of one the four currently known members of the synuclein family (alpha, beta, gamma, and synoretin), and are listed in Table 4. These neuronal cytosolic proteins are enriched at presynaptic terminals and may play a role in synaptic plasticity. Alpha-synuclein (alphaS) was mapped on chromosome 4q21.3-22q [107]. The first described autosomal-dominant PD was caused by a missense mutation in the alphaS gene [108]. AlphaS filaments in the cytoplasm of nerve cells form a major component of Lewy bodies (LBs) and Lewy neurites in sporadic PD and DLB. These changes probably result in the loss of neuronal function [109] and are the most specific and sensitive markers for dementia in patients with PD and DLB [33]. AlphaS-positive inclusions (mainly but not excusively LBs) have been found in > 60% of familial AD with mutations in PS and APP genes [110], and more recently in 48–60% of sporadic AD [111,112].

Unlike PD and DLB, alphaS-positive inclusions in multiple system atrophy (MSA) are found in cytoplasm and nuclei of both nerve cells and glial cells, mainly oligodendrocytes. From the clinical point of view, MSA includes striatonigral degeneration, Shy-Drager syndrome, and olivopontocerebellar atrophy, depending on the predominant symptom (respectively axial parkinsonism and gait disturbances, postural hypotension, cerebellar syndrome) [113]. Dementia is usually absent [113], but patients frequently exhibit executive deficits with no impairment in language or

visuospatial skills [114]. These symptoms reflect frontal and cerebellar involvement of alphaS-positive inclusions [115].

C. Amyloid-Beta Protein Pathologies

Both the biochemistry and the genetics of the amyloid-beta protein (A-beta) are described above. Main disorders of A-beta are listed in Table 4.

Cerebral amyloid angiopathy (CAA) may cause lobar cerebral hemorrhages and, less frequently, ischemic brain lesions, especially in nonhypertensive elderly [116]. It thus shares features with VaD. Nevertheless, the pathology (fibrillar amyloid gradually replacing the arteriolar media) and its increasing prevalence with age are characteristics shared with degenerative disorders [117]. Sporadic CAA is common in AD, and several mutations of the APP gene have been described in familial CAA [118–120]. Therefore, it has been suggested that CAA was the microvascular link between parenchymal (AD) and VaD [121].

V. CLINICAL CLASSIFICATION

This classification is based on using clinical phenomena to classify diseases. It derives from more than a century of classic brain lesion studies in humans, and more recently from structural and functional neuroimaging. These data allow clinical neuroscientists to distinguish between two patterns of CNS involvement: cortical and subcortical. Together with the neurological examination, these two major syndromes aid clinicians in making a clinical diagnosis of dementia or other cognitive disorders.

A. Subcortical Dementias

The term subcortical dementia has been replaced by frontosubcortical dementia (FSCD) because of the advances of our understanding in the basic circuitry of basal ganglia and frontal lobes. The striatum, globus pallidus, anterior and medial thalamus, and substantia nigra are interconnected with the prefrontal cortex in multiple parallel circuits with unique functional properties [122–124]. The broad dichotomy between cortical dementia and frontosubcortical dementia has been challenged [125–128], but is a very useful tool for the clinician in terms of diagnosis and understanding some of the basic processing of cognitive functions.

A third category has emerged since the original descriptions of subcortical dementia. FTD, DLB, and CBD have both cortical and frontosubcortical features. Compared to patients with the classic cortical dementia of AD, patients with FSCD show prominent executive deficits, explicit memory impairment with retrieval deficit and no significant aphasia, apraxia, agnosia or encoding memory impairment [29,30,129]. These deficits are presented in Table 5, where differential characterisitics of FSCD and AD are summarized. As an example, one disease is presented here. Other FSCDs are summarized in Table 6.

Progressive supranuclear palsy (PSP) is characterized by supranuclear ophthalmoplegia, axial dystonia, pseudobulbar palsy, bradykinesia, postural instability, and dysarthria [99]. Historically and clinically, PSP is the quintessential example of FSCD [130], but early severe dementia is rare [131]. Recently, a clinicopathologic analysis of nine patients with PSP showed greater frontal lobe atrophy compared to controls, which correlated with increasing NFT densities, and a correlation with clinical dementia [132]. These findings concur

Table 5 Main Symptoms of Frontosubcortical Dementias Compared to Alzheimer's Disease

Feature	FSCD	AD
Attention	Normal (slow)	Normal
Speed of cognitive processing	Slow	Normal
Language	Most often preserved	Impaired
Speech	Dysarthric	Normal
Visuospatial skills	Impaired (poor planning, perseveration errors)	More impaired
Executive functions:		
Set planning and shifting	Severely impaired	Impaired late
Verbal fluency	Severely impaired (especially letter fluency)	Impaired (especially category fluency)
Memory impairment	Retrieval deficit	Encoding deficit

Table 6 Classification of Dementias and Related Cognitive Disorders According to Their Clinical Profile

Frontosubcortical dementia	Cortical dementia	Both
Degenerative		
PSP	Alzheimer's disease	Frontotemporal dementia
Multiple system atrophy		Dementia with Lewy Bodies
Spinocerebellar ataxias		Corticobasal degeneration
Idiopathic basal ganglia calcification		Leukodystrophies
Wilson's disease		
Huntington's disease		
Neuroacanthocytosis		
Vascular		
Binswanger	Multi-infarct dementia	Multi-infarct dementia
Lacunar state		
Strategic infarcts (pallidum and caudate)	Strategic infarct (angular gyrus syndrome)	
Infectious		
AIDS Dementia Complex		Others
Whipple		Normal pressure
Neurosyphilis		Hydrocephalus
Creutzfeldt-Jakob disease		Toxic-metabolic
Demyelinating		Post-traumatic
Multiple sclerosis		Vasculitis

with neuroimaging data showing a reduced frontal perfusion or metabolism in PSP and impaired executive functions [133,134].

B. Cortical Dementias

Cortical dementias, mostly AD, have been discussed above. FTD can present with features of FSCD or with cortical dementia syndrome. Primary progressive aphasia syndrome (PPA) was described relatively recently by Mesulam [135,136] and is a cortical form of FTD. The main core of PPA is a fluent or nonfluent aphasia, starting as an anomia with phonemic paraphasias, unlike AD [137]. There are no significant apathy, disinhibition, memory, visuospatial or visual recognition impairments within the initial 2 years of the disease. Mild acalculia and ideomotor apraxia may be present in the first 2 years. The neuropathology lacks AD-type changes. Neuronal loss, gliosis, mild spongiform changes within superficial layers in the left perisylvian cortex with ubiquitin-positive, tau-negative inclusion bodies or rarely tau-positive neuronal and glial inclusions, and sometimes Pick bodies have been described.

VI. CONCLUSION

These different classifications by etiology, genetics, pathophysiology, and clinical features have had their importance in the history of dementia and behavioral neuroscience, and all of them are still relevant in the 21st century. Increasingly they are converging to provide a molecular pathogenesis relevant to clinical presentations. The clinical classification is crucial in terms of which cognitive systems are involved and gives clues to the anatomical basis of the disease. Together with the associated neurological signs, it allows the clinician to make a diagnosis.

The most recent classifications (genetics and pathophysiology) offer new insights in the dementias and cognitive disorders. Although familial AD comprises only a small proportion of all dementias, it has provided considerable information about the biochemical pathways involved in sporadic forms and how to develop new drugs, such as the antiamyloid vaccine [138], and other mechanism-based strategies.

Selective vulnerability of brain regions and subpopulations of neurons and glial cells is one of major issue of most of dementias and cognitive disorders. The pattern of vulnerability determines the clinical presen-

tation. The pathophysiology of this selective cellular risk has not yet been explained, and will be the critical next step in linking pathophysiology to clinical syndrome.

The issue of phenotypic differences not only between families with different mutations but also within families having the same mutation, remains unsettled. This may suggest that other genetic and/or environmental factors play a role in the pathogenesis of these diseases.

Similarities at the clinical, pathological, and molecular levels among different diseases imply the existence of common pathways in all neurodegenerative disorders. Cell death pathways, for example, appear to involve similar apoptotive cascade across disease entities, and oxidative stress appears to be a common contributive factor to many disorders. Protein aggregation increasingly links many disorders.

More basic and translational research is needed to understand both relationships and differences of major cognitive disorders and dementias. The resolution of issues in basic neuroscience will enhance with our understanding of molecular genetics and our ability to provide effective treatments of affected patients.

I. INTRODUCTION

Modern psychobiological theory conceptualizes personality as a self-organizing, complex adaptive system involving a bidirectional interaction between heritable neurobiological dispositions to behavior (temperament) and developing concepts about self and external objects (character). As introduced by the seven-factor psychobiological model of personality in 1993 [1,2], the concepts of temperament and character synthesize advances from a wide variety of scientific disciplines—evolutionary biology, genetics, neuroscience, theory of learning, sociology, philosophy—each contributing from its specific angle to the present eclectic understanding of personality development and structure. "Biological" temperament traits and "conceptual" character traits, two distinct but interacting components of personality, are distinguished based on the corresponding neurobiological and psychological mechanisms underlying behavior. These mechanisms provide guidelines for testable hypotheses about

etiology and treatment of personality disorder. Clinically, the temperament and character traits are used to classify and diagnose personality disorder and to differentiate its clinical subtypes.

In this paper, we first review the basic aspects of the seven-factor psychobiological model of personality and then outline treatment implications, based on this model, for extreme personality variants classified as personality disorder.

II. TEMPERAMENT AND CHARACTER (NATURE AND NURTURE)

Structurally, the seven-factor model describes four temperament traits (Harm Avoidance, Novelty Seeking, Reward Dependence, and Persistence) and three character traits (Self-Directedness, Cooperativeness, and Self-Transcendence) (Tables 1 and 2).

The temperament traits are largely heritable (up to 60%), relatively stable over lifetime, and universal across cultures and ethnic groups. These traits are

Table 1 Descriptors of Individuals Who Score High and Low on the Four Temperament Dimensions

	Descriptors of extreme variants	
Temperament dimension	High	Low
Harm Avoidance	pessimistic	optimistic
	fearful	daring
	shy	outgoing
	fatigable	energetic
Novelty Seeking	exploratory	reserved
	impulsive	deliberate
	extravagant	thrifty
	irritable	stoical
Reward Dependence	sentimental	detached
	open	aloof
	warm	cold
	affectionate	independent
Persistence	industrious	lazy
	determined	spoiled
	enthusiastic	underachiever
	perfectionist	pragmatist

etiologically associated with basic (or primary) emotions of fear (Harm Avoidance), anger (Novelty Seeking), attachment (Reward Dependence), and perseverance (Persistence). In contrast, character

Table 2 Descriptors of Individuals Who Score High and Low on the Three Character Dimensions

	Descriptors of extreme variants	
Character dimension	High	Low
Self-Directedness	responsible	blaming
	purposeful	goal-less
	resourceful	passive
	self-accepting	wishful
	disciplined	undisciplined
Cooperative	tender-hearted	intolerant
	empathic	insensitive
	helpful	selfish
	compassionate	revengeful
	principled	opportunistic
Self-Transcendent	imaginative	conventional
	intuitive	logical
	acquiescent	doubtful
	spiritual	materialistic
	idealistic	relativistic

traits are weakly heritable, tend to change with age and maturation, and are associated with social (or secondary) emotions, such as honor, integrity, morality, altruism, respect. Roughly, temperament is what we are born with, character is what we make out of ourselves.

The Temperament and Character Inventory (TCI) has been developed to measure the above temperament and character traits (Table 3). As described in the TCI Manual [3], the psychobiological model has been translated into many languages, its psychometric validity confirmed in clinical and nonclinical samples, its

Table 3 Temperament and Character Inventory (TCI)

Harm Avoidance (HA)
  HA1: worry and pessimism vs. uninhibited optimism
  HA2: fear of uncertainty
  HA3: shyness with strangers
  HA4: fatigability and asthenia
Novelty Seeking (NS)
  NS1: exploratory excitability vs. stoic rigidity
  NS2: impulsiveness vs. reflection
  NS3: extravagance vs. reserve
  NS4: disorderliness vs. orderliness
Reward Dependence (RD)
  RD1: sentimentality
  RD2: sociability vs. aloofness
  RD3: attachment vs. detachment
  RD4: dependence vs. independence
Persistence (PS)
  PS1: eagerness of effort vs. laziness
  PS2: work hardened vs. spoiled
  PS3: ambitiousness vs. underachieving
  PS4: perfectionism vs. pragmatism

Self-Directedness (SD)
  SD1: responsibility vs. blaming
  SD2: purposefulness vs. lack of goal direction
  SD3: resourcefulness vs. helplessness
  SD4: self-acceptance vs. self-striving
  SD5: congruent second nature
Cooperativeness (CO)
  C1: social acceptance vs. social intolerance
  C2: empathy vs. social disinterest
  C3: helpfulness vs. unhelpfulness
  C4: compassion vs. revengefulness
  C5: pure hearted vs. self-serving
Self-Transcendence (ST)
  ST1: self-forgetful vs. self-conscious
  ST2: transpersonal identification vs. Self-differentiation
  ST3: spiritual acceptance vs. rational materialism
  ST4: enlightened vs. objective
  ST5: idealistic vs. practical

cross-cultural applicability established in many different ethnic groups, countries, and continents.

III. TEMPERAMENT AND CHARACTER: TWO DISTINCT MEMORY AND LEARNING SYSTEMS

Temperament (or the "emotional core" of personality) involves heritable dispositions to early emotions (such as fear, anger, and attachment), and related automatic behavior reactions (such as inhibition, activation, and maintenance of behavior) in response to specific environmental stimuli (danger, novelty, and reward, respectively). Temperament traits are based on presemantic perceptual processing of visuospatial information and affective valence regulated by the corticostriatolimbic system, primarily the sensory cortical areas, amygdala, and the caudate and putamen (the so-called procedural memory). In other words, temperament traits are heritable biases in procedural learning that underlie associative conditioning of automatic behavior responses to danger, novelty, and reward. Temperament traits are genetically homogeneous, independently inherited, relatively stable over lifetime, and cross-culturally universal [4].

Character (or the "conceptual core" of personality) involves higher cognitive functions, such as abstraction and symbolic interpretation, analytical and inductive logic, symbolism, etc., regulated by the hippocampus and neocortex. These functions (also called propositional memory) are critical for cognitive processing of sensory percepts and affects regulated by temperament, leading to the development of abstract conceptual and volitional processes. Character traits reflect one's developing concepts about oneself and the external world [2].

Basic differences between character and temperament are presented in Table 4.

Table 4 Key Differences Between Temperament (associative or procedural learning) and Character (conceptual or propositional learning)

Variable properties	Temperament	Character
Awareness level	automatic	intentional
Memory form	percepts procedures	concepts propositions
Learning principles	associative conditioning	conceptual insight
Role of subject in mental activity	passive reproductive	active constructive
Key brain system	Limbic system Striatum	Temporal cortex Hippocampus
Form of mental representation	stimulus-response sequences varying additively in strength	interactive networks (conceptual schema) varying qualitatively in configuration
Etiological components		
Genetic heritability	40–60%	10–15%
Family environment	0%	30–35%
Random environment	40–60%	40–60%

IV. INTEGRATED VIEW OF PERSONALITY: TEMPERAMENT AND CHARACTER INTERACT TO PRODUCE PERSONALITY

Personality is conceptualized as a self-organizing, complex adaptive system characterized by multiple internal and external, constraining and facilitating factors, interacting nonlinearly to finally funnel into only one (out of several possible) developmental outcome [4]. Personality development is graphically presented as a fitness landscape, where hills and valleys represent high and low adaptive levels, respectively. Periods of stability (i.e., local adaptive optima represented by hills) alternate with relatively rapid transitions (through the valleys) to new adaptive levels [4].

Heritable biological dispositions develop into actual temperament traits, amenable to observation and measurement (i.e., avoidant, exploratory, persistent, or sociable behaviors) as a nonlinear function of the relative strength of the underlying disposition and the characteristics of the interacting environment (e.g., suppression or facilitation of certain behaviors).

With growing perceptual and cognitive capacities, early percepts and affects based on temperament are transformed into more complex concepts about self and the external world. This internalization of new concepts and their associated social emotions (honor, pride, altruism) further neutralizes raw temperament traits, most importantly fear and anger, and provides the stage for personality to crystallize around positive, gratifying experiences associated with attachment. In other words, through this bidirectional interaction of temperament and character, developing concepts about self and the external world modify the significance and the salience of sensory percepts and affects regulated by temperament, and vice versa. Temperament regulates what we notice, and, in turn, character modifies its meaning, so that the salience and significance of all experience depend on both temperament and character.

V. DIFFERENTIATING NORMAL FROM DEVIANT PERSONALITY: WHEN TO TREAT AND WHO NEEDS TREATMENT

The distinction between temperament and character, i.e., between biological and psychological mechanisms underlying behavior, provides guidelines for testable hypotheses about etiology, diagnosis, and treatment of personality disorder. This is not possible for models that confound temperament and character. The TCI has repeatedly proven useful to predict categorical diagnoses of personality disorder in numerous clinical and nonclinical samples, cross-culturally, in patients with and without personality disorder and varying mood and anxiety states [3].

The concepts of temperament and character are essential to decompose the symptoms of personality disorder into *common features* shared by all subtypes (used for diagnosis) and *distinguishing features* unique for each subtype (used for differential diagnosis) [4]. The following major findings are noteworthy:

Low scores on Self-Directedness and Cooperativeness correlate highly with the number of symptoms for personality disorder (Tables 5 and 6) The TCI character traits predict the presence or absence of

Table 5 Correlations Between TCI Scales and Total No. of Symptoms for PDs, Cluster A, Cluster B, and Cluster C Inpatients ($N = 136$)

any personality disorder (Table 7). In other words, poorly developed character traits, especially low Self- directedness and Cooperativeness, represent the core feature of personality disorder, extending across all clinical subtypes. This accounts for chronic

difficulties in accepting responsibility, setting long-term goals, fragile self-esteem, lack of capacity to be alone, unstable self-image, uncertain identity, etc., so typical of personality disorder. Usually, these patients are also uncooperative (revengeful, opportunistic, unhelpful, without stable ethical principles). As shown in Table 6, Self-Transcendence correlates with borderline, narcissistic, and histrionic symptoms (accounting for dissociative tendencies in these cases) and schizotypal and paranoid symptoms (accounting for magical thinking and rich imaginary life in these patients). On the other hand, when coupled with high Self-Directedness and Cooperativeness, Self-Transcendence indicates maturity, spirituality, and creativity rather than psychopathology.

Once the probability for the presence of personality disorder is established based on character, temperament is used for differential diagnosis. In this regard:

1. Each DSM cluster is differentiated based on one of the TCI temperament dimensions (Table 5).

2. The A cluster, which includes schizoid, schizotypal, and paranoid personality (i.e., the "aloof" cluster), is characterized by low Reward Dependence (detached, cold, independent individuals).

3. The B cluster, which includes borderline, anti-social, histrionic, and narcissistic personality (i.e., the "impulsive" cluster), is characterized by high Novelty Seeking (exploratory, impulsive, extravagant, irritable individuals).

4. The C cluster, which includes avoidant, dependent, self-defeating and obsessive-compulsive personality (i.e., the "fearful" cluster), is characterized by high Harm Avoidance (fearful, shy, pessimistic individuals).

5. The fourth temperament trait, Persistence, predicts Obsessive-Compulsive traits especially when coupled with high Harm Avoidance.

6. Categorical subtypes of personality disorder are distinguished based on their unique pattern of correlations with temperament traits of Harm Avoidance, Novelty Seeking, Reward Dependence, and Persistence (the temperament traits interact in all possible factorial combinations to produce symptoms for each of the 11 DSM clinical subtypes of personality disorder) (Table 6).

VI. MATURE CHARACTER IS PROTECTIVE AGAINST PERSONALITY DISORDER

Maladaptation is predominantly a function of character, not temperament. Extreme temperament variants alone do not reliably distinguish between normal adaptation and maladapted personality. Some individuals with low Reward Dependence are socially withdrawn, disinterested, and detached, but these features cause no obvious impairment in professional functioning and no signs of personal suffering and distress. Also, neither low nor high temperament scores inherently mean better adaptation, as each extreme has specific adaptive advantages and disadvantages (e.g., high Harm Avoidance is adaptively advantageous when hazard is likely, and not so when hazard is unlikely but still anticipated).

Extreme temperament traits are associated with long-term personal, social, and/or occupational impairments (i.e., maladaptation) only when accompanied by low character traits. In other words, mature character reduces the risk of maladaptation and personality disorder. Individuals high in Novelty Seeking and low in Harm Avoidance may have an impulsive or antisocial personality disorder if they are low in Self-Directedness and Cooperativeness, or may be energetic businessmen or inquisitive scientists without personality disorder if their character is mature, i.e., if they are self-directed and cooperative.

VII. SOME TEMPERAMENT TYPES PROTECT AGAINST PERSONALITY DISORDER

Temperament and character dimensions interact to create composite types or configurations (Figs. 1 and 2). These composite types manifest a number of behaviors directly associated with one of the underlying traits (e.g., impulsivity reflects Novelty Seeking, social attachment reflects Reward Dependence), but also a number of qualitatively new behaviors or emerging properties created by the interactions (e.g., high Harm Avoidance interacts with high Persistence to create obsessive symptoms).

Each of the composite temperament types affects differentially one's risk of immature character and personality disorder (Table 8). Temperament types with high Reward Dependence are protective against personality disorder, presumably because dependency, attachment, sentimentality, and responsivity to social reward facilitate behaviors that conform to local sociocultural norms. In addition, high Reward Dependence facilitates character development, especially Cooperativeness, as indicated by their positive intercorrelation. Accordingly, the "reliable" temperament type (high Reward

Temperament type	Harm Avoidance	Novelty Seeking	Reward Dependence
Cautious	high	low	high
Methodical	high	low	low
Passive-Aggressive	high	high	high
Explosive (Borderline)	high	high	low
Antisocial	low	high	low
Histrionic	low	high	high
Reliable	low	low	high
Schizoid	low	low	low

Figure 1 Temperament traits interact to create composite types (three traits produce eight possible combinations).

Character type	Self-directedness	Cooperativeness	Self Transcendence
Organized	high	high	low
Auticratic	high	low	low
Dependent (irritable)	low	high	low
Downcast (melancholic)	low	low	low
Disorganized (Schizotypal)	low	low	high
Fanatical (paranoid)	high	Low	high
Moody (cyclothymic)	low	high	high
Creative	high	high	high

Figure 2 Character traits interact to create composite types (three traits produce eight possible combinations).

Dependence, low Harm Avoidance, low Novelty Seeking) is at the lowest risk of personality disorder.

In contrast, some temperament types, especially those with high Harm Avoidance and/or high Novelty Seeking, increase the risk for personality disorder, presumably because proneness to anxiety and depression (Harm Avoidance) and impulsivity and anger (Novelty Seeking) interferes with character maturation (especially with the development of Self-Directedness, which is negatively correlated with Harm Avoidance. The explosive (or borderline) type, with high Novelty Seeking, high Harm Avoidance, but low Reward Dependence, has the highest risk of personality disorder. This type is characterized by susceptibility to anxiety and depression, impulsivity, and indifference to sociocultural pressures.

Contrary to the common belief, the "flexible" or "adaptable" personalities, i.e., those with average

Table 8 Relative Risk of Immature Character as a Function of Temperament Type in a General Community Sample ($N = 300$)

	Mild		Pronounced		All	
Temperament type	i/N	immature %	i/N	immature %	immature %	RR
Reliable (nhR)	2/24	8	0/12	0	6	0.2
Histrionic (NhR)	5/32	16	1/18	6	12	0.4
Schizoid (nhr)	5/22	23	0/9	0	16	0.5
Passive-Dependent (nHR)	4/19	21	1/11	9	17	0.5
Flexible (average)			5/15	33	33	1.0
Passive-Aggressive (NHR)	8/20	40	4/10	40	40	1.2
Antisocial (Nhr)	10/19	53	2/6	33	48	1.4
Obsessional (nHr)	22/35	63	4/9	44	59	1.8
Borderline (NHr)	20/29	69	8/10	80	72	2.1

RR = Relative Risk or ratio of observed proportion to that in general population.
i/N = immature characters/number of cases (immature character defined as combined score of Self-Directedness and Cooperativeness > 58 (33rd centile in the sample).
Mild types = at least one temperament trait low or high in terms of percentile scores, i.e., lowest or highest one-third (low = 0–33%, high = 67–100%), other traits low-average (34–50%) or high-average (50–66%).
Pronounced types = all temperament traits low or high.
Lowercase letters (h, n, r) and capital letters (H, N, R) indicate low and high values for temperament traits

scores on all three temperament traits, are not protected against maladaptation. They have an average (not a decreased) risk of personality disorder (Table 8).

VIII. INTEGRATION OF CATEGORICAL AND DIMENSIONAL ASSESSMENT OF PERSONALITY DISORDER

The DSM system conceptualizes personality disorder as categorical, mutually exclusive syndromes of deviant behavior classified as separate diagnostic categories. These categories, however, overlap to the extent that psychometric tests based on the DSM criteria always yield multiple personality diagnoses for one patient. In contrast, the TCI temperament traits differentiate categorical DSM diagnoses without any overlap [5].

The TCI integrates elements of categorical diagnosis into its dimensional assessment of personality disorder. Note that each of the composite temperament types presented in Figure 3 corresponds clinically to one of the traditional DSM categories of personality disorder. Physicians use these "dimensional categories" for time-efficient and vivid clinical portrayal of individual cases. At the same time, the TCI temperament and character

dimensions are easily extracted from any particular composite type for independent diagnostic analyses and treatment planning. In summary, the TCI captures more information about severity of impairment and patterns of behavior in terms of quantitative ratings than does the DSM system, and does so without sacrificing the utility of traditional categorical labels.

IX. PERSONALITY DISORDER: SOCIAL OR CLINICAL DIAGNOSIS?

The DSM clinical definition of personality disorder has a significant social connotation, as one of the general criteria is that maladaptive behavior "deviates markedly from the expectations of sociocultural norms." Indeed, clinicians frequently diagnose personality disorder based solely on the extent to which one's behavior is adjusted to the local society.

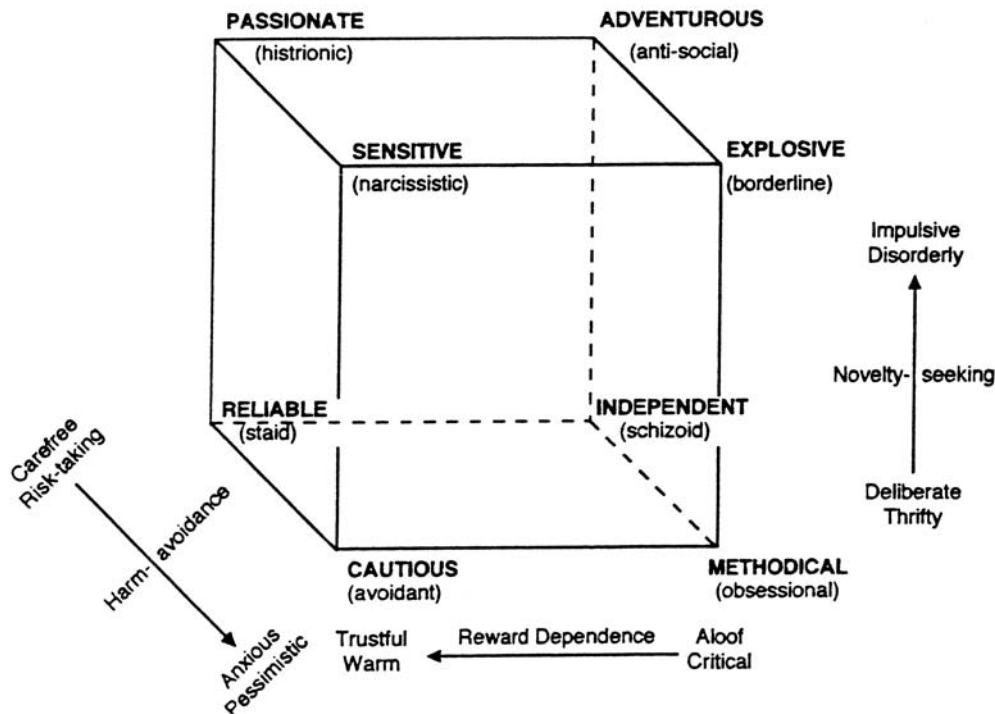
As noted, temperament profiles with high Reward Dependence have a low incidence of diagnosed personality disorder, whereas those with high Harm Avoidance and/or high Novelty Seeking increase the incidence substantially. Sociocultural pressures are always norm favoring, promoting phenotypes within


Figure 3 Temperament configuration.

the range of accepted norms. In our society, the normative phenotype is not the one with average personality traits (as one would expect given the adaptive flexibility of such configurations) but the one with high Reward Dependence, presumably due to easy conditioning of socially accepted behaviors compared to other temperament traits. Adults with high Harm Avoidance and/or high Novelty Seeking are more likely to be diagnosed as "personality disorder" and to be treated to change or eliminate behaviors associated with their temperament traits (Table 9).

Similarly, child psychiatry classifies three broad groups of mental disorders in children with high Novelty Seeking (e.g., Attention Deficit Hyperactivity Disorder, Conduct Disorder), or high Harm Avoidance (e.g., Depression, Anxiety Disorders), or low Reward Dependence (e.g., Schizophrenia, Autism). These children are diagnosed as "cases" and treated early in life. In contrast, children with high Reward Dependence (i.e., those sociable, attached, and dependent) are selectively permitted to develop without psychiatric intervention.

At the present level of human civilization, natural selection of biologically dominant and adaptable phenotypes has become almost irrelevant for our survival and reproduction. The latter appear to be now more associated with social dominance and successful behavioral adaptation to the society (achieved primarily by social selection targeting our personality features). Through its selective permissiveness for specific personality traits, modern society appears to be relying (at least partly) on psychiatry to selectively funnel individuals into a relatively narrow spectrum of desired psychological phenotypes.

X. MULTIFINALITY OF OUTCOMES: ONE TEMPERAMENT TYPE HAS MORE THAN ONE CHARACTER OUTCOME

Each of the eight composite character outcomes (Fig. 4) can be predicted from the initial temperament traits, taking into account temperament-character interactions, sociocultural norms, random events

Table 9 Four Dissociable Brain Systems Influencing Stimulus-Response Patterns Underlying Temperament

Brain system (related personality dimension)	Principal neuromodulators	Relevant stimuli	Behavioral response
Behavioral activation (Novelty Seeking)	Dopamine	Novelty CS of reward CS or UCS of relief of monotony or punishment	Exploratory pursuit Appetitive approach Active avoidance Escape
Behavioral inhibition (Harm Avoidance)	GABA serotonin (dorsal raphe)	Aversive conditioning (pairing CS-UCS) Conditioned signals for punishment, novelty, frustrative nonreward	Formation of aversive CS Passive avoidance, extinction
Social attachment (Reward Dependence)	Norepinephrine serotonin (median raphe)	Reward conditioning (pairing CS-UCS)	Formation of appetitive CS
Partial reinforcement (Persistence)	Glutamate serotonin (dorsal raphe)	Intermittent reinforcement	Resistance to extinction

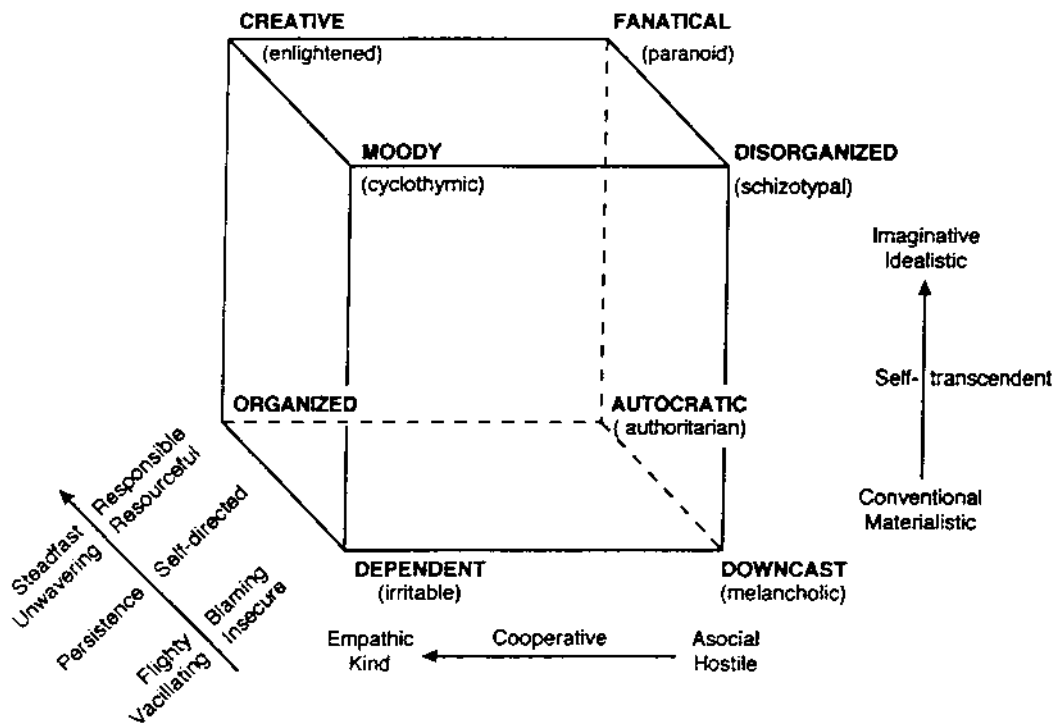
CS, conditioned signals; UCS, unconditioned signals.
Source: Ref. 6.


Figure 4 Character configuration.

unique to the individual, and social learning within the family [4]. With all this taken into account, it turns out that a single initial temperament configuration may lead to several different character outcomes. This aspect of development is referred to as *multifinality* [4].

The spectrum of possible character outcomes for each antecedent temperament type ranges from those more mature (achieved under optimal conditions) to those less mature (achieved under suboptimal conditions). For example, computer-simulated character development for the explosive (borderline) temperament type (i.e., high Harm Avoidance, high Novelty Seeking, low Reward Dependence), with all of the above contributing factors taken into account, is restricted to the development of only two character outcomes—both immature, but one relatively more mature (the melancholic character) than the other (the disorganized character). The most likely outcome is the melancholic character, prone to chronic depression and severe personality disorder (all three character traits are poorly developed). A small number of individuals with borderline temperament will develop the disorganized (or schizotypal) character outcome with high Self-Transcendence, but low Self-

Directedness and Cooperativeness (this type is characterized by magical thinking, perceptual aberration, and proneness to suicide and psychosis). Chances for other character outcomes for this temperament type are relatively low. Computer-simulated character development for other temperament types have been defined as well.

XI. CHARACTER (IM)MATURITY AND MENTAL (DIS)ORDER

Following the subscale structure of the TCI character traits (a total of 15 subscales for the three traits), full character development involves a sequence of 15 successive developmental steps, corresponding to the 15 subscales. Each new step in development emerges as a result of complex nonlinear facilitating and inhibitory interactions among heritable predispositions, social learning, and individual experiences (Table 10).

These 15 steps in character development are a theoretical ideal, leading to maximal scores on all three character dimensions. As character development depends on many internal and external, antecedent and

Table 10 Fifteen-Step Personality Development

Steps	Self-Directed	Cooperative	Self-Transcendent
TCI Tier 1			
1. co1		tolerant vs. suspicious (trustful vs. mistrustful)	
2. sd1	responsible vs. blaming (confident vs. shameful)		
3. st1			obedient vs. intractable (respectful vs. judgmental)
TCI Tier 2			
4. sd2	purposeful vs. aimless (moderate vs. indulgent)		
5. co2		empathic vs. cruel (prudent vs. scornful)	
6. st2			conscientious vs. unjust (worshipful vs. defiant)
TCI Tier 3			
7. sd3	resourceful vs. inept (hopeful vs. helpless)		
8. co3		generous vs. disagreeable (kind vs. hostile)	
9. st3			spiritual vs. materialistic (contemplative vs. greedy)
TCI Tier 4			
10. sd4	self-accepting vs. vain (humble vs. impatient)		
11. co4		forgiving vs. revengeful (compassionate vs. callous)	
12. st4			enlightened vs. possessive (joyfully free vs. controlling)
TCI Tier 5			
13. sd5	integrity vs. conflict (peaceful vs. undisciplined)		
14. co5		wise vs. unprincipled (loving vs. harsh)	
15. st5			creative vs. dualistic (idealistic vs. practical)

concomitant, facilitating and inhibitory factors, for some individuals full character development of all three traits is simply not possible.

Clinically, the 15 steps are organized into seven hierarchical levels of character disorder (divisions are made at points where developmental failures occur most frequently) (Table 11).

This hierarchical model of underlying character defects is used to classify progressive severity of mental order vs. disorder and provides a theoretical framework for treatment planning (discussed below).

A. Severely Disorganized Behaviors and Psychoses

Problems at the first level, involving basic trust (step 1) and confidence (step 2), are characteristic of individuals with history of sexual or physical abuse, and is associated with *highly disorganized disorders and psychosis*. Following Karasu [7], such patients have severe borderline and narcissistic disorders with "dyadic deficits" if they are arrested at character step 1 (which leads to impairments in the sense of self along with impaired mother-child relations) or

Table 11 A Hierarchical Model of Mental Order and Disorder
Based on Level of Personality Development

Character deficits	Associated mental health features
Level I "Walking Together"	(disorganized disorders)
1. co1—mistrust	self-injurious behavior
2. sd1—doubt & shame	sado-masochistic sexuality
Level II "Working Together"	(severe personality disorder)
3. st1—poor impulse control	bipolar affective lability
4. sd2—aimlessness	unemployment, criminality
5. co2—lack of empathy	polysubstance abuse
Level III "Feeling Together"	(mild personality disorder)
6. st2—no conscience	
7. sd3—low self-esteem	social dysfunction
8. co3—selfishness	frequent negative emotions
Level IV "Spiritual Together"	
9. st3—materialism	personal dissatisfaction
10. sd4—arrogance	lack of generativity
11. co4—revengefulness	occasional negative emotions
Level V "Minds Thinking as One"	
12. st4—possessiveness	mature but lack of joy &
13. sd5—integrated	lack of serenity
Level VI "Listening in Silence"	mature but lack of
14. co5—unloving at times	intuitive wisdom
Level VII "Experiencing in Unity"	mature but judgmental
15. st5—dualistic	& not fully harmonious

Subscales are designated by sd (Self-Directedness), co (Cooperativeness),
st (Self-Transcendence), and the number of the subscale shown in Table 7 (1–5).

"dyadic conflicts" if they are arrested at character step 2 (which leads to severely impaired object relations, such as difficulty of the child separating from the mother). Such fundamental impairments predispose to vulnerability to psychosis.

B. Severe Personality Disorders

Problems at the second level involve *severe personality disorders* with negativism, disobedience, and lack of purposefulness and empathy. This level, characterized by problematic three-person (i.e., mother-child-father) relationships, includes patients with "triadic deficits" if they are arrested at step 3 (which leads to poor impulse control and reduced capacity for intimacy and social

commitment) or "triadic conflicts" (arrested at step 4 or 5, leading to milder Oedipal conflicts, such as inhibited sexuality or impaired internalization of group values [7]. Such individuals have severe problems in working, socialization, and impulse control.

C. Mild Personality Disorder, Alcoholism, Anxiety Disorder, Major Depression

Problems at the third level, with low conscientiousness, low self-confidence, low resourcefulness, and little generosity, are typical of individuals with *mild personality disorder, type 1 alcoholism, anxiety disorder, or major depression,* which are associated with mild problems

in self-esteem, and lack of social intimacy or group identification.

D. Higher Levels of Maturity and Well-Being

The fourth and higher levels involve progressive steps in cognitive and spiritual development, predominantly observed with mature individuals seeking fulfillment with better health and happiness. Such overall personality integration can be measured by the sum of scores on all three character dimensions, consistent with Jung's notion of the self-transcendent leader. These higher levels of personality integration may be associated with psychopathology at times of existential crisis.

The above hierarchical model of mental order and disorder is essential to custom-tailor treatment strategies for individual patients (see later).

E. Age and Immaturity

Character immaturity is associated with younger age. This indicates maturation (i.e., remission of maladaptive and most extreme behaviors) with increasing age. In general, three dimensions of personality change substantially with age. Novelty Seeking decreases with age by ∼18%, so that older individuals become less impulsive (more reflective), less rule breaking (more orderly), and less quick tempered (more stoical). Cooperativeness increases markedly in most children during school age and then increases by 12% on average after age 18. Self-Directedness increases markedly in most people during adolescence and young adulthood, increasing on average by 9% after age 18.

The decreasing prevalence of personality disorder with age is attributable to the increased development of both Self-Directedness and Cooperativeness with age. The additional tendency for Novelty Seeking to decrease with age explains the finding that, without intervention, patients with impulsive personality disorders (e.g., Antisocial, Histrionic) show more improvement with time than those with anxious or eccentric personality disorders.

Age, therefore, is taken into account in evaluating character development. For example, teenagers and young adults are often still developing in Self-Directedness and Cooperativeness. Here, their low character scores suggestive of a personality disorder may improve owing to continued character development through family, education, and personal effort. Older adults, with fully developed Self-directedness

and Cooperativeness, may still not be fully satisfied. They may need to develop a firm basis for transpersonal meaning in their life, which is unaffected by their inevitable morbidity and mortality. Accordingly, they may need to develop higher Self-Transcendence for fuller self-knowledge and serenity. If so, a more appropriate measure of character development for individuals > 35 years of age can be based on the sum of all three character dimensions.

XII. PSYCHOBIOLOGICAL SUMMARY OF CHARACTER TRAITS

As one would intuitively expect, empirical data are more impressive for the "biological" temperament traits than for the "social" character traits. Yet, recent data are beginning to shed more light on the neuropsychological mechanisms underlying character traits as well [2]. Specifically, psychophysiological markers of neocortical processing, such as the P300 event-related potential and Contingent Negative Variation, are correlated with measures of character, but not temperament. For example, Self-Directedness, but not temperament traits, correlates moderately with the evoked potential P300 in parietal leads ($r = .4$, $P > .002$). Likewise, Cooperativeness, but not temperament, correlates with the Contingent Negative Variation (this was particularly obvious for the Empathy subscale, $r = .4$). These are the first empirical findings to associate character, but not temperament, to higher cortical functions in the CNS.

XIII. PSYCHOBIOLOGY OF TEMPERAMENT

Four major temperament traits are now understood as genetically independent dimensions, with distinct learning and neurophysiological features. These are discussed below.

A. Psychobiology of Harm Avoidance

1. Definition

Harm Avoidance involves a heritable bias in the inhibition of behavior in response to signals of punishment and frustrative nonreward.

2. Psychobiological Data for Harm Avoidance

Recent findings suggest that both GABA and serotonergic projections from the dorsal raphe underlie individual differences in behavioral inhibition as measured

by the temperament trait of Harm Avoidance. Ascending serotonergic projections from the dorsal raphe nuclei to the substantia nigra inhibit nigrostriatal dopaminergic neurons and are essential for conditioned inhibition of activity by signals of punishment and frustrative nonreward. PET studies show that Harm Avoidance is associated with increased activity in the anterior paralimbic circuit, specifically the right amygdala and insula, the right orbitofrontal cortex, and the left medial prefrontal cortex. This activation pattern corresponds well to the 5HT2 terminal projections of the dorsal raphe. However, 5HT2 receptor numbers have been correlated with Harm Avoidance only in studies of platelets.

Benzodiazepines disinhibit passive avoidance conditioning by GABA-ergic inhibition of serotonergic neurons originating in the dorsal raphe nuclei. Higher plasma GABA levels have also been correlated with low Harm Avoidance. Plasma GABA has also been correlated with other measures of anxiety proneness, and correlates highly with brain GABA levels.

Recent neuropsychological studies confirm that Harm Avoidance is associated with individual differences in classical aversive conditioning and other aspects of behavior inhibition, whereas other dimensions of personality are uncorrelated.

A gene on chromosome 17q12 that regulates the expression of the serotonin transporter has been found to account for 4–9% of the total variance in Harm Avoidance in four of six tests of this relationship. Psychobiology of Harm Avoidance is summarized in Table 12.

B. Psychobiology of Novelty Seeking

1. Definition

Novelty Seeking reflects a heritable bias in the initiation or activation of appetitive approach in response to novelty, approach to signals of reward, active avoidance of conditioned signals of punishment, and skilled escape from unconditioned punishment.

2. Psychobiological Data for Novelty Seeking

Mesolimbic and mesofrontal dopaminergic projections have been shown to have a crucial role in incentive activation of each aspect of Novelty Seeking in animals. In humans, individuals at risk for Parkinson's disease have low premorbid scores in Novelty Seeking, but not other dimensions of personality, supporting the importance of dopamine in incentive activation of pleasurable behavior.

Table 12   Reported Psychobiological Correlates of Harm Avoidance

Variable	Effect
Neuroanatomy (PET)	
Medial prefrontal (L)	increased activity (behavioral inhibition)
Anterior paralimbic (R)	increased activity (sensitivity to threat)
Neuropsychology	
Aversive conditioning	greater associative pairing with punishment ($r = .4$)
Eyeblink startle reflex	potentiation of response to aversive stimulus (effect size 1.9)
Posner validity effect	greater slowing of responses after invalid cues ($r = +.3$)
Spatial delayed response	better ability to delay responses after ingesting amphetamines ($r = +.5$)
Neurochemistry	
Platelet 5HT2 receptor	fewer receptors ($r = -.6$)
Plasma GABA	lower level ($r = -.5$)
Neurogenetics	
5HT transporter promoter	greater reuptake activity

The association of increased striatal activity with high Novelty Seeking is more specifically associated with higher density of the dopamine transporter, suggesting that Novelty Seeking involves increased reuptake of dopamine at presynaptic terminals, thereby requiring frequent stimulation to maintain optimal levels of postsynaptic dopaminergic stimulation. Novelty Seeking leads to various pleasure-seeking behaviors, including cigarette smoking, which may explain the frequent observation of low platelet MAO B activity because cigarette smoking has the effect of inhibiting MAO B activity in platelets and in brain.

Studies of candidate genes regulating dopamine transmission, such as the dopamine transporter (DAT1) and the type 4 dopamine receptor (DRD4), have provided evidence of association with Novelty Seeking and no other dimension of temperament. The dopamine transporter, which is responsible for presynaptic reuptake of dopamine and a major site of action of drugs including stimulants like methyl-phenidate and the antidepressant bupropion, is encoded by locus SLC6A3 (alias DAT1) on chromosome 5p. Polymorphisms at this gene locus are associated with Attention Deficit Disorder and other disorders related to variation in Novelty Seeking. Likewise polymorphisms at the DRD4 locus have been associated with Attention Deficit Disorder, opioid dependence, and other traits related to Novelty Seeking.

Psychobiology of Novelty Seeking is summarized in Table 13.

C. Psychobiology of Reward Dependence

1. Definition

Reward Dependence reflects a heritable bias in the maintenance of behavior in response to cues of social reward.

Table 13 Reported Psychobiological Correlates of Novelty Seeking

Variable	Effect
Neuroanatomy (PET)	
Medial Prefrontal(L)	decreased activity (behavioral disinhibition)
Dorsolateral Prefrontal	decreased activity (behavioral disinhibition)
Cingulate	increased activity (behavioral activation)
Caudate (L)	increased activity (behavioral activation)
Neuropsychology	
Reaction time	slower to respond if not reinforced (neutral stimuli, $r = -.4$)
Stimulus intensity (N1/P2 ERP)	augmentation of intensity of cortical responses to novel auditory stimuli ($r = .5$)
Sedation threshold	more easily sedated by diazepam (lower threshold, $r = -.3$)
Rey word list memory	deterioration of verbal memory when excited (after ingesting amphetamine, $r = .6$)
Neurochemistry	
Dopamine transporter	higher density observed in striatum
Platelet MAO B	lower activity (associated with cigarette smoking)
Neurogenetics	
Dopamine receptor D4	association with long alleles of exon III variant
Dopamine transporter	greater reuptake activity

2. Psychobiological Data for Reward Dependence

Reward Dependence is associated with individual differences in formation of conditioned responses to signals of reward. This is also supported by its association with individual differences in paired-associate learning. Noradrenergic projections from the locus ceruleus and serotonergic projections from the median raphe are thought to influence conditioning of responses to signals of reward. In humans, short-term reduction of norepinephrine release by acute infusion of the alpha-2 presynaptic agonist clonidine selectively impairs paired-associate learning, particularly the acquisition of novel associations.

The noradrenergic locus coeruleus is located at the same posterior level of the brain stem as the serotonergic median raphe, and both of these posterior mono-amine cells innervate structures important to formation of paired associations, such as the thalamus, neocortex, and hippocampus. High Reward Dependence is associated with serotonergic increased activity in the thalamus, which is consistent with proposals about the importance of serotonergic projections to the thalamus from the median raphe in modulation of social communication.

Noradrenergic mechanisms are also supported by the finding of low levels of urinary MHPG (a norepinephrine metabolite) with high Reward Dependence.

High Reward Dependence is associated with hyper-cortisolemia in patients with melancholia, but not in nondepressed individuals.

Psychobiology of Reward Dependence is summarized in Table 14.

D. Psychobiology of Persistence

1. Definition

Persistence reflects a heritable bias in the maintenance of behavior despite frustration, fatigue, and intermittent reinforcement.

2. Psychobiological Data for Persistence

Less work is available about Persistence than the other three temperament dimensions, because it has been distinguished as an independently inherited dimension only since 1993. It can be objectively measured by the partial reinforcement extinction effect (PREE) in which persistent individuals are more resistant to the extinction of previously intermittently rewarded

Table 14 Reported Psychobiological Correlates of Reward Dependence

Variable	Effect
Neuroanatomy (PET)	
Thalamus	increased activity (facilitates sensory processing)
Neuropsychology	
Reward conditioning	increased associative pairing with rewards ($r = .3$)
Paired Associates	better learning of novel associations ($r = .5$)
Posner Validity Effect	faster resonses after valid cues ($r = -.4$)
Neurochemistry	
Urinary MHPG	less excretion of norepinephrine metabolite ($r = -.4$)
Plasma cortisol	higher morning cortisol when depressed ($r = .3$)
Urinary Harman	greater excretion of indoleamine product in alcoholics high in reward dependence ($r = .7$)
Neurogenetics	
5HT-2c receptor	allelic association (effect size 2.0)

behavior than other individuals who have been continuously reinforced. Recent work in rodents showed that the integrity of the PREE depends on projections from the hippocampal subiculum to the nucleus accumbens. This glutaminergic projection may be considered as a short circuit from the behavioral inhibition system to the behavioral activation system, thereby converting a conditioned signal of punishment into a conditioned signal of anticipated reward. This connection is probably disrupted in humans by lesions of the orbitomedial cortex that may have a specific antipersistence effect of therapeutic benefit to some severely obsessive-compulsive patients. Bilateral cingulotomy, which reduces Harm Avoidance only, is less effective in reducing persistent compulsive behavior than cingulotomy combined with orbitomedial lesions.

Psychobiology of Persistence is summarized in Table 15.

XIV. TEMPERAMENT AND CHARACTER ARE TREATED SIMULTANEOUSLY

Roughly speaking, "hard-wired" temperament traits are primarily treated by pharmacological intervention. Some psychotherapeutic correction is possible, especially with behavior therapy, because associative conditioning has a pivotal role in the development of temperament traits. In contrast, commonly used psy-

chotropic drugs rarely induce significant changes in the internalized concepts about self and external objects. Character, in other words, is more amenable to psychotherapeutic intervention.

Temperament and character are optimally treated simultaneously with combined psychotherapy and pharmacotherapy, where drug treatment of the biological disposition is combined with psychotherapy of associated psychological mechanisms. In other words, medications are used to temporarily reduce anxiety, anger, impulsivity, or obsessionality related to temperament traits, setting the stage for long-term conceptual changes and character maturation in psychotherapy.

XV. PSYCHOTHERAPY GUIDELINES FOR LOW CHARACTER VARIANTS

In clinical practice, the TCI temperament and character scores are reviewed with the patient to identify their patterns of automatic behavior reactions (i.e., their temperament profile) and their cognitive concepts of themselves and others (their character profile). This is used to guide treatment planning for both pharmacotherapy and psychotherapy.

Psychotherapy guidelines presented here refer to patients with low Self-Directedness and low Cooperativeness, with mild to severe personality disorder (levels II and III in Table 10). Our approach is

Table 15 Reported psychobiological correlates of Persistence

Variable	Effect
Neuroanatomy	
Orbitomedial cortex	disconnection reduces perseveration
Neuropsychology	
Gambling style	perserveration in bet size despite continuing losses
Key word list learning	learning without reinforcement ($r = .5$)
Neurochemistry	
Glutaminergic connection	essential for PREE[a] in rodents
Subiculum to N. accumbens	
Neurogenetics	
5HT2c receptor	allelic association (effect size 2.0)

[a]Partial reinforcement extinction effect (PREE) is persistence or increased resistance to extinction following intermittent reinforcement.

integrative and eclectic, involving technical synthesis (eclecticism) and theoretical synthesis (integration) of various schools of psychotherapy and a variety of treatment techniques.

As an exception to the above eclecticism, we rarely recommend supportive psychotherapy for immature individuals with personality disorder, because it focuses at strengthening their existing coping mechanisms (which are by definition maladaptive in personality disorder) and thus only reinforces personal and social problems of these patients. Pure supportive-realistic therapy is recommended in most severe cases of personality pathology and psychoses, where safety and survival are of primary concern (these are described in level I in Table 10).

XVI. TREATMENT GOALS AND OUTCOME PLANNING

Patients are asked to identify their expectations and treatment goals in psychotherapy as autonomously as possible. Frequently, this is accomplished by reviewing with them the TCI temperament and character scores, which helps them identify targets for work. There has to be at least one area in which the therapist and patient are in agreement regarding treatment goals.

Not every patient with immature character can be helped to achieve his or her desired level of maturity. In addition to some general indicators of poor prognosis (e.g., low capacity for insights), one of the most important prognostic factors is the compatibility of the desired character outcome with the actual temperament type. As noted before, one initial temperament configuration may lead to several, but not all, of the eight possible character outcomes. Some character outcomes are *incompatible* with some initial temperaments and are therefore not achievable in therapy.

XVII. PREVENTION OF IMMATURITY: ENVIRONMENT IS CRITICAL

The effect of sociocultural factors on personality is less specific than that of genetic factors, influencing success in adaptation rather than its form or personality style. This is consistent with recent findings about the importance of family and local culture in character development. Family environment does not influence temperament, but explains about 35% of variability of character traits. Hence, psychosocial disorganiza-

tion in the rearing environment of a child has a substantial influence on the risk of personality disorder. This is essential for preventive strategies as even temperament configurations with high risk of personality disorder might be overcome in the early stages in homes and communities that provide security and limits on behavior in a warm, compassionate manner, as well as encouraging self-directed choice and the value of respect for other people.

XVIII. IF EVERYTHING ELSE FAILS, EVERYDAY LIFE EVENTS CAN HELP

As noted, some patients are not likely to benefit from psychotherapy. For those patients, many aspects and events of everyday life, acting randomly, sometimes positive and inspiring (such as illuminating interpersonal contacts, work-related progress), but sometimes negative and destabilizing (such as tragic events, personal downfalls), may initiate character maturation by challenging the present level of adaptation. Often, the emergent changes are sudden and associated with a new perspective on life and new goals and values, which cannot be achieved by logic, medication, or advice alone.

XIX. IDEAL, OPTIMAL, AND COMPROMISE OUTCOMES

Treatment outcomes range from ideal to optimal to compromise. *Ideal* outcomes correspond to the ideally mature personality, with maximal development of all three character traits. These outcomes are not always possible, especially for patients with personality disorder who usually have initial temperament configurations incompatible with high scores on all character dimensions. However, whenever possible, ideal outcomes are pursued as the ultimate standard of maturity.

More frequently, treatment is planned to enable the patient to achieve the best possible adaptation for the present temperament traits and local social circumstances. This is called an *optimal* character outcome.

If, for any reason, the optimal outcome can not be achieved, we chose the *compromise* outcome, i.e., we work with the patient to raise the level of his or her adaptation compared to that at baseline, but do not attempt to reach the maximal adaptation possible for that patient.

XX. "BACK TO THE FUTURE" RECOVERY COURSE

In the fitness landscape of personality development, the hills represent developmental points of more or less successful local adaptation and are thus relatively stable. In contrast, the valleys represent brief transition periods and are thus relatively unstable. The "U-shaped" developmental pattern (see below) explains why extreme temperament types and their associated extreme behaviors, which are clearly not optimal (i.e., are maladaptive relative to the possible maximum for that individual), tend to be stable.

Personality disorder represents a point of developmental stability for many individuals. By definition, it involves maladaptation, i.e., less than optimal adaptation or poor adaptation, but still some adaptation, to the local environment. In other words, personality disorder represents a suboptimal developmental outcome, with established, although maladaptive, personal and social roles, support network, etc. Each new step in development must increase one's adaptation to be more successful in balancing multiple internal and external constraints. Search for higher adaptive hills, however, is discouraged by the necessity of initially regressing to an unstable, transitional developmental level (a valley). This is referred to as the U-shaped developmental pattern, and is commonly observed in complex dynamic systems.

In psychotherapy, patients are expected to give up their current (although maladaptive) personal and social stability in the local environment (i.e., their present hill). They first have to regress (to take a step down) to an unstable, transitional level of development, and then, based on more mature concepts about self and the external world (developed in psychotherapy), to "climb" to a higher adaptive hill with new personal and social roles and better overall adaptation. This "regressive progression" or "back to the future" course derives directly from the U-shaped developmental pattern mentioned earlier, and accounts for both the chronicity and the treatment resistance of individuals with personality disorder.

XXI. STEPWISE CHARACTER DEVELOPMENT: NEVER TOO LATE FOR HEALING

The subscale structure of the TCI was formulated to specify character in terms of 15 component steps of its development, each reflecting one component subscale of three major character traits. As shown in Table 9, stepwise character development follows a spiral pattern, where each revolution around the spiral and each new step of character development introduces a new triad of developmental tasks. For example, during the first revolution around the spiral, a person encounters problems of trust vs. mistrust (Cooperativeness/subscale 1), confidence vs. shame (Self-Directedness/subscale 1), and obedience vs. rebelliousness (Self-Transcendence/subscale 1). As character matures, individuals successively face new developmental tasks associated with other component subscales of Self-Directedness, Cooperativeness, and Self-Transcendence.

This spiral pattern of character development provides the opportunity to correct "developmental errors" that have occurred at any of the previous steps. For example, as character develops to reach a new step in Self-Directedness (e.g., Resourcefulness/subscale 3), one gets "in line" historically with issues of purposefulness and responsibility (subscales 1 and 2 of Self-Directedness), encountered earlier in development. This alignment facilitates retrospective revisions ("retrospective healing") of errors at these earlier developmental steps in psychotherapy. Such retrospective revisions are possible for previous steps within the same trait for all character traits.

XXII. PSYCHOTHERAPY OF CHARACTER: PRACTICAL PEARLS

1. The central message is "Do something with the patient, not something to the patient." This way, the patient feels somewhat in control and this might help keep him or her in treatment.

2. Immature patients usually want psychotherapy "their way," with many conditions and demands. Flexibility in approach, but firmness in basic values, with creativity and readiness to step away from the "rules" is essential to resolve these "no way out" situations.

3. Reflecting their unstable self-image (i.e., low Self-Directedness), patients with personality disorder alternatively feel inferior and omnipotent, assaultive and self-destructive, sensitive to rejection but usually provoking it. These and similar tendencies may cause countertransference problems with a potential loss of professional objectivity; constant supervision and a

support network are therefore necessary. (*Reassuring note for psychotherapists*: These patients are almost never as good as they look when they are doing well, and almost never as bad as they look when they are not doing well.)

4. Psychotherapy of patients with personality disorder takes place constantly (during any and every kind of contact with the patient), not only during the psychotherapy sessions proper. Frequently, what is happening between sessions may be as important for the favorable outcome as the sessions themselves.

5. At least initially, the therapy is supplemented by as much structuring of the patient's life as needed. This may range from simple direction, via day hospital programs, to inpatient hospitalization. Structuring is not expected to generate personality change but to temporarily improve behavior control. Prolonged structuring robs the patient of the opportunity to become more self-reliant and to learn from experience. With very immature patients, psychotherapy means "reparenting"—focusing on some very basic psychological and physical issues, such as general health, diet, social skills, education, help with real life problems, and encouragement.

6. Individuals with personality disorder tend to minimize their own symptoms and problems, even the most serious ones, such as suicide attempts or medical illnesses. These "blind spots" for their own problems reflect mechanisms they have developed since early age to avoid disturbing feelings and thoughts. Hence, they generally feel a much lower level of distress with their own symptoms than people around them. Confrontations (not explanations!) are used to increase their level of discomfort with their own symptoms, which improves their recognition of these symptoms and their motivation to change them. These patients tolerate confrontations very well, provided they trust their therapist. They need an extraordinarily high level of stimulation (sometimes achieved through confrontations) in any relationship, including therapy. This "hunger" for stimuli indicates an early exposure to either lack of stimulation (neglect) or extreme stimulation (abuse) by their caretakers.

7. The greater the character development at baseline, the better the response to psychotherapy is likely to be. High degrees of cognitive dysfunction, as indicated by low character development and/or extensive cognitive distortion in personal authenticity (see the section on the performance scales in the TCI), make improvement in psychotherapy difficult but not impossible.

XXIII.   TREATMENT PLANNING

Baseline temperament configurations are carefully reviewed and taken into account for psychotherapy planning as well, not just in pharmacotherapy.

A.   High Reward Dependence and High Harm Avoidance (Passive-Aggressive and Cautious Temperaments)

When both Reward Dependence and Harm Avoidance are high, there is a great risk of facilitating dependency in patients if directive techniques are used. Nondirective brief, time-limited therapies should be closely maintained in these cases. Reduction of anxiety, by relaxation or antidepressant therapy, is critical to set the stage for work on character development.

B.   Low Harm Avoidance and High Reward Dependence (Passionate and Cyclothymic Type)

In these cases, although the therapist should be nondirective about the patient's basic treatment goals, directive techniques can be safely utilized. Patients who are also high in Cooperativeness are likely to do well with brief directive psychotherapy focused on solving specific interpersonal problems. Such cooperative patients are likely to have good social skills in general or to have the basis for developing them quickly.

C.   High Reward Dependence and Low Self-Directedness (Dependent Personalities).

These patients are considered good candidates for dynamic therapy despite their personality dysfunction because of their good capacity for transference associated with high Reward Dependence. However, it is unclear whether the results with psychodynamic techniques are more effective here than other techniques.

High Persistence is usually an asset in achieving character development, provided it is not extreme, as in Obsessive-Compulsive personality, when it interferes with treatment.

Low Reward Dependence may limit development of Cooperativeness unless special attention is devoted to developing empathy and compassion.

Low Novelty Seeking may limit development of Self-Transcendence unless special attention is devoted to insight-based meditation techniques.

XXIV. PSYCHOTHERAPY OF CHARACTER: SPECIFIC TECHNIQUES FOR SPECIFIC TRAITS.

Cognitive-behavioral therapy, psychoanalysis, transactional analysis, and reality therapy focus primarily at developing Self-Directedness.

Some experiential techniques that facilitate acceptance of others or development of cooperative behavior include Rogerian counseling, logotherapy, and interpersonal psychosynthesis..

Attainment of Self-Transcendence is a goal of Jungian analysis, Assaglioli's psychosynthesis, insight meditation as practiced in Buddhism and mystical forms of other religions, and relaxation-based meditation techniques of advanced autogenic training.

XXV. ADVANCED STAGES OF PSYCHOTHERAPY

In the course of successful therapy, as character matures and new concepts and associated secondary or social emotions develop, patients neutralize extreme temperament traits and the related basic emotions of fear and anger. Behaviors change accordingly, from being primarily reactive, i.e., steered by basic emotions and automatic responses regulated by temperament, to being primarily proactive, i.e., steered by secondary emotions and active symbolic constructs regulated by character.

XXVI. PHARMACOTHERAPY GUIDELINES FOR EXTREME TEMPERAMENT VARIANTS

Pharmacological therapy of extreme behaviors can be either *symptomatic*, aimed at correcting target clinical symptoms, or *causal* aimed at correcting neurobiological dispositions underlying deviant traits.

XXVII. SYMPTOMATIC PHARMACOTHERAPY OF EXTREME TEMPERAMENT VARIANTS

Pharmacotherapy cannot be usefully organized around discrete subtypes of personality disorder. These subtypes are described as clinical syndromes (each involving clusters of symptoms, i.e., single acts of deviant behaviors). The efficiency of drug treatments is more accurately observed at a symptom level than at the syndrome level. Also, the target symptoms are not unique to any categorical subtype, but are shared by other subtypes of personality disorder as well. Next, some of the classified personality disorder subtypes are heterogeneous composites that can be further decomposed into one or more subcategories, each potentially requiring specific pharmacotherapy.

Another problem with symptomatic treatments is that they are based on the phenotypic similarity between some Axis I and Axis II syndromes (i.e., treatments established for Axis I symptoms are used to treat "similar" behaviors observed on Axis II). Yet, common pathogenesis for Axis I and Axis II disorders has not been established, leaving open to question the validity of these treatments "by analogy."

However, at the present level of psychiatric theory and practice, symptomatic treatments are considered standard for patients with personality disorder. Most pharmacological trials are focused on acute symptoms (e.g., suicidality, paranoia, depression), but an increasing number of authors advocate long-term pharmacotherapy of chronic pathology as well (e.g., impulsiveness, affective dysregulation) in addition to acute treatments. In that regard, most authors agree that the following four **symptom domains** underlie chronic pathology of personality disorder: (1) aggression and behavioral dyscontrol; (2) affective symptoms and mood dyscontrol; (3) anxiety; and (4) cognitive-perceptual distortions including psychotic symptoms.

Note that these four symptom domains represent behavioral (clinical) correlates of the *underlying* temperament and character dimensions: high Novelty Seeking corresponds to the symptom domain of impulsiveness and aggression, high Harm Avoidance to the symptom domain of anxiety and depression), low Reward Dependence to the symptom domain of affective dysregulation and detachment, and low character traits to the symptom domain of cognitive disturbances. In other words, the identifica-

tion of these four target symptom domains has narrowed the gap between categorical and dimensional approach to personality disorder and between causal and symptomatic pharmacotherapy of these patients. In the remainder of this chapter, we discuss the causal therapy of personality disorder. Symptomatic pharmacotherapy is described elsewhere in detail [2].

XXVIII. CAUSAL PHARMACOTHERAPY OF EXTREME TEMPERAMENT VARIANTS

Causal pharmacotherapy of extreme temperament traits derives from fundamental neurobiological processes underlying personality and mental disorder. Responses to antidepressants in major depression, e.g., can be predicted by temperament traits to a substantial degree, and not by the number, type, severity, or course of depressive symptoms. Patients who are dysphoric and highly sensitive to social approval (i.e., who are high in Harm Avoidance and Reward Dependence) are most likely to improve on selective serotonin uptake inhibitors (SSRIs). In contrast, those who are highly fearful but not socially dependent are most likely to improve on noradrenergic uptake inhibitors, like desipramine. Likewise, children with Attention Deficit Hyperactivity Disorder are high in Novelty Seeking (i.e., low in central dopaminergic function) and are efficiently treated with drugs that increase dopamine release and inhibit its reuptake, such as methylphenidate. (*Note*: Treatment strategies suggested below are still tentative and need further systematic study.)

XXIX. PHARMACOLOGICAL GUIDELINES FOR CLINICAL SYNDROMES WITH EXTREME UNDERLYING TEMPERAMENT DIMENSIONS

A number of clinical and personality syndromes involve extreme deviation of a single temperament trait. For example, most cases of major depression are characterized by elevated Harm Avoidance (i.e., symptoms of anxiety, pessimism, fatigability), without comorbid deviation of other temperament or character traits. Here, pharmacological manipulation of high Harm Avoidance with SSRIs is indicated (high 5HT2 activity in the prefrontal cortex is postulated to under-

lie Harm Avoidance, and SSRIs eventually downregulate 5HT2 receptors, leading to symptomatic improvement).

When more than one extreme temperament trait underlies clinical symptoms, treatment planning is more complex. Harm Avoidance is usually the strongest motivator of behaviors and the first temperament trait to develop in the phylogeny of learning in animals, from invertebrates to man, followed by Novelty Seeking, and Reward Dependence. Hence, a person with the so-called approach-avoidance conflict (where both Harm Avoidance and Novelty Seeking are high) will usually tend to inhibit behavior to avoid danger (Harm Avoidance) rather than to activate behavior in pursue of novelty (Novelty Seeking) in response to novel situations. Such motivational hierarchy is used to prioritize pharmacotherapy in clinical syndromes with more than one underlying extreme temperament trait: behaviors associated with high Harm Avoidance (e.g., depression, anxiety) are usually clinically more urgent than disorderliness or impulsivity associated with Novelty Seeking or dependency associated with Reward Dependence, etc. One exception to this is hazardous behaviors associated with high Novelty Seeking which are for safety reasons always treated first.

Most psychotropics are not very specific, adding to the complexity of pharmacological intervention in personality disorder. The selected drug usually affects not only the targeted underlying dimension, but also other dimensions and symptom domains (e.g., SSRIs improve both the symptom domain of anxiety and the symptom domain of aggression). This nonspecificity may reflect the multifinality phenomenon (where different behaviors derive from the same underlying antecedent), or multiple action sites of a single drug affecting several neurophysiological systems at the same time. When carefully manipulated, this nonspecificity may be advantageous in treatment of clinical cases with multiple underlying extreme temperament dimensions (see below).

Psychobiological planning of pharmacotherapy also involves other factors (e.g., social, cultural, family) to customize treatment for individual patients. Even the patient's character structure is taken into account for pharmacological intervention. For example, if Self-Directedness is low (with consequent intolerance, blaming, and revengefulness), mood stabilizers are used to prevent acting out, self-injury, and assaultive behaviors.

XXX. PHARMACOLOGICAL TREATMENT OF PERSONALITY SYNDROMES DOMINATED BY EXTREME HARM AVOIDANCE

The following temperament types and their corresponding traditional personality syndromes are characterized by high Harm Avoidance:

Methodical temperament type (corresponding to the traditional category of Obsessive personality)

Explosive temperament type (corresponding to the traditional category of Borderline personality)

Sensitive temperament type (corresponding to the traditional category of Passive-Aggressive personality)

Cautious temperament type (corresponding to the traditional category of Avoidant personality).

A. Methodical Temperament Type/ Obsessive Personality

High Harm Avoidance, high Persistence, low Novelty Seeking, and low Reward Dependence underlie the *methodical* or *obsessive* temperament type. The majority of methodical individuals, even severe variants, are well adjusted in the society (e.g., as accountants or administrators). Those who also have poor character development are almost invariably maladapted and diagnosed as *obsessive-compulsive* personality disorder (described as inflexible; devoted to work to the exclusion of pleasure; preoccupied with details, rules, and regulations; unable to relax; no sense of humor; etc).

Harm Avoidance is associated with high central 5HT2 activity. Accordingly, OCD patients show increased central serotonergic activity, most prominently in the serotonin pathway from midbrain raphe nuclei to the basal ganglia. Pharmacological treatment of these patients involves "serotonergic" drugs, usually SSRIs (e.g., fluoxetine, fluvoxamine, citalopram, paroxetine, sertraline). The SSRIs increase the amount of active serotonin in all major serotonergic pathways by inhibiting its reuptake into the presynaptic terminal. The increased serotonin affects presynaptic somatodendritic 5HT1A receptors, leading to the disinhibition of serotonergic neurons, increased release of serotonin in the synapse, and downregulation of postsynaptic 5HT2 receptors. Clinically, this is expected to reduce anxiety, depression, and obsessive symptoms.

Drugs that block 5HT2 receptors and also inhibit serotonin and norepinephrine reuptake, such as nefazodone, are useful for obsessive temperaments as well. Similarly, some of the "old-timers," such as chlomipramine, efficiently improve clinical syndromes with high Harm Avoidance, but also syndromes with high Reward Dependence, presumably by affecting both central serotonergic and noradrenergic transmitter systems.

Augmentation strategies, with pindolol (a 5HT1A antagonist) or buspirone (a 5HT1A agonist leading to 5HT1A down regulation and ultimately 5HT2 downregulation) are frequently indicated either to speedup the onset of action of SSRIs or to reestablish the efficacy of SSRIs for patients who have reached a plateau after initially responding.

Benzodiazepines are efficiently used for composite temperament types with dominant Harm Avoidance, including Obsessive personality. These drugs increase GABA-ergic inhibition of serotonergic neurons originating in the dorsal raphe nuclei and facilitate symptomatic improvement. Similarly, gabapentin, a GABA analog, might be helpful for obsessive patients as well.

Severe obsessive temperaments, with low character and extremely high Harm Avoidance, are sometimes treated with antipsychotics, preferably those with significant 5HT2 antagonism (such as risperidone, olanzapine, quetiapine, clozaril, ziprasidone). High activity of these receptors has been demonstrated in OCD symptoms, panic, depression, anxiety, and sexual dysfunction, but also in psychosis and hallucinations.

As a general note for all personality and mood syndromes with high Harm Avoidance, high Harm Avoidance at baseline predicts poorer responses to antidepressants, and vice versa.

Psychotherapy tips: Obsessive temperaments are alexithymic (unable to recognize own emotions), with low capacity for attachment (reflecting their low Reward Dependence), and with a characteristic tendency to dissociate from own symptoms and engage in endless rational analyses of their behavior, a form of flabbergasting to avoid disturbing emotions (this is sometimes called "pseudo-intellectualization"). These features make them more likely to benefit from cognitive behavior techniques (which are more directive, focused on identifiable symptoms, and on the here-and-now). In contrast, mild and moderate obsessive temperaments (high Harm Avoidance, but only mild decrease in Reward Dependence), are candidates for

dynamic psychotherapy because of their capacity for attachment and transference, which makes therapy less ''academic'', more personalized and thus more likely to yield results.

B. Explosive Temperament Type/ Borderline Personality

High Harm Avoidance, high Novelty Seeking, and low Reward Dependence underlie the Explosive (borderline) temperament type. This type has the highest risk of immature character outcome, leading to symptoms diagnosed as Borderline personality disorder. Mild variants are dysphoric, opportunistic, and alienated, whereas moderate and severe variants manifest chronic depression, chronic feelings of emptiness and boredom, low frustration tolerance, distrust of others, impulsivity, unstable relationships, labile mood, frequent acting outs, suicidal gestures, etc.).

Pharmacological treatment of borderline personality is complex. This syndrome is characterized by more than one extreme temperament trait: Harm Avoidance motivates cautious behaviors and passive avoidance of danger; Novelty Seeking motivates active exploratory behaviors, impulsivity, and disorderliness; whereas low Reward Dependence underlies their detachment and insensitivity to social pressures. These conflicting motivations invariably generate a stalemate between activation and inhibition of behavior (the earlier mentioned approach-avoidance conflict).

Recent advances in the psychobiological understanding of the approach-avoidance conflict (high Harm Avoidance coupled with high Novelty Seeking) point to the importance of anterior serotonergic cells in the dorsal raphe nucleus which intermingle with the dopaminergic cells of the ventral tegmental area. Both cell groups innervate the same structures (e.g., basal ganglia, accumbens, amygdala), providing opposing dopaminergic-serotonergic influences in the modulation of approach and avoidance behavior.

High Harm Avoidance generates chronic anxiety, depression, fatigability, dissatisfaction. High Novelty Seeking makes these patients unpredictable, with frequent acting outs, impulsivity, and self-injurious behaviors, drug/ETOH abuse (many of them need detoxification). Finally, because of their usually very low character traits, these individuals are chronically struggling with basic issues of trust, self-esteem, identity, purpose and meaning of life, etc.

Treatments of choice for the explosive temperament type are SSRIs, which are used here to treat not only the underlying high Harm Avoidance, but other symptoms as well. Namely, the SSRIs have been shown to be effective in several symptom domains: depression, anxiety, impulsivity, anger, hostility, mood reactivity, psychoticism, hyperphagia, rejection sensitivity. These symptoms correspond well to the distribution of 5HT2 receptors in the prefrontal cortex (depression) and hypothalamus (impulsivity and bulimia). Treatment with SSRIs downregulates these receptors and decreases Harm Avoidance symptoms. Another explanation for this multifinality of action is that SSRIs activate feedback loops involving multiple neurotransmitter systems and leading to symptomatic improvement in several symptom domains (e.g., the earlier mentioned dopaminergic-serotonergic loop in the modulation of approach and avoidance behaviors). Finally, some of these drugs, originally thought to specifically affect the serotonin system only, affect other transmitter systems as well, accounting for the multifinality of their effects (e.g., paroxetine has been recently postulated to inhibit both serotonin and norepinephrine reuptake). Augmentation strategies, with pindolol or buspirone, are indicated here for patients who plateau after initial good response.

SSRI's' are frequently combined with mood stabilizing GABA analogs (e.g., gabapentin) to treat mood swings and affective reactivity so typical of borderlines. GABA analogs are likely to be efficient because higher plasma GABA levels correlate with low Harm Avoidance. Other mood stabilizers (lithium, valproate, and lamotrigine) have been used nonspecifically here to reduce impulsivity, depression, and self-injury.

Most of the explosive symptoms are caused by the approach-avoidance conflict between high Harm Avoidance and high Novelty Seeking. Hence, SSRIs are frequently combined with dopamine agonists (to reduce symptoms associated with high Novelty Seeking), such as psychostimulants, which increase dopamine release and inhibit its reuptake (e.g., methylphenidate) or with antidepressants with dopaminergic agonism (bupropion). Similarly, pramipexole (a selective D3 agonist) has been postulated to be efficient in treatment of ''unstable'' and chronic depression.

Depressed patients with volatile or borderline temperaments have average improvement (54%) on antidepressants. Women particularly may respond better to noradrenergic drugs to the extent that they are much higher in Harm Avoidance than in Reward Dependence.

Severely explosive temperaments, especially those with very high Harm Avoidance, are sometimes treated with antipsychotics, preferably 5HT2 receptor antagonists to reduce symptoms associated with 5HT2 hyperactivity (anxiety, depression, sexual dysfunction, bulimia, OCD symptoms, psychotic decompensation).

Psychotherapy tips for explosive individuals: Supportive-realistic therapy ("reparenting") is recommended for severe cases, cognitive-behavior techniques for moderate and mild cases. Psychotherapy focuses on the development of more realistic concepts of the self and the world (while aggression and anxiety are temporarily controlled by medication). These internalized concepts are expected to provide long-term neutralization of aggression and depression.

C. Avoidant Personality/Cautious Temperament Type

High Harm Avoidance, high Reward Dependence, and low Novelty Seeking underlie the Cautious temperament type. Mild variants are high-strung, shy, careful, and cautious. When character development is also low, this type is diagnosed as Avoidant personality disorder (i.e., preoccupation of being criticized or rejected in social situations, feelings of inadequacy, social inhibition, hyperscrupulousness, passive-dependency). However, owing to their high sensitivity to social pressures (associated with high Reward Dependence), Cautious individuals are relatively rarely diagnosed as immature or maladapted (hence, their anxiety and shyness are more accurately diagnosed as Social Phobia).

These patients are primarily treated with SSRIs, because of the dominant Harm Avoidance in the background of their presentation. They respond well to antidepressants in a relatively high proportion of cases (71%). One study has shown superiority of predominantly noradrenergic antidepressants (desipramine) over predominantly serotonergic antidepressants (chlomipramine) in Harm Avoidance and Reward Dependent females with the Cautious temperament type). The exact mechanism of this effect is not clear. One explanation is that desipramine activates alpha-1 noradrenergic mechanisms, resulting in the excitation of serotonergic neurons and down regulation of 5HT2 receptors, with improved Harm Avoidance behaviors. Another possibility is that desipramine activates alpha-2 presynaptic inhibitory receptors, decreasing *temporarily* postsynaptic serotonergic activity, this leading to initial improvement of

symptoms (the study lasted only 6 weeks, leaving open the possibility that a more continual noradrenergic inhibition of serotonin release could have caused upregulation of 5HT2 receptors and worsening of the symptoms after initial response). Finally, via its noradrenergic activity, desipramine might have harmonized the Reward Dependence of these women, reducing their problems associated with dependency and leading to symptomatic improvement in their mood and anxiety. Clearly, serotonergic and noradrenergic mechanisms underlying Harm Avoidance and Reward Dependence need further systematic study. The above discussion also illustrates that our treatment proposals ought to be interpreted as a theoretical framework only, not as finalized algorithms to treat personality and its disorders.

Psychotherapy tips: Depending on the degree of their character development, cautious individuals are treated with supportive-realistic approach (for those with personality disorder) or dynamic and insight-oriented approach (for mild and moderate variants).

D. Passive-Aggressive Personality/ Sensitive Temperament Type

High Harm Avoidance, high Novelty Seeking, and high Reward Dependence constitute the Sensitive temperament type. Mild variants are easily upset (frustrated or distressed), attention-seeking, submissive, and anxious. When character development is also low, this temperament type is diagnosed as Passive-Aggressive personality disorder (with symptoms of procrastination, obstruction, negativism, and other forms of camouflaged aggression and dysphoria).

Passive-aggressive personality is unique because all three temperament traits are elevated, leading to potentially numerous motivational conflicts. Usually, passive-aggressive symptoms reflect underlying conflicts between high Harm Avoidance (fear of punishment) and high Reward Dependence (need for approval and support). High Novelty Seeking contributes to the presentation with symptoms of disorderliness and irritability. Venlafaxine (with serotonergic, noradrenergic, and dopaminergic effects sequentially activated with increased dosing) is usually efficient for individuals with Sensitive temperaments. Venlafaxine is mostly affecting Harm Avoidant behaviors with its serotonergic activity, but is also expected to harmonize Novelty Seeking and

Reward Dependence with its dopaminergic and nor-adrenergic activity, respectively. Similarly, a trial of bupropion (a noradrenergic-dopaminergic agonist) might be useful in these cases. These "dirty" drugs affect multiple neurotransmitter systems. In temperament profiles, such as the Sensitive type, where more than one temperament trait is generating clinical symptoms, such drug nonspecificity might be advantageous.

Depressed patients with Sensitive type respond well to antidepressants in a relatively high proportion of cases (73%). As noted, Harm Avoidance superordinates hierarchically the other temperament traits and usually dominates the clinical picture, even in cases when other temperament traits are also high (such as Passive-Aggressive personality). Hence, passive-aggressive patients respond to SSRIs by improving fearfulness, dysphoria, anxiety, etc. SSRIs are also useful here to harmonize their anger associated with high Novelty Seeking (see earlier). This "toning down" of Harm Avoidance and Novelty Seeking usually sets the stage for more sociable behaviors, empathy and compassion, associated with high Reward Dependence.

The demonstrated superiority of noradrenergic TCAs (desipramine) over serotonergic TCAs (chlomipramine) in Harm Avoidant females with high Reward Dependence is the basis for trying noradrenergic noradrenergic TCAs (desipramine, nortriptyline), especially in nonresponders to SSRIs. It is noteworthy that some authors found no evidence for differential response to noradrenergic or serotonergic drugs.

Augmentation with lithium carbonate, dopaminergic agonists, or switching to monoamine oxidase inhibitors may be helpful if high Novelty Seeking is considered problematic. These adjunctive medications are indicated to decrease impulsiveness and increase rational planning.

XXXI. PHARMACOLOGICAL TREATMENT OF PERSONALITY SYNDROMES AND TEMPERAMENT TYPES DOMINATED BY HIGH NOVELTY SEEKING

Adventurous temperament type (corresponding to the traditional category of Antisocial Personality)
Passionate temperament type (corresponding to the traditional category of Histrionic Personality)

A. ADVENTUROUS TEMPERAMENT TYPE / ANTISOCIAL PERSONALITY

Low Harm Avoidance, high Novelty Seeking, and low Reward Dependence constitute the Adventurous temperament type. Mild variants tend to be impulsive, careless, disorderly, extravagant, daring, adventurous, unconventional, oppositional, etc. When character traits are also low, severe variants are diagnosed as Antisocial Personality Disorder, where the above symptoms are complicated by active antisocial acts and crime.

Antisocial disorder is an exception to the rule that high Self-Directedness always protects against personality disorder. In fact, many antisocial individuals can be quite resourceful, self-disciplined, and successful in their antisocial activities (i.e., they are self-directed), but their low Cooperativeness (i.e., intolerance, revengefulness, low empathy), together with their social deviation and frequent criminality, makes them maladapted.

The dominant behavior motivator in adventurous temperaments is high Novelty Seeking with symptoms of impulsivity, disorderliness, extravagance, various pleasure-seeking behaviors, alcoholism, food addiction, and use of stimulating drugs. As noted, Novelty Seeking is associated with higher density of the dopamine transporter, suggestive of increased reuptake of dopamine at presynaptic terminals, thereby requiring frequent stimulation to maintain optimal levels of postsynaptic dopaminergic stimulation. Indeed, double-blind trials have shown that psychostimulants, such as methylphenidate, which increase central dopaminergic function, are beneficial in the treatment of inattentive and hyperactive adults who are impulsive and aggressive, especially when the symptoms have begun in childhood.

SSRIs improve impulsivity and "affective aggression" ("hot temper") in antisocial individuals, presumably because increased serotonergic function downregulates 5HT receptors, with subsequent increase in dopamine release in the mesocortical and mesolimbic dopaminergic neurons (behaviorally, this is observed as reduction in symptoms associated with high Novelty Seeking).

Multiple double-blind trials have shown that lithium reduces affective display and aggression in both normal subjects and impulsive-aggressive individuals. Lithium blocks the firing rate of rapidly firing neurons by reducing their ability to restore normal levels of phosphatidylinositol biphosphate (PIP2) after its hydrolization. As noted, dopaminergic

mesolimbic neurons in high Novelty Seeking individuals require frequent stimulation ("stimulus hunger") to maintain normal dopaminergic postsynaptic function. Lithium appears to be able to dampen the ability of these neurons to fire rapidly, thus reducing impulsivity and other Novelty Seeking symptoms. Lithium should not be given to antisocial persons without aggression and impulsivity; it does not diminish nonaggressive antisocial behaviors (such as lying or stealing).

Benzodiazepines and alcohol have a disinhibitory effect on avoidance behavior, facilitate violence, and further impair passive avoidance learning in impulsive antisocial persons. This effect is attributed to the reduction of Harm Avoidance (already low in these cases), leaving Novelty Seeking completely unopposed to motivate behavior.

Psychotherapy tips for adventurous individuals: Group therapy is generally considered useful for these patients. This setting is therapeutic for the social deviance, low cooperativeness, lack of empathy, and disregard of others.

B. Passionate Temperament Type/ Histrionic Personality

High Novelty Seeking, high Reward Dependence, and low Harm Avoidance constitute the Passionate temperament type. Mild variants tend to be versatile, attention seeking, pleasure seeking, and impulsive, but trusting and sensitive to cues of social reward. When character development is also low, the Passionate type is diagnosed as Histrionic personality disorder (i.e., these individuals tend to be impulsive, ambitious, self-indulgent, sexually seductive, manipulative, insecurely vain, gullible, and self-centered, with rapidly shifting shallow emotions and frequent episodes of "reactive" dysphoria).

The Passionate temperament type is unique in that their dominant motivation, i.e., hunger for stimulation associated with high Novelty Seeking (manifested as sensation seeking, attention seeking, and pleasure seeking), is *not* conflicting, but is synergistic with their other important motivator, high Reward Dependence (i.e., need for approval, attention, support).

Histrionic individuals are optimally treated with medications targeting not only their high Novelty Seeking, but also their high Reward Dependence, such as bupropion, which inhibits reuptake of both norepinephrine and dopamine. Increased synaptic dopamine optimizes dopaminergic activity in the ventral tegmentum—mesolimbic "pleasure pathway"—and reduces pleasure-seeking behaviors. In addition, through its noradrenergic effect on Reward Dependence, bupropion reduces these patient's need for external gratification.

As with adventurous individuals, SSRIs and psychostimulants are frequently used. SSRIs improve impulsivity and hot temper, presumably by manipulating the underlying high Novelty Seeking (increased 5HT2A function initially inhibits mesocortical and mesolimbic dopaminergic neurons). Psychostimulants, such as methylphenidate, also increase central dopaminergic function and could be beneficial in the treatment of passionate individuals. Mood stabilizers (especially topiramate and gabapentin) are used here nonspecifically, to reduce extreme reactivity of mood and rapid mood swings of Passionate individuals.

Adventurous (antisocial) and passionate (histrionic) symptoms tend to run in the same family and to co-occur in the same person. These two phenotypes share the underlying high Novelty Seeking and low Harm Avoidance. Reward Dependence, however, is low in adventurous and high in passionate individuals. As noted earlier, Reward Dependence facilitates conditioning of behaviors under social pressure. This explains the decrease in the severity of antisocial symptoms from Antisocial Personality (with low Reward Dependence and "major" violent and property criminality) to Histrionic Personality, with high Reward Dependence and "minor" criminality (promiscuity, manipulation). The same factor, high Reward Dependence in passionate individuals, explains their better response to psychotherapy and their greater likelihood to achieve character maturation in psychotherapy than antisocial individuals.

XXXII. PHARMACOLOGICAL TREATMENT OF PERSONALITY SYNDROMES AND TEMPERAMENT TYPES DOMINATED BY HIGH REWARD DEPENDENCE

A. Reliable Temperament Type/ Cyclothymic-Dependent Personality

High Reward Dependence, low Harm Avoidance, and low Novelty Seeking constitute the Reliable temperament type. Mild variants tend to be composed (rarely frustrated or distressed), careful, and trusting, whereas

severe variants are described as very susceptible to social pressure, sensitive to rejection, sentimental, attached, trusting. When character development is also low, this temperament type is diagnosed as Dependent (cyclothymic) personality disorder. These patients are hyperthymic ("moody"), scrupulous, gullible, and prone to reactive depression, and to lack initiative and depend on others for reassurance and own decisions.

Noradrenergic projections from the locus ceruleus and serotonergic projections from the median raphe are thought to influence reward conditioning. High Reward Dependence is associated with low levels of urinary MHPG (a norepinephrine metabolite). In addition, high Reward Dependence is associated with increased serotonergic activity in the thalamus, which is consistent with proposals about the importance of serotonergic projections to the thalamus from the median raphe in modulation of social communication.

Most people with even marked variation of the reliable temperament type are well adjusted and well functioning. In fact, this temperament type is associated with the lowest risk of immaturity and maladaptation. Reliable individuals are very responsive to social pressure and are easily conditioned to acquire socially acceptable behaviors. Usually, they seek help when depressed (which is their typical response to frustration and nonreward). In contrast to endogenomorphic depression, their depression is exogenomorphic (also called "characterological"); i.e., biological markers are usually not found (such as decreased REM latency, increased REM frequency, positive Dexamethasone Suppression Test). Their response to antidepressants is poor ($<40\%$), but they respond (improve) to positive events (the so-called good-news depression).

Patients with this temperament type are most likely to respond to SSRIs, and sometimes to MAOIs and TCAs. Bupropion is sometimes effective in reducing their symptoms, presumably by optimizing dopaminergic activity in the mesolimbic "pleasure" pathway and through its noradrenergic inhibitory effect on Reward Dependence (which reduces their dependency on external gratification). Mood stabilizers with some antidepressant properties (e.g., lamotrigine) are sometimes helpful.

Psychotherapy tips: Individuals with reliable temperaments respond exceptionally well to psychotherapy, and equally well to psychodynamic and cognitive behavior approaches.

XXXIII. PHARMACOLOGICAL TREATMENT OF PERSONALITY SYNDROMES AND TEMPERAMENT TYPES WITH LOW REWARD DEPENDENCE:

A. Independent Temperament Type/ Schizoid Personality

Low Harm Avoidance, low Novelty Seeking, and low Reward Dependence constitute the Autonomous temperament type. Mild variants tend to be composed (rarely frustrated or distressed), private, and oppositional. Moderate and severe variants, with very low scores on all temperament traits, are described as isolative, detached, noninvolved, solitary, indifferent to praise or criticism, and emotionally cold and aloof. When character traits are also low, this temperament type maladapted and diagnosed as Schizoid Personality Disorder (characterized by social detachment, restricted range of expressed emotions in interpersonal settings, indifference to praise and criticism, no close friends or confidants other than family members, and preference for solitary activities and fantasy ("loners").

The "negative symptoms" of schizoid individuals (emotional detachment, indifference, aloof emotions) respond well to antidepressants and atypical neuroleptics. In fact, these patients have excellent responses to antidepressant drugs of *any type* in a higher proportion of cases (88%) than any other temperament type. In addition, the so-called atypical neuroleptics, with serotonin-dopamine antagonism (the "SDAs"), like risperidone, olanzapine, or quetiapine, are used in refractory cases. In schizophrenia, the above negative symptoms are believed to reflect dopamine deficiency in the mesocortical pathway. Serotonin-dopamine antagonists increase dopamine in this pathway and reduce the negative symptoms.

Psychotherapy tips: These patients are mostly treated with behavior modification techniques, because of their low capacity for attachment and poor motivation.

XXXIV. PSYCHOBIOLOGICAL INTEGRATION OF TREATMENT

The seven-factor psychobiological model distinguishes components of personality that differ in terms of their etiology, pattern of development, and responses to psychotherapy and pharmacotherapy. This provides a foundation for integrating clinical diagnosis and treat-

ment planning in a manner that is both general (as a theoretical framework) and specific (sensitive to differences among individual patients). Based on the structural, clinical, and neurochemical characteristics of temperament and character, pharmacotherapy and psychotherapy can be systematically matched to the observed temperament structure and actual stage of character development of each individual. This is clearly a unique advantage over other available approaches. The choice of techniques likely to benefit the patient depends on the stage of personality integration. A brief outline of this integrative psychobiological approach is given in Table 16.

Treatment is organized into seven levels corresponding to the seven underlying problem levels described in Table 10. With respect to personality disorder of particular interest are levels 2 and 3 and, somewhat less frequently, levels 1 and 4.

A. First Treatment Level: Walking Together

The first treatment level involves supportive and reality-based techniques, including basic trust building, encouragement, and teaching of basic living skills. The goal here is to assure the safety of patients with severe disorganization and destructive impulses. Trust-building and encouragement within safe limits are basic components of all therapy, and are essential at this level because patients are overwhelmed with negative emotions, such as most patients with explosive (borderline) temperaments and severely immature character (melancholic or schizotypal). However, if the patient is psychotic or prepsychotic, therapy is limited to supportive function. Such supportive intervention may require concomitant somatic therapies like electroconvulsive therapy or antipsychotic medication. The "holding" or reparenting aspects of the psychotherapeutic environment are crucial at this level, including the therapist's being dependable, nonretaliatory, and compassionate despite frequent crises, and able to provide a more optimistic understanding of the patient's needs and opportunities than the patient. This allows the patient to build trust, some optimism, and self-confidence.

B. Second Treatment Level: Working Together

The second treatment level involves direction and cognitive-behavioral techniques that emphasize rational cognitive analysis and repetitive behavioral

drills to improve impulse control and discipline. This level involves initial treatment of individuals with moderately severe personality and mood disorders with poor impulse control and emotional lability, such as most antisocial, severe obsessional, or mild borderline patients. Pharmacotherapy for labile affect and impulsivity, such as mood stabilizers, and for hostility, including low-dose neuroleptic, may be beneficial. Discussion of personality structure and emotional needs in such patients is focused on their understanding of their temperament structure and basic emotional needs, along with education about mature ways of satisfying those needs. For example, hatha yoga and martial-arts training are appealing methods for teaching self-control at this level, leading to enhancement of self-esteem and impulse control. Such structured approaches minimize conflict about setting limits, but there must be much patient repetition of practical problem-solving skills and encouragement by discussion of attractive role models. This makes constructive use of such patient's craving for pleasure and power.

C. Third Treatment Level: Feeling Together

The third treatment level involves nondirective dynamic, humanistic, and interpersonal techniques to foster increases in conscientiousness, resourcefulness, and generosity. At this stage direction is counterproductive because the patient needs to internalize group values and to develop confidence in his or her self-willed action. Depression and anxiety are common at this level and may be treated with antidepressants as needed in combination with the non-directive therapy. The standard six exercises of autogenic training are useful at this level, providing relaxation and preparation for meditative exercises at more advanced levels.

D. Fourth Treatment Level: Spiritual Together

The fourth treatment level involves experiential and existential therapy techniques such as meditation and spiritual identification exercises. This involves a conscious expansion of the self-concept to include a transpersonal (i.e., spiritual) component in addition to the mind and body. Antidepressant or antianxiety medication may be useful at times of existential crisis, but are used sparingly and transiently because strong motiva-

Table 16 Integrative Psychobiological Treatment of Personality and Psychopathology

Level	Developmental steps	Methods of treatment
I. Supportive-realistic therapy		
	1. Trust	Acceptance, trust-building Establish supportive environment Antipsychotic medication if needed Detoxification if needed
	2. Stop denial & vain self-sufficiency	Maintain safety and support Teach basic living skills and social interdependence
II. Directive rational-expressive-behavioral therapy		
	3. Obedience, stop defiance	Instruction about temperament Set limits and respect for boundaries

	4. Purposefulness	Explore goals and role models
		  & make a searching personal inventory
		Model problem-solving skills
		  for analysis and imitation

	5. Empathy	Encourage sharing of personal feelings
		Empathy training & teamwork
		+ objectively monitor treatment compliance
		+ pharmacotherapy of impulsivity,
		  violence, craving
		  (e.g. lithium, Tegretol, valproate)
		+ treatment of comorbid depression
		+ conditioning of impulse control
		  by repetitive drills & homework

III. Nondirective dynamic-humanistic-interpersonal therapy		
	6. Conscientiousness	Discursive reflection on goals & values as motivation to adapt Identification with role models

	7. Resourcefulness	Non-directive discussion of options
		  for coping with problems,
		  then self-willed action
		Persistence/resourcefulness training

	8. Generosity	Making amends, helping others Sharing, accepting help from others + monitor treatment compliance by self-report + education about character steps + cognitive analysis of basic emotions, defenses, and virtues + antidepressant medication if needed
IV. Experiential-existential therapy		
	9. Spirituality	Charitable action Mindful meditation with undistracted body scanning & automatic breathing Disidentification with mind-body Identification as mind-body-spirit Spiritual empowerment/communion

Level	Developmental steps	Methods of treatment
	10. Humility, patience	Self-knowledge, disclosure, acceptance— letting go of unimportant expectations
	11. Compassion	Recognize social interdependence Identification in spirit with others Consider work with support groups + cognitive analysis of mature character development
V. Transcendence therapy		
	12. Detachment, freedom (unconditional joy and trust)	Whole-hearted compassionate activity Contemplation with automatic devout vocalization All-inclusive identification
	13. Integrity, power, peace, courage	Spirit-guided contemplation (Ego-less channeling) Integration of personal goals and values, eliminating distractors Empowerment of Mind (integrating of mind and spirit) Mind-body healing practices + cognitive analysis of conditions for joy & peace
VI. Advanced spiritual guidance		
	14. Unity of wisdom & love	Social integration for love with enhanced intuitive awareness Superconscious contemplation the intuitive source of transpersonal guidance of (spirit = all-inclusive self) + cognitive analysis of unity and obstacles to integration
VII. Full integration		
	15. Creativity, bliss	Maintain contemplative awareness in all daily activities Objectless contemplation (nondual consciousness) with creative visualization + integrated creative development

tion is needed to promote the leaps of faith needed to transform consciousness and self-concepts.

E. Advanced Levels (V, VI, and VII) of Development and Maturity

The fifth and higher developmental and treatment levels involve advanced guidance in meditation and other techniques needed to transcend ordinary self-concepts. Such individuals' mature personality devel-opments are seldom impaired by ordinary standards, but seek superior character integration, emotional fulfillment, and healthy longevity.

Mood Disorders in Childhood and Adolescence
Basic Mechanisms and Therapeutic Interventions

MELISSA P. DELBELLO and ROBERT A. KOWATCH

University of Cincinnati College of Medicine, and Children's Hospital Medical Center, Cincinnati, Ohio, U.S.A.

I. INTRODUCTION

Child and adolescent mood disorders are complicated in their clinical presentations, and little is known regarding their neurobiology. These disorders commonly manifest with abnormalities in cognition, affective regulation, vegetative behaviors, and perception. Furthermore, children and adolescents who are diagnosed with mood disorders are at high risk for suicide attempts [1,2]. The developmental course and presentation of pediatric mood disorders and the presence of co-occurring disorders may vary with the age and pubertal status of the child [3–5]. Bipolar disorders are particularly complex since their initial presentation is often one of a severe, sometimes psychotic depression that later develops into mania or hypomania. The neurobiology of pediatric mood disorders involves multiple neurotransmitter and neuroendocrine systems and several brain regions. However, compared to adult mood disorders, little is known about the biological basis of pediatric mood disorders. Nonetheless, understanding the neuropathophysiology of pediatric mood disorders is essential so that effective treatment strategies may be developed.

II. EPIDEMIOLOGY AND CLINICAL CHARACTERISTICS

Psychoanalytic theory once taught that children could not experience depression before adolescence [6]. Subsequent research has demonstrated that children develop internal mood states between the ages of 12–18 months [7]. Children who are diagnosed with a mood disorder are commonly referred to clinicians because of "bad behavior" or a decline in school performance. Often children will present with irritability, oppositional and negative behavior, school refusal, and severe outbursts. Sometimes children will present with unexplained physical complaints in excess of a clear medical cause. A child who has a mood disorder might present with hyperactive, impulsive, and severely aggressive behavior, as if driven by a motor, and at the same time deny that anything is wrong. None of these pictures is the layperson's perception of a child who has a mood disorder, and yet the first two presentations are typical for depression and the third is typical for bipolar disorder [8].

A.   Epidemiology

Prevalence rates of major depressive disorder (MDD) in children and adolescents range from 0.4% to 8.3% [9–16]. Depressive disorders occur more frequently in adolescents than in children. Prevalence rates of depressive disorders in children and adolescents are only slightly lower than in adults [17], for which 12-month prevalence of major depression is reported to be 10%. MDD in childhood appears to occur at approximately the same rate in girls and boys. However, during adolescence the gender differences observed in adult populations become apparent, with the approximately 2:1 female to male ratio [18]. Prevalence rates for dysthymia are 0.6–1.7% in children and 8% in adolescents [19,20].

Wozniak and colleagues [21] reported that of 262 consecutively referred children to a pediatric psychopharmacology clinic, 16% met DSM-III-R criteria for mania. Bipolar disorders are as prevalent in adolescents as they are in adults, with an estimated prevalence of 1% [2,11,12,22]. Recently, Lewinsohn and colleagues administered diagnostic assessments to a large randomly selected community sample of adolescents (n = 1507) and a subset was again assessed at age 24 years. They found that the lifetime prevalence of bipolar disorder was 1% during adolescence and 2% during young adulthood. Lifetime prevalence of subsyndromal bipolar disorder was 5%. Less than 1% of adolescents who had MDD switched to bipolar disorder by age 24 years [2]. This is in contrast to the results of others who have found "switch" rates of 33% in prepubescent children with MDD [23].

B.   Signs and Symptoms

1.   *Depressive Disorders*

Depressive disorders are characterized according to the Diagnostic and Statistical Manual, Fourth Edition (DSM-IV), as major depressive disorder (MDD), depressive disorder not otherwise specified (NOS), or dysthymic disorder [24].

According to DSM-IV, for a diagnosis of MDD, there must be a disturbance of mood (sadness and/or in children, irritability) most of the day, nearly every day, *or* there must be loss of interest or pleasure in all, or almost all, activities most of the day, nearly every day. In addition to a disturbance of mood and/or a loss of interest, five or more of the seven other associated symptoms must be present. The symptom complex must be present for at least 2 weeks. MDD tends to be episodic with either full or partial recovery between episodes (a cyclical disorder). Episodes of MDD cause significant deficits in the child's usual functioning that might be evidenced by a decline in school performance, withdrawal from peers, or conflict with peers and siblings. In depressive disorder NOS, the disorder is episodic, but the episodes will be below the criteria for MDD because of fewer symptoms or shorter duration. Episodes of depressive disorders NOS may be precursors of future MDD episodes or occur independently. Dysthymic disorder refers to a chronically depressed mood, less intense than MDD but with no prolonged well states. The duration of the illness is of at least 1 year in children, and irritability may be present instead of depressed mood. Seventy percent of children who have dysthymic disorder will develop MDD [25].

Although the diagnostic criteria for mood disorders in children and adolescents are generally the same as those for adults, differences in symptomatic expression are substantial, and are outlined below:

1.   *Irritability (depressed mood)*. Dysphoria may be characterized by statements and appearance of sadness, loneliness, unhappiness, hopelessness, irritability, hypersensitivity, negative attitude, and being difficult to please. DSM-IV allows children to have irritability instead of a "depressed mood."

2.   *Self-deprecation (guilt and worthlessness)*. Self-deprecatory thinking is manifest by thoughts of worthlessness, guilt, persecution, death, and suicidal ideation. In this age group, it is common to project feelings of lowered self-esteem into beliefs of persecution, i.e., "everyone hates me" or "I am not a good kid." Cognitively, it may be difficult for children to express guilt, but feelings of worthlessness and self-blame are evident in their behavior and in their statements.

3.   *Agitation (psychomotor changes)*. Agitation is evident by difficulty getting along with others, including fighting, disrespect for authority, and excessive hostility. The increased conflict with others as a result of agitation is what often leads to the referral of a child. The presence of agitation and oppositional behavior can result in misdiagnosis of attention deficit hyperactivity disorder (ADHD) or oppositional defiant disorder. The oppositional or inattentive behavior will typically resolve with treatment of the depression.

4.   *Sleep disturbance (insomnia or hypersomnia)*. Sleep problems include initial, middle, and terminal

insomnia, difficulty awakening in the morning, and excessive sleepiness (hypersomnolence). Depressed children will often experience the subjective feeling of initial insomnia, which is not always objectively confirmed. Middle insomnia is not uncommon in small children (getting in bed with parents and siblings). Terminal insomnia is less common in depressed children and adolescents than in depressed adults.

5. *Change in school performance (poor concentration)*. Teachers may complain about daydreaming, poor concentration and attention, poor motivation, loss of interest in school activities, incomplete schoolwork and homework, and lowered grades. Because of poor concentration, children and adolescents may be misdiagnosed with ADHD. However, their history will often reveal no difficulty with attention prior to the episode of depression

6. *Decreased socialization (loss of interest or pleasure)*. Children and adolescents with MDD might not seek out friends or participate in social activities.

7. *Change in attitude regarding school (loss of interest)*. Children and adolescents with MDD may present with school refusal as the primary problem for referral. Although some of these children may have separation anxiety disorder, many have lost interest and pleasure in school.

8. *Somatic complaints*. Although "somatic complaints" is not a DSM-IV symptom of depression, in children it is a common symptom of MDD. Children with MDD often present to pediatricians with vague complaints of headaches, stomachaches, or other physical symptoms for which the physician can find no cause.

9. *Fatigue*. The depressed child or adolescent frequently complains of mental and physical fatigue and becomes less active. A child who was active in sports may complain of tiredness, less energy, and even boredom, resulting in diminished participation. Frequently there will be substantial overlap in the vegetative symptoms of loss of energy, sleepiness, and loss of interest.

10. *Change in appetite and/or weight*. Children will typically become "picky" eaters, crave sweets, or become overeaters. Commonly, depressed children will not demonstrate expected developmental weight gain—rather, actual weight loss.

11. *Suicidal ideation*. Children and adolescents may demonstrate suicidal plans and intent similar to that of adults. More typically, younger children describe passive suicidal ideation, such as wishing they were dead, but they do not have a plan.

2. Bipolar Disorders

A child or adolescent who has at least one episode of mania is classified as having bipolar I disorder. However, a child or adolescent who has had one or more episodes of major depression, no episodes of mania, and at least one episode of hypomania, is classified according to DSM-IV as having bipolar II disorder [24]. Cyclothymia is a disorder of at least 1-year duration, in which there are periods of hypomanic and depressive symptoms that do not meet criteria for mania or major depression. The child or adolescent is not without symptoms for more than 2 months at a time. Bipolar not otherwise specified (NOS) is a diagnostic category frequently used in children and adolescents since their mood episodes might not meet full DSM-IV criteria for duration of symptoms, or they might have recurrent hypomanic episodes without depression.

Pediatric bipolar disorder often presents differently from in adults. Most commonly, children and adolescents present with irritability, ultrarapid cycling, and mixed manic states. Disruptive behavioral disorder and ADHD are typically comorbid. Prepubertal-onset MDD with a family history of bipolar disorder may also be an early sign of pediatric bipolar disorder [3–5,23].

The following are examples of DSM-IV criteria for mania in children and adolescents.

1. *Elevated or expansive mood*. The child may be much happier than their situation warrants. Inappropriate "goofiness" and silliness are common. During a manic phase, patients will often have no insight about the inappropriateness of their moods.

2. *Irritability*. The child may become very belligerent, highly irritable with frequent, intense, and prolonged temper tantrums or "affective storms." An adolescent may appear extremely oppositional, belligerent, short, curt, or hostile, accounting for the common misdiagnosis of oppositional defiant or conduct disorder.

3. *Inflated self-esteem or grandiosity*. The child or adolescent may think he or she has "superpowers" or "can beat up anyone in the world" or "can teach the class better than any of the teachers," despite failing school.

4. *Decreased need for sleep*. The child or adolescent may refuse to go to bed before 1 or 2 AM and only sleep 3–4 hours a night without tiring.

5. *More talkative than usual*. The child or adolescent may repeatedly blurt out answers during class and appear to "know more than the teacher." Their speech

may become very rapid and pressured to the point where it is continuous, and at times unintelligible or difficult to follow.

6. *Fight of ideas or racing thoughts*. The child or adolescent may report that he or she have "too many ideas and can't get them out fast enough." They may describe "thinking faster than others".

7. *Distractibility*. The manic child or adolescent may report that he or she cannot pay attention in class because their thoughts are moving along too fast or there is too much going on around them.

8. *Increase in goal-directed activity*. The child or adolescent will appear very restless and shift from activity to activity rapidly, without necessarily completing any of them.

9. *Excessive involvement in pleasurable activities that have a high potential for painful consequences*. The child may become hypersexual and inappropriately touch dolls, peers, or adults in an attempt to engage them in "sex". Adolescents may display promiscuous sexual behavior, or binges of drinking, drugging, or shopping.

C.   Comorbidity

Mood disorders in children and adolescents are often masked by the presence of other co-occurring psychiatric diagnoses. In a recent epidemiological study, 50% of children and adolescents who had a psychiatric disorder had at least one co-occurring disorder [26]. In those with an affective disorder, 24% also had conduct or oppositional disorders, 17% had ADHD, and 17% had an anxiety disorder. Kovacs and colleagues found that the second most common diagnosis in children with affective illness is conduct disorder (23%) [27]. In one study, half of hospitalized adolescents diagnosed with a substance use disorder were found to also have a mood disorder [28].

The most common comorbid diagnoses in children with MDD are anxiety (30–80%), disruptive (10–80%) and substance use (20–30%) disorders [19]. Anxiety disorders commonly co-occur in children with MDD (41%) and typically persist even after the depressive episode remits [29]. Furthermore, the presence of social anxiety disorder in adolescence predicts MDD in young adulthood [30]. Also common in children with MDD is ADHD. Weinberg and Emslie found that 33% of children diagnosed with MDD also met criteria for ADHD [31].

Half of children diagnosed with dysthymic disorder have a co-occurring disorder [25]. Anxiety disorders are commonly comorbid in children and adolescents with dysthymic disorder, especially separation anxiety disorder in children (33%) and generalized anxiety disorder in adolescents (67%) [32]. Conduct disorder (30%), ADHD (24%), and enuresis or encoporesis (15%) are also common in children with dysthymic disorder [19].

The most common comorbid diagnosis among bipolar youth is ADHD. Despite the high co-occurrence of juvenile mania and ADHD, which has been reported in several studies, the relationship between these disorders remains unclear [5,21,33–39]. Explanations for this high comorbidity include juvenile mania with ADHD being a distinct form of early-onset bipolar disorder [34], ADHD being a prodrome of juvenile mania, or simply misclassification due to symptom overlap between the two conditions [35]. Several studies have demonstrated that ADHD is more common in prepubertal-onset bipolar disorder than in adolescent-onset bipolar disorder, suggesting that ADHD may be a marker for a developmentally early form of bipolarity [3,34,40]. Milberger and colleagues investigated whether ADHD with comorbid bipolar or major depressive disorder was two separate disorders or secondary to diagnostic overlap, and found that after overlapping diagnostic criteria were accounted for statistically, 79% maintained their diagnosis of MDD and 56% maintained their diagnosis of bipolar disorder [41]. Other reports support that children and adolescents with bipolar disorder with ADHD have two distinct disorders [42,43]. Faraone and colleagues assessed familial risk in children with ADHD with and without bipolar disorder and healthy volunteer children. They found that both ADHD groups had elevated familial rates of ADHD compared with healthy volunteers. However, a five times elevated risk for bipolar disorder was found among relatives when the proband had bipolar disorder but not when the proband had ADHD alone. Additionally, they reported an elevated risk for severe MDD in relatives of the ADHD+ bipolar probands and that both ADHD and bipolar disorder occurred in the same relatives more often than expected by chance, suggesting that ADHD with comorbid bipolar disorder is a familial distinct form of ADHD related to pediatric bipolar disorder [34,44].

Another disorder that is frequently comorbid in children with bipolar disorder is conduct disorder. Kovacs and Pollock found among 26 bipolar children and adolescents 69% were also diagnosed with conduct disorder. Several studies report that conduct disorder in youth with bipolar disorder predicts a worse clinical course [4,45]. Adolescents with bipolar disorder

are five times more likely to develop a substance use disorder than those without bipolar disorder [46]. Recently, Biederman and colleagues [47] used familial risk analysis to disentangle the association between bipolar, substance use, and conduct disorder and reported that bipolar disorder in children and adolescents was a risk factor for substance use disorders, independent of conduct disorder. Furthermore, they found that the effects of bipolar and conduct disorders in probands combined additively to predict the risk for substance use disorders in relatives and therefore, that bipolar and conduct disorder are two distinct illnesses that commonly co-occur. Finally, children and adolescents with pervasive developmental disorders may be at increased risk for developing mania [48,49].

D. Differential Diagnosis

The differential diagnoses for pediatric mood disorders include ADHD, oppositional defiant disorder, conduct disorder, anxiety disorders, including posttraumatic stress disorder (PTSD), and pervasive developmental disorders. However, pediatric mood disorders commonly present with comorbid disruptive behavior, attention deficit, and pervasive developmental and anxiety disorders. Therefore, the assessment of a child or adolescent for a pediatric mood disorder should include identifying age-specific clinical manifestations of mood disorders. Children and adolescents with ADHD without a mood disorder do not have grandiosity, elation, euphoria, extreme irritability, hypersexuality, feelings of guilt or worthlessness, or suicidal ideation. With careful delineation of specific symptoms, these disorders can be separated. Fristad and colleagues used the adult Mania Rating Scale to evaluate a group of prepubertal children with either mania or ADHD [50]. They found this scale to be useful in differentiating manic children from the hyperactive children with the manic children reporting an elevated mood, increased motor activity/energy, decreased need for sleep, increased irritability, pressured speech, flight of ideas, disruptive behavior, thought disorders, and a lack of insight.

Children and adolescents with conduct disorder and without a mood disorder typically do not feel remorseful for their predatory actions. Like children and adolescents with mood disorders, those with PTSD might also present with mood lability and difficulty with sleep and concentration. However, the presence of nightmares, startle and avoidance behaviors, flashbacks, and severe anxiety with a history of trauma suggests PTSD as a primary diagnosis. Although the hyper-

sexuality associated with bipolar disorder might be confused with PTSD, <1% of bipolar children with hypersexual behaviors have been sexually abused [51]. Additionally, although substance use and mood disorders commonly co-occur, it is important to assess for substance-induced mood disorders. The presence of mood symptoms during periods of abstinence, drug screens, and duration and severity of mood symptoms might be helpful in determining the relationship between mood symptoms and substance use.

Medical illnesses can cause mood disturbances and need to be investigated prior to assuming a primary psychiatric etiology. For example, symptoms of thyroid disease, infectious mononucleosis, systemic lupus, temporal lobe epilepsy, or anemia may mimic those of MDD or bipolar disorder.

E. Natural Course

The developmental course of mood disorders suggests that there is a continuum of pathology from childhood to adulthood. Similar to adults with depressive disorder, children and adolescents with MDD often have a chronic course.

Most studies report that the average length of a MDD episode in children and adolescents is 7–9 months [52–55]. In a study of 42 child outpatients with MDD, Kovacs and colleagues found that 59% had recovered (asymptomatic for 2 months) by 1 year and 92% had recovered by 18 months [52]. Similarly, Strober and colleagues found that 81% of 58 adolescent inpatients with MDD had recovered by 1 year and 98% by 2 years from the time of admission, with the average time to recovery of 27.5 weeks from admission [54]. McCauley and colleagues found that 80% of predominantly outpatient children with MDD recovered by 1 year [56].

However, once recovered, children and adolescents with MDD have a high rate of relapse. Recurrence (i.e., a new episode of depression) has been reported in up to 72% of depressed children and adolescents followed for 3–8 years, with similar rates seen in inpatients and outpatients (55–60). For example, Poznanski and colleagues reported that 50% of outpatient adolescents with MDD were depressed when contacted 6.5 years later [61]. Eastgate and Gilmour contacted 19 of 36 child inpatients with depression 7–8 years after their episode and reported that 42% were psychiatrically ill, 21% with MDD [62].

Furthermore, 70% of children and adolescents with early-onset MDD continue having episodes of MDD into adulthood. Kandal and Davies [63] described

poor adult outcomes in a large sample of adolescents (n = 1004) identified as having depressive symptoms using a self-report scale. Similarly, in a retrospective, long-term follow-up study of 80 depressed and 80 nondepressed outpatient adolescents, Harrington and colleagues [64] reported that depressed adolescents were more likely than nondepressed adolescents to have MDD in adulthood; however, they noted that most adult depressions are not preceded by adolescent depression. Weissman and colleagues studied 73 patients with adolescent onset MDD into adulthood and found that while 37% survived without an episode of major depression in adulthood, there was substantial increased risk of suicide and adult MDD in those with as compared to those without adolescent MDD [65].

Although there are few investigations of the outcome of childhood-onset dysthymic disorder, children with dysthymic disorder are likely to develop depressive disorders and recurrent affective illnesses [25]. Moreover, the presence of an externalizing disorder predicts a worse outcome in children with dysthymia [25]. Mean episode length is typically 4 years, and children with dysthymia usually develop their first episode of MDD within 2–3 years after the onset of dysthymic disorder [25,52,60].

According to one study, prepubertal-onset depression has been associated with high rates (up to 33%) of bipolar disorder in adolescence and adulthood [23]. However, adolescent depression is only associated with a 1% risk of switching to bipolar disorder [2]. Strober and colleagues followed 58 adolescents who had been admitted to a psychiatric unit for MDD and found that during the 24-month follow-up period, mania occurred in 28% of those patients who had a psychotic depression [54]. Predictors of bipolarity included a depressive syndrome that consisted of rapid onset, psychomotor retardation, mood-congruent psychotic features, a family history of bipolar disorder, the presence of bipolar disorder in three successive generations, and pharmacologically induced mania [66]. In a similar follow-up study of depressed prepubertal children, Geller and colleagues reported that bipolarity was predicted by a family history of major mood disorders or schizoaffective disorder [67].

The outcome of bipolar disorder in children and adolescents has received little study. McGlashen interviewed 62 adult patients who met DSM-III criteria for mania and divided them into two groups—35 with adolescent-onset mania, and 31 with adult-onset mania [68]. He reported that the adolescent-onset group had more hospitalizations, displayed more psychotic symptoms, and were more frequently misdiagnosed with schizoaffective disorder than the adult-onset group. Surprisingly, the adolescent-onset group had a superior outcome to the adult-onset group in terms of social relationships and ability to work.

In contrast, Geller and colleagues reported diagnostic stability in 91 prepubescent and early adolescent subjects. At 6 months, 86% continued to have mania and only 14% recovered. The presence of conduct disorder predicted worse outcome [4]. At 1-year follow-up, 89 of the patients were assessed and rate of recovery was 37%; however, the rate of relapse after recovery was 38% [69]. In these studies recovery was defined as no mania or hypomania for at least 2 weeks, and relapse was defined as having full DSM-IV criteria for mania or hypomania and a Childhood Global Assessment Scale score of ≤60 for at least 2 weeks.

There are very few outcome studies of adolescent mania. Retrospective studies have indicated poor outcomes with high rates of suicide [70]. In the largest and to our knowledge the only, prospective follow-up studies of adolescent mania, Strober and colleagues found 96% of adolescents with bipolar disorder recovered from index affective episode at 5 years and 44% of those had one or more relapses by 5 years. A pure depressive episode at index hospitalization was associated with longer time to recovery. Mixed manic states and cycling index episodes were associated with multiple relapses [71].

In summary, until fairly recently it was commonly believed that pediatric mood disorders did not exist. However, there are now data to support that pediatric mood disorders are highly prevalent and associated with high rates of suicide and comorbid disorders [5,72,73]. Furthermore, children and adolescents with mood disorders will generally exhibit a chronic course and continue to have a mood disorder into adulthood.

III. BIOLOGY

As compared to mood disorders in adults, there have been relatively few investigations of the biology of childhood and adolescent mood disorders. Moreover, these studies are difficult to implement in children and adolescents since they often require several blood draws, subjects remaining still over long periods of time, and the cooperation of the children and adolescents. Owing to the recent data-based characterization of the clinical manifestations of pediatric mood disorder, there has been an increase in biological studies

of children and adolescents with bipolar and major depressive disorders.

A. Genetics

Although there have been few molecular genetic studies of children with mood disorders, familial risk studies suggest that early-onset MDD may be a more familial form of the illness than adult-onset MDD. Based on twin studies, childhood and adolescent MDD is significantly heritable (0.50–0.65) in both boys and girls [74]. Children of depressed parents are three times more likely to have a lifetime episode of MDD. Furthermore, early-onset MDD is associated with an increased familial risk of MDD as compared to late-onset MDD [75–77]. However, a family history of MDD is associated with recurrence and continuity of MDD into adulthood in patients with prepubertal-onset MDD and not adolescent-onset MDD [78]. Although the molecular basis of pediatric MDD remains to be determined, there is a familial component to early-onset MDD, particularly in patients who have a more protracted illness course (79).

Overall, family studies have confirmed an increased risk of bipolar disorder, ADHD, and alcoholism in relatives of probands with pediatric bipolar disorder as compared to adult bipolar probands. For example, Biederman and colleagues [33] reported that a family history of affective disorders predicted development of bipolar disorder in children with ADHD at 4-year follow-up. Todd and colleagues found an elevated rate of alcoholism in adult male relatives of bipolar children as compared to relatives of children with MDD and healthy volunteers. Paternal affective disorder and alcoholism predicted offspring affective disorder. The authors suggest that corisk for the two disorders in an individual may interact to lower the observed age at onset of one of the two disorders, potentially through genetic and/or environmental interactions [80].

Children who have a parent with bipolar disorder are also at an increased risk for developing mood disorder. In a review of BP offspring studies that included only investigations that evaluated children and adolescents, rates of mood disorders ranged from 5% to 67% compared to rates in offspring of healthy volunteers of 0–38% [81].

Two molecular genetic studies have been reported in children with bipolar disorder [82,83]. The first study examined the linkage disequilibrium of catechol-O-methyltransferase (l-COMT) in bipolar children since the children described in the sample have high rates of rapid and ultradian cycling (75%), and in adults rapid

cycling has been associated with the low-activity allele of l-COMT. Transmission disequilibrium tests were not significant for preferential transmission of l-COMT for the ultradian rapid-cycling subgroup or for the entire sample. The authors suggest several explanations for their finding, including the possibility that ultradian cycling in this pediatric sample may be genetically heterogeneous from the phenomenon in bipolar adults, the ultradian cycling in children may not persist in all of the bipolar children when they reach adulthood, or their sample size may be too small [82]. In the second study, the transmission disequilibrium test for the serotonin transporter-linked promoter region (HTTLPR) short and long alleles was negative in the children with bipolar disorder, suggesting either a lack of involvement of this locus or insufficient power in the study to detect differences [83].

The relationship between velocardiofacial syndrome and pediatric bipolar disorder is of particular interest to understanding the genetic basis of bipolar disorder in children. Velocardiofacial syndrome, a genetic syndrome involving >40 somatic anomalies, as well as learning disabilities and behavioral disorders, is associated with a microdeletion on chromosome 22q11. In a series of patients with velocardiofacial syndrome, 64% met DSM-III-R criteria for a spectrum of bipolar disorder with full syndromal onset in late childhood or early adolescence (mean age at onset 12 years). Given the high prevalence of childhood-onset bipolar disorder in this population, further genetic investigations of chromosome 22 are warranted in the search for a molecular basis of pediatric bipolar disorder [84].

Future familial risk studies, in conjunction with molecular genetic investigations, may help identify the mode of genetic transmission for pediatric mood disorders. Children and adolescents who have a mood disorder and a family history of mood disorders may be the ideal population for performing molecular genetics studies, since this group may have a particularly genetic form of illness.

B. Neurotransmitter Studies

The neurobiological basis of mood disorders involves a range of disturbances in noradrenergic, serotonergic, dopaminergic, cholinergic, GABA-ergic, and other neurotransmitter systems [85]. Evidence from neuroanatomic, neurophysiologic, neurochemical, and behavioral studies in humans and animals supports that mood disorders are modulated by interacting neural networks that are often widely spatially distributed [86–90].

Peripheral studies of neurotransmitters have primarily focused on norepinephrine, serotonin, and acetylcholine [91–94]. Norepinephrine has been the most-studied catacholamine in adults with MDD [95–97]. However, DeVilliers and colleagues [98] found no difference in noradrenergic function between MDD adolescents and healthy controls.

Serotonin (5-hydroxytryptamine) regulation has also been evaluated in adults with MDD [99–102]. Studies measuring baseline CSF 5-hydroxyindole acetic acid (5HIAA) are equivocal. The most comprehensive studies suggest that there is a subgroup (30–40%) of depressed adults with low CSF 5HIAA; this subgroup may show more aggression, anxiety, impulsivity, and suicidality. Ryan and colleagues [103] reported that in response to L-5-hydroxytryptophan (5HT), prepubertal children with MDD (N = 37) secreted less cortisol and more prolactin than normal controls (N = 23), suggesting a dysregulation of central serotonergic systems in childhood MDD. This finding has been confirmed in a more recent study that reported children with a high familial risk for developing MDD secreted similar levels of prolactin in response to a 5HT infusion as MDD children, but significantly more than healthy volunteer children who did not have a family history of mood disorders, suggesting that abnormalities in serotonergic neurons may be a trait marker for childhood MDD [104].

Future studies are necessary to confirm the theoretical framework for the neurotransmitter systems involved in child and adolescent MDD, which was proposed by Rogeness and colleagues [105]. They suggested that dopaminergic function is low (facilitory neurotransmission) and noradrenergic and serotonergic (inhibitory neurotransmission) functions are high.

C. Neuroendocrine Studies

Abnormalities of the hypothalamic-pituitary-adrenal (HPA) axis, the hypothalamic-pituitary-thyroid (HPT) axis, and the hypothalamic-pituitary-growth-hormone (HPGH) axis have been reported in MDD adults. However, abnormal cortisol secretion, as measured by repeated samples over a 24-hour period or by nocturnal sampling, has not been identified in most studies of children and adolescents with MDD [106–109]. In contrast, at the approximate time of sleep onset, MDD adolescents exhibited cortisol elevation [110,111]. In one study, there was a trend toward elevated cortisol levels near sleep onset in adolescents who had recurrent MDD as compared to those who had no further MDD episodes [111]. De Bellis and

colleagues [112] reported that prepubertal MDD children had *lower* cortisol levels during the first 4 hours of sleep compared that did healthy controls.

In contrast to studies involving MDD adults, Birmaher and colleagues [113] found no significant difference in baseline or postcorticotropin-releasing hormone (CRH) stimulation values of cortisol or adrenocorticotropin-releasing hormone (ACTH) between prepubertal children with MDD and healthy controls. Post-CRH ACTH may be elevated in MDD children who have been abused as compared to those who have no history of abuse [114], suggesting that increased ACTH may be associated with stressful life events and not MDD. Nonsuppression of cortisol by dexamethasone has been reported in several studies of MDD children and adolescents [115–119].

Kutcher and colleagues [109] reported that nocturnal growth hormone (GH) secretion was significantly elevated in MDD adolescents as compared to controls. However, this finding has not been replicated [112]. In one study, MDD adolescents did not differ from healthy controls in 24-hour GH measures; however, blunting of GH secretion was evident in MDD adolescents with suicidal ideation but not those without suicidal ideation [120]. Blunting of growth hormone–release in response to hypoglycemia, desipramine, clonidine, and growth hormone-releasing hormone (GHRH) in MDD children and adolescents has been reported, even after the depression remits, suggesting that this may be a trait, rather than state, marker for pediatric MDD [121–123]. Furthermore, in a recent study, Birmaher and colleagues [124] demonstrated blunted GH secretion in response to GHRH in children with a high familial risk for developing MDD as compared to healthy controls without a familial risk for MDD, providing additional support that the decreased growth hormone response is a trait marker for pediatric MDD. While these are among the most replicated neuroendocrine findings in pediatric MDD, GH is regulated by many neurotransmitters, limiting the interpretability of these findings. Moreover, the specificity of these findings remains uncertain [19].

There are several studies examining thyroid abnormalities in children and adolescents with mood disorders. Kutcher and colleagues [109] reported that nocturnal thyroid-stimulating hormone (TSH) values were elevated in children with mood disorder as compared to healthy volunteers, but there was no significant difference in total amount of TSH secreted throughout the night. In a study assessing thyroid hormones in MDD children, Dorn and colleagues [125] reported that all subjects were euthyroid. However,

boys with MDD exhibited lower thyroxine (T4) and TSH levels than control boys. No differences were found between girls with MDD and control girls. Tri-iodothyronine (T3) uptake was lower in the MDD children compared with healthy controls. West and colleagues [126] found that mean serum thyroxine (T4) concentrations were significantly lower in bipolar adolescents with ADHD than in those without ADHD, suggesting that bipolar disorder with ADHD may be a distinct illness.

In summary, neuroendocrine studies provide preliminary data which suggest that some of the abnormalities involved in adult MDD may also be present in childhood and adolescent MDD. However, further research is necessary to determine state, trait, and developmental factors that may contribute to these findings.

D. Sleep Studies

Sleep studies involving children and adolescents with MDD have not consistently found the same changes that have been reported in adults with MDD. Only one of four studies to evaluate sleep in MDD *children* [127–130] identified decreased rapid eye movement (REM) latency and increased sleep latency in MDD children [127]. Puig-Antich and colleagues [131] found that children who had recovered from an episode of MDD had shorter first REM latencies and a greater number of REM periods compared with themselves when depressed and normal children, suggesting that this may be a marker for a prior MDD episode.

Sleep studies of *adolescents* with major depression have inconsistently reported reduced REM latency and prolonged sleep latency in MDD adolescents as compared to healthy volunteers [132–139].

E. Neuroimaging Studies

Brain-imaging techniques available to study mood disorders may be broadly divided into two groups: those that image the *structure* of the central nervous system, which include computed tomography (CT) and magnetic resonance imaging (MRI), and those that image the *function* of the central nervous system, including positron emission tomography (PET), single-photon emission computed tomography (SPECT), magnetic resonance spectroscopy (MRS), and functional magnetic resonance imaging (fMRI). Despite recent advances in MRI techniques permitting high-resolution thin-slice images for more valid morpho-

metric analyses and the development of noninvasive functional methodologies such as fMRI and MRS, there are few neuroimaging investigations involving children and adolescents with mood disorders.

1. Structural Neuroimaging

There have been few structural neuroimaging studies of children and adolescents with MDD. Hendren and colleagues used MRI to study a mixed group of 37 psychiatric inpatients between the ages of 8 and 12 years, three of whom were hospitalized for treatment of MDD [140]. Two of the three adolescents with MDD had clinical abnormalities on MRI, which included asymmetrical lateral ventricles and a small area of abnormal signal intensity in the "left anterior basal ganglia or medial temporal lobe." In the only published study to examine brain morphometry in pediatric MDD, Steingard and colleagues [141] retrospectively evaluated the MRI scans of children with MDD or dysthymia (N = 65) and found that frontal lobe volume was decreased and lateral ventricular volume was increased as compared to hospitalized psychiatric controls (N = 18). No group difference was found in total cerebral volume. These results are similar to findings from MRI studies of adults with MDD that suggest prefrontal abnormalities [142,143].

Botteron and colleagues [144] compared bipolar children and adolescents to healthy subjects using MRI and found reduced structural asymmetry of the cerebral hemispheres. Additionally, four of the eight bipolar subjects had ventricular abnormalities or deep white matter hyperintensities as compared to one of five control subjects, although the sample size was too small to provide statistical power. To our knowledge, there are only two additional published brain morphometry studies of adolescents with bipolar disorder, both from the same research group [145,146]. The first study compared cortical regions of adolescents with schizophrenia and bipolar disorder and then combined patient groups and compared them to healthy volunteer adolescents. When patient groups were combined, they had significantly reduced intracranial volumes, elevated frontal and temporal fluid fractions, and decreased brain circumferences and thalamic volumes as compared to healthy volunteers; however, there were no differences between patient groups. Furthermore, the authors examined effect sizes for the differences in structures between bipolar adolescents and healthy controls, and found enlarged frontal and temporal fluid, lateral ventricular volumes, and decreased intracranial volumes (large effect sizes)

in bipolar adolescents. Because of multiple comparisons, the authors caution the interpretability of these results. In summary, these studies suggest that, similar to findings from morphometric studies of adults with bipolar disorder, frontal-temporal abnormalities may also be present in bipolar adolescents. Studies of adults with mood disorders have also found abnormalities in the hippocampus, amygdala, thalamus, caudate, putamen, globus pallidus, and cerebellar vermis [147]. Future morphometric studies of these brain regions in children and adolescents with mood disorders are necessary.

2. Functional Neuroimaging

PET and SPECT studies in adults with mood disorders have produced variable results, possibly owing to differences in subject selection criteria, diagnostic procedures, severity of illness, medication status, demographic characteristics, imaging techniques, and analytic methods. FMRI is a newer functional imaging technique that does not involve exposure to ionizing radiation and thus is repeatable and noninvasive, making it particularly advantageous for studies involving children and adolescents.

To our knowledge, there have been only three published functional neuroimaging studies in children or adolescents with mood disorders. Kowatch and colleagues [148] used technetium-99m hexamethylpropylene amine oxime (^{99m}Tc-HMPAO) single photon emission tomography (SPECT) to compare relative regional cerebral blood flow (rCBF) between unmedicated MDD adolescents (N = 7) and normal controls (N = 7). The authors describe relative increases in rCBF in the mesial, right superior-anterior, and left inferolateral temporal lobe and decreases in the left parietal lobe, anterior thalamus, and right caudate in MDD adolescents. These findings suggest that adolescents with MDD exhibit rCBF abnormalities similar to those found in adults with MDD with involvement of the limbic-thalamic-cortical circuit and portions of the basal ganglia [88,89].

In another ^{99m}Tc-HMPAO SPECT study, evaluating untreated MDD adolescents (N = 14) and age-matched normal controls (N = 11), Tutus and colleagues [149] calculated a relative perfusion index (PI) as the ratio of regional cortical activity to the whole brain activity and reported significant reduced PI in the left anterofrontal and left temporal cortical regions of untreated MDD adolescents. SPECT scans repeated after MDD adolescents were treated and their depression remitted demonstrated a return toward normal.

This study suggests that adolescents with MDD may have state-dependent regional cerebral blood flow deficits in frontal and temporal regions and right-left perfusion asymmetry compared with normal subjects, similar to results in studies of MDD adults [87].

In a more recent study, Dahlstrom and colleagues [150] used SPECT to study serotonin and dopamine transporter levels in drug-naïve children and adolescents with MDD (N = 31) and children and adolescents without depression (N = 10). They found significantly higher serotonin transporter availability in MDD children in the hypothalamic/midbrain region suggesting that abnormalities in serotonin might play a role in the physiology of pediatric MDD.

Proton magnetic resonance spectroscopy (MRS) is a noninvasive neuroimaging technique that allows in vivo measurement of brain neurochemistry. The major components observed in a proton spectrum of the brain are N-acetylaspartate (NAA), glutamate/glutamine/GABA (Glx), creatine (Cr), choline (Cho), and *myo*-inositol (mI). Steingard and colleagues [151] found elevated Cho/Cr ratios in the medial frontal gray matter of MDD adolescents as compared to healthy volunteers, providing additional evidence for frontal abnormalities in MDD adolescents. Castillo and colleagues [152] found increased prefrontal and temporal Glx concentrations in children with bipolar disorder, suggesting that in addition to structural abnormalities, neurochemical dysfunction may be present in these brain regions.

Although the exact mechanism by which lithium exerts its antimanic and antidepressant effects is unknown, at therapeutic concentrations, lithium is an inhibitor of inositol monophosphatase and polyphosphate-1-phosphatase, which are involved in replenishing *myo*-inositol supplies. Thus, it is postulated that the therapeutic effects of lithium are mediated through depletion of *myo*-inositol [153]. Davanzo and colleagues [154] compared anterior cingulate *myo*-inositol levels in manic children (N = 11) before and 1 week after lithium treatment and found that acute lithium treatment was associated with a significant reduction in the *myo*-inositol/Cr ratio, particularly in lithium responders as compared to nonresponders. The authors also reported that at baseline bipolar children had an elevated *myo*-inositol/Cr ratio as compared to demographically matched healthy volunteers. However, many of the bipolar children were taking several concomitant medications during the study. Nonetheless, to our knowledge, this is the first study in bipolar youth to provide support for lithium-induced modification of the phosphoinositide cycle.

Additional structural and functional neuroimaging investigations are necessary to further characterize the neurophysiology of pediatric mood disorders. Furthermore, combining longitudinal imaging and outcome studies will maximize the interpretability of the imaging data and identify neurobiological predictors of illness course and treatment response.

IV. TREATMENT

A. Depressive Disorders

During the past 10 years there have been several treatment studies that have provided important information regarding the treatment of MDD in children and adolescents. In general, tricyclic antidepressants (TCAs), i.e., imipramine, amitriptyline, and nortriptyline, are not more efficacious than placebo for treating MDD in children or adolescents and are not indicated as first-line agents for this disorder. Moreover, selective serotonin reuptake inhibitors (SSRIs), i.e., fluoxetine, paroxetine, and sertraline, have been show to be effective in treating both children and adolescents with MDD. However, there are very few placebo-controlled studies of SSRIs for the treatment of children and adolescents with MDD. Although there are several ongoing studies assessing the long-term efficacy of SSRIs for the treatment of pediatric depression, there are currently no published maintenance treatment studies. Specific psychotherapies such as cognitive behavior therapy and interpersonal psychotherapy may also be helpful in treating children and adolescents with MDD. However, it is unclear how best to integrate psychotherapy and antidepressant treatment.

1. Pharmacotherapy

There have been six double-blind trials of TCAs for the treatment of MDD in children and six double-blind trials in adolescents. The consensus from these 12 trials is that TCAs are no more effective than placebo in child and adolescent MDD and are thus not indicated as first-line treatments for MDD in children or adolescents [155]. However, these studies generally were of small samples of patients with mild to moderate depression. Additionally, some of the studies included patients with secondary depression who are more likely to respond to placebo. In fact, placebo response in most of these studies was 50–70%, greater than that observed in placebo-controlled studies of depressed

adults. Moreover, small dosages were administered for possibly too short a period of time to observe large response rates [155]. There have been six reports of sudden cardiac death in children and adolescents treated with the TCA desipramine, which also limits the use of these agents in child and adolescent MDD [156,157]. Current recommendations are to use TCAs as fourth- or fifth-line treatments after adequate trials of other agents [158]. Monoamine oxidase inhibitors (MAOIs) may also be effective for MDD adolescents who are partial responders to TCAs. However, side effects may be severe and include hypertensive crisis if a patient is noncompliant with a low-tyramine diet [159].

The SSRIs are well tolerated in children and adolescents and have many fewer side effects than TCAs [160]. There have two double-blind trials of fluoxetine and several open studies that have shown fluoxetine to be efficacious in the treatment of MDD in children and adolescents. In the first study, Simeon and colleagues treated 40 adolescents with MDD with fluoxetine in a placebo-controlled double-blind study. They reported that approximately two-thirds of the patients showed marked or moderate clinical global improvement with both fluoxetine and placebo, and fluoxetine was superior to placebo on all clinical measures except for sleep disorder [161]. In 1997, Emslie and colleagues [162] reported the results of a second double-blind placebo-controlled study of fluoxetine in children and adolescents (ages 8–18 years) with MDD [162]. There were 96 subjects randomized, and 27/48 (56%) were rated as much or very much improved on fluoxetine compared with 16/48 (33%) on placebo ($P = .02$). There have been two open-label prospective studies in which sertraline was reported to be effective in treating adolescent MDD [163,164]. Results from the largest double-blind study to date of an SSRI in children and adolescents with MDD (N = 285) found paroxetine was superior to both imipramine and placebo [165]. All of the SSRIs have side effects, including mild gastrointestinal upset, sedation, and behavioral activation.

Less information is available regarding the use of other "atypical" antidepressant agents in MDD children and adolescents. Some promising results have been reported with nefazodone [166], but a small placebo-controlled trial of venlafaxine found no difference from placebo [167].

There are several studies of lithium in children and adolescents with MDD. Geller and colleagues [168] evaluated the efficacy of lithium vs. placebo in the

treatment of adolescents with MDD who were refractory to tricyclics and who had a family history of bipolar disorder. The rationale for this study was that prepubescent children with MDD and a family history of bipolar disorder commonly develop bipolar disorder. However, they found no group difference in response, suggesting that lithium may not be effective in the treatment of patients with prepubescent MDD who are at high familial risk for developing bipolar disorder. However, there are two open studies suggesting that lithium may be effective in the augmentation of tricyclics for refractory MDD in children and adolescents [169,170]. Bupropion may be effective for treating depressive disorders with comorbid ADHD, although controlled trials are needed [171].

2. Psychotherapy

There have been no controlled trials of psychoanalytic therapy for the treatment of children and adolescents with MDD. However, recent research has demonstrated that certain types of short-term psychotherapy, particularly cognitive behavior therapy (CBT), are effective for treating MDD in children and adolescents [172]. Brent and colleagues studied 107 adolescent patients with MDD who were randomly assigned to individual CBT, systemic behavior family therapy, or individual nondirective supportive therapy [173]. They found that the adolescents who were treated with CBT had a lower rate of MDD at the end of treatment that those who were treated with supportive therapy. Moreover, adolescents with MDD treated with CBT had higher remission rates that the two other groups. However, when the same subjects were evaluated 2 years after this trial, there were no long-term differences in rates of recovery or recurrence of MDD [174].

Another short-term psychotherapy, interpersonal therapy (IPT), focuses on working through disturbed personal relationships that may contribute to depression. Mufson and colleagues recently performed a controlled, 12-week trial of IPT in which 48 MDD adolescents were randomly assigned to either weekly IPT or clinical monitoring, which was the control condition [175]. In their intent-to-treat sample, 75% who received IPT compared with 46% who received the control condition met recovery criteria at the end of 12 weeks of treatment. They concluded that IPT is efficacious for reducing depressive symptoms and improving social functioning and interpersonal problem-solving skills in MDD adolescents.

3. Treatment Guidelines for Child and Adolescent MDD

A consensus conference was held in 1998 in which a group of national experts in child and adolescent mood disorders developed a consensus algorithm (the Texas Medication Algorithm Project; TMAP) for the treatment of MDD in children and adolescents [176]. The TMAP MDD treatment is illustrated in Figure 1. The first stage in this algorithm is monotherapy with a SSRI. If the child or adolescent does not respond to the first SSRI, then the recommendation is to switch to an alternative SSRI. The seventh and last step of this algorithm is to use ECT. This TMAP algorithm is very useful, as it embodies the current state of knowledge for the treatment of child and adolescent MDD and offers clinicians a rational way to proceed in treating this disorder.

B. Bipolar Disorders

Treatment of pediatric bipolar disorder consists of two phases—treatment of the acute affective episode and maintenance treatment. There have been very few controlled studies of acute treatment for mania in children and adolescents bipolar disorder [177]. Furthermore, there has only been one maintenance treatment study [178]. The American Psychiatric Association issued their "Practice Guideline for the Treatment of Patients with Bipolar Disorder" in which the treatment of bipolar disorder in children and adolescents is also reviewed. These practice guidelines are useful for a further review of several topics that are beyond the scope of this chapter [179].

1. Lithium

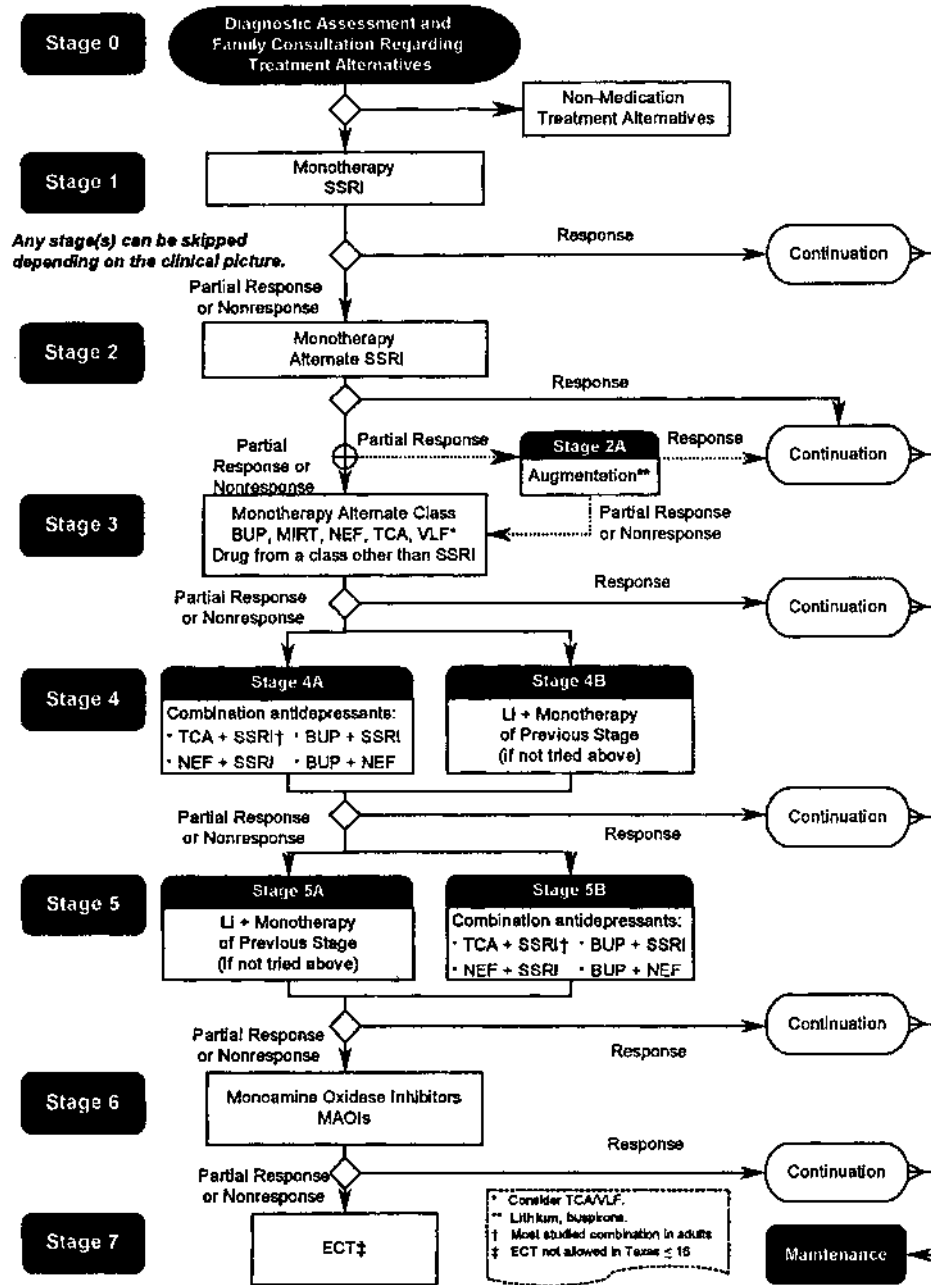
Lithium is the most studied treatment for pediatric bipolar disorder and is the only Food and Drug Administration (FDA)-approved medication for the treatment of acute mania and bipolar disorder in adolescents or children (ages 12–18 years). In a survey of the literature, Youngerman and Canino [180] found that in open trials of lithium in children with bipolar disorder, the positive response rate was 66%, similar to that seen in adults treated with lithium. There have been four [181–184] crossover studies of lithium in pediatric bipolar disorder. The average number of subjects in these studies was 18 and response rates ranged from 33% to 80%. In the only placebo-controlled prospective study of a mood stabilizer in pediatric bipolar disorder, Geller and colleagues [177] administered lithium in a double-blind fashion to 25


Figure 1 Medication algorithm for treating children and adolescents who meet *DSM-IV* criteria for major depressive disorder. The Children's Medication Algorithm Project algorithms are in the public domain and may be reproduced without permission, but with appropriate citation. The authors bear no responsibility for the use of these guidelines by third parties. SSRI = selective serotonin reuptake inhibitor; BUP = bupropion; MIRT = mirtazapine; NEF = nefazodone; TCA = tricyclic antidepressant; VLF = venlafaxine; ECT = electroconvulsive therapy. Adapted from Crismon et al. (1999).

adolescents with bipolar disorder and substance dependence. After 6 weeks of treatment, subjects treated with lithium showed a significant decrease in substance use and a significant improvement in global assessment of functioning (46% in the lithium-treated group vs. 8% in the placebo group). This report clearly demonstrated the efficacy of lithium carbonate for the treatment of bipolar adolescents. Predictors of poor lithium response in children and adolescents include prepubertal onset [185], presence of co-occurring ADHD [186], personality disorders [187], and mixed mania [188]. In general, for the treatment of an acute mood episode in children and adolescents, lithium should be titrated to a dose of 30 mg/kg/day in three divided doses, which will typically produce a level of 0.8–1.2 mEq/L.

Lithium may also be useful for the maintenance treatment of bipolar disorder in children and adolescents. Since the majority of patients with bipolar disorder experience recurrent episodes of illness, maintenance treatment is generally advised. In the only maintenance treatment study for pediatric bipolar disorder, Strober and colleagues [178] conducted an 18-month naturalistic follow-up study of 37 adolescents whose bipolar disorder had been stabilized with lithium during hospitalization. Despite intensive follow-up, 35% of these patients discontinued lithium, and 92% of those who discontinued subsequently relapsed as compared to 38% of those who were lithium compliant, supporting the possible prophylactic effect of lithium [178].

Common side effects of lithium in children and adolescents include hypothyroidism, nausea, polyuria, polydipsia, tremor, acne, and weight gain. Lithium levels and thyroid function tests should be carefully monitored, and thyroid supplementation should be initiated when indicated [189].

2. Antiepileptics

Response rate to divalproex in open-label studies involving manic adolescents has ranged from 53% to 82% [39,190–193]. The successful use of carbamazepine as monotherapy and adjunctive treatment has also been reported in children and adolescents with bipolar disorder [39,194,195].

In the only study to directly compare mood stabilizers, Kowatch and colleagues [39] compared lithium, divalproex, and carbamazepine for the treatment of 42 acutely manic or hypomanic children and adolescents during a 6-week random-assignment, open prospective investigation. The mean response rates of the intent to treat sample were 40% and 53% for divalproex sodium, 46% and 38% for lithium, and 31% and 38% for carbamazepine as measured by a CGI change score of 1 or 2 and a >50% change from baseline Young Mania Rating Scale, respectively. Divalproex demonstrated the largest effect size (1.63), followed by lithium (1.06) and carbamazepine (1.00). All three drugs were fairly well tolerated, with nausea being the most common side effect for each of the medications. In general, divalproex should be titrated to a dose of 20 mg/kg/day, which will typically produce a serum level of 80–120 µg/ml, and carbamazepine should be titrated to a dose of 15 mg/kg/day to produce a serum level of 7–10 µg/mL [39].

Common side effects of divalproex in children are weight gain, sedation, and tremor [196]. There has been considerable concern regarding the possible association between divalproex and polycystic ovarian syndrome (PCOS). Initially, the reports of PCOS were in women with epilepsy who were taking divalproex [197]. It was unclear whether this association was from divalproex-induced obesity, which might lead to elevated androgen levels, a direct effect of divalproex, or related to epilepsy. Recently, Bauer and colleagues reported that epilepsy, and not the medications may be associated with increased risk for PCOS [198]. Further investigations of the risk of developing PCOS for female bipolar adolescents are necessary. Carbamazepine is less commonly used in children because of the potential for developing aplastic anemia and severe dermatological reactions, such as Stevens-Johnson syndrome. Other frequent side effects include hyponatremia, nausea, and sedation [39].

Since 1990 there have been several new anticonvulsants developed for the treatment of epilepsy. Although data are limited regarding the efficacy and tolerability of these agents for the treatment of bipolar disorder, they are of potential interest because of decreased side effects and drug interactions. There have been two positive reports with a total of 17 bipolar children and adolescents who were treated with lamotrigine as adjunctive therapy [199,200]. Lamotrigine was well tolerated, and none of the children developed a rash. The most common side effects of lamotrigine are dizziness, tremor, somnolence, nausea, asthenia, and headache in 8–20% of patients. Rarely, severe cutaneous reactions such as Stevens-Johnson syndrome and toxic epidermal necrolysis have been described [201]. The risk of serious rashes is approximately three times greater in children and adolescents <16 years old compared with adults and is higher in patients taking concomitant valproate

[202]. Therefore, its use in treating children and adolescents is somewhat limited.

Although preliminary evidence from open studies in adults suggested gabapentin was effective as adjunctive therapy and monotherapy for the treatment of bipolar mania and depression and as an augmenting agent in the maintenance phase of bipolar disorder [203], more recent double-blind controlled studies of gabapentin as adjunctive therapy to lithium or valproate and as monotherapy suggest it is no more effective than placebo for the treatment of mania [204,205]. There has been one case report suggesting that gabapentin may be useful for the treatment of adolescent mania, however, further controlled studies are necessary [206]. Gabapentin is generally well tolerated in children and adolescents [207,208] and may therefore be particularly useful for treating bipolar youth who also have an anxiety disorder [204].

Preliminary data from open studies suggest that topiramate has antimanic properties when used as adjunctive treatment and as monotherapy [209]. There is one case report of a bipolar child who was treated with topiramate and divalproex and experienced significant cognitive dysfunction [210]. Word-finding difficulties have been reported in up to one third of patients treated with topiramate [211]. Encephalopathy has also been reported in patients treated with topiramate, particularly when it is used concomitantly with valproate [212,213]. In contrast to other medications used to treat bipolar disorder, topiramate is associated with anorexia and weight loss [203,209], which is advantageous in some children and adolescents who have gained weight from treatment with other psychotropics.

Preliminary uncontrolled data suggest effectiveness of other new antiepileptics, including tiagabine, oxcabamazepine, and zonisamide in adults with bipolar disorder. Currently, there are no reports of the effectiveness of these medications for the treatment of children and adolescents with bipolar disorder. Other new antiepileptic agents, which have not yet been investigated in the treatment of patients with bipolar disorder, include levetiracetam and vigabatrin.

3. Atypical Antipsychotics

There have been several case series and open-label reports suggesting that atypical antipsychotics such as clozapine [214–216] olanzapine [217–219], risperidone [220], and quetiapine [221,222] are effective for the treatment of pediatric bipolar disorder. In a more recent double-blind placebo-controlled study of 30 manic or mixed adolescents, quetiapine in combination with divalproex was found to reduce symptoms of mania, depression, and psychosis better than divalproex monotherapy, suggesting that quetiapine is effective for the treatment of adolescents with bipolar disorder. In this study, quetiapine was titrated to a dose of 450 mg/day and was well tolerated. Sedation was the most common side effect reported in both treatment groups [223].

4. Other Pharmacological Agents

Although open-label and controlled data are lacking, other psychotropic medications such as nimodipine, a calcium channel blocker [224] melatonin [225], and omega-3 fatty acids may be effective for the treatment of pediatric bipolar disorder.

Stimulant medications may be effective for the treatment of comorbid ADHD in children and adolescents with bipolar disorder; however, adequate mood stabilization with the other pharmacological treatments is necessary prior to initiating stimulant medications [43,226].

5. Treatment of Bipolar Disorders

It is reasonable to maintain a child or adolescent who has had a single manic episode on a mood-stabilizing agent for 12–18 months, and then if he or she is euthymic and asymptomatic to gradually reduce the mood stabilizing agent over 2–3 months [227]. If manic symptoms recur, the mood-stabilizing agent should be reintroduced. If the child is not responding or partially responding to a mood stabilizer, the addition of a second mood stabilizer or an atypical antipsychotic might be required.

Some bipolar children and adolescents maintained on a mood-stabilizing agent may develop a depressive episode after an acute manic episode and while maintained on a mood-stabilizing agent. The role of antidepressants in the treatment of bipolar depression remains unclear. Lithium is considered the first-line therapy for the treatment of acute bipolar depression in adults, since recent evidence supports that typical antidepressants may exacerbate the course of bipolar disorder by precipitating mixed or manic states [228]. However, in children and adolescents the efficacy of lithium in the treatment of bipolar depression is unclear. Recently, in a retrospective chart review and the only report to assess the treatment of bipolar depression in children and adolescents, Biederman and colleagues [229] found that depressive symptoms were 6.7 times more likely to improve when patients

received an SSRI than when they did not. In contrast, tricyclics, stimulants, mood stabilizers, and typical antipsychotics were not significantly associated with improvement in depressive symptomatology. SSRIs may have mood-destabilizing effects; however, because too few subjects were being treated with mood stabilizers at the time when manic symptoms reemerged, the authors did not evaluate the protective effects of mood stabilizers in preventing the destabilizing effects.

Other antidepressants, such as bupropion, may be less likely to precipitate manic symptoms [230], although some reports suggest that this may not be the case [231]. Nonetheless, when treating a bipolar child with antidepressants, it is important to monitor the patient's mood and behavior carefully for any signs of mania, since these agents may sometimes precipitate a manic episode.

There have been no treatment studies involving children and adolescents with hypomania (bipolar II disorder), cyclothymia, or bipolar NOS. Mood stabilizers, as well as antidepressants, may be effective in treating these disorders; however, future investigations are necessary [232].

A multimodal treatment approach, combining psychopharmacological and psychotherapeutic therapies for pediatric bipolar disorders, is almost always useful. The psychotherapeutic strategies previously discussed for depressive disorders in children and adolescents may also be indicated for the management of bipolar disorders. However, psychotherapeutic interventions have not been systematically studied in bipolar youth. It is necessary to educate children and adolescents and their families and teachers about bipolar illness, the importance of medication compliance, and the need for regular monitoring of mood stabilizer serum levels and other laboratory measures. Instructing patients and/or their parents to keep a daily record of the level of depressive and manic symptoms ("mood charting") is a tool that may help monitor symptom presence and recurrence [233].

V. FUTURE DIRECTIONS

The recognition and treatment of pediatric mood disorders remains a major challenge for clinicians. Despite recent advances in the field, investigations in the areas of outcome, neurobiology, and treatments are necessary to advance our understanding of depressive and bipolar disorders in children and adolescents.

Anxiety Disorders in Childhood and Adolescence
Basic Mechanisms and Therapeutic Interventions

TIFFANY FARCHIONE, SHAUNA N. MACMILLAN, and DAVID R. ROSENBERG

Wayne State University, Detroit, Michigan, U.S.A.

I. INTRODUCTION

Anxiety can be defined as dread or apprehension [1]. Anxiety in and of itself is not considered a disorder and is seen across the age span and may even be adaptive in certain situations (e.g., anxiety one might feel in a threatening environment such as during an earthquake). In contrast, anxiety disorders are characterized by pathologic anxiety, in which anxiety interferes with achievement of goals or quality of life. Thus, to diagnose a particular anxiety disorder in a person, interference in psychosocial and/or academic/occupational functioning must be present. In the pediatric population, anxiety disorders are relatively common (5–18%) [see 2 for review], with prevalence rates comparable to some physical disorders, such as asthma and diabetes [3].

Nonetheless, recognition of child and adolescent anxiety disorders has been slow in coming. In the first edition of the *Diagnostic and Statistical Manual of Mental Disorders* [4], there were few references to childhood anxiety disorders. "Overanxious reaction of childhood" first appeared in the *DSM-II* [5]. Then, in the *DSM-III* [6], four childhood anxiety disorders were recognized (overanxious disorder, separation anxiety disorder, simple phobia, and social phobia), as well as other childhood disorders with prominent anxiety

symptoms. That edition also acknowledged that adult anxiety disorders could begin in childhood. Finally, in the *DSM-IV* [7], the terminology used to describe childhood anxiety disorders was changed, and became more consistent with the adult terminology. For instance, "overanxious disorder" was changed to "generalized anxiety disorder with childhood onset." Although these changing criteria have facilitated the assessment and treatment of childhood anxiety disorders, they have left researchers with a "moving target," making it difficult to apply earlier research to current diagnoses [8].

Neurobiologic and clinical trials in pediatric anxiety disorders have lagged far behind adult studies. For instance, recent reviews of the literature reveal a paucity of neuroimaging data in childhood anxiety disorders [9–11], and most of these studies have been conducted in the past 10 years. However, through the usetremendous strides are now being made toward better characterizing the developmental neurological underpinnings of these debilitating illnesses. Studying these disorders in children near the onset of illness also has tremendous advantages. Specifically, many potentially confounding factors are eliminated including central nervous system (CNS) active medications and long-term illness duration. Recent investigation suggests that pediatric and adult anxiety may have distinct

functional brain activation patterns (Fig. 1). It should be noted, however, that several unique challenges are involved in studying children and adolescents with anxiety disorders. For instance, there are inadequate normative data and imprecise definition of groups (note the changing definition of overanxious disorder/generalized anxiety disorder). Also, a lack of well-standardized and reliable methods of neurobiologic measurements has made comparisons from lab to lab problematic. Moreover, without rapid, standardized, automated methods of measuring, analysis of large samples is difficult [9].

Not only has research examining the neurobiologic basis of childhood anxiety lagged behind adult studies, but treatment studies have only recently begun to focus on children. Treatment research is admittedly often more complex in children although the U.S. government is now mandating that medications used in pediatric populations undergo rigorous testing. It is no

longer acceptable for pharmaceutical companies to develop a particular compound, test it exclusively in adults, and then extrapolate the data to child populations. This has enormous implications for the psychopharmacologic study of pediatric anxiety disorders and will undoubtedly lead to more effective treatment of these children. Pediatricians have long recognized that children are not simply "little adults." Recent determination that the tricyclic antidepressants, while very effective in treating adults with major depressive disorder (MDD), are no more effective than placebo in treating child and adolescent MDD [12] underscores this point.

There are currently few controlled trials of either psychotherapeutic or psychopharmacologic interventions for children with anxiety disorders. With regard to psychotherapeutic treatments, cognitive behavioral therapy (CBT) is currently regarded by many as the therapy of choice because, among the various psycho-

The regions outlined include the dorsolateral prefrontal cortex (above) and the amygdala (below). The gray shades indicate the magnitude of signal intensity change in these regions. The lighter shades of gray are indicative of greater activation than the red color. (Courtesy of Dr. Deborah Yurgelun-Todd, Cognitive Neuroimaging and Neuropsychology Laboratory, McLean Hospital.)

social approaches, it is the only treatment with controlled data supporting its efficacy [13]. CBT has been shown to be effective both immediately posttreatment [14–19] and at 6- or 12-month follow-up [17–19].

II. CHILDHOOD ANXIETY DISORDERS

A. Separation Anxiety Disorder

Separation anxiety disorder (SAD) is characterized by excessive anxiety concerning separation from the home or a major attachment figure [7]. It is one of the most common childhood anxiety disorders, with estimates of prevalence ranging from 3.5% to 5.4% [20]. As many as 33% of children presenting to outpatient anxiety disorder clinics will have SAD as their primary diagnosis [21]. Although separation anxiety is considered developmentally normal beginning ~ 10 months of age, it typically wanes by ~ 18 months [3]. Most children can accept the temporary absence of their primary attachment figure, usually their mother, and be comforted by others by age 3 years [22]. By definition, SAD must have its onset before age 18 years, although some suggest that an adult-onset form of this disorder may exist [23]. SAD is seen most often in prepubertal children [24], with an average age of onset of ~ 7.5 years [25]. Clinical samples suggest an equal prevalence in boys and girls [25], but epidemiologic studies point to a female predominance [26].

Children with SAD may refuse to go to school, be reluctant to sleep alone, have nightmares about separation, or have physical complaints. Different symptoms are more prominent depending on the age of the child. Children under 8 years old typically exhibit school refusal and excessive fear that harm will come to a parent; those 9–12 years of age have excessive distress at the time of separation; those aged 13–16 years have school refusal and physical complaints [3].

As with all anxiety disorders, comorbidity is common in SAD. For instance, in children with comorbid tic disorders and anxiety, Coffey et al. [27] demonstrated that SAD, in particular, may be associated with tic severity. In addition to comorbidity, SAD may be a risk factor for developing other anxiety disorders. In a retrospective survey of adults with anxiety disorders, Lipsitz et al. [28] found a higher prevalence of childhood SAD in adults with two or more anxiety disorders, suggesting that SAD may be a risk factor for multiple anxiety disorders. A number of recent studies have focused on a potential role for SAD as a predictive factor in the development of panic disorder in

adolescence and adulthood. Silove et al. [29] found that women with panic disorder reported a higher rate of childhood SAD, and Battaglia et al. [30] suggested that SAD may be a predictor for early onset of panic disorder.

Some studies have suggested that SAD is more common in young children, while other anxiety disorders emerge in adolescence [31,32]. Westenberg et al. [33] have suggested that SAD is more likely to develop in children with lower levels of psychosocial maturity, generalized anxiety disorder (GAD) is more likely in children with higher levels of psychosocial maturity, irrespective of chronological age.

Little is known about the biological processes underlying SAD. Recently, however, studies have begun to implicate abnormal carbon dioxide (CO_2) sensitivity in the pathogenesis of SAD and other anxiety disorders [34–38]. Pine et al. [34] suggested that level of anxiety was related to perceived elevations in CO_2. To test this hypothesis, they compared anxiety symptoms in children with congenital hypoventilation syndrome, children with other chronic illnesses, and healthy controls. Children with congenital hypoventilation syndrome had significantly fewer anxiety symptoms than controls, and controls had fewer than the chronically ill group. For children meeting criteria for an anxiety disorder, the greatest difference in prevalence was between the congenital hypoventilation group (15%) and children with asthma (47%). To examine the underlying physiology of these differences, Pine et al. [35,36] compared ventilatory function in children with anxiety disorders to healthy controls during CO_2 inhalation and while breathing room air. Children with anxiety disorders had larger minute ventilation and higher respiratory rate during CO_2 inhalation, and more variable breathing on room air. These differences correlated with subjective symptom ratings, and findings were consistent with adult studies in patients with panic disorder. Of note, the changes experienced by anxious children during CO_2 inhalation were considered similar to physiologic changes experienced by adults during panic attacks, and these changes were especially pronounced in children with SAD.

Stress-induced increases in catecholamines and glucocorticoids have been implicated in the pathogenesis of many illnesses, including anxiety disorders. In addition to metabolic responses, emotional and cognitive responses to stressors may be mediated by adrenal hormones and central corticotropin-releasing factor (CRF) systems [39]. In an animal model of separation anxiety, Lyons et al. [40] showed that, upon separation

from a group, squirrel monkeys had increased plasma cortisol and adrenocorticotropic hormone (ACTH), as well as higher levels of cerebrospinal fluid (CSF) homovanillic acid (HVA). In a review of preclinical data, Heim and Nemeroff [41] found a suggestion in the literature that early-life stress results in persistent central CRF hyperactivity and increased stress reactivity in adulthood. Consistent with these data, women who were sexually abused in childhood have increased pituitary-adrenal and autonomic responses [42].

To date, there are few double-blind, placebo-controlled studies of psychopharmacologic treatment for SAD. However, data suggest that the tricyclic antidepressant (TCA) imipramine may be an effective treatment for SAD [43]. Three children with severe SAD and comorbid panic disorder and agoraphobia improved on a combination of imipramine and alprazolam [44]. In a study conducted by Gittelman-Klein and Klein (45) comparing 6 weeks of treatment with imipramine + a special psychosocial treatment program vs. placebo + psychosocial treatment for 6 weeks in 20 children 7–15 years of age with school refusal, a phenomenon closely associated with SAD [24], school attendance and anxiety were significantly improved in patients treated with imipramine as compared to placebo. They were not able to confirm this finding in subsequent investigation [46]. Berney et al. [47] also reported no superiority of clomipramine vs. placebo in treating children with school phobia. In a 4-week double blind, placebo-controlled study of clonazepam (0.5–2 mg/day) in 15 anxious children suffering primarily from SAD, Graae et al. [48] reported that clonazepam treatment was not superior to treatment with placebo. It should be noted that many clinicians use buspirone for SAD either alone or in combination with other medication and behavioral treatments. While there has been no controlled study of its use for SAD, there are case studies suggesting possible efficacy [49,50].

More recent investigation of imipramine vs. placebo in combination with CBT suggests efficacy and safety of the imipramine + CBT combination over placebo + CBT [51]. This study defined 75% school attendance as representing treatment remission. Over 50% of patients treated with imipramine achieved remission, whereas only 16% treated with placebo achieved remission.

In spite of the aforementioned possible benefit of the TCA imipramine in combination with CBT, in recent years, the selective serotonin reuptake inhibitors (SSRIs) are becoming the first-line treatment for all anxiety disorders including SAD. This reflects their more favorable side-effects profile and recent investigation suggesting efficacy in non–obsessive-compulsive disorder (OCD) anxiety disorders. Open-label fluoxetine was reported to be effective in children with non-OCD anxiety disorders including SAD [52]. More recently, the Research Units of Pediatric Psychopharmacology (RUPRP) Anxiety Group [53] compared fluvoxamine to placebo in a double-blind 8-week comparison of 128 children and adolescents with GAD, SAD, and social phobia. Fluvoxamine was superior to placebo in reducing anxiety in all three conditions, with 79% of patients responding to fluvoxamine as compared to < 30% responding to placebo. Mean doses of fluvoxamine were 100 mg/day with doses started at 25 mg/day and titrated to a maximum of 250 mg/day in 6 to 12-year-old children and 300 mg/day in teenagers 13–17 years of age. It is particularly noteworthy that the improvement in pediatric anxiety disorder patients receiving fluvoxamine was greater than improvement reported in adults treated with benzodiazepines or TCAs. Walkup [54] has recently reported that long-term treatment with fluvoxamine of non-OCD anxiety can be effective with additional benefit being noted after the initial acute trial of the SSRI. It is unlikely that fluvoxamine will be FDA approved on the basis of this study, since the FDA requires that investigations of medication be targeted toward one specific disorder rather than the three anxiety disorders studied by the RUPP Anxiety Group [55]. While many clinicians continue to prescribe benzodiazepines either prior to or during the titration phase of SSRIs (whose effect can be delayed 6–8 weeks), caution is indicated, particularly if there is a history of substance abuse in the child and/or family. Short-term use of benzodiazepines such as alprazolam or clonazepam is recommended. There are no published data on the other SSRIs.

B. Generalized Anxiety Disorder (formerly Overanxious Disorder)

Generalized anxiety disorder (GAD) is characterized by excessive fear or worry about a number of different events or activities for at least 6 months [7]. In previous versions of the DSM, GAD was known as overanxious disorder (OAD), and, while most of the diagnostic criteria are comparable, the OAD criteria for excessive self-consciousness and need for reassurance are not required to diagnose GAD. Prevalance estimates for GAD/OAD range from 2.4% to 6% of children [56,57]. In one of the largest samples, Whitaker et al. [58] reported a lifetime prevalence of GAD in

adolescents of 3.7%. There is an approximately equal prevalence of GAD in boys and girls until adolescence, at which time GAD becomes more prevalent in females [59].

GAD can be differentiated from other anxiety disorders based on the diffuse nature of the anxiety symptoms. In GAD, fear and anxiety are experienced in a number of situations. In contrast, the primary fear in SAD is of separation and, in panic disorder, anxiety centers around the fear of having a panic attack [60]. Among the primary worries experienced by children with GAD are concerns about competence and performance in school and athletic activities [7]. Anxiety is often accompanied by somatic symptoms such as restlessness, fatigability, difficulty concentrating, irritability, muscle tension, or sleep disturbance [7]. Finally, children with GAD tend to present at an older age than those with SAD [3].

Given that children with GAD tend to present with a variety of somatic complaints, the differential diagnosis contains multiple medical causes that must be ruled out. In adolescence, excessive use of caffeine or other stimulants is particularly common and easily ruled out by careful history [61]. In the context of a suggestive history or physical exam, one must be wary of hyperthyroidism, hypoglycemia, lupus, and pheochromocytoma [61].

There are few neurobiologic studies in pediatric patients with GAD. In the only neuroimaging study to date of childhood GAD, De Bellis and colleagues [62] reported increased right and total amygdala volumes in 12 children 8–16 years of age suffering from GAD as compared to 24 age- and sex-matched normal controls (two matched controls per GAD patient) (Fig. 2). This finding, however, was not correlated with severity of anxiety.

The amygdala is, in fact, considered a key structure in processing of fear and anxiety information [see 63 for review]. The amygdala receives extensive connections from thalamic and cortical exteroceptive systems, as well as subcortical visceral afferent pathways, making it a central structure in the fear processing pathways (Fig. 3).

A number of studies have investigated potential physiologic markers for GAD. As with SAD, GAD is associated with CO_2 hypersensitivity [35]. Some studies suggest that there is a differential hypersensitivity among the anxiety disorders and that, in fact, patients with GAD are significantly less sensitive to the effects of CO_2 than are patients with panic [64–66]. In a study examining neuroendocrine markers of anxiety in 20 male adolescents (14 of whom had GAD, 6 had GAD
Figure 2 Right [$t(1,33) = 2.44$, $p = .02$] amygdala volume means (cm^3) and standard deviations adjusted for intracranial volume of children and adolescents with generalized anxiety disorder (GAD) and matched comparison subjects. (Reprinted by permission of Elsevier Science. A Pilot Study of Amygdala Volumes in Pediatric Generalized Anxiety Disorder, by DeBellis, Casey, Dahl et al., Biological Psychiatry 48(1):51–57, 2000, by the Society of Biological Psychiatry.)

and SAD), Gerra and colleagues [67] demonstrated that anxious subjects have significantly higher levels of growth hormone (GH), prolactin (PRL), beta-endorphin (beta-ED), and ACTH at baseline. Following a series of psychological stressors, anxious subjects had significantly higher levels of norepinephrine, GH, and testosterone and their nonanxious controls. Beta-EP and PRL decreased significantly in the anxious subjects following the stressor, but remained unaffected in the healthy control subjects. Taken together with adult data [68–70], these studies suggest a role for hypothalamic-pituitary-adrenal axis dysregulation in the pathogenesis of GAD.

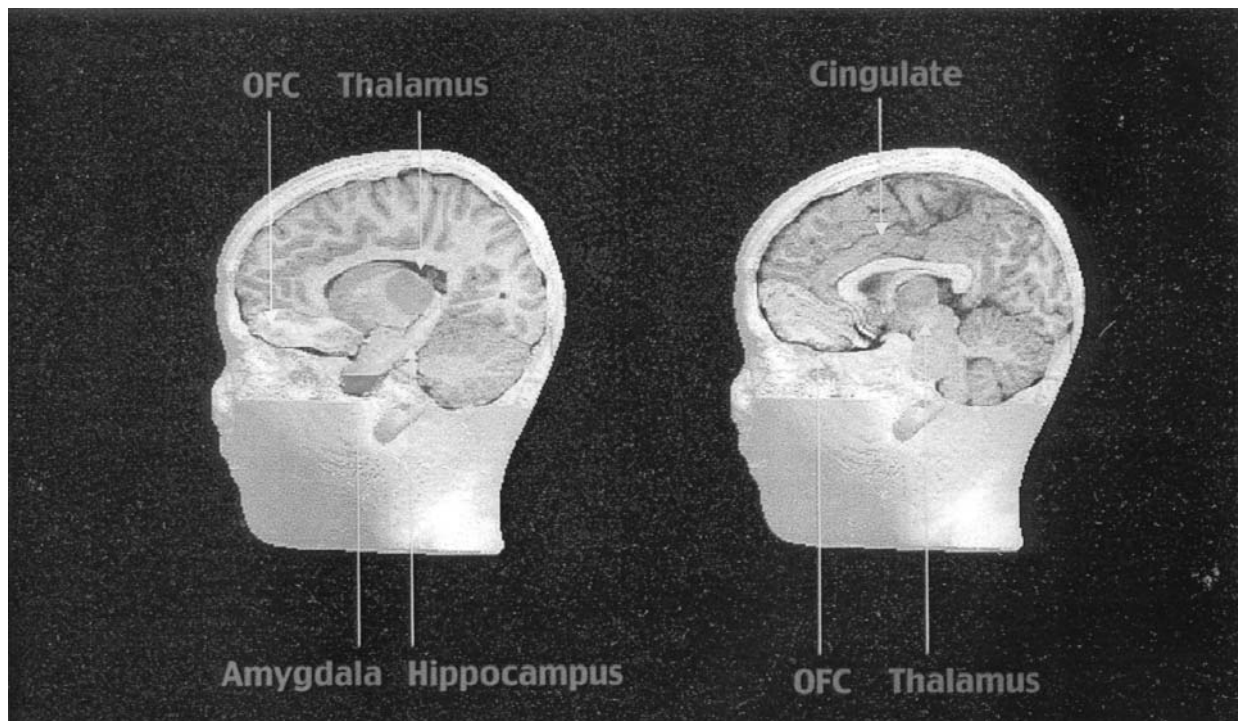
With regard to treatment of GAD, data are very limited. There have been no published double-blind, placebo-controlled studies examining the medications commonly prescribed to treat this disorder. However, as mentioned above, one such trial of fluvoxamine for treatment of social phobia, SAD, and GAD was recently completed and found that fluvoxamine is superior to placebo [53]. There is also an ongoing multicenter, double-blind, placebo-controlled industry-sponsored trial of sustained-release venlafaxine (ER) in children and adolescents with GAD. Additionally, there is a large, industry-sponsored trial


Figure 3 Structures such as the thalamus, cingulate, amygdala, hippocampus and the orbital frontal cortex (OFC) are activated in the emotion fear. (Created by Frank P. MacMaster.) Functional Neuroimaging in Child Psychiatry, 2000, 224–241.)

in progress of the 5HT1A agonist buspirone for GAD in young people aged 5–17 which had recruited 350 subjects within 5 months [13]. The results of this study have not yet been analyzed.

With respect to psychotherapeutic interventions, a number of studies have shown that CBT is superior to no treatment and to nondirective therapy [see 71 for review]. Additionally, Barrett and colleagues [72] demonstrated that, in 52 adolescents (age 14–21) who had undergone cognitive behavioral therapy for anxiety an average of 6 years prior to this study, 85.7% no longer met diagnostic criteria for any anxiety disorder. These patients had been treated with either CBT alone or CBT in combination with family management, both of which were equally effective at long-term follow-up.

C. Social Phobia (Social Anxiety Disorder)

Social phobia (SP) is characterized by a marked fear of social or performance situations in which the child may be observed or evaluated [7]. Patients fear that they will embarrass or humiliate themselves; thus, exposure to the feared situation almost invariably causes anxiety. In severe cases, this anxiety may take the form of a panic attack. SP can be either discrete or generalized. The qualification of generalized is added to the diagnosis if the patient fears most social situations [7]. Among 15 to 54-year-olds, there is a 7–8% 1-year prevalence and 13–14% lifetime prevalence. However, the onset of this disorder is typically prior to or during adolescence [73]. Recent prevalence estimates in children and adolescents range from 0.5% to 4.0% [74]. In community samples, SP is more common in women than men. The opposite has been found in clinical samples [75].

SP is a serious, disabling disorder associated with a decreased quality of life [76]. While most of the reported quality-of-life measures are more specific to adult populations, the fact that 38.1% of SP patients do not graduate high school (compared to 30.1% without SP) is of particular concern in adolescents [76]. Also, a lifetime diagnosis of SP was associated with greater likelihood of having failed at least one grade.

Comorbidity is particularly problematic in SP, as 70–80% of SP patients have at least one comorbid mental disorder [73]. Also, low scores on SP scales in childhood may predict development of conduct disorder in adolescence [77]. Although patients with comorbidity are more likely to seek treatment than those with only SP (51% seek treatment, compared to 20% in SP alone), these patients are also more likely to attempt suicide (15.7% vs. 1%) [78].

With regard to etiology, some studies suggest that *behavioral inhibition* may be a marker for anxiety proneness. Behavioral inhibition is a term first used by Kagan and colleagues [79] to describe a pattern of withdrawal from unfamiliar stimuli. In a 3-year follow-up study of children with behavioral inhibition, Biederman et al. [80] found that inhibited children were at risk for the development of anxiety disorders, with significantly greater risk for multiple diagnoses. A more recent study suggested that inhibited temperament in childhood was associated with generalized social anxiety in adolescence, but not separation anxiety, specific fears, or performance anxiety [81]. Inhibited children can also be distinguished from noninhibited children based on several physiological parameters, including elevated heart rates, urinary catecholamines, and salivary cortisol [82]. Similar physiologic markers are present in several childhood anxiety disorders [67,83]. Additionally, children are more likely to have behavioral inhibition if a parent suffers from MDD or panic [84]. In fact, having a parent who suffered from both MDD and panic conferred a two-fold risk for behavioral inhibition in the child.

Unlike some of the other anxiety disorders, neuroendocrine studies have failed to offer insight in the biology of SP. In a study of girls with SP (mean age 15.6 years ± 1.5 years), Martel et al. [85] found no difference in salivary cortisol levels between SP patients and controls either at baseline or during a stressor.

To date, there are no data from double-blind, placebo-controlled studies specific to pediatric SP. As mentioned previously, the RUPP Anxiety Group [53] found fluvoxamine to be superior to placebo in treating children with anxiety disorders including social phobia. Paroxetine was recently FDA approved for treating SP in adults, and Glaxo SmithKline has initiated a multicenter double-blind, placebo-controlled study of paroxetine for SP in children and adolescents. Wyeth-Ayerst has also initiated a multicenter double-blind, placebo-controlled study of sustained-release venlafaxine ER in children and adolescents with SP. The sedative side effects of benzo-

diazepines typically contraindicate their use for SP. While there are no controlled studies of buspirone for SP, a recent case study suggested possible efficacy in an adolescent with SP [86].

Beta blockers are commonly prescribed to treat SP, especially the subtype with performance anxiety, or "stage fright." In spite of this common clinical practice, there are currently no FDA-approved indications for the use of beta-blockers in psychiatric disorders, and there have been no controlled studies of these medications in children and adolescents. Among the beta blockers, propranolol has been the most studied in neuropsychiatric disorders. Some evidence suggest that may be effective in the treatment of anxiety [87,88]; however, this effect seems to be due more to propranolol's peripheral actions (e.g., decreasing heart rate) than its effect on central noradrenergic beta receptors.

Psychotherapeutic interventions, particularly CBT, have been shown to be effective in the treatment of social phobia [see 89 for review]. In children, it appears that CBT combined with family management may be superior to CBT alone [19], both acutely and at 12-month follow-up. This may be due, in part, to an effect on parental anxiety. In a study examining the role of parental anxiety on treatment outcome in children with anxiety disorder, Cobham and colleagues [90] showed that children of anxious parents did better if parent anxiety management was combined with child CBT.

D. Panic Disorder

Until fairly recently, panic was considered a diagnosis to be made strictly in adults. In fact, some controversy still exists as to whether this diagnosis can be made in children and adolescents [91–93]. However, several cases of adolescent-onset panic have been described, both in current cases [94,95] and in retrospective repots [96,97]. As in adults, panic disorder is characterized by recurrent panic attacks and persistent concerns about having future attacks [7]. While patients with adult-onset and early-onset panic disorder do not seem to differ in symptom severity or social functioning, the early-onset form tends to carry with it higher comorbidity and is possibly a result of greater familial loading for anxiety disorders [98]. For instance, children of parents with panic disorder are significantly more likely to have the disorder themselves [99].

Some studies have indicated that normal and pathologic anxiety may be mediated by different mechanisms. For instance, Sinha et al. [37] showed that, in response to CO_2-induced panic, cortisol levels in

panicking patients with panic disorder decreased, while those of healthy comparison subjects and nonpanicking panic disorder patient did not. It is likely that childhood and adult anxiety may have different mechanisms as well. For example, in contrast to adult studies, children with anxiety do not have a blunting of growth hormone (GH) response to clonidine [100]. However, in response to the α_2 agonist yohimbine children with anxiety disorders had increased subjective anxiety, increased adrenergic reactivity, and a decreased GH response, all consistent with literature in adults [101]. Yohimbine is known to increase norepinephrine (NE) release in the hippocampus via increased locus ceruleus firing, leading to behavioral and biologic correlates of anxiety. According to Sallee et al. [10], the combined yohimbine and clonidine data suggest that presynaptic NE sensitivity may be present in early-onset anxiety disorders, but that the overactive noradrenergic system is not necessarily accompanied by the α_2 downregulation seen in adults.

E. Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) is a chronically disabling condition characterized by repetitive ritualistic behavior and recurrent intrusive thoughts [7]. Frequent obsessions include fears of contamination (35%) and thoughts of harming oneself or loved ones (30%). The most commonly reported compulsions in children and adolescents are washing and cleaning (75%), checking (40%), and straightening (35%) [3]. The lifetime prevalence of OCD is $\sim$ 2–3% [102], with > 80% of cases having their onset in childhood and adolescence [103]. OCD onset tends to be earlier in boys than girls, with a peak in puberty and in early adulthood [102]. In a study examining comorbidity in 70 children with OCD. Thirty percent of these patients had a comorbid tic disorder. Other common comorbid diagnoses were MDD (26%) and developmental disorders (24%).

As was the case in SP, OCD illustrates again that not all anxiety disorders have known neuroendocrine correlates. Using electrodermal activity and heart rate as markers of autonomic activity, Zahn et al. [105] found no differences between children with OCD and normal controls.

In contrast to other anxiety disorders, more information has been gleaned from neuroimaging studies of children and adolescents with OCD. Neurobiologic studies have implicated a pharmacologically reversible glutamatergic thalamocortico-striatal dysfunction in pediatric OCD [10].

1.   Volumetric Studies

An early study using quantitative x-ray computerized tomography (CT) found reduced caudate volumes in young males with OCD [106]. Behar et al. [107] also reported significantly increased ventricular brain ratios suggestive of decreased striatal volume in 16 adolescent OCD patients. Using morphometric magnetic resonance imaging (MRI), Rosenberg and colleagues [108] found that 19 treatment-naïve OCD patients age 7–17 had significantly smaller striatal volumes than did age- and sex-matched healthy comparison subjects (Fig. 4). Reduced striatal volumes were correlated with increased OCD symptom severity but not with increased illness duration. This is consistent with Rauch et al.'s [109] suggestion that striatal dysfunction represents a primary locus of pathology in OCD.

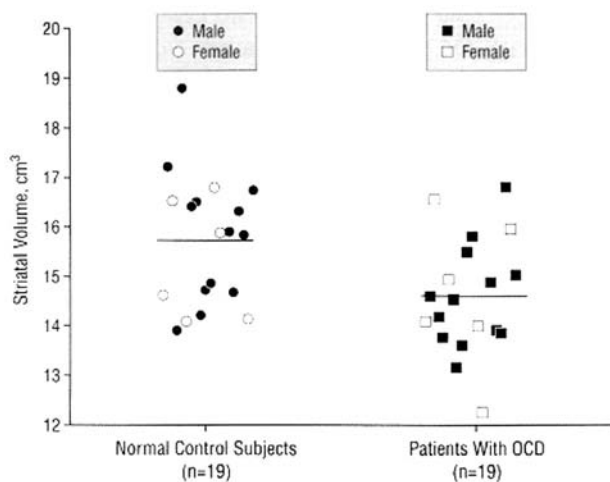
Interestingly, OCD symptoms seen in patients with pediatric autoimmune neuropsychiatric disorders associated with group A beta-hemolytic streptococal (GABHS) infections, called PANDAS, have been found to have increased basal ganglia volumes [110–112]. In these patients, increased antibody titers of anti-streptolysin O and antideoxyribonuclease B have been reported to be correlated with increased basal ganglia volumes [112]. Remarkably, immunotherapy (e.g., plasmapheresis) has been reported to be effective in reducing OCD symptoms in some patients with PANDAS [113] and reducing basal ganglia volumes [114].


Figure 4   Reduced striatal volume in obsessive compulsive disorder (OCD) patients vs. controls. Lines indicate means. (Reprinted from Rosenberg, Keshavan, O'Hearn et al., 1997. Fronto-Striatal Measurement of Treatment-Naïve Pediatric Obsessive-Compulsive Disorder. Arch Gen Psychiatry 54:824–830.)

These findings underscore the need for precise neurobiological studies to identify possibly distinct subtypes of OCD with different patterns of brain abnormality. Ultimately, such work has the potential to determine differential treatment intervention in pediatric OCD patients based on different patterns of brain abnormality [10]. Moreover, perturbation of specific neural networks in either direction (e.g., increased or decreased) may result in emergence of OCD symptoms.

Abnormalities in the striatum in pediatric OCD patients have prompted investigation in ventral prefrontal cortex and the striatum. The ventral prefrontal cortex sends dense efferent projections to the striatum and thalamus [115–119]. Neuropsycho-

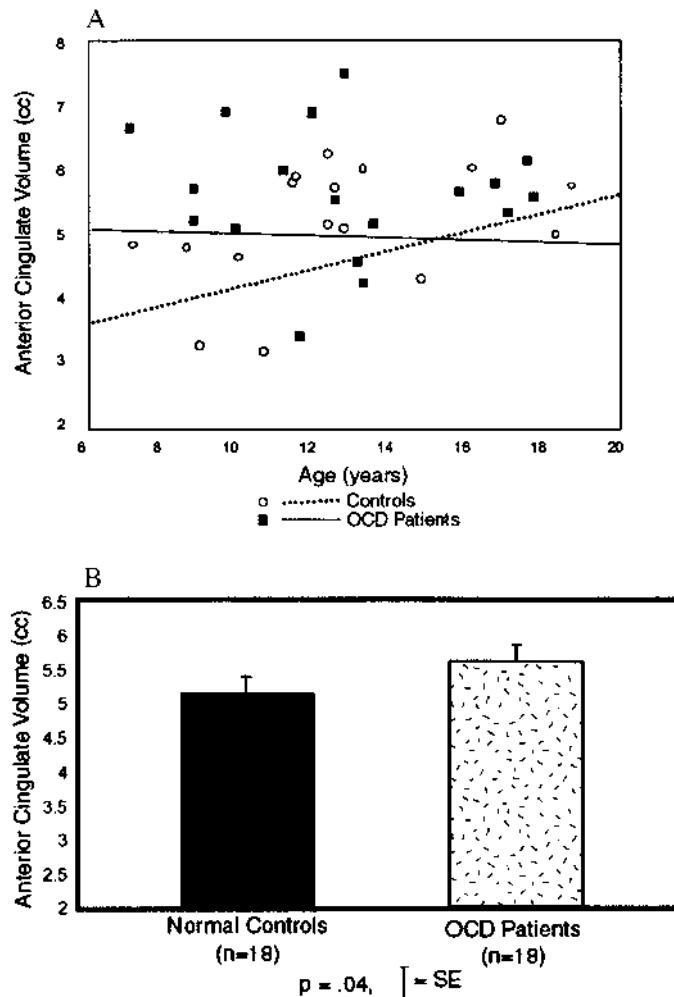
logical and neurocognitive studies of tasks purported to probe ventral prefrontal cortical function had suggested abnormalities in pediatric OCD patients compared to controls [120]. Subsequent volumetric MRI investigation demonstrated increased ventral prefrontal cortical volumes in anterior cingulate cortex in pediatric OCD patients compared to controls, particularly younger pediatric OCD patients, with no abnormalities observed in posterior cingulate cortex or in dorsolateral prefrontal cortex [121] (Fig. 5). Specifically, the normal age-related increase in anterior cingulate volume observed in controls was absent in childhood OCD patients. In these OCD patients, increased anterior cingulate volumes were


Figure 5 (A) Anterior cingulate volume vs. age in pediatric obsessive compulsive disorder patients and healthy comparison subjects. Note that the age-related increase in anterior cingulate volume observed in healthy children is absent in pediatric patients with obsessive compulsive disorder. (B) Anterior cingulate volume by group. (Reprinted by permission of Elsevier Science. Toward a Neurodevelopmental Model of Obsessive-Compulsive Disorder, by Rosenberg and Keshavan, Biological Psychiatry 43(9):623–640, 1998, by the Society of Biological Psychiatry.)

positively correlated with severity of OCD but not duration of illness.

The thalamus serves as the final subcortical input to frontal cortex [122]. A previous volumetric MRI study [123] found no significant differences in thalamic volume between adult OCD patients and controls. The patients studied in this report, however, had been treated with SSRIs. This led Gilbert et al. [124] to conduct a volumetric MRI study in 21 treatment-naïve pediatric OCD patients and 21 age- and sex-matched controls. Increased thalamic volumes were observed in treatment-naïve pediatric OCD patients compared to controls. A significant decrease in thalamic volume was observed after 12 weeks of monodrug therapy with the SSRI paroxetine (Fig. 6). Decrease in OCD symptom severity was highly correlated with reduction in thalamic volume (Fig. 7). Specifically, increased thalamic volume before treatment with paroxetine predicted better response to the medication. There was no significant reduction in thalamic volume in pediatric OCD patients treated with CBT [125]. Recent investigation by Nolan et al. [2001] found that this decrease in thalamic volume was primarily localized to medial, not lateral, thalamus. Using a newer and more sophisticated technique of brain chemistry, proton magnetic resonance spectroscopy

(1-H MRS), functional neurochemical marker abnormalities were localized to medial but not lateral thalamus in pediatric OCD patients compared to controls [126,127]. Amponsah et al. [128] presented data suggesting a trend for increased N-acetyl-aspartate (NAA) concentrations as measured by 1-H MRS in pediatric OCD patients after 12 weeks of treatment with paroxetine. NAA is known to be a reliable indicator of neuronal viability [129].

2. Brain Chemistry/Glutamate

Alterations in glutamatergic-serotonin interactions in ventral prefrontal-striatal-thalamic circuitry in pediatric OCD were suggested by several basic science reports in the literature. Becquet et al. [130] demonstrated that the caudate nucleus, a primary locus of abnormality in OCD [109], receives an especially high glutamate innervation from the prefrontal cortex. Indeed, most of the axon terminals in the caudate nucleus are glutamatergic afferents [116,117]. Glutamate concentrations in the striatum are markedly reduced after ablation of frontal cortex [118,119]. An

Figure 6 Thalamic volume by diagnostic and treatment condition with groups not sharing the same letter are significantly different at *P* < .05. (Adapted from Gilbert, Moore, Keshavan et al., 2000. Decrease in Thalamic Volumes of Pediatric Obsessive-Compulsive Disorder Patients Taking Paroxetine. Arch Gen Psychiatry 57(5):449–456.)

(Reprinted from Gilbert, Moore, Keshavan et al., 2000. Decrease in Thalamic Volumes of Pediatric Obsessive-Compulsive Disorder Patients Taking Paroxetine. Arch Gen Psychiatry 57(5):449–456.)

in vivo glutamate control over presynaptic serotonin release in the caudate nucleus has also been demonstrated [115,131], while serotonergic neurons impact on striatal glutamate concentrations [132].

Using 1-H MRS, Rosenberg et al. [133] found significant elevations in left caudate but not occipital glutamatergic concentrations in OCD patients compared to controls (Figs. 8 and 9). After 12 weeks of monodrug therapy with the SSRI paroxetine, caudate glutamatergic concentrations decreased to levels not significantly different from those in controls. Reduction in glutamergic concentrations in the left caudate nucleus was robustly correlated with reduction in OCD symptom severity (Fig. 10). Pretreatment caudate glutamatergic concentrations tended to predict treatment response with higher pretreatment concentrations predictive of better response to paroxetine. Taken together, these findings suggest that OCD in children and adolescents may be associated with reversible, glutamate-mediated dysfunction of a ventral prefrontal-striatal-thalamic system.

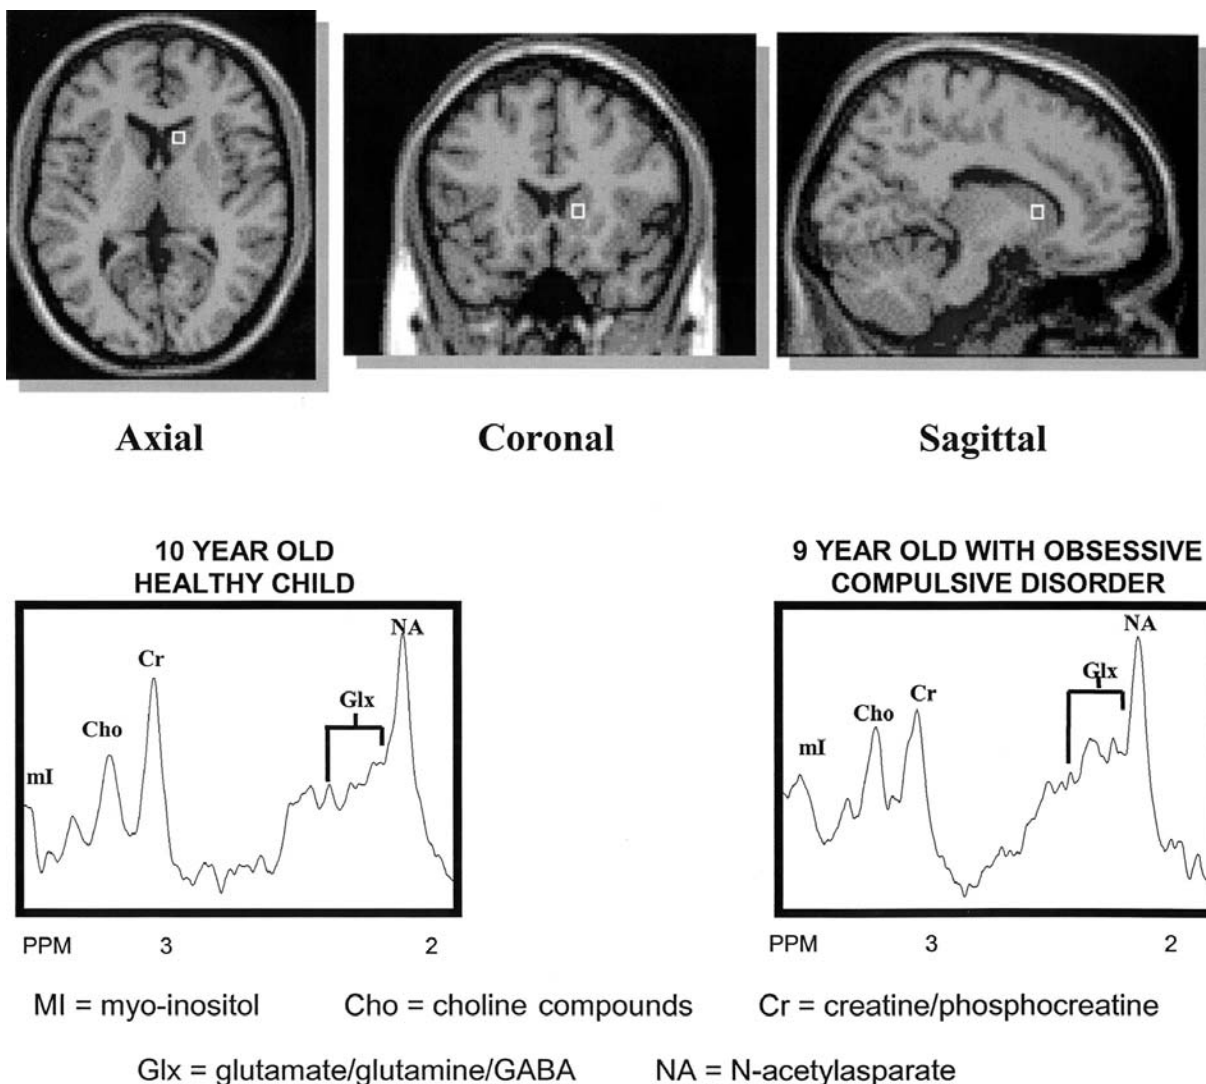
Most of the research guiding current prescribing practices in children and adolescents comes from studies in adults [134]. Pediatric OCD is an exception


Figure 8 Illustration of voxel placement in left caudate nucleus. 1-H MRS of a 0.7-mL volume of interest centered in the left caudate in a 10-year-old healthy control and a 9-year-old treatment-naïve patient with obsessive-compulsive disorder as shown on the T1-weighted MR images. (Adapted from Rosenberg, MacMillan, Moore, 2001. Brain Anatomy and Chemistry May Predict Treatment Response in Pediatric Obsessive-Compulsive Disorder. Intl J Neuropsychopharmacology 4:179–190.)
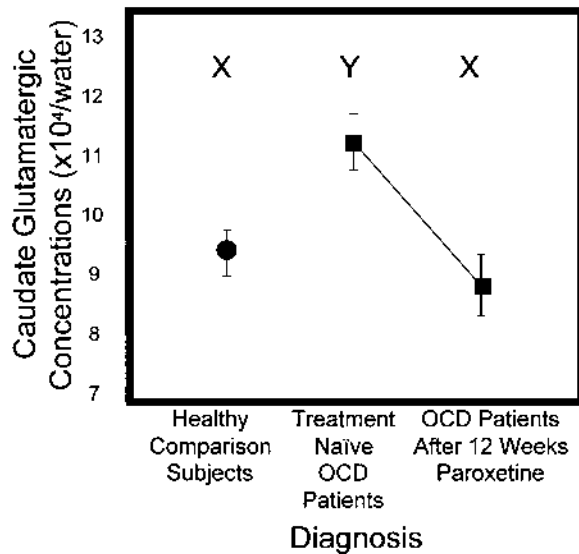

Figure 9 Caudate glutamatergic concentration by diagnostic and treatment condition. Groups not sharing the same letter are significantly different at $P < .05$. (Adapted from Rosenberg, MacMaster, Keshavan et al., 2000. Decrease in Caudate Glutamatergic Concentrations in Pediatric Obsessive-Compulsive Disorder Patients Taking Paroxetine. to this. There are currently three FDA-approved medications for treatment of child and adolescent OCD—fluvoxamine, sertraline, and clomipramine. A recent 13-week multicenter placebo-controlled investigation of fluoxetine conducted by Eli Lilly in 103 child and adolescent OCD patients 7–17 years old [135] found that fluoxetine was associated with significantly greater reduction in OCD symptom severity than was placebo. SmithKline Beecham also recently conducted a large multicenter study of paroxetine in pediatric OCD [136] and found that paroxetine was safe and effective in treating pediatric OCD patients. While citalopram has not been studied in pediatric OCD, it is likely to be effective in OCD patients. Because of their more favorable side-effects profiles, the SSRIs are typically used as first-line treatment before clomipramine.

In treatment-refractory OCD patients, combination of an SSRI with risperidone has been shown to be superior to placebo in adult patients [139,140]. Double-blind placebo-controlled studies augmenting SSRI therapy with lithium and thyroid hormone [141], trazadone [142], buspirone [143], and clonazepam [144] have not demonstrated benefit of augmentation with active medication over that of placebo

augmentation. In adults augmentation of SSRI with haloperidol is superior to augmentation of placebo in treatment-refractory OCD patients with coexistent tics [145,146]. This combination was not effective in OCD patients without coexistent tics. Augmentation of an SSRI regimen with pimozide in refractory OCD patients has also been shown to be superior to placebo in OCD patients with coexistent chronic tic disorders or schizotypical personality disorders [146]. It should be noted that haloperidol and pimozide have potentially irreversible side effects, including tardive dyskinesia. This limits their use in children and adolescents. The atypical neuroleptics are being used more commonly in the clinical setting in refractory OCD patients.

It should be noted that CBT is recognized to be an effective treatment for children and adolescents with OCD [147–150]. A recent National Institute of Mental Health investigation is comparing SSRI (sertraline), CBT, combination therapy, and placebo in children and adolescents with OCD (personal communication, John March, M.D.). The results of this study have not yet been presented. Recent investigation has also found relatively high response rates with

relaxation therapy (personal communication, John Piacentini, Ph.D.).

F. Posttraumatic Stress Disorder

Much like panic disorder, the diagnosis of post-traumatic stress disorder (PTSD) has only recently been applied to children. In 1891, Terr's [151] report of the Chowchilla school bus kidnapping was one of the first to describe PTSD in children. PTSD can occur at any age, as it is precipitated by an extreme stressor [152]. Based on the DSM-VI, there are four major criteria that must be met for the diagnosis of PTSD. These include exposure to a stressor, reexperiencing the event, avoidance of stimuli, and persistent increased arousal [7]. The stressor itself must be of a life-threatening or involve the threat of serious injury. PTSD can result from direct, witnessed, or verbal exposure to the stressor [153].

A number of comorbidities and associated symptoms can occur with PTSD. Separation anxiety is fairly common, in part because children may be responding to prior threats to loved ones, but also because most children react to traumatic events with attachment behavior [154]. Among the most common comorbidities are depression spectrum conditions, ranging from demoralization to melancholic MDD [155,156]. This corresponds with recent data from Breslau et al. [157] that suggest a marked increase in risk for MDD in patients with PTSD. Conversely, patients with PTSD following traumatic exposure were at increased risk for depression, while those with exposure who did not develop PTSD were also at risk for depression, suggesting that there may be a common underlying mechanism in PTSD and MDD.

In PTSD, neuroendocrine data in adults and children are fairly consistent. In adults, PTSD is associated with high levels of urinary cortisol; in fact, urinary cortisol following a traumatic event (motor vehicle accident) has been shown to predict the development and severity of PTSD [158]. Urinary catecholamine concentrations reflect plasma and peripheral sympathetic nervous system activity, tonic stimulation of the adrenal medulla, and metabolic breakdown of norepinephrine. De Bellis and colleagues [83] showed that children with PTSD had higher urinary catecholamine excretion than either healthy children or children with GAD/OAD, suggesting that this may be specific to PTSD rather than a marker of anxiety disorders in general. In a study of adult women who had been sexually abused in childhood, Helm et al. [42] showed that perturbations of the hypothalamic-pituitary-adrenal axis and autonomic hyperactivity that result from trauma can persist over time.

Thus far, there have been two neuroimaging studies of PTSD in children and adolescents—one morphometric study, and one spectroscopic. In a study of 44 maltreated children with PTSD, De Bellis et al. [159] found that children with PTSD had an overall reduction in brain volume that correlated with level of environmental stress, smaller medial and posterior corpus callosum, and increased volume of right and left lateral ventricles. In contrast to studies in adults, some with childhood onset of their illness [160–163], children with PTSD did not have reduced hippocampal volume. However, these findings are consistent with models of early-life stress in nonhuman primates [164]. In a sample of 11 children with PTSD, De Bellis et al. [165] found that maltreated children with PTSD had significantly lower NAA levels than healthy controls in the anterior cingulate, suggesting possible neuronal dysfunction in pediatric PTSD. Recent data suggest that 1-H MRS NAA assessment may be more sensitive for detecting neuronal abnormalities than conventional volumetric MRI studies [166].

Until very recently, there were no approved medications for the treatment of PTSD in children or adults. Sertraline has been shown to be effective in double-blind, placebo-controlled studies in adults, particularly with regard to the avoidance/numbing symptom cluster [167]. It was recently approved by the FDA for use in adults. Given the similarities between adult- and childhood-onset PTSD with regard to neuroendocrine factors [83], trials of this drug in children with PTSD are warranted. Future directions for medication development seem to be focused on matching therapy more closely with the pathophysiology of individual disorders. For instance, Friedman [168] suggests that, in PTSD, there are a number of physiologic targets for drug development. He discusses possible roles for CRF antagonists, neuropeptide-Y enhancers, drugs that downregulate glucocorticoid receptors, and more—many of which either are being developed or are in preclinical trials.

As with the other anxiety disorders, the psychotherapeutic intervention for PTSD that has the most empirical support is CBT [see 169 for review]. A study by March and colleagues [170] suggests that CBT is effective both accurately and at 6-month follow-up in children with PTSD.

G. Specific Phobia

Specific phobia is characterized by marked and persistent fear of a particular object or situation. This fear must be excessive and unreasonable and may be cued by the presence or anticipation of the feared stimulus, and the onset of anxiety symptoms occurs immediately [7]. Estimated prevalence rates for specific phobias range from < 1% to 9.2% [171,172]. Although there are a number of different theories suggesting that negative life experiences have an impact on phobia onset, a recent study by Magee [173] found that, of 12 discrete events and 10 chronic stressors, only assault by a relative and verbal aggression between parents influenced the onset of specific phobias. Specific phobias can generally be classified into three categories: (1) environmental/situational; (2) animal; and (3) blood/injection/injury [174]. These classifications also apply to phobias in children and adolescents [175]. While some studies suggest age and gender differences in frequency of particular phobias [174,176], no such studies have been performed in children. The most successful treatments for specific phobia are behavioral desensitization techniques such as systematic desensitization, modeling, and flooding [171]. To date, there is no evidence to support pharmacologic treatment of specific phobias. However, in the case of severe, disabling phobias, SSRIs such as fluvoxamine may be effective [177].

III. FUTURE RESEARCH DIRECTIONS

Although we are learning more about the brain circuits involved in anxiety disorders (Fig. 3), much remains to be done. To date, there has been very little family/genetic research in childhood-onset anxiety disorders. In part, this is because of the lack of psychometrically sound instruments for assessing anxiety, along with prior misconceptions regarding the nature of childhood anxiety [178]. However, two recent observations have spurred an interest in the heritability of anxiety. First, although better characterized in psychotic and mood disorders, there is evidence that there may be heritable forms of adult anxiety disorders that are characterized by onset in childhood [179]. The idea that SAD may be a heritable form of panic is one example [30]. Second, rather than inheriting a disorder, children may inherit a predisposition for that disorder [180]. In this context, neuroendocrine and neuroimaging findings may point toward candidate susceptibility genes. However, it is unlikely that neuroimaging

and neuroendocrine data can be used to identify putative markers in the immediate future, primarily owing to the difficulties in replicating findings of susceptibility loci [10].

Pharmacogenetics is another area of genetic research that holds great promise in the study of childhood anxiety disorders. In this discipline, genetic information is used to guide drug design, thus taking individual variation in drug metabolism and response into account [10]. It is likely that this field will eventually intersect with imaging studies [181], especially given recent spectroscopic findings related to treatment response [128,133].

Psychotic Disorders in Childhood and Adolescence
Basic Mechanisms and Therapeutic Interventions

ANDREW R. GILBERT and MATCHERI S. KESHAVAN

Western Psychiatric Institute and Clinic, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, U.S.A.

I. INTRODUCTION

Once considered a form of autism, childhood-onset psychosis is currently described as a condition continuous with and, perhaps, more severe than adult-onset schizophrenia. Advances in treatment and research have improved our understanding, diagnosis, and management of childhood-onset psychosis. Childhood-onset psychosis was often compared to early infantile autism [1], but later described by Kolvin as a distinct pediatric condition [2]. Several studies since Kolvin's work have examined childhood psychosis, greatly contributing to the classification and elucidation of the disorder [3–5].

Currently, childhood-onset psychosis is defined by the same criteria used for adult schizophrenia. Therefore, there must be positive symptoms—hallucinations, delusions, and/or thought disorder. No single finding is pathognomonic, as any of these overall symptoms can be observed in patients suffering from disorders of affect or organic brain disease. A primary psychosis in childhood and adolescence generally manifests itself in the form of childhood-onset schizophrenia, a rare form of schizophrenia. There are certain characteristics of childhood-onset schizophrenia, however, that are different from the adult-onset illness. First, while a decline from a previous level of function-

ing is a necessary prerequisite for the diagnosis of schizophrenia beginning in childhood, childhood-onset schizophrenia patients may have never achieved the expected level of functioning. Second, the content of the psychotic symptoms in childhood-onset schizophrenia differs according to the developmental level and age of the patient [6]. Furthermore, others have reported that patients with childhood-onset schizophrenia have considerably less frequent systematic delusions than adult schizophrenics [7]. Another study reported that the ratings of premorbid adjustment for schizophrenic children are poorer than those for adult schizophrenics [8].

In light of the observation that early age of onset is associated with poorer premorbid adjustment, Asarnow and Ben-Meir suggested that childhood-onset schizophrenia may represent an early-onset form of adult schizophrenia [8]. Murray proposed that early-onset schizophrenia might reflect a form of illness with a greater genetic loading, male preponderance, and possibly a greater contribution by neurodevelopmental pathology [9]. Others have pursued investigations of patients with onset of schizophrenia close to the "sensitive" periods of development, such as the peripubertal period, in order to better elucidate the proposed neurodevelopmental pathogenesis of the illness [10].

Since hallucinations and delusions are frequently seen in pediatric populations and may result from a variety of disorders, the diagnosis of childhood-onset psychosis is a difficult one. Often, patients with psychotic symptoms secondary to affective disorders are misdiagnosed with a primary psychosis [11]. Recently, a subgroup from the larger population of children with nonschizophrenic nonaffective psychoses, "multidimensionally impaired" disorder (MDI), has been described and studied [12]. Children with MDI have no thought disorder, but may experience transient hallucinations or delusions and emotional lability, and may demonstrate poor interpersonal skills [11].

As suggested above, it is important to consider the developmental phase of individuals with the illness when making a diagnosis. Furthermore, the developmental stage significantly influences treatment; medications, educational and family interventions, and supportive psychotherapy are often tailored to the developmental capacity of the patient as well as the stage of the illness.

In this chapter, we will review the clinical features, course, outcome, and management of childhood-onset psychosis, with particular emphasis on childhood-onset schizophrenia.

II.   HISTORICAL BACKGROUND

Psychotic disorders have been described as far back as 1000 BC [13]. Modern descriptions of schizophrenia, however, began to appear in the literature only in the late 18th and early 19th centuries. Morel first described a condition, dementia praecoce, as an illness beginning in adolescence and leading to a gradual deterioration. Kraepelin later integrated several descriptions of schizophrenialike illnesses into a single entity he labeled dementia praecox [14]. The occurrence of schizophrenia in childhood was also described at the time of Kraepelin. However, childhood-onset psychosis was generally considered a type of autistic or pervasive developmental disorder. Kolvin later demonstrated that autism was a disorder distinct from "later onset" psychoses of childhood [2].

Although few have studied childhood-onset schizophrenia, several studies have recently examined the disorder [3,7,15–19]. An understanding of the neurodevelopmental course of schizophrenia has likely inspired much of this research. Currently, schizophrenia in youth appears to be a more severe form of the same heterogeneous disorder as in adults. The outcomes of current studies, and future studies of

children with MDI and atypical psychoses, should better explain the condition and approaches toward treatment.

Schizophrenia is very rare in children below the age of 9. It is about 50 times more prevalent in the general population than in children under 12 years of age. At the beginning of adolescence, there is a sharp increase in the onset of cases, and the number of new cases increases throughout the teenage years. The estimated incidence of schizophrenia in children under 12 years is 3:10,000 [20]. Childhood-onset schizophrenia has a slight male predominance, ~1.5 or 2 males:1 female. There is some evidence that schizophrenic children may be more commonly observed in families of lower socioeconomic status [21].

III.   CLINICAL PICTURE

The symptoms of childhood-onset schizophrenia are similar to but often more severe than the symptoms of schizophrenia. Recent studies have suggested that the diagnosis of schizophrenia can be made in children using the same criteria as applied to adults [3,5,22,23]. Both positive and negative symptoms are observed in childhood-onset schizophrenia. Positive symptoms are considered to result from an excessive activity of certain brain processes; in contrast, negative symptoms are suggestive of deficient functioning in specific neuronal systems. Positive symptoms include hallucinations, delusions, "positive" formal thought disorder, and disorganized and bizarre behaviors. Negative symptoms are enduring traits of poverty of speech and thought, affective flattening, inability to experience pleasure, diminution of social contact, inattention, anergia, and lack of persistence in work or social functioning. This distinction has significant implications for diagnosis, prognosis, and treatment [24–26]. DSM-IV suggests that delusions and hallucinations in childhood may be less elaborated than in adulthood, and that visual hallucinations may be more common [27]. Furthermore, disorganized speech and behavior are seen in a variety of more common disorders of childhood, such as Communication Disorders, Pervasive Developmental Disorders, Attention Deficit/Hyperactivity Disorder, and Stereotypic Movement Disorder [27]. The differential diagnosis of childhood-onset psychosis also includes affective disorders, as mood disturbances can often be observed in schizophrenia. It is also important to consider Obsessive-Compulsive Disorder (OCD) when diagnosing childhood-onset psychosis because pedia-

tric patients with OCD may exhibit ideas that are sometimes difficult to distinguish from delusions [21].

In childhood and adolescence, the developmental stage of the patient must be considered when attempting to separate immature fantasy from delusional thinking. Children's tendency to blur the distinction between fantasy and reality, in combination with their inability to fully utilize logical reason, renders it difficult to define delusions in individuals much younger than 5 years old. In general, delusions are found least frequently in children under the age of 10; they tend to be simple, nonsystematized, and centered on disturbances of identity. Hypochondriacal, persecutory, and grandiose delusions appear slightly more often in prepubertal children—and considerably more often in adolescents [2,28–35].

Disturbances in emotions are another hallmark of schizophrenia and become increasingly evident as the illness progresses. Mood disturbance may present as anxiety, perplexity, elevation, or depression. With a loss of ego boundaries and the onset of referential thinking, young schizophrenics often experience marked anxiety early in the illness. They are perplexed by a chaotic inner world that they struggle to understand and articulate. Depression may occur at any time during the illness, but it frequently appears as adolescents gain insight into their growing functional impairments—an awareness that may lead to suicidal behaviors.

The childhood-onset schizophrenia patient often presents with nonspecific somatic complaints, such as constipation, bloating, vague muscle aches, back pain, headaches, disturbed sleep, decreased appetite, fatigue, and listlessness. Objective findings may include avoidance of eye contact, absence or rapidity of eye blinks, staring spells, and a disturbance in eye tracking (i.e., saccades and smooth pursuit eye movements) [36].

Disturbances in neurological maturation, cognition, emotional capacity, and social competency characterize the premorbid condition of schizophrenia [28]. Several studies have suggested that childhood-onset schizophrenia is associated with more severe developmental abnormalities than later-onset schizophrenia [3,4,8,34,37,38]. Adolescents with chronic schizophrenia since childhood or shortly after puberty are likely to have exhibited marked disturbances in neurological growth, with slower motor development, inferior coordination, echolalia, delayed and unclear speech, tactile sensitivity, and nonpurposeful rituals. Such neurodevelopmental findings are nonspecific and do not meet criteria for a pervasive development disorder [2,34,39]. A recent NIMH study of 49 patients with childhood-onset schizophrenia revealed that 55% had language abnormalities, 57% had motor abnormalities, and 55% had social abnormalities years before the onset of psychotic symptoms [3,40]. Cognitive disturbances in early-onset schizophrenia frequently manifest with intellectual impairments, attention deficits, and distractibility [34,41]. Cognitive deficits of this sort commonly give rise to impaired school performance characterized by learning problems, failing grades, truancy, hyperactivity, dropping out of school, and dysfunctional teacher-student relations. The same NIMH study previously mentioned reported that a high percentage (66.3%) of patients had either failed a grade or required special education placement prior to the onset of their illness [3,40]. Other cognitive abnormalities noted include obsessional manifestations, perfectionistic needs, magical thinking, daydreams, and intellectual preoccupations [28,41].

Preschizophrenic individuals have also frequently demonstrated emotional deficits, impaired affective control, angry outbursts, detachment, hypersensitivity, and passivity, as well as depressive features and anxious behaviors [39,42,43]. Other abnormalities observed in the preschizophrenic adolescent include impairment in establishing and maintaining interpersonal relations, poor peer group adjustment, social withdrawal, shyness, introversion, and diffidence. Social isolation and seclusion have been found to result more from the individual being regarded by peers as odd and eccentric than from shyness [43]. Antisocial behaviors are more likely expressed toward family members rather than as a social delinquency [43].

Although premorbid behavioral patterns vary greatly among schizophrenics, clinicians more commonly report these features to be consistent with a schizoid personality type. The schizoid personality of the prepsychotic adolescent is similarly described with traits of passivity, introversion, detachment, and autistic thinking. Preschizophrenic youths are less likely to have intimate friends and social dates, and will choose solitary activities of watching TV, listening to radio, or playing computer games, often to the exclusion of competitive sports and other social activities [44]. Additional personality types described less commonly include avoidant, paranoid, histrionic, and compulsive disorders. Manifestations of a premorbid personality disturbance, which are associated with a poor prognosis, have been observed more often in the earlier-onset schizophrenic syndromes rather than later-onset acute episodes [45].

Schizophrenia has been classified into a variety of subtypes throughout the years. An early study sug-

gested that the majority of children with schizophrenia belong to the undifferentiated subtype [46]. The traditional classification of subtypes outlined below is continued in DSM-IV [27]. A recent study of childhood-onset schizophrenia, however, suggested no significant differences between adults and children when comparing the prevalence of particular subtypes of schizophrenia [16].

Catatonic type is characterized by marked psychomotor disturbance involving stupor, negativism, rigidity, excitement, and posturing. *Disorganized type* is associated with marked loosening of associations, incoherence, grossly disorganized behavior, and flat or grossly inappropriate affect, as well as fragmented delusions and hallucinations lacking a coherent theme. *Paranoid type* is characterized by preoccupation with one or more systematized delusions or presence of frequent hallucinations related to a single theme; symptoms characteristic of disorganized and catatonic types are absent. *Undifferentiated type* is associated with prominent psychotic symptoms that do not meet criteria for other subtypes. *Residual type* is diagnosed by the occurrence of at least one prior episode of schizophrenia with a current clinical picture absent of prominent psychotic symptoms, although signs of the illness persist.

IV. ETIOLOGY AND PATHOPHYSIOLOGY

There is strong evidence that schizophrenia is a neurodevelopmental disorder: the typical onset of the disorder in adolescence, the occurrence of structural and neurofunctional abnormalities at the onset of the illness, and the fact that these abnormalities do not appear to progress with time in most cases [10,47–49]. Several models of the pathophysiology of schizophrenia suggest that causal factors early in development, intra- or perinatally, lead to the brain abnormalities found in the illness. These models further suggest that a "fixed" lesion from early life interacts with normal neurodevelpment occurring later [47,48]. Other models suggest that postnatal developmental abnormalities, like periadolescent synaptic pruning or myelination defects, are responsible for illness pathogenesis [50,51]. These early and late neurodevelopmental models both point to the importance of studying childhood-onset illness; childhood and adolescence may be critical windows of abnormal neurodevelopment in both early- and late-onset schizophrenia.

Understanding the brain mechanisms that regulate neurodevelopment may contribute to our understanding of the pathogenesis of childhood and adult-onset schizophrenia. Excitatory amino acid neurotransmitters such as glutamate are good candidates to be examined in this context. The predominant excitatory neurotransmitter in the mammalian brain, glutamate is responsible for neuronal migration and neuronal survival during early development, neuronal plasticity during adolescence, and neuronal excitability and viability throughout life [52]. Studies of schizophrenia patients have revealed evidence of reduced cerebrospinal fluid glutamate levels, altered glutamate metabolism, and abnormal gene expression of glutamate receptor subunits [53–55]. A glutamatergic hypothesis of schizophrenia has emerged, suggesting that there are the following three critical "windows" of vulnerability: early brain development, adolescence, and early course of illness. The hypothesis suggests that abnormal glutamatergic activity may alter neurodevelopment during these windows [52]. Further study of psychosis in childhood and adolescence may greatly contribute to a better understanding of this hypothesis.

While the etiology of both early- and late-onset schizophrenia remains to be elucidated, biological substrates for the conditions continue to be explored through neuroimaging and genetic studies. As current theory suggests that childhood-onset schizophrenia is continuous with adult-onset schizophrenia, there is great incentive to examine early-onset illness for important etiologic clues [3].

A. Neuroimaging

Recent studies have demonstrated that many of the same morphological differences between adult-onset schizophrenia patients and controls are seen in childhood-onset schizophrenia as well [3,56,57]. A recent NIMH study revealed that patients with childhood-onset schizophrenia had an 8–9% reduction in total cerebral volume as compared to controls [18]. These reduced volumes negatively correlated with total score on the Scale for the Assessment of Negative Symptoms (SANS), leading researchers to consider a more potent neurological basis for childhood-onset schizophrenia [18,58]. In contrast to findings in adult-onset schizophrenia, one study revealed that temporal lobe volumes were larger in childhood-onset schizophrenic patients than in controls. A 2-year follow-up reported significant decreases in hippocampus and superior temporal gyrus (STG) volumes over time during the early course of the illness [18,59,60]. Other

studies have reported that hippocampus and amygdala volumes are not reduced in childhood-onset schizophrenia and that limbic structure reductions may be a consequence rather than a cause of schizophrenia [18,61]. Consistent with adult-onset schizophrenia findings, several studies have reported ventricular enlargement in patients with childhood-onset schizophrenia [18]. Rapoport reported that over a 2-year period, childhood-onset cases showed a significantly greater increase in ventricular volume than controls [15]. Rapoport also reported a significant decrease in midsagittal thalamic area over a 2-year period in patients with childhood-onset schizophrenia [15]. Consistent with adult-onset schizophrenia studies, Frazier and colleagues reported increased volumes in the caudate, putamen, and globus pallidus in neuroleptic-treated childhood-onset schizophrenia patients [56].

Functional imaging studies of patients with childhood-onset schizophrenia have revealed similar findings compared to later-onset patients. A positron emission tomography (PET) study revealed hypofrontality in childhood-onset patients [57]. Magnetic resonance spectroscopy (MRS) studies have revealed decreases in n-acetylaspartate (NAA), a putative marker of neuronal integrity in the frontal cortex and hippocampus of childhood-onset schizophrenia patients [62,63].

B. Genetics

Family, twin, and adoption studies have demonstrated that genetic factors play an important role in the etiology of schizophrenia [64,65]. Age of onset may be significantly affected by genetic influences, as one study revealed a higher correlation between concordant monozygotic twins than between affected siblings and concordant dizygotic twins [66]. This study also reported no significant difference in the rates of more disabling psychotic disorders (schizophrenia and schizoaffective disorder) in the relatives of childhood-onset patients than in the relatives of adult-onset patients. However, there was a significant excess of schizotypal and paranoid personality disorders in the relatives of the childhood-onset patients [66]. Recently, a smooth pursuit eye movement study reported that the anticipatory saccades were greater in the relatives of childhood-onset patients than in adult-onset patients [67].

Recent research has revealed an association between a chromosome 22q11 deletion (velocardiofacial syndrome; VCFS) and schizophrenia in adults. The rate of interstitial deletions of chromosome 22q11 has been found to be higher in adult-onset schizophrenia (2.0%) than in the general population [68,69]. A recent study of very early onset schizophrenic patients found that 6.4% of 47 patients studied had 22q11 deletions. The study also found that the patients with deletions had more pronounced premorbid impairments of language, motor, and social development. The authors concluded that the 22q11 deletions may be associated with an earlier age of onset of schizophrenia, possibly as a result of marked neurodevelopmental abnormalities [70].

V. TREATMENT

Current treatment of schizophrenia in adults involves the judicious use of antipsychotic medication to reduce acute symptoms, maintenance medication to sustain the period of recovery, and psychoeducation of both patient and family to ameliorate factors related to relapse. Unfortunately, carefully designed placebo-controlled studies of the efficacy of antipsychotics in childhood and adolescence are few, and studies of psychoeducational approaches are essentially nonexistent. This section briefly reviews current approaches to the pharmacological and psychoeducational treatment of childhood- and adolescent-onset psychoses.

A. Antipsychotic Medication

There are very few drug treatment studies of child and adolescent psychoses. Three controlled trials of first-generation antipsychotics for the treatment of child and adolescent schizophrenia reported the following results: (1) no difference in treatment effect between haloperidol and placebo [71]; (2) ~50% improvement with thiothixene or thioridazine [72]; (3) a significant treatment effect by haloperidol as compared to placebo [73,74]. Two double-blind trials of second-generation antipsychotics in the treatment of child and adolescent schizophrenia revealed the following results: (1) clozapine was superior to haloperidol [75]; (2) olanzapine was superior to risperidone, which was superior to haloperidol (all three were effective) [11]. A recent double-blind haloperidol-clozapine comparison revealed that clozaril significantly reduced negative and positive symptom scores greater than haloperidol following 6 weeks of monotherapy [11].

B. Side Effects

As atypical antipsychotics have replaced typical agents as the first-line treatment approach to childhood-onset

psychosis, treatment side effects are more commonly those associated with atypical agents. The most common side effects seen with atypical antipsychotics are weight gain, sedation, and dizziness. Agranulocytosis, seizure disorder, and weight gain are side effects of both first- and second-generation antipsychotic medications that have been reported in children and adolescents [11,76]. Clinical potency differentiates typical neuroleptics' tendency to cause certain side effects. Low-potency agents generally produce more antiadrenergic (e.g., hypotension) and anticholinergic (e.g., dry mouth, sedation, blurred vision) effects, while high-potency antipsychotics tend more frequently to result in extrapyramidal symptoms (EPS) (e.g., acute dystonia, akathisia, and Parkinsonism). EPS, tardive dyskinesia (TD), and neuroleptic malignant syndrome (NMS) can be seen with both typical and atypical antipsychotic use. Recently, several open trials of second-generation antipsychotics have revealed a low incidence of EPS, TD, and NMS in childhood and adolescent psychosis treatment [11].

C. Guidelines for Acute Management

There are no absolute, established guidelines for management of childhood-onset psychoses. Most clinicians apply similar approaches as those used in adult-onset psychoses. A complete biopsychosocial approach to the condition is likely the most salient approach to management. While use of atypical antipsychotics have been found to be effective in a limited number of studies of childhood-onset schizophrenia (as well as anticonvulsants in early-onset bipolar disorder), it is important to recognize that medications are only one part of the treatment plan [11]. Patients and their families need to be educated about the potential severity of the condition and the major life changes that will accompany the illness. Compliance with medications and supportive therapy as well as familial support are critical to the management of psychoses. In general, pharmacological management of childhood-onset psychoses should be approached with the following principles: (1) adding one agent at a time; (2) maximizing the use of one agent before adding another; (3) dosages should be started low; (4) medications should not be stopped abruptly [11].

SUMMARY

Psychosis in childhood and adolescence is very real and disabling, and may be more severe than later-onset forms of the disorder. The concept that childhood-onset schizophrenia is continuous with adult-onset schizophrenia has stimulated child and adolescent research studies examining the neurodevelopmental and genetic etiology of psychosis and schizophrenia. As more patients with childhood psychoses are enrolled in research, structural and functional neuroimaging studies may reveal important differences in brain regions and processes that contribute to the disorder. Furthermore, genetic studies may better elucidate the contribution of other conditions, such as VCFS, which may be risk factors for the development of the disorder. The diagnosis, treatment, and management of pediatric psychosis continue to evolve and develop through prospective research studies and as the condition becomes better recognized and studied by clinical and academic psychiatrists.

Neurobiology of Autism and Other Pervasive Developmental Disorders
Basic Mechanisms and Therapeutic Interventions

ANTONIO Y. HARDAN

Western Psychiatric Institute and Clinic, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, U.S.A.

I. INTRODUCTION

Pervasive developmental disorders (PDDs) are described as severe pervasive impairments in several developmental areas such as social interaction, communication, or stereotyped behavior, interests, and activities [1]. Five diagnoses are included under PDD. These are autistic disorder, Asperger's disorder, Rett's disorder (RTT), childhood disintegrative disorder (CDD), and pervasive developmental disorder not otherwise specified (including atypical autism). The validity of autism and RTT disorder as a diagnostic category is well established, but the validity and definition of the other PDDs is more controversial [2]. Autism is the prototypic disorder and will be discussed first.

II. AUTISM

Autism is a neurodevelopmental disorder manifested by 36 months of age and is characterized by abnormalities in social skills and behavior, verbal and nonverbal communications, symbolic and imaginative play, reasoning, and related complex behavior [1]. The prevalence rate is 0.02–0.05% under age 12 [3–4]. However, a more recent survey reported 10-15/10,000 prevalence for PDDs, suggesting that the prevalence may be considerably higher than previously thought [5]. In fact, when using less rigorous criteria prevalence rates ranged from 1/250 to 1/1,000 [6–8]. Further, if severe mental retardation with some autistic features is included, the rate can rise as high as 20/10,000. Autistic disorder is found more frequently in boys than in girls. Three to five times more boys have the disorder, but autistic girls tend to be more seriously affected and more likely to have family histories of cognitive impairment than do boys [9].

Although autistic disorder was first considered to be psychosocial or psychodynamic in origin, evidence has accumulated over the past two decades to support a biological substrate. Autism is currently considered to be a disorder of early brain development involving neuronal organizational events. Studies of brain structure have implicated several aspects of brain development including the elaboration of dendritic and axonal ramifications, the establishments of synaptic connection, and cell death [10]. Even though neuropathologic studies have provided evidence of structural abnormalities in cortical and subcortical structures, theoretical model has focused more on one single structure than on neural systems. In fact, one current debate involves

the relative roles played by disturbances of the frontal lobe and the cerebellum in the pathophysiology of autism [11]. The frontal systems models suggest that abnormalities in the prefrontal cortex is expressed functionally as a reduced capacity in shifting attention leading to the cognitive and behavioral symptoms observed in autism. The frontal dysfunction model is supported by functional imaging, neuropsychologic, and neurophysiologic studies [11–13]. In contrast, the cerebellar model proposes that impaired ability to shift attention is originated in the vermis as evidenced by the structural and neurophysiologic abnormalities observed in this structure [14–15]. However, recent structural and functional imaging findings suggest that the anatomic abnormalities are generalized, involving several brain areas and resulting from an abnormal development of connections in yet to be defined functionally disturbed neural networks that include the cerebral cortex, limbic system, and cerebellum [16–18].

A. Pathology

Autopsy studies in autism have failed to show any abnormalities of gross brain structures. There have been, however, several reports of increased brain size and weight [10,19,20]. In a review of 19 autopsy cases with autism, brain weight was found to be increased more in children than in adults [10–19]. Microscopic analysis of cerebral and subcortical regions of a number of autistic individuals revealed increased cell-packing density and decreased cell size in the hippocampus, subiculum, entorhinal cortex, amygdala, mamillary body, and medial septal nucleus bilaterally [10–19]. Outside the forebrain, additional abnormalities have been observed in the cerebellum and include decreased numbers of Purkinje cells, predominantly in the posterior neocerebellar cortex and adjacent archicerebellar cortex, while the vermis is less affected [10,19,20]. These observations suggest abnormalities in neuronal alignment and in the elaboration, pruning, and selective elimination of neuronal processes in the cerebral cortex and cerebellum.

B. Genetic Factors

There is mounting evidence that autism has a strong genetic basis. In several surveys, between 2% and 5% of siblings of those with autism also had autistic disorder, a rate that is 20–60 times greater than in the general population [21,22]. Genetic studies have also reported higher rates of concordance in identical twin pairs, although absolute rates vary from one study to

another [23–25]. A recent British twin study showed 60% concordance rate for 25 pairs of monozygotic twins and no concordance for 25 pairs of dizygotic twins [25], with an estimate of heritability of 91–93%. When a broader spectrum of related cognitive and social abnormalities is considered, 92% of monozygotic twins were concordant versus only 10% of dizygotic pairs [25].

Investigators examining the genetics of autism recognize that more than one gene appears to be involved [26], or that several loci are involved with up to 15 loci possible [27]. A broader phenotype of autism has also been suggested which includes milder social and language-based cognitive deficits [25]. In fact, clinical reports and multiple-incidence (multiplex) family studies suggest that the genetic liability for autism may be expressed in some of the non-autistic relatives in a phenotype that is milder but quantitatively similar to the symptoms of autism [28].

C. Biochemical Factors

Studies of the hypothalamic-pituitary and thyroid functioning in autism have not led to consistent results when studied both at baseline and in response to stress or to challenge tests [29]. The noradrenergic functioning appears to be free of marked alterations in most individuals with the possibility of a subgroup of cases exhibiting overresponsiveness to stress [29]. In contrast, abnormalities of the serotoninergic and dopaminergic systems have been reported.

1.   Serotonin

The study of peripheral and central levels of serotonin (5-hydroxytryptamine; 5-HT) or its precursors or metabolites has stimulated the most neurochemical research in autism. This interest was originally sparked by an early report of high blood levels of 5-HT in autism [29]. Most subsequent studies have focused on blood levels of 5-HT and have been consistent in reporting elevated plasma 5-HT in at least one-third of patients with autistic disorder [30,31]. However, this finding is not specific to this disorder since people with just mental retardation also display this abnormality. Investigations of the platelet storage of 5-HT has also been conducted but results have not been consistent [31]. A study of hyperserotonemic relatives of children with autism found some suggestive differences in platelets 5-HT uptake and the numbers of platelets 5-HT receptors in subgroups of the relatives [33]. Recent studies have focused on the serotonergic receptor

gene. One investigation reported no differences in allele and genotype frequency for the 5-HT$_2$ receptor [34], and another found evidence of linkage and association between the serotonin transporter gene and autism [35]. However, the latter finding could not be replicated [36].

Investigations of the serotoninergic system have also included the examination of tryptophan, a dietary precursor of 5-HT. Tryptophan levels at baseline and after dietary manipulation and challenge tests have been reported with conflicting results [37–40], suggesting that further research is warranted. Levels of 5-hydroxyindoleacetic acid (5-HIAA), the main metabolite of 5-HT has also been examined. Results of studies measuring urinary levels of 5-HIAA have not been concordant with one investigation reporting increased urinary levels of 5-HIAA [41] and others not detecting any differences between autistic subjects and controls [42–43]. Cerebral spinal fluid (CSF) 5-HIAA levels have also been measured with mostly negative findings suggesting that central 5-HT metabolism is minimally if at all affected in autism [44–45].

2. Dopamine

The dopaminergic system has also been investigated in individuals with autism mostly through the measurement of homovanillic acid (HVA) (the major dopamine metabolite) in CSF, plasma, and urine. Studies of CSF HVA levels have not been consistent with some investigators reporting elevated concentration [44–46] and others not [45,47]. In the one study of plasma HVA, no differences were observed between unmedicated autistic subjects and normal controls [43]. In contrast, several studies of urinary levels of HVA have reported that the excretion of this metabolite is elevated in autism, but a more recent and large study was not successful in replicating this finding [29]. Therefore, the peripheral and central levels of dopamine metabolites appear to be unchanged or only slightly altered in autism.

3. Neuropeptides and Neurotrophins

Neuropeptides play an important role in central neurotransmission and neuromodulation which led several investigators to examine the potential function of these substances in the pathophysiology of autism. Initial research has focused on the opioid system in light of early reports of efficacy of opiate antagonist in the treatment of self-injurious behavior in autism [48]. Subsequent treatment studies have failed to replicate these findings and did not support a significant

role of this system in autism [50,51]. A recent study examined blood levels of certain neuropeptides and neurotrophins in healthy children and in children with either autism, mental retardation, or cerebral palsy (CP) [52]. Concentrations of substance P and antibodies to myelin basic protein did not differ among the four groups. However, most children with autism (97%) had elevated concentrations of neurotrophin 4, vasoactive intestinal peptide, brain derived neurotrophic factor, and calcitonin-related gene peptide; few (9%) children with CP and none (0%) of the healthy group had elevated levels. Interestingly, most children with mental retardation (92%) also had elevated levels of neuropeptides and neurotrophins, and the pattern of increase of these substances did not distinguish children with autism from those with mental retardation only [52].

D. Electroencephalography and Neurophysiology

The incidence of electroencephalographic (EEG) abnormalities in individuals with autism have ranged from 10% to 83% depending on inclusion criteria, level of mental retardation, and method of interpretation of EEG [53–55]. Common EEG abnormalities include diffuse or focal spikes, slow waves, paroxysmal spike and slow wave activity, and mixed discharges, this last pattern being the most frequently one observed [55]. Epilepsy is also common in autism with a cumulative prevalence by young adulthood of 20–35% [56,57]. The onset of seizures can occur at any age, but its development is more common in early childhood and adolescence [58,59].

Various methods have been used to assess the neurophysiological systems in autism. Studies of evoked potential have essentially been limited to the study of auditory brainstem potential, and results have not been consistent. Early studies have reported a high incidence of abnormalities [60,61]. However, subsequent investigations with more rigorous methodologies that excluded children with underlying neurological conditions and controlled for age and sex did not show differences between autistic children and controls. [62,63]. Studies of attentional abnormalities have demonstrated the integrity of the N$_{100}$ and N$_{200}$ potentials related to basic attentional processes [63–65]. In contrast, studies using contemporary methods have provided evidence of abnormalities in P$_{300}$ in individuals with autism, an event-related potential that is generated by the brain's processing of sensory stimuli [66]. This pattern reflects reliance by the cerebral cortex

on less efficient and alternative neural pathways for processing of information [66].

E. Eye Movement

Eye movement studies have originally reported abnormalities in postrotatory nystagmus and nystagmus during REM sleep [67]. These findings were attributed subsequently to poorly designed methodologies [68]. Recent studies have used newly developed paradigms to examine the functional integrity of different systems and structures including the cerebellum, brainstem, basal ganglia, and frontal and parietal cortex. In a study of responses to vestibular stimulation, autistic children exhibited abnormalities suggestive of neurophysiologic dysfunction perhaps involving the brainstem [68]. In a visually guided saccades study to unpredictable targets, normal eye movements, although hypometric horizontally, were reported in mentally retarded individuals with autism in comparison to non-mentally retarded controls [69]. Two well-designed independent studies found no abnormalities of vestibulo-ocular reflexes, or in pursuit of visually-guided saccadic eye movements [70,71]. In a recent eye movement study, visually guided saccades were normal in non-mentally retarded individuals with autism suggesting the absence of functional disturbances in the cerebellar lobules VI and VII, and in automatic shifts of visual attention. However, deficits were observed in two volitional saccade tasks, the oculomotor delayed-response task and the antisaccade task, indicating possible dysfunction in the prefrontal cortex and its connections with the parietal cortex [72].

F. Immunological Factors

Several immunological factors have been identified in individuals with autism, suggesting the pathogenetic role of autoimmunity in this severe developmental disorder. Genetic susceptibility, association with viral infection, and immunologic dysfunction have all been reported [73]. Abnormal cell-mediated immunity and abnomal T-cell subsets have been described in some patients with autism [74,75]. Brain autoantibodies to neural antigens such as myelin basic protein (anti-MBP) and neuron-axon filament protein (anti-NAPF) have been found at higher rates in autistic children than in normal controls [76–79]. Recently, abnormal cytokine profiles with a decrease in TH 1 cytokine-producing cells and an increase in TH 2 cytokine-producing T-cells have been observed [80].

Immune-modulating treatments such as intravenous immunoglobulin have been reported to be beneficial in some but not all children with autism [76,81,82]. Taking into consideration that autoimmune abnormalties have been observed in only a subset of patients with autism, it is unlikely that an immune disorder is the only or primary causal factor. Immunological factors may be contributing to the onset of autism or to some of its clinical features. This observation is supported by the recent report of high correlation between the expression of monoclonal antibody D8/17 and severity of compulsive behaviors in a subgroup of autistic children [83].

G. Neuroimaging

1. Quantitative MRI

Structural imaging studies in autism have found a variety of morphometric alterations involving several brain structures including brain size [84–87], cerebellum [17,18,88], hippocampus and amygdala [89], corpus callosum [90–92], and basal ganglia [93] (Table 1). Initial imaging studies have focused on area measurements of the posterior fossa structures and have led to equivocal and controversial findings. A series of studies reported the existence, in the neocerebellar vermis, of either a generalized hypoplasia [94] or a selective hypo and/or hyperplasia of lobules VI and VII [14,15,95]. However, several replication studies using rigorous methodology failed to detect evidence of either of these findings [17,18,88,96,97]. In contrast to area measurement, volumetric investigations have been more consistent, with most studies reporting increased cerebellar volume [17,18].

Increased cerebellar volume is concordant with recent MRI studies reporting increased brain size in autism [84–87]. These findings are consistent with head circumference studies observing increased head size [98,99] and macrocephaly in autism [100,101]. These findings are the most consistent observations in autism and suggest that brain enlargement may be a biologic marker for this disorder. This increase in brain size appears to be the consequence of enlargement of parietal, temporal, and occipital but not the frontal lobe [84–86], and seems to be more evident in children than in adults [10–87]. Although the pathophysiology of brain enlargement in autism remains unclear, these data suggest that developmental brain processes such as synaptic pruning may be responsible for this abnormal growth.

Table 1 Morphometric Neuroimaging Findings in Autism

Structure	Finding	Replicability
Total brain[a]	Increased	+ +
Cerebellum[a]	Increased	+
Cortical lobes[a]		
Frontal	No differences	0
Temporal	Increased	0
Pareital	Increased	0
Occipital	Increased	0
Amygdala[a]	Decreased	−
Hippocampus[a]	Decreased	−
Basal ganglia[a]		
Caudate	Increased	0
Putamen	No differences	0
Globus pallidus	No differences	0

Posterior subregions	Decreased	+
Total brainstem[b]		−
Pons	Decreased	−
Midbrain	Decreased	−
Medulla	Decreased	
Total vermis[b]	Decreased	−
Lobules I–V	Decreased	− −
Lobules VI–VII	Decreased	− −
Lobules VIII–X	Decreased	−
Ventricular system[a]		
Lateral ventricles	Increased	+
Third ventricles	Increased	+
Fourth ventricles	Increased	+

[a]Volume.
[b]Area measurement.
Replication key: 0 = no replication; + = one or two replication; + + = several replications; − = one or two articles with different findings; − − = several articles with different findings

2. Magnetic Resonance Spectroscopy

To date, two studies using magnetic resonance spectroscopy (MRS) have been reported in the literature [102,103]. A ^{31}P MRS study of the dorsal prefrontal cortex of 11 non-mentally retarded individuals with autism and 11 age-, IQ-, gender-, race-, and SES-matched healthy controls, found decrease levels of phosphocreatine (PCr) and esterified ends in the autistic group [102]. Interestingly, severity of autism was associated with alterations of MRS metabolites. The second study used ^{1}H MRS to measure N-acetyl aspartate (NAA), creatine + phosphocreatine (Cr + PCr),

and choline (Cho) levels in the right medial prefrontal cortex in a group of non–mentally retarded adults with autistic spectrum disorder and matched controls [103]. Higher concentrations of NAA, and Cr + PCr, and Cho were found in the autistic group. NAA concentration was significantly related to the scores on the Yale-Brown Obsessive Compulsive Scale, and Cr + PCr was significantly related to the Autism Diagnostic Interview summary score [103].

3. Positron Emission Tomography and Single-Photon Emission Computed Tomography

Most initial studies with positron emission tomography (PET) or single-photon emission computed tomography (SPECT) in individuals with autism have failed to show focal reductions or elevations in glucose metabolism or oxygen utilization [104–107]. Correlational studies that compared metabolic rates of paired regions in autistic young adult men and controls found unusual metabolic patterns in frontal/parietal regions and the neostriatum and thalamic regions that subserve directed attention [108]. In contrast to the limited findings reported by early studies, recent PET investigations have been able to find localized brain abnormalities in autism. The differences are probably due to the improvement in the spatial resolution of the imaging methods (roughly from 20 mm to 5 mm) and to the application of the whole-brain statistical parametric mapping analysis instead of the region-of-interest method used in the past.

In a PET investigation of the metabolic maturation of the frontal cortex in preschool autistic children, a transient frontal hypoperfusion was found in autistic children (ages 3 and 4), suggesting a delayed frontal maturation consistent with the clinical data and cognitive performance reported in the literature [109]. In a follow-up study of neocortical brain dysfunction, marked bilateral hypoperfusion was found in the temporal lobes, centered in the associative auditory and adjacent multimodal temporal cortex, in a group of autistic children [110]. Thalamic abnormalities have also been reported [111,112]. In a study of subjects performing expressive language tests, alterations of the thalamic blood flow was found in autistic patients relative to that of the healthy control group [112]. Furthermore, autistic subjects differed from controls in the blood flow of the dentatothalamocortical pathway [112], a brain pathway that is important for language production and sensory integration. Finally, in a study of 17 patients with autism, significant metabolic reductions in both the anterior

and posterior cingular gyri were observed, but no metabolic abnormalities were observed in the amygdala and the hypocampus [113].

4. Functional MRI

The advent of functional MRI (fMRI) has provided new opportunities to investigate brain functions in pervasive developmental disorders. In a study of social intelligence using fMRI, non–mentally retarded individuals with autism activated the frontotemporal regions but not the amygdala when making mental inferences from the eyes [114], supporting the amygdaloid dysfunction hypothesis [10]. In a subsequent study, the same investigators assessed local processing and visual search abilities in a group of individuals with autism and controls using the Embedded Figures Task [115]. Several cerebral regions were similarly activated in the two groups, but individuals with autism demonstrated greater activation of ventral occipitotemporal regions, while normal controls showed generally more extensive task-related activation including the prefrontal cortical areas [115]. These findings suggest that the cognitive strategies adopted by the two groups are different on a task in which people with autism have been reported to demonstrate superiority over controls [115]. In a study of face discrimination, individuals with autism demonstrated a pattern of brain activity that is consistent with feature based strategies that are more typical of nonface object perception [116]. Results from the face-discrimination task showed that, compared to controls, activation in the fusiform gyrus was decreased in the autistic group, but was increased in the inferior temporal gyri [116]. Recently, a study of eight males with autism and eight matched normal controls reported different patterns of activation between the two groups during visually paced finger movement compared to a control condition that consisted of visual activation in the absence of motor response [117]. Findings from these fMRI studies suggest that individuals with autism when compared to healthy controls depend on different neural systems and sometimes use abnormally large neuronal networks to execute simple and complex cognitive functions.

H. Therapeutic Interventions

Since pharmacotherapy is of limited benefit in targeting the core symptoms of autism, psychosocial interventions are essential in the management of social, communication, and behavioral impairment. Treatment is aimed at increasing prosocial behaviors, decreasing aberrant behaviors, and assisting in the development of verbal and nonverbal communication. Educational and behavioral methods are currently considered the treatments of choice. Behavior modification techniques have proven to be effective in decreasing aberrant behaviors and reinforcing socially acceptable interaction and encouraging self-care skills. Structured classroom training in combination with behavioral approaches and language remediation are effective treatment strategies for a large number of autistic children. These strategies should be complemented and, even better, preceded by the introduction of in-home early intervention. The implementation of such modalities or training programs may yield to gains in the areas of language and cognition and decreases in maladaptive behaviors. These training programs are rigorous, require much of parents' time, and require as much structure as possible and daily program for as many hours as possible. Therefore, careful training of parents and in-home workers is essential to achieve considerable improvement in the target symptoms.

While no drug has been found to treat all the symptoms of autism, psychotropic agents are a valuable adjunct in comprehensive treatment programs to target a wide range of associated symptoms, including aggression, impulsivity, low level of tolerance for frustration, self injurious behaviors, hyperactivity, and obsessive-compulsive symptomatology. Drug therapy is also beneficial in treating comorbid disorders such as depressive and anxiety disorders.

Several studies of the effects of various typical antipsychotics in autistic children have been conducted. The use of typical antipsychotic is hampered by the potential for side effects and specifically tardive dyskinesia in light of the increased incidence of this movement disorder in this population [118]. Haloperidol remains the best-studied agent with several published controlled studies indicating the effectiveness of the agent in targeting hyperactivity, stereotypies, social withdrawal, irritability, and mood lability [119,120]. Pimozide has also been shown to be effective in children with autism in one well-designed study [121]. Recently, risperidone, a high-potency atypical antipsychotic with combined dopamine type 2 and 5-HT$_2$ receptor antagonism has been shown to be effective in several open-label studies and one placebo-controlled study in decreasing the rates of aggressivity, hyperactivity, and self-injurious behavior in children, adolescents, and adults with autism [122,123]. Other

novel antipsychotics, such as clozaril and olanzapine, have reportedly been effective in the treatment of individuals with autism, but no controlled trials have been published so far [124–125].

The serotonin reuptake inhibitors (SRIs) have been used to target obsessive-compulsive and stereotyped behaviors. Clomipramine, a tricyclic antidepressant (TCA) with potent inhibition of 5-HT, has been shown in a well-designed study to be more effective than placebo in improving the core symptoms of autism, anger/uncooperativeness, hyperactivity, and obsessive-compulsive symptoms [126]. However, subsequent studies have failed to replicate these findings and have reported a high incidence of side effects including QT_c prolongation [127,128]. Owing to the adverse effects associated with clomipramine, selective SRIs (SSRIs) have been considered to be a safer alternatives with their better tolerability and lack of significant cardiac side effects. To date, only one double-blind placebo-controlled study of fluvoxamine, an SSRI, have been reported to be effective in adults with autism [129]. Fluvoxamine was effective in reducing repetitive thoughts and behaviors, maladaptive behavior, and aggression [129]. In contrast, a well-designed and controlled study using fluvoxamine in children and adolescents with autism failed to show positive results [130]. Other SSRIs, including fluoxetine, paroxetine, and sertraline, have also been shown to be effective in the treatment of individuals with autism, but no controlled trials have yet been conducted [130].

Several others medications have also been used to treat individuals with autism. Two well-designed studies of methylphenidate were found to be effective in decreasing hyperactivity [131,132]. However, adverse effects were observed at high rates, including social withdrawal, dullness, sadness, and irritability. Two alpha 2-adrenergic agonists, clonidine and guanfacine, were found in several trials to be effective in the treatment of related symptoms of autism including hyperactivity and anxiety [130,133,134]. Despite early reports of potential benefit, naltrexone, an opioid receptor antagonist, has failed to demonstrate efficacy in improving the core and related symptoms of autism [51–135]. Finally, data are also available, though limited in some instances, on numerous agents that appear to be either promising such as lamotrigine [136], divalproex sodium [137], mirtazapine [130], buspirone [138], propanolol [139], donepezil [130], and vancomycin [140] or not encouraging in the example of amantadine [141], secretin [142,143], fenfluramine [144], and intravenous immunoglobulin [82].

III. OTHER PERVASIVE DEVELOPMENTAL DISORDERS

A. Asperger's Disorder

Individuals with Asperger's disorder show severe, sustained impairment in social interaction and restricted repetitive pattern of behavior, interests, and activities [1]. Unlike autistic disorder, in Asperger's disorder there are no significant delays in language, cognitive development, or age appropriate self-help skills. Hans Asperger, an Austrian physician, first described a syndrome applied to people with normal intelligence who exhibit qualitative impairment in reciprocal social interaction and behavioral oddities without delays in language development [145]. This syndrome was originally named *autistic psychopathy*, but was later changed to Asperger's disorder or syndrome to avoid misinterpretation with sociopathy [147]. Estimates for the prevalence of the disorder have ranged from 3.6/1000 to 1/10,000 [145,146]. This disorder is more commonly found in boys than in girls, and the male/female ratio is higher than in autism.

The validity of Asperger's disorder as an entity distinct from high-functioning autism or autism has been debated [147], but important differences have been reported [148]. Asperger's disorder is characterized by a later age of onset, a better prognosis, more prominent clumsiness, and less severe social/communicative deficits when compared with individuals with high-functioning autism. Furthermore, evidence from the DSM-IV field trials supports the distinction of Asperger's disorder from both autism and PDD, NOS [149]. Recent studies comparing children with Asperger's disorder and children with autistic disorder reported that children with Asperger's disorder were more likely to look for social interaction and seek vigorously to make friends [149]. The overlap between Asperger's disorder and other diagnostic concepts such as nonverbal learning disabilities (NLD) provide further evidence to support the differences between the Asperger's disorder and high-functioning autism since the former was frequently associated with NLD profile while the latter was not [150].

The cause of Asperger's disorder is unknown, but genetic studies, even though limited, suggest the presence of genetic factors and possible relation to autistic disorder. Originally, Asperger observed that the disorder is more commonly found in fathers of the boys who had the disorder [145]. Several pairs of identical twins have been reported who have Asperger's disorder

[151], and some of the clinical characteristics of this disorder appear to be more common in fathers of affected individuals [152]. Data on birth complications suggest an increased rate of prenatal and perinatal complications [145–151] but not as much as non–mentally retarded individuals with autism [152]. Neurochemical and neurophysiological studies have been limited. A sleep study of eight patients with Asperger's disorder showed decreased sleep time in the first two-thirds of the night, REM sleep disruption, and increased number of shifts into REM sleep from a waking epoch, suggesting a defective sleep control systems in this disorder [153].

Several neuroimaging studies have been reported examining individuals with Asperger's disorder. Structural brain studies have reported focal areas of cortical polymicrogyria and cortical defects [154], left occipital lobe damage [155], thinning of the posterior corpus callosum [154], and enlargement of the right lateral ventricles [156]. Recently, qualitative area measurements of specific brain structures were measured in 8 individuals with Asperger's disorder [157]. In comparison to controls, no abnormalities were found in the midsagittal areas of vermal lobules I–V, and VI and VII, total area of the midsagittal corpus callosum, and the hippocampal body [157]. SPECT studies have reported left occipital hypo-perfusion without global or regional differences in blood flow or oxygen metabolism [158], and abnormalities in right hemisphere functioning [156]. A recent PET study examining individuals with Asperger's disorder reported significant reductions in both the anterior and posterior cingulate gyri while performing a serial verbal learning test [113]. No differences were found in the metabolism of the amygdala or the hippocampus between the affected group and controls [113]. Finally, fMRI studies have reported a wide range of findings in Asperger's disorder, including difficulties with face perception [159], no activation in the amygdala while decoding emotional expression [114], and abnormalities in the pattern of brain activation during face discrimination involving increased activity in the inferior temporal gyri and decreased activation in the fusiform gyrus [116].

No controlled trials are available examining the effectiveness of psychosocial or pharmacologic inter-ventions in Asperger's disorder. Treatment strategies have been developed based solely on clinical experi-ence. Specialized educational placements, social and communications skills training, and real-life skills are often necessary [160].

B. Rett's Disorder (RTT)

In 1966, Andreas Rett, an Australian physician, iden-tified a syndrome in 22 girls who appeared to have had a normal development for a period of at least 6 months, followed by severe developmental deteriora-tion [161]. The onset of this disorder is characterized by progressive symptoms in which children developed some behaviors suggestive of autism associated with deceleration of brain growth and aberrant behaviors and symptoms not typical of autism [1]. The sympto-matology of RTT include characteristic hand move-ments (hand washing and hand wringing), severe mental retardation, ataxia, and breath-holding spells [1]. The diagnostic criteria include apparently normal prenatal and perinatal development with normal head circumference at birth followed by decelerated head growth, loss of purposeful hand movements, lack of social engagement, and marked communicative and cognitive delay [1]. The onset of the condition is between 5 and 48 months, and has been essentially observed only in girls, with two exceptions [1]. The estimated prevalence of RTT is 1/10,000 to 1/23,000 live female births [162].

The biologic and genetic foundations of RTT were not clear until recently, when it was reported that mutations in the X-linked $MECP_2$ gene were detected in ~50% of RTT patients [164]. Methyl-CpG-binding protein 2 (MeCP2) is an abundant chromosomal protein that binds specifically to methylated CpG dinucleotides in the genome and mediates the tran-scription repression through interaction with histion deacetylase and the corepressor SIN3A. Because MECP2 mutations have not been shown in all affected subjects, other genetic factors may be involved in the pathogenesis of RTT including the X chromosome and autosomal loci [165]. Genetic contributions to RTT have previously been suspected because of the exis-tence of a small number of familial cases where higher degrees of concordance in monozygotic than dizygotic twins were reported [166].

Associated features of RTT include seizures in up to 84% of affected children and disorganized EEGs with some epileptiform discharges is observed in almost all young children with RTT, even in the absence of clin-ical seizures [167]. Nonspecific patterns on EEGs have been reported including rhytmical slowing (most com-mon), diffuse and scattered or bilateral-synchronous spikes or sharp waves, slow spike-wave complexes, and intermittent spike or slow-wave activity followed by suppression of background activity [167,168]. The most common types of seizures are generalized tonic-

clonic and partial complex seizures, with overall lower frequency and decrease severity after the teenage years except for partial seizures [169]. An additional associated feature is irregular respiration, with episodes of hyperventilation, apnea, and breath-holding. Interestingly, the disorganized breathing occurs in most patients while they are awake; during sleep, breathing usually normalizes [170]. This pattern suggests normal brainstem control of ventilation and that disordered breathing seen during wakefulness is due to abnormality of cortical influence on ventilation [170].

Several neurobiologic abnormalities have been reported in RTT. Autopsy studies have described decreased brain weight in RTT ranging from 14% to 80% with diffuse cortical atrophy but without degenerative evidence [171]. Further neuropathologic findings include deficient pigmentation of the substantia nigra [172] and locus coeruleus [173], abnormalities of dendritic architecture of pyramidal neurons [174], gerneralized cerebellar atrophy with associated cell loss, gliosis in the granular, Purkinje, and molecular layers [175], and mitochondrial inclusions [174]. Several metabolic abnormalities have been suggested including decreased cortical and subcortical levels of choline acetyltransferase [176], elevated CSF beta-endorphins immunoreactivity, glutamate, and lactate levels [177,178], and decreased CSF brain gangliosides [179]. However, replication studies are either lacking or have failed to support these findings [180,181].

Structural and functional neuroimaging studies have been reported in RTT. Qualitative CT and MRI studies have not been consistent in reporting structural abnormalities in the frontal cortical area, brainstem, and thalamus [182,183]. Recent quantitative morphometric MRI measurements of girls with RTT revealed reduced cerebellar and cerebral volumes which is consistent with the neuropathologic studies [184,185]. Evidence of greater loss of gray matter in comparison with white was also found especially in the caudate, prefrontal, posterior-frontal, and temporal regions [184,185]. Functional imaging studies have been limited. Few reports of magnetic resonance spectroscopy (MRS) have been published, and results are not concordant [186–188]. Most of these studies involved relatively small numbers of subjects and studied one region of the brain (single-voxel); only one study used spectroscopic imaging performed in one slice. Recently, a multislice high-resolution ^{1}H MRS imaging study was conducted in 17 girls with RTT and found metabolic impairments involving both gray and white matter in the cortical lobes and the insular cortex [189]. Average Cho concentrations were higher possibly from gliosis,

and average NAA concentrations were lower in the affected subjects, suggesting reduced neuronal and dendritic tree size. Finally, in a SPECT study involving a small number of subjects, decreased cerebral blood flow was observed predominantly in the frontal lobes, indicating the loss of hyperfrontality in RTT [168].

Psychosocial and pharmacologic therapy is aimed at symptomatic intervention. Behavioral therapy is useful to control self-injurious behavior and may help in regulating the breathing disorganization. Many patients become wheelchair-bound with muscle wasting and rigidity. Physiotherapy has been beneficial for the muscular dysfunction. Medications are often necessary for the treatment of seizures and behavioral dyscontrol. Several investigators have demonstrated the efficacy of ketogenic diet and carbamazepine, especially when there is a predominance of partial-complex seizures [190]. Psychiatric symptoms can be treated pharmacologically, but no controlled data are available.

C. Childhood Disintegrative Disorder

CDD is characterized by marked regression in several areas of functioning after at least 2 years of apparently normal development [1]. This condition was originally referred to as *dementia infantilis* and later on was called *disintegrative psychosis*. It was first described by Theodor Heller in 1908 as a deterioration of several months occurring in 3- and 4-year-olds who had normal early development [191]. This deterioration is characterized by a loss of social skills and speech together with a severe disorder of emotions, behavior, and relationships, leading to symptomatology that closely resembles children with autism [1]. Limited epidemiological data are available. CDD is estimated to be at least one-tenth as common as autistic disorder, with an estimated prevalence to be about one case in 100,000 boys [192,193]. The ratio of boys to girls seems to be between four and eight boys to one girl. To date there have been 106 reported cases [192,193].

The pathogenis of CDD is unclear, but neurobiological factors are certainly involved. The unusual and distinctive onset typically prompts a search for general medical conditions. A number of CNS disorders, including the neurolipidoses, adrenoleukodystrophy, and metachromatic leukodystrophy, have been associated with this disorder. Limited family and genetic data are available with no significant family history found in one small study of 10 children with CDD [194]. To date, no investigations have examined neurochemical abnormalities in CDD, and no chromosomal abnormalities have been reported [192,193]. Two

autopsy studies of patients who possibly had CDD revealed evidence of cerebral degeneration suggestive of lipidosis [195,196]. The frequent association of EEG abnormalities and seizure disorders has also suggested an unidentified neuropathological process. [192,193]. Several studies have shown high rates of EEG abnormalities and seizure disorders similar to those reported for autism [193]. Finally, a CT scan study of 10 patients with CDD reported that five scans were normal and the reminder showed nonspecific abnormalities [193].

No specific pharmacologic or psychosocial interventions have been identified or developed to treat CDD. The treatment approach is the same as that for autism, taking in consideration the clinical similarity between the two disorders.

D. Pervasive Developmental Disorder, Not Otherwise Specified

PDD NOS is characterized by severe impairment in social interaction or communication skills or the presence of stereotyped behavior, interests, and activities [1]. It represents a subthreshold or residual subclass within the PDD class. It is more common than autism, affecting one in 200 children, and has overall a better prognosis [197]. Limited neurobiological research is available, given the heterogeneity of this group and difficulties with the diagnostic concept. Treatment is very similar to that for other PDDs, combining psychosocial and psychopharmacologic interventions targeting aberrant and disruptive behaviors.

IV. SUMMARY

PDDs are very complex, and our understanding of the pathophysiology of these disorders has increased greatly over the past 15 years, although basic questions have yet to be answered. With the exception of autism and RTT, studies in the phenomenology, epidemiology, natural course, and treatment of these conditions are needed. Genetic and molecular biological studies are promising and have led to significant progress, especially for RTT. Many genes appear to influence the phenotypic manifestations of autism and Asperger's disorder, and the next decade is critical for the identification of specific genes involved in these developmental disorders. Neuroimaging studies using PET, SPECT, fMRI, and MRS will provide the tools to examine in vivo brain functioning and help identify the different neural networks involved

in the debilitating symptoms of PDD. Finally, investigations of the plasma concentrations of neuropetides and neurotrophins are potentially useful for understanding the developmental neurobiology of these disorders and monitoring and assessing the efficacy of psychosocial and psychopharmacologic interventions.

Cognitive Deficits in Schizophrenia

CAMERON S. CARTER and STEFAN URSU

Western Psychiatric Institute and Clinic, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, U.S.A.

I.   INTRODUCTION

Since the earliest description of schizophrenia, cognitive deficits have been noted to be a prominent and enduring aspect of the illness [1]. During the past decade, however, there has been a dramatic increase in interest in this aspect of the psychopathology of schizophrenia. There appear to be at least two reasons for this phenomenon. The first reflects an increased awareness of the functional significance of impaired cognition in schizophrenia, and the treatment refractoriness of cognitive deficits [2]. The second factor reflects the emergence of cognitive neuroscience as a major, new, integrative neuroscientific discipline, the tools and constructs of which are being increasingly applied to investigations of the neural basis of cognitive deficits in brain disorders [3,4].

Cognitive dysfunction is a highly clinically relevant aspect of schizophrenia. A number of studies during the past decade [5–8] have strongly suggested that cognitive deficits are highly correlated with poor outcome and functional disability in this illness. Impaired cognition more strongly predicts poor social and occupational functioning than the positive symptoms, such as hallucinations and delusions, which have traditionally been the targets of therapy. Yet it is clear that the typical neuroleptics have no positive impact on this domain of functioning. The existing data for atypical agents are mixed and suggest only limited benefit, at best [2,9–12], with the majority of patients treated with our best atypical agents continuing to be markedly cognitively impaired. The question whether the modest cognitive improvements translate into improved social or occupational functioning of patients has not adequately been addressed, and the evidence for such associations is still unclear [9,13,14]. As a result of this new knowledge regarding the clinical significance of cognitive deficits in schizophrenia, there has been a renewed interest in understanding and treating cognitive deficits in schizophrenia, in an effort to move the treatment of this illness beyond symptom control and relapse prevention and toward rehabilitation and disability reduction.

Accompanying this growing awareness of the functional importance of cognitive impairments has been a dramatic advance in the tractability of the problem, owing to the development of cognitive neuroscience and its application in clinical neuroscience research. In this new field of neuroscience, methods from experimental cognitive psychology are integrated with physiological methods such as human functional neuroimaging or single cell recording in behaving non-human primates. As one of the most active areas in neuroscience it has provided a wealth of new knowledge regarding the neural basis of cognition. It has also provided psychiatric investigators with a powerful new

methodology for investigating the neural basis of impaired cognition in schizophrenia. A prerequisite for applying these tools, however, is knowledge of the kinds of cognitive deficits which are common in schizophrenia, of their reliable measurement, and of their application in functional imaging and electrophysiological studies in clinical populations.

In this chapter we will discuss the range of cognitive deficits observed in patients with schizophrenia, beginning with a discussion of the involvement of the major cognitive systems of attention, memory, and language processing, as well as deficits in sensory processing. We will then discuss an overarching cognitive theory to account for the range of cognitive deficits present in schizophrenia, namely, the disruption of what has been referred to as cognitive control or executive functions. Finally, we will selectively review the literature relating cognitive dysfunction to specific neural systems in schizophrenia with an emphasis on how this literature might provide clues for future directions in the treatment of cognitive dysfunction in this illness.

II.   THE SCOPE OF IMPAIRED COGNITION IN SCHIZOPHRENIA

A range of approaches may be used to study cognitive dysfunction in schizophrenia. Many studies have used batteries of neuropsychological tasks to characterize cognitive deficits in schizophrenia. This approach has a number of strengths, including standardization of test administration and extensive normative data against which to compare the performance of a specific patient. Such assessments remain very valuable tools in clinical assessment.

However, this approach has three major limitations in the investigation of cognitive deficits in schizophrenia. First, the tasks used in neuropsychological batteries are complex and cannot isolate distinct cognitive functions. Second, even when factor analyses are used to identify profiles of deficits, the specificity of such profiles is confounded by differential discriminating power across for domains [15,16]. In the simplest sense this can be understood as the problem that if a patient has poor motivation or is otherwise not engaged with the task, they will show their worst performance on the most difficult tasks. Since factors of clusters of tasks in a neuropsychological battery are not matched for their sensitivity to such a generalized deficit, differential patterns of performance may create a false impression of a specific profile of deficits. It is important to note that many experimental cognitive

studies of cognition in schizophrenia are also subject to this confound. However, because of the flexibility of task, design solutions are available within this experimental framework that make it possible to control for this confound and identify deficits in specific cognitive processes in schizophrenia [17,18]. The third limitation of the clinical neuropsychological approach relates again to the complexity of the tasks, which renders them unsuitable for use in neuroscientific studies such as functional brain imaging, which has become a critical tool for the investigation of the neural basis of impaired cognition in schizophrenia.

Because of the above limitations, this review will emphasize those studies which are amenable to analysis and interpretation using the tools and constructs of experimental cognitive psychology. This approach has dominated the empirical study of human cognition for four decades. It promotes the use of a common taxonomy of cognition and provides a theoretical clarity which is grounded in a vast empirical literature. It also permits a mechanistic approach to the investigation of cognitive dysfunction in schizophrenia in which task design is theoretically driven and implemented in a systematic, hypothesis driven manner. Most importantly, this approach can be integrated with human and nonhuman neuroscientific studies. For completeness, we will begin with a brief review of disturbances of perceptual processes in schizophrenia, which have been extensively studied and have potentially important implications for our understanding of the neurobiology of this illness. We will then focus the remainder of the paper on the deficits in higher cognitive functions such as attention and memory, and the executive functions that govern these cognitive systems that appear to be so relevant for functional outcome in this illness.

III.   PERCEPTUAL DISTURBANCES IN SCHIZOPHRENIA

Disturbances have been observed at a number of levels of information processing in schizophrenia, including mechanisms which are traditionally considered perceptual or preattentive [19–21]. In addition to psychophysical performance data (e.g., reaction times, accuracy), many of these studies have used cortical evoked potentials (ERP) to index the altered information processing seen in this illness.

Processing of early sensory information in schizophrenia has been studied extensively using paradigms in which two subsequent auditory stimuli are presented

at relatively short time intervals (ranging from tens to hundreds of milliseconds). In normal subjects, early sensory gating is manifested as decreased response to the second stimulus, commonly referred to as prepulse inhibition (PPI). Numerous studies have shown decreased prepulse inhibition in schizophrenia patients, measuring behaviors such as the startle response [22,23], or the P50 component of the auditory event-related potential. Several studies have described correlations of these indices with symptoms and/or treatment effects [24–26], but the functional significance of the former is still debated [27–29]. Psychotic manic patients display a similar reduction of P50 suppression, but while antipsychotic treatment normalizes the suppression in these patients, it does not do so in schizophrenia [30], suggesting that the P50 inhibition is a trait deficit in this illness. The mismatch negativity, the earliest attention-independent response to deviant stimuli [31,32], and the amplitude [27,33,34] and PPI [24,35] of the N100 component of the ERP (the earliest attention-dependent index of stimulus selection) are all reduced in schizophrenia.

The impaired sensory gating of auditory stimuli has been proposed as a possible mechanism underlying other cognitive deficits present in schizophrenia, in which the unmodulated processing of sensory information disrupts higher level cognitive functions. However, the corollary to this formulation is that evidence for top-down modulation of early sensory processing [36,37] may offer an alternative explanation for disturbed sensory gating in schizophrenia. According to this hypothesis, disrupted sensory gating may be secondary to impaired attentional modulation of the sensory cortex. Further research is necessary to discriminate between early information-processing disturbances and attentional impairments as underlying the subtle disturbances in perceptual processes observed in this illness.

IV. ATTENTION DEFICITS IN SCHIZOPHRENIA

The construct of attention refers to an array of mental processes which ultimately determine to what degree information is processed and responded to and to what degree it is ignored. Taxonomies of attention have generally sorted these processes into a few broad classes of functions [38,39]. Our conception of attention has become increasingly constrained by our knowledge of brain function, and has emphasized mechanisms by which both perceptual and response

related processes may be modulated by attention [39], as well as the interactive nature and parallel organization of the neural circuitry [40]. Within these widely accepted theoretical frameworks, a common distinction that is made is between executive processes, which are involved in the control of attention in a task appropriate manner, and local changes in the activity of information processing pathways through which attentional modulation of stimulus processing and response selection occur [38,41].

In their taxonomies of attention, cognitive psychologists have generally distinguished among vigilance, or maintaining an attentive state over time, preparation (getting ready for a stimulus to appear), and selective attention [38]. These three elements of attention have been extensively studied in schizophrenia, and a specific pattern of deficits, in which some aspects of attention are impaired while others are preserved, is evident.

The continuous-performance task (CPT) [42] is a cognitive paradigm which has been used repeatedly to investigate attention in schizophrenia over the years. Patients attend to a sequence of stimuli appearing on a monitor and respond when a prespecified target stimulus appears. Schizophrenia patients are impaired on this task, especially when the difficulty of the task is increased by degrading the stimulus to make it harder to discriminate targets from nontargets [43], or by adding a memory load by instructing subjects to respond to targets that are repeats of previous stimuli. Interestingly, impairment on the CPT is evenly distributed across the duration of the testing session; it does not get worse the longer the subjects are performing [2]. Hence, *vigilance* in schizophrenia, defined as the ability to maintain an attentive state over time, is intact.

Preparatory attention refers to the ability to take advantage of a cue warning the subject to prepare for an upcoming stimulus [38]. For example, in a spatial cuing task [44] subjects watch for the occurrence of a simple stimulus, and at a variable interval prior to its appearance a cue (either an arrow pointing to where it will occur, or a brightening of a box marking one of the locations) informs the subject where the stimulus is likely to occur. Normal subjects are faster to respond when the cue correctly predicts the location of the probe. Studies using variants of this task have been conducted in schizophrenia [45–50], and the results are actually very mixed from study to study. One consistent finding with this task is patients *are* able to improve their performance with a cue just like normals. They use the cue to prepare effectively for the target, taking advantage of the prior knowledge to

detect the target more quickly. We found a similar result using a task known as the Global/Local task [19] in which subjects are shown a complex visual stimulus consisting of a large letter made up of many copies of a smaller letter. They are asked to decide which of two target letters, one of which is always present, has occurred. The target may be at either the small letter (local) level, or at the large letter (global) level. When patients were instructed that on a given block of trials 80% of the targets would appear at a particular level, they were able to significantly improve their performance for targets at that level, to the same degree as normal subjects. In other words, they were able to use prior knowledge about at which level the target was likely to occur and improve their response time. Hence, one can conclude that as is the case for vigilance, the preparatory aspect of attention is intact in schizophrenia.

The third class of attentional processes that we will consider is *selective* attention. This refers to the processing of information which is relevant for appropriate task performance, but not information that is irrelevant for performance. A selective attention deficit will result in distractibility. The classical experimental paradigm used to investigate selective attention is the Stroop task, one the most widely applied procedures in cognitive science [51,52]. In the Stroop task, subjects are required to name the colors of colored words, which may themselves be the names of colors. Because word reading is automatic, when the word is a color name it affects subjects responses, despite the fact that they are instructed to ignore it. For example, if the word and the color are incongruent (e.g. the word RED printed in blue), then subjects are slower or make errors (they say the word instead of the color), an effect referred to as *interference*. When the word and the color are congruent (e.g., the word RED printed in red), they respond more quickly, an effect referred to as *facilitation*.

The original version of the Stroop task used cards, and many studies using this approach were performed in schizophrenia over the years. The interpretation of most of these studies was unfortunately confounded by a failure to take into account general impairments such as slower overall response times of patients with schizophrenia [53]. More recent studies have used computerized presentation of single stimuli and on line monitoring of response times and accuracy. Compared to controls, patients make more errors in response to incongruent stimuli, and show increased facilitation with congruent stimuli, suggesting that patients with schizophrenia show more of an effect of

task irrelevant information, i.e., a selective attention deficit [46,53–55]. Increased distractibility in schizophrenia has also been shown using the antisaccade task, where subjects must overcome the prepotent response to make a saccadic eye movement to the location of onset of visual stimulus, and instead make a saccade to a location in the opposite visual field [56].

The systematic study of attention in schizophrenia suggests that certain aspects of this cognitive domain, such as vigilance and preparation, are intact. However, selective attention, the ability to respond to task-relevant information in the face of distracting, task irrelevant information, is reliably impaired in this illness.

V. MEMORY

As with the construct of attention, the term memory refers to a broad class of cognitive functions. Most models of memory make the broad distinction between short- and long-term memory. The concept of short term memory has best been extensively elaborated by Baddeley [57], who has described a system called *working* memory, which functions on a time scale of just a few seconds. Baddeley's model of the working memory system consists of a set of buffers for the short-term storage of information, and a central executive, which is responsible for manipulating the contents of the system. Information held in working memory may or may not be encoded into long-term memory (for example, a phone number retrieved from a directory may be retained just long enough to dial but not recalled later if the line was busy), depending on the context involved.

Models of long-term memory are based largely on studies of amnestic individuals who have damage to their medial temporal lobes and show a remarkable inability to acquire new memories for events. A common broad distinction which is made is between declarative and nondeclarative memory systems [e.g., 58,59]. Declarative or explicit memory involves the conscious recollection of facts and occurrences. Nondeclarative, or implicit, memory refers to a range of knowledge and abilities including motor and cognitive skills which do not require conscious recollection of the occurrences through which they were learned. Extensive research using memory tasks in schizophrenia has established that, like attention, certain aspects of memory are reliably impaired, while others are preserved.

Working memory has been extensively studied in schizophrenia and shown to be impaired in this illness.

Working memory for spatial information has been shown to be impaired in a number of studies of schizophrenia [60–63]. Working memory for verbal information has also been shown to be impaired [54,64]. Verbal working memory appears to be most evident when patients are challenged with a high information load [65], when distraction is present [61], and when executive functions are engaged by the requirement that patients manipulate, rather than just rehearse, information in working memory [66]. It is unclear whether working memory disturbances in schizophrenia reflect deficits in maintenance processes [62], executive processes [67], or both [60]. Patients are often impaired on tasks that place demands on executive functions (such as the Stroop task) but have minimal working memory demands. Selective attention deficits have been also shown to strongly correlate with working memory impairments in schizophrenia [67]. Our interpretation of these results is that the evidence more strongly supports impairments in executive processes rather than in impairments solely in the buffer systems in working memory. This view is supported by the fact that schizophrenia patients generally perform well on simple span tasks [66,68], which measure the integrity of the buffers. Clarifying the precise mechanisms underlying working memory impairments in schizophrenia is an active area of investigation in the cognitive neuroscience of schizophrenia. Since there is some evidence that different neural systems underlie storage and executive functions of working memory in the human brain, the results of these studies may have important implications for our understanding of the neurobiology of cognitive disability in schizophrenia.

In contrast to the well-established working memory deficits in schizophrenia, whether or not declarative memory is impaired in this illness is controversial. This reflects in part the methodological difficulties of evaluating declarative memory in the presence of deficits in attention and working memory. Patients are undoubtedly impaired on declarative learning and memory tests such as word list learning [10,68–71]. However, impaired executive processes and selective attention could account for these deficits. A classical finding is that patients with schizophrenia show impaired recall but intact recognition performance on list-learning tasks. It has also been shown that schizophrenia patients can actually improve their recall performance into the normal range when they are provided cues for use during the task to facilitate learning [70]. In addition, studies have found that recall is improved in schizophrenia when strategies to improve encoding such as semantic chunking are provided [72].

These studies suggest that schizophrenia patients have difficulties not so much with declarative learning per se, but with executive processes associated with the encoding and retrieval of items from declarative memory. The pattern of performance of patients with schizophrenia is much more like that seen in patients with frontal lobe lesions than with lesions of the medial temporal lobe, an observation that lends weight to the emphasis placed on the frontal lobes in investigations of the neural substrates impaired cognition in schizophrenia.

In contrast to studies of declarative memory in schizophrenia, the results of studies of nondeclarative memory are relatively unambiguous. Compared to normal controls, schizophrenia patients acquire procedural knowledge as well as normal subjects [e.g., 10,68,70]. For example, patients acquire simple motor skills at the same rate and to the same level of precision as do normal subjects.

However, the literature related to one aspect of memory thought to reflect a nondeclarative form of memory, semantic priming, is far from clear. Semantic priming tasks examine the behavioral effects of the strength of associations between related concepts in semantic memory, i.e., knowledge acquired implicitly during development. In one version of a semantic priming task, a lexical decision task, a subject is asked to respond to a letter string by deciding whether it is a word or not, or in other paradigms subjects are asked to by pronounce the word out loud. In these priming tasks the stimulus to which the subject is required to respond (the target) is immediately preceded by another stimulus to which the subject does not respond (the prime). Response times to targets which are words are faster if the prime is a word, rather than a nonword, and faster again if the prime is semantically related to the target than if it is semantically unrelated. Faster reaction times for related, compared to unrelated, prime-target pairs are referred to as the semantic priming effect. An early study using this paradigm [73] suggested that schizophrenia patients showed increased semantic priming. Relative to controls, it was reported that patients showed faster response times to making a lexical decision when it was preceded by a related word (e.g., DOCTOR followed by NURSE). This finding proposed to reflect increased spread of activation in the networks representing semantic knowledge in schizophrenia.

Subsequent studies using this approach have been frustratingly mixed. There have been some replications [74–76] but also a number of nonreplications [77–79].

This has led to the suggestion that increased semantic priming is not a reliable finding in schizophrenia, or may be confounded by clinical state, cohort, or medication effects. It is noteworthy that those studies which have reported this finding all involved medicated patients. Based on the results of many studies of different forms of nondeclarative memory in schizophrenia it appears likely that a number of aspects of nondeclarative memory (procedural learning and priming effects) are preserved in this illness.

VI. UNDERSTANDING IMPAIRED COGNITION IN SCHIZOPHRENIA

A. The Concept of Impaired Executive Functions

The notion that impaired executive functions underlie impaired higher cognition in schizophrenia has formed the basis of many general theories of impaired cognition in schizophrenia [4,67,80–82]. We also believe that this is an informative and parsimonious way of understanding the range of cognitive deficits seen in this illness. However, the term executive functions needs clarification, since it has been used in relationship to a number of domains of cognition in cognitive psychology as well as in relation to a wide range of tasks in clinical neuropsychology. Executive functions encompasses a broad range of mental processes involved in initiating and maintaining controlled information processing and coordinated actions [83]. These processes include goal or context representation and maintenance, strategic processes such as attention allocation and stimulus-response mapping, and performance monitoring [40,65,84]. Deficits in executive functions have been frequently reported in schizophrenia using a range of methodologies from neuropsychology and experimental cognitive psychology. A disturbance in the ability to initiated and maintain controlled information processing can clearly account for the pattern of deficits of selective attention, working memory, and declarative memory performance seen in patients with this illness. We believe that it is important to emphasize the diversity of executive functions and to point out that the *specific* abnormality or abnormalities within the executive system in schizophrenia have yet to be identified. To date, well-articulated theories emphasizing impaired context representation and maintenance [82,85], attention allocation [80], and performance monitoring [86–89] have all been hypothesized, with some data supporting each of these

alternatives having been presented. No single theory of impaired executive functions has garnered overwhelming empirical support over other theories to this point. Further research is needed to clarify whether a disruption of one specific aspect of executive functions in schizophrenia is sufficient to account for the range of higher cognitive deficits observed or whether multiple different executive deficits exist, each of which may contribute to different aspects of cognitive disability.

For future investigations directed toward understanding the precise nature of impaired executive functions in schizophrenia, the tools and constructs of cognitive neuroscience are likely to play a critical role. The discrete, elemental processes of executive functions described above have begun to be linked to discrete elements of a distributed neural network serving executive functions in the brain. This new knowledge is allowing us to begin, for the first time, to develop the beginnings of a functional-anatomic understanding of cognitive deficits in schizophrenia.

B. The Neural Basis of Cognitive Deficits in Schizophrenia

It seems fair to say that in recent years more investigation has been undertaken into the neural substrates of cognitive functions in schizophrenia than perhaps any other aspect of the illness. We believe that this reflects in part the fact that, in addition to its increasingly obvious clinical importance, investigation of the neural basis of cognitive deficits is more tractable than is the case for other aspects of the illness. Cognition in schizophrenia can be reliably and objectively measured using methods from experimental cognitive psychology, while assessment of symptoms such as hallucinations and delusions relies on patient self-report and clinical inference. Also, cognitive activation has become a standard method of examining brain behavior relationships in cognitive neuroscience. The methodology is mature and there is a rapidly increasing base of knowledge regarding the neural basis of normal cognition which provides the necessary framework for designing and interpreting results from clinical studies involving patients.

Results to date suggest that patients with schizophrenia do have reliable disturbances in activity in the neural network involved in executive processes, which includes the dorsolateral prefrontal cortex (DLPFC) and the anterior cingulate cortex (ACC) [65,90–95]. This is not to imply that these are the only regions that have been reported to be abnormal

in functional imaging studies of schizophrenia. Disturbances have also been reported in temporolimbic regions including the hippocampus [96,97], the superior temporal gyrus [98–101], and the striatum and cerebellum [90,102]. The significance of altered activity in temporolimbic regions of the brain in schizophrenia for cognition remains unclear. It is possible that activity in these regions is related to other aspects of the illness, such a delusions and hallucinations [103]. In this chapter we are focusing on cognition in schizophrenia, and our emphasis on the role of the frontal cortex in this chapter reflects the central role impaired executive functions play in these deficits, the well-established relationship between the function of the frontal lobes and executive control, and the growing literature linking impaired executive functions in schizophrenia to disturbances in the functions of the frontal cortex.

The first functional imaging study in schizophrenia, conducted by Ingvar and Franzden [104], reported that schizophrenia patients showed a loss of the normal hyperfrontal pattern of blood flow while performing a neuropsychological task. Since that time many, but certainly not all, studies of schizophrenia have reported reduced blood flow or metabolism in the DLPFC in schizophrenia [90,102]. This finding is not as reliable when patients are studied at rest [105], and we and others have argued that it is most reliably present when patients are performing tasks which engage cognitive systems known to reflect neural activity in this region of the brain, such as working memory tasks [65,94,106,107].

Much of the focus on hypofrontality in schizophrenia has centered on the DLPFC; however, the ACC, another critical element in the neural network subserving executive functions in the normal brain, has also frequently been found to be functioning abnormally in functional imaging studies of this illness. Tamminga and colleagues [97] found decreased resting ACC (and hippocampal) metabolism in an unmedicated group of schizophrenia patients. Buchsbaum and colleagues [108,109] have also reported cingulate hypometabolism in unmedicated subjects. In a fascinating correlational study between symptoms and resting cerebral blood flow measures using positron emission tomography (PET) [103], blood flow in the ACC correlated specifically with schizophrenia patients' level of behavioral disorganization.

With regard to its function during cognition, a number of studies have examined ACC activity in schizophrenia during cognitive activation. During a single photon emission computer tomography (SPECT)

study in which unmedicated subjects performed the Tower of London, a test of executive function, decreased ACC activity was observed [90]. Decreased ACC activation responses in schizophrenia have also been reported during two other classical measures of executive functions—an auditory-verbal supraspan memory task [100], and verbal fluency [98]. Our own group reported that schizophrenia patients showed reduced ACC activation during the Stroop task, a challenging selective attention task which elicits response conflict which must be overcome by the participant [92]. Based on recent work [65,110] using event-related functional magnetic resonance imaging (fMRI) in normal subjects it has been hypothesized that the ACC serves a very specific, evaluative function associated with the executive control of cognition. It appears that the ACC detects, online, cognitive states that may be associated with poor task performance, such as the occurrence of conflicts between simultaneously activated but incompatible response tendencies. Increased activity in this region may then provide a signal to other components of the executive system, indicating the need for increased attentional engagement and more effective controlled processing (e.g., through improved attention allocation). In a recent event-related fMRI study [93] we reported that error-related activity in the ACC is reduced in schizophrenia. We also found in this study that patients failed to show the usual posterror adjustments in performance seen in control subjects. The functional significance of the physiological disturbances in the ACC revealed by the neuroimaging studies described above may be that an impairment in the performance monitoring function of this brain region contributes to impaired executive functions in schizophrenia.

C. The Clinical Significance of Cognitive Deficits in Schizophrenia

As noted in the introduction of this chapter, there is a growing awareness of the clinical significance of impaired cognition in schizophrenia. The association between cognitive deficits in schizophrenia and the relative treatment refractoriness of this aspect of the illness has drawn attention to the need for further understanding of its neurobiological substrates. There has also been a tendency to see cognitive deficits as reflecting an independent dimension of schizophrenia, unrelated to the positive and negative symptoms that have traditionally defined the illness. However, we believe that it is unlikely that impaired cognition is completely independent, either at the behavioral level

or at the neural systems level, from the other mental perturbations of schizophrenia, and that an understanding of impaired cognition and its potential relationship to other signs and symptoms will result in a richer clinical understanding of the illness than we have had in the past.

Given the association between executive functions and frontal lobe function, for example, it might be expected that symptoms which would be likely to be associated with frontal deficits, particularly negative symptoms and behavioral disorganization, would be associated with cognitive disability. There is some support for the association between negative symptoms and spatial working memory [60,61]; however, reviews of the literature [2,111,112] show many negative studies, and our own group has not consistently found relationships between impaired executive functions and negative symptoms [54,67]. One factor in the unreliability of associations between negative symptoms and cognitive deficits might reflect the practical difficulty of distinguishing drug-induced parkinsonism from true-negative symptoms in medicated patients.

A second, perhaps even more important, factor underlying the above variability in findings may be the assumptions made in many studies regarding the structure of symptoms in schizophrenia. Many older studies used a two-factor model, classifying symptoms into positive and negative factors. More recently, however, a number of studies have suggested that the factor structure of schizophrenia is more complex, and includes a disorganization factor which is separate from the positive and negative factors and is composed of items previously considered belong to each of the other two dimensions [113–115]. In our own more recent work we have taken this three-factor approach. In both medicated and unmedicated groups of patients we have occasionally found relationships among negative symptoms and deficits in selective attention and verbal working memory. In contrast, we have consistently found robust relationships between these measures of cognitive disability and the syndrome of disorganization [67,116]. This is consistent with previous theories regarding the relationship of disorganization and attentional disturbances [117]. This idea was in fact articulated by Bleuler nearly a century ago [118], when he argued that disturbances in the control of attention were responsible for the associational disturbances that distinguished the schizophrenias from the other major psychoses. Based on these results we suggest that there is in fact some overlap between cognitive symptoms of schizophrenia and other aspects of the clinical syndrome, particularly

with behavioral disorganization. This view of a Bleulerian cognition/disorganization dimension to the illness might give clinicians a fresh perspective on the source of some patients functional difficulties and also define a target syndrome for new treatment development.

VII. TREATMENT STRATEGIES TARGETING COGNITIVE DISABILITY IN SCHIZOPHRENIA

The current data on the effects of the currently available antipsychotic treatments suggest at best limited benefits on cognitive dysfunction in schizophrenia [10,11]. There is evidence from a number of clinical trials that atypical antipsychotic agents offer some advantages of typical agents [119]; however, these benefits are limited. Minimizing the use of adjunctive therapies such as anticholinergics, benzodiazpines, beta blockers, and other agents that can worsen cognitive functioning, is also an important aspect of the pharmacotherapy of cognition in schizophrenia. How then do we proceed to address this shortcoming of our current therapy?

The first step toward developing effective treatments for cognitive disability in schizophrenia will be to continue the paradigm shift which is already under way in the field. The emphasis, to date, on positive and more recently negative symptoms as outcome measures for therapies for schizophrenia needs to be expanded to include measures of cognitive function, specifically, measures of attention and memory.

Unlike our treatments for positive symptoms, which were developed serendipitously, the development of treatments for impaired cognition in schizophrenia may proceed based on our developing knowledge of the likely pathophysiological mechanisms underlying this aspect of the illness. Functional neuroimaging studies suggest that disturbances in DLPFC and ACC circuitry related to executive functions may account for many of these deficits. Disturbances in elements of the local circuitry of these regions that have been reported in postmortem brains of schizophrenia patients may provide clues to potential pharmacological strategies for remediating the function of these circuits. Reductions in markers of inhibitory interneuron function, reductions in markers of glutamatergic function, and reductions in afferent dopaminergic modulatory input have been reported in both of these regions [120–123]. New agents which remediate one or more of these disturbances might provide a whole new avenue

for disability reduction in schizophrenia. Preliminary work administering glycine cycloserine and D-serine [124–126] to enhance glutamatergic function supports the feasibility of this approach. New agents which enhance glutamatergic effects though more specific mechanisms are under development. Similarly, transient benefits on cognitive function have been observed after stimulant challenge [92,127], which in our study extended beyond effects on working memory to include improvement in measures of the organization of language production. Agents that enhance phasic dopamine in the cortex may also have promise in treating cognitive dysfunction in schizophrenia.

It is possible and even likely that cognitive rehabilitation strategies targeting the potential neuroplasticity of the frontal cortical-based circuits mediating executive functions will also be of benefit in treating cognitive deficits in schizophrenia. Preliminary data using methods adapted from cognitive rehabilitation treatments for closed head injury combined with optimizing pharmacotherapy and other psychosocial interventions support the possible efficacy of this approach [128].

VIII. CONCLUSIONS

Over the past decade there has been a growing awareness of the clinical importance of cognitive disability in schizophrenia. Deficits observed cut across a number of domains of cognitive functioning including selective attention and working memory. These deficits can be understood as a disturbance in executive functions—a complex set of operations required for the efficient execution of each of these cognitive systems. Functional brain-imaging studies also suggest that these higher cognitive deficits are related to physiological dysfunction in circuits underlying executive functions in the brain, including the DLPFC and the ACC. At the local circuit level, disturbances in glutamatergic and GABA-ergic neurotransmission, and the modulation of these by dopamine are likely to be present. The development of therapies targeting these disturbances at the local circuit level in medial and dorsolateral prefrontal cortex promises to begin a new phase in the therapeutics of schizophrenia in which the focus will be on disability reduction in this illness.

Neuroimaging Findings in Schizophrenia
From Mental to Neuronal Fragmentation

LAWRENCE S. KEGELES and MARC LARUELLE

Columbia University, New York, New York, U.S.A.

I. INTRODUCTION

Over the last 20 years, the ability to image the living human brain underwent enormous developments, opening direct windows into brain function and cellular processes associated with health and disease. Brain imaging techniques are classically divided into structural, functional, and chemical imaging, although the distinctions among these domains are somewhat arbitrary. These techniques are based either on the injection of radioactive moieties whose distribution is recorded with positron emission tomography (PET) or single photon emission computerized tomography (SPECT), or on the direct detection of molecules based on their intrinsic magnetic properties with magnetic resonance imaging (MRI and fMRI) or spectroscopy (MRS).

This chapter will summarize important results obtained using brain imaging techniques in schizophrenia research, and the various insights on the pathophysiology and treatment of schizophrenia gained by these results. A more detailed technical discussion of these various imaging modalities is found in Chapter 7 of this volume.

II. STRUCTURAL IMAGING

Tomographic imaging, beginning with CT scanning and shortly thereafter MRI, has enabled rapid progress in studying brain structure in vivo. Following the initial CT report of enlarged ventricles in schizophrenia [1], a large number of CT studies replicated this observation [reviewed in 2–4]. This finding is the most replicated and well-established brain imaging finding in schizophrenia, and was historically important in establishing that schizophrenia is a brain disease. It should be noted, however, that the distribution of ventricular-brain ratios in patients with schizophrenia overlaps with the distribution in control subjects, and that this phenomenon is also found, although to a lesser extent, in other psychiatric conditions such as bipolar disorder [5]. As enlarged ventricular-brain ratio appears to be present at onset of illness, this finding was also critical in supporting the hypothesis that schizophrenia might be associated with an abnormal neurodevelopmental process.

These CT findings of enlarged ventricles and cortical sulci in schizophrenia were soon replicated with MRI, a technique which offers spatial and gray-white

matter resolution superior to CT and has the additional advantage of requiring no ionizing radiation. For these reasons, it has largely supplanted CT scanning for structural brain research.

A. Findings in Schizophrenia

Notable in the MRI volumetric literature is variability of findings for a given brain region. Sources of this variability in findings for given brain structures include actual subject variability across different study samples, as well as variation in technical aspects of MRI. For example, studies have used a range of MRI pulse sequences, slice thicknesses, and spatial resolution, as well as criteria for defining regional anatomic boundaries [6].

Regarding whole-brain volume, a review of 31 studies found that a minority (19%) reported volume differences, and of these, four reported decreases and one reported a volume increase [6]. Consistent with a small effect, a meta-analysis of 31 studies (946 patients and 921 control subjects) found whole-brain volumes were 98% of control volumes.

The largest and most replicated structural brain finding is increased size of the lateral and third ventricles, but not the fourth ventricle [6]. A meta-analysis of 58 studies [7] drew similar conclusions, showing a larger effect for the left lateral ventricle than the right, marked effects in temporal horns, and again a significant effect in third but not fourth ventricles. Lateral and third ventricular volumes were enlarged as much as 25–30% above healthy controls.

Whole temporal lobe volumes were found in the meta-analysis [7] to be $\sim$ 98% of control volumes—i.e., in line with whole brain reductions—but substructures showed greater volume deficits. Hippocampus and hippocampus-amygdala were found to have $\sim$ 5–6% volume deficits bilaterally. Another meta-analysis found bilateral hippocampal volume reductions of 4% [8]. Superior temporal gyri were reduced several percent except for the right posterior superior temporal gyrus, which was increased $\sim$ 3% in volume. Temporal lobe deficits, the most robust of MRI volumetric findings in schizophrenia, have been found in several studies to correlate with symptoms. Medial temporal lobe reductions have shown correlations with positive symptoms [9,10] and with logical memory impairment [10]. Associations between superior temporal gyrus deficits and hallucinations were reported by Barta et al. [11] and Flaum et al. [12]. Measures of thought disorder and superior temporal gyrus volumes have been shown to be correlated [13].

Frontal lobe volumes were 95% of control values, or 98% adjusted for total brain volume reduction [7]. A review of 33 studies showed that 55% of the studies found volume abnormalities but that 45% did not [6]. These small effects could be consistent with the small (8%) reduction in cortical thickness found in postmortem work [14] that corresponded to significant abnormalities in densities of certain cell types. Frontal lobe deficits, themselves smaller and less replicated than the temporal lobe findings, have shown fewer clinical correlates, but left prefrontal cortical white matter volume deficits were found to be associated with the Scale for Assessment of Negative Symptoms (SANS) [15].

Relative volumes of basal ganglia structures were higher in patients by 2–4% in caudate but by > 20% in globus pallidus [7]. This may be a medication effect, since studies of patients receiving atypical antipsychotic medications show smaller increases than patients taking typical neuroleptics, and patients taking minimal or no antipsychotic medications have no change or even a decrease in basal ganglia volumes [16,17].

Thalami were found to be reduced in relative volume by 3–4% on meta-analysis, consistent with a review that found abnormalities in four of six studies of this region.

B. Summary and Significance

In conclusion, the major findings to date are [1] very minor deficits of whole brain or intracranial volume; [2] consistently replicated enlargement of the lateral and third ventricles; [3] parenchymal deficits in the temporal lobes, including medial temporal lobe structures such as hippocampus and superior temporal gyrus, frequently reported to be more pronounced on the left compared to the right side. While frontal lobes have been implicated functionally in schizophrenia, volumetric deficits have been less reliably found, possibly because any such deficits are near threshold of detectability with MRI methods. Subcortical structures including thalamus and basal ganglia have been reported to show volume changes, with increases in basal ganglia generally thought to be medication related.

These volume deficits have been found to be associated with clinical manifestations of the illness, including positive symptoms, memory impairment, thought disorder, and negative symptoms. Frontal lobe [18] and temporal lobe [19] volume deficits have been found to progress in longitudinal studies, although

an earlier study reported absence of cortical or ventricular volume progression [20]. Because of its absence of ionizing radiation, MRI is a modality particularly suited to longitudinal studies, including the prodrome, and this is an area of active research. Such studies will help address the issue of timing of anatomic disturbances relative to symptom onset, and the relative roles of neurodevelopment and neurodegeneration in the illness.

III. FUNCTIONAL IMAGING

Over the last 40 years, measurement of neuronal activity underwent major technical advances, each bringing new insights about alterations in brain regional function in schizophrenia. The main imaging modalities included SPECT studies with the xenon inhalation technique, PET studies measuring rate of glucose utilization with $[^{18}F]$fluorodeoxyglucose $([^{18}F]FDG)$ or measuring regional blood flow with $H_2^{15}O$, and more recently fMRI, using blood-oxygen-level-dependent (BOLD) contrast. Each of these techniques provided improvements in terms of spatial and temporal resolution, as discussed in Chapter 7.

A. Resting-State Studies

In 1974, Ingvar and Franzen [21] published a landmark report describing lower flow in anterior compared to posterior regions of the brain, a finding termed hypofrontality. A large number of studies have attempted to replicate this finding [for review see 22,23–29]. Hypofrontality has not been consistently replicated, and the opposite observation (hyperfrontality) has been reported, especially in acutely ill patients. The lack of consistent pattern emerging from these studies has been interpreted as reflecting the heterogeneity of the illness and of the "baseline" or "resting" conditions. Regarding the heterogeneity of the condition, an influential study was the report of Liddle et al. [30], who described several patterns of flow alterations in psychomotor poverty (hypofrontality), disorganization (anterior cingulate overactivity), and reality distortion (underactivity of left temporal lobe). Many of these findings have been replicated; for example, several studies suggested that low prefrontal flow or metabolism at baseline might be associated with severity of negative symptoms. Abnormalities in temporal region have frequently been reported and have been linked with positive symptoms and noted more frequently on the left side. Temporal activation has also be

recorded during the experience of hallucinations by several investigators, although the details of anatomical activation patterns differed. Regarding the impact of antipsychotic medications, an increase in basal ganglia activity has been the most reliable finding.

B. Task-Related Activation Studies

Hypofrontality has been more consistently observed during performance of executive and working memory tasks engaging the frontal cortex. For example, lower activation of the frontal cortex has been reported during the Wisconsin card sort task [31], the Tower of London task [32], word generation task [33,34], or n-back task [35]. A general problem with these observations is that the level of performance in the patient group is generally found to be diminished compared to controls, raising questions regarding the interpretation of these data as reflecting a primary abnormality of prefrontal cortex and its connectivity, a lower engagement of the patients during the tasks, or some combination of both factors [see discussion in 36]. Another very interesting approach is to examine patterns of covariance between regions during task performance [37].

The introduction of fMRI, allowing multiple determinations of dorsolateral prefrontal cortex (DLPFC) activation at various WM loads has provided new insights into the relationship between working memory tasks and DLPFC activation in schizophrenia. Increasing working memory load while keeping other aspects of the task constant is easily achieved with parametric tasks such as the n-back test, and, in healthy subjects, a significant relationship is observed between working memory load and DLPFC activation [38,39]. Using this new approach, a more subtle pattern of alterations in DLPFC activation (decreased efficiency and lower disengagement threshold) is emerging from studies in patients with schizophrenia. The concept of efficiency refers to the magnitude of DLPFC activation required to perform a task at a given level. Manoach et al. [40,41] demonstrated that, on a working memory task designed specifically to engage schizophrenic patients, patients showed greater DLPFC activation for a given level of performance than controls. Callicott et al. [42] examined the effect of parametric increases in the n-back test and found that patients with schizophrenia had greater DLPFC activation than controls on the 1-back and 2-back condition (low to moderate working memory load). These data suggest that schizophrenia might be associated with reduced DLPFC efficiency, i.e., with larger metabolic

activation to reach a given level of performance in a relatively easy task. Several studies [40–42] also documented that, at high working memory load, patients with schizophrenia show decreased performance and decreased activation compared to controls. This observation also suggests that most earlier brain imaging studies were performed in a range where the complexity or load of the task reached the disengagement threshold for patients, resulting in apparent hypofrontality.

In conclusion, functional imaging studies during resting state as well as during task-related activation documented that schizophrenia is associated with a disrupted pattern of activation in cortico-limbic networks, and that the prefrontal cortex is a critical deficient node in this network.

IV. NEUROCHEMICAL AND NEUROPHARMACOLOGICAL IMAGING

A. PET and SPECT Neurochemical Imaging

The principles of PET and SPECT neurochemical imaging are reviewed elsewhere in this volume. Numerous PET and SPECT radiotracers are currently available to study key proteins in the living brain, such as receptors, transporters, and enzymes. Regarding schizophrenia, the majority of clinical investigations studied various aspects of dopaminergic transmission. Dopamine (DA) D_2 receptors were the first neuroreceptors visualized in the living human brain [43]. Since then, several DA related radiotracers have been developed, allowing the study of many aspects of dopaminergic transmission (DA synthesis, DA release, D_1 and D_2 receptors, DA transporters). Given the availability of these tools and the important role that DA transmission is believed to play in schizophrenia, it is not surprising that most of the research effort focused on this system. Despite marked limitations, these studies provide a relatively consistent picture suggesting that schizophrenia, at least during periods of clinical exacerbation, is associated with dysregulation of DA transmission.

1. Imaging DA Transmission

The classical DA hypothesis of schizophrenia, formulated over 30 years ago, proposed that a hyperactivity of the dopaminergic transmission is associated with this illness [44,45]. This hypothesis was essentially based on the observation that all antipsychotic drugs provided at least some degree of D2 receptor blockade, a proposition that is still true today [46,47]. As D2

receptor blockade is most effective against positive symptoms, the DA hyperactivity model appeared to be most relevant to the pathophysiology of positive symptoms. That sustained exposure to DA agonists such as amphetamine can induce a psychotic state characterized by some salient features of positive symptoms of schizophrenia (emergence of paranoid delusions and hallucinations in the context of a clear sensorium) also contributed to the idea that positive symptoms might be due to sustained excess dopaminergic activity [48,49]. These pharmacological effects indeed suggest, but do not establish, a dysregulation of DA systems in schizophrenia.

On the other hand, negative and cognitive symptoms are generally resistant to treatment by antipsychotic drugs. Functional brain imaging studies suggested that these symptoms are associated with prefrontal cortex (PFC) dysfunction [36]. Studies in non-human primates demonstrated that deficits in DA transmission in PFC induce cognitive impairments reminiscent of those observed in patients with schizophrenia [50], suggesting that a deficit in DA transmission in the PFC might be implicated in the cognitive impairments presented by these patients [51,52]. In addition, a recent postmortem study described abnormalities of DA terminals in the PFC associated with schizophrenia [53]. Thus, a current view on DA and schizophrenia is that subcortical mesolimbic DA projections might be hyperactive (resulting in positive symptoms) and that the mesocortical DA projections to the PFC are hypoactive (resulting in negative symptoms and cognitive impairment). Furthermore, these two abnormalities might be related, as the cortical DA system generally exerts an inhibitory action on subcortical DA systems [54,55].

The advent in the early 1980s of techniques based on PET and SPECT for measuring indices of DA activity in the living human brain held considerable promise for investigating these questions.

Striatal DA Transmission

D_2 RECEPTORS. Striatal D_2 receptor density in schizophrenia has been extensively studied with PET and SPECT imaging (Table 1). In a recent meta-analysis [56], we identified 17 imaging studies comparing D_2 receptor parameters in patients with schizophrenia (total of 245 patients, 112 neuroleptic naive, and 133 neuroleptic free), and controls (n = 231), matched for age and sex [57–73]. These studies are summarized in Table 1. Radiotracers included butyrophenones ([^{11}C]N-methyl-spiperone, [^{11}C]NMSP,

Table 1 Imaging Studies of Striatal D_2 Receptor Parameters in Drug Naive and Drug-Free Patients with Schizophrenia

Class radiotracer	Radiotracer	Study	n Controls	n Patients (DN/DF)[a]	Method	Outcome	Controls (mean ± SD)[b]	Patients (mean ± SD)[b]	P	Effect size[c]	Ratio SD

n = 4, and [^{76}Br]bromospiperone, n = 3), benzamides ([^{11}C]raclopride, n = 3, and [^{123}I]IBZM, n = 5), or the ergot derivative [^{76}Br]lisuride, n = 2). Only two out of 17 studies detected a significant elevation of D_2 receptor density parameters. However, meta-analysis revealed a small (12%) but significant elevation of striatal D_2 receptors in patients with schizophrenia. No clinical correlates of increased D_2 receptor binding parameters have been reliably identified. The aggregate D_2 receptor increase reported in vivo is much lower than the increase reported in postmortem studies, supporting the idea that postmortem results were affected by antemortem medications. Studies performed with butyrophenones (n = 7) show an effect size of 0.96 ± 1.05, significantly larger than the effect size observed with other ligands (benzamides and lisuride, n = 10, 0.20 ± 0.26, $P = 0.04$). This difference might be due to differences in vulnerability of the binding of these tracers to endogenous DA, and elevation of endogenous DA in schizophrenia [74,75]. Other potential explanations for this difference, such as contributions of D4 receptors or states of receptor oligomerization, have also been proposed but remain largely unsubstantiated.

DOPA DECARBOXYLASE ACTIVITY. Five studies reported rates of DOPA decarboxylase in patients with schizophrenia, using [^{18}F]DOPA (76–79) or [^{11}C]DOPA [80] (Table 2). Four out of five studies reported increased accumulation of DOPA in the striatum of patients with schizophrenia, and the combined analysis yielded an effect size of 0.92 ± 0.45, which is significantly different from zero (p = 0.01). The variability of the DOPA accumulation was larger in the schizophrenic group than in the control group. Several of these studies reported the observation of high DOPA accumulation in psychotic paranoid patients, and low accumulation in patients with negative or depressive symptoms, and catatonia. While the relationship between DOPA decarboxylase and DA synthesis rate is unclear (DOPA decarboxylase is not the rate-limiting step of DA synthesis), these observations are compatible with higher DA synthesis activity of DA neurons in schizophrenia, at least in subjects experiencing psychotic symptoms.

AMPHETAMINE-INDUCED DA RELEASE. As discussed above, endogenous DA competition is a source of errors for *in vivo* measurement of D_2 receptors. On the other hand, the recognition of this phenomenon implies that D_2 receptor imaging, combined with pharmacological manipulation of DA release, enables func-

tional evaluation of DA presynaptic activity. Indeed, over the last decade, numerous groups demonstrated that acute increase in synaptic DA concentration is associated with decreased in vivo binding of [^{11}C]raclopride and [^{123}I]IBZM. These interactions have been demonstrated in rodents, nonhuman primates, and humans, using a variety of methods to increase synaptic DA [for review of this abundant literature, see 81]. It has also been consistently observed that the in vivo binding of spiperone and other butyrophenones are not as affected as the binding of benzamides by acute fluctuations in endogenous DA levels [81].

The decrease in [^{11}C]raclopride and [^{123}I]IBZM in vivo binding following acute amphetamine challenge has been well validated as a measure of the change in D_2 receptor stimulation by DA due to amphetamine-induced DA release. Manipulations that are known to inhibit amphetamine-induced DA release, such as pretreatment with the DA synthesis inhibitor alpha-methyl-para-tyrosine (αMPT) or with the DAT blocker GR12909, also inhibit the amphetamine-induced decrease in [^{123}I]IBZM or [^{11}C]raclopride binding [82,83]. Combined microdialysis and imaging experiments in primates demonstrated that the magnitude of the decrease in ligand binding was correlated with the magnitude of the increase in extracellular DA induced by the challenge [69,83], suggesting that this noninvasive technique provides an appropriate measure of the changes in synaptic DA levels.

Three out of three studies demonstrated that amphetamine-induced decrease in [^{11}C]raclopride or [^{123}I]IBZM binding was elevated in untreated patients with schizophrenia compared to well-matched controls [67,69,70]. A significant relationship was observed between the magnitude of DA release and transient induction or worsening of positive symptoms. The increased amphetamine-induced DA release was observed in both first-episode/drug-naive patients and patients previously treated by antipsychotic drugs [84]. Combined analysis of the results of two studies revealed that patients who were experiencing an episode of illness exacerbation (or a first episode of illness) at the time of the scan showed elevated amphetamine-induced DA release, while patients in remission showed DA release values not different from those of controls [84]. These findings were generally interpreted as reflecting a larger DA release following amphetamine in the schizophrenic group. Another interpretation of these observations would be that schizophrenia is associated with increased affinity of D_2 receptors for

DA. Development of D_2 receptor imaging with radio-labeled agonists is needed to settle this issue [85].

Direct evidence has been provided that disinhibition of subcortical DA activity might be associated with prefrontal pathology in schizophrenia. In patients with schizophrenia, low NAA concentration in the dorsolateral prefrontal cortex (DLPFC), a marker of DLPFC pathology, is associated with increased amphetamine-induced DA release [86]. Pretreatment with ketamine, an N-methyl-d-aspartate (NMDA) antagonist, is associated with large increase in amphe-tamine-induced decrease in [^{123}I]IBZM binding [87]. This observation demonstrated that blockade of gluta-matergic-mediated regulation of DA release results in increased amphetamine-induced DA release, and pro-vides a link between the classical dopamine hypothesis and the NMDA deficiency hypothesis [88–90] of schi-zophrenia.

BASELINE DA RELEASE. A limitation of the amphe-tamine challenge imaging studies is that they measure changes in synaptic DA transmission following a non-physiological challenge (i.e., amphetamine) and do not provide any information about synaptic DA levels at baseline, i.e., in the unchallenged state. Several labora-tories reported that, in rodents, acute depletion of synaptic DA is associated with an acute increase in the in vivo binding of [^{11}C]raclopride or [^{123}I]IBZM to D_2 receptors [for review, see 81]. The increased bind-ing was observed in vivo but not in vitro, indicating that it was not due to receptor upregulation [91], but to removal of endogenous DA and unmasking of D_2 receptors previously occupied by DA. The acute DA depletion technique was developed in humans using αMPT, to assess the degree of occupancy of D_2 recep-tors by DA [91,92]. Using this technique, higher occu-pancy of D_2 receptors by DA was recently reported in patients with schizophrenia experiencing an episode of illness exacerbation, compared to healthy controls [71]. Again assuming normal affinity of D2 receptors for DA, the data are consistent with higher baseline DA synaptic levels in patients with schizophrenia. This observation was present in both first-episode/drug-naive and previously treated patients.

DA TRANSPORTERS. The data reviewed above are consistent with higher DA output in the striatum of patients with schizophrenia, which could be explained by increased density of DA terminals. Since striatal DA transporters (DAT) are exclusively localized on DA terminals, this question was investigated by mea-suring binding of [^{123}I]β-CIT [93] or [^{18}F]CFT [48] in patients with schizophrenia. Both studies reported no differences in DAT binding between patients and con-trols. In addition, Laruelle et al. [93] reported no asso-ciation between amphetamine-induced DA release and DAT density. Thus, the increased presynaptic output suggested by the studies reviewed above does not appear to be due to higher terminal density, an obser-vation consistent with postmortem studies that failed to identify alteration in striatal DAT binding in schi-zophrenia [94–99].

Prefrontal DA Transmission

The majority of DA receptors in the PFC are of the D_1 subtype [100,101]. In postmortem studies, no evi-dence was found for an alteration in D_1 receptors in the DLPFC of patients with schizophrenia [102,103], and D_1 receptor gene expression is unaltered [104]. A PET study with [^{11}C]SCH 23390 reported decreased density of D_1 receptors in younger patients with schi-zophrenia [63]. In addition, low PFC D_1 density was associated with the severity of negative symptoms and poor performance on the Wisconsin Card Sort Test (WCST). In contrast, a more recent study using the superior radiotracer [^{11}C]NNC 112 reported increased D_1 receptor availability in the DLPFC of patients with schizophrenia [105]. Furthermore, increased [^{11}C]NNC 112 binding was associated with poor performance at the n-back, a test involving working memory [105]. The reasons for the discrepant results obtained with [^{11}C]SCH 23390 and [^{11}C]NNC 112 remain to be elu-cidated, but it is interesting to note that the binding of the two radiotracers is differentially affected by endo-genous DA competition and receptor trafficking [81].

2. Studies of Nondopaminergic Receptors in Schizophrenia

Receptors related to the GABA and 5HT systems have been studied in vivo in schizophrenia. Postmortem stu-dies reported abnormalities of both systems in schizo-phrenia. A robust body of findings suggests deficiency of GABA-ergic function in the PFC in schizophrenia [for reviews, see 106,107]. In vivo evaluation of GABA-ergic systems in schizophrenia has so far been limited to evaluation of benzodiazepine receptor den-sities with SPECT and [^{123}I]iomazenil, and three out of three studies comparing patients with schizophrenia and controls reported no significant regional differ-ences [108–110]. While some significant correlations with symptoms clusters and regional benzodiazepine densities have been observed [108,109,111,112], these

relationships have not been replicated by other studies. Thus, together, these studies are consistent with an absence of marked abnormalities of benzodiazepine receptor concentration in the cortex of patients with schizophrenia. Alterations of GABA-ergic systems in schizophrenia might not involve benzodiazepine receptors [113], or be restricted to certain cortical layers or classes of GABA-ergic cells that are beyond the resolution of current radionuclide-based imaging techniques. Recent developments in GABA imaging with MRS described below are a promising new avenue to study in vivo GABA-ergic function in schizophrenia.

Abnormalities of 5HT transporters (SERT), $5HT_{2A}$ receptors, and, more consistently, $5HT_{1A}$ receptors have been described in postmortem studies in schizophrenia [see references in 114]. Given the relatively recent development of radiotracers to study 5HT receptors, only a limited number of imaging studies have been published. The concentration of SERT in the midbrain measured by $[^{123}I]\beta$-CIT is unaltered in patients with schizophrenia [93]. Studies with more specific SERT ligands are warranted to assess the distribution of SERT in other brain areas, such as the PFC, where their density has been reported to be reduced in three out of four postmortem studies [114]. Decrease in $5HT_{2A}$ receptors has been reported in the PFC in 4 out of 8 postmortem studies [114,115]. Three PET studies in drug naive or drug free patients with schizophrenia reported normal cortical $5HT_{2A}$ receptor binding [115–117], while one study reported a significant decrease in PFC $5HT_{2A}$ binding in a small group (n = 6) of drug-naive schizophrenic patients [118]. The most consistent abnormality of 5HT parameters reported in postmortem studies in schizophrenia is an increase in the density of $5HT_{1A}$ receptors in the PFC, reported in seven out of eight studies [114]. Several groups are currently evaluating the binding of this receptor in vivo with PET and $[^{11}C]$WAY100907.

3. Receptor Occupancy by Antipsychotic Drugs

Maybe the most widespread use of neuroreceptor imaging in schizophrenia over the last decade has been the assessment of neuroreceptor occupancy achieved by typical and atypical antipsychotic drugs, a topic that has been the subject of recent reviews [119,120]. Neuroreceptors studied included mainly D2 receptors, but also $5HT_{2A}$ and D1 receptors. The main conclusions from this line of research are as follows:

1. Studies repeatedly confirmed the existence of a threshold of occupancy of striatal D2 receptors ($\sim$ 80%) above which extrapyramidal side effects are likely to occur [121].
2. In general, studies failed to observe a relationship between degree of D2 receptor occupancy and clinical response [122,123]. Yet, most studies were performed at doses achieving > 50% occupancy, and the minimal level of occupancy required for therapeutic response remains undefined. Two studies performed with low doses of relatively selective D_2 receptor antagonists (haloperidol and raclopride) suggested that 50–60% occupancy was required to observe a rapid clinical response [124,125].
3. Clozapine, at clinically therapeutic doses, achieved only 40–60% D_2 receptor occupancy [121,123,126], which, in conjunction with its anticholinergic properties, accounts for its low liability for extrapyramidal symptoms (EPS).
4. Occupancy of $5HT_{2A}$ receptors by "$5HT_{2A}/D_2$ balanced antagonists" such as risperidone does not confer protection against EPS, since the threshold of D_2 receptor occupancy associated with EPS is not markedly different between these drugs and drugs devoid of $5HT_{2A}$ antagonism [127–130].
5. Studies with quetiapine suggested that, at least with this agent, transient high occupancy of D_2 receptors might be sufficient to elicit clinical response [131,132].

An interesting question relates to putative differences in degree of occupancy achieved by atypical antipsychotic drugs in striatal and extrastriatal areas. Pilowsky et al. [133] reported lower occupancy of striatal D_2 receptors compared to temporal cortex D_2 receptors in seven patients treated with clozapine, using the high-affinity SPECT ligand $[^{123}I]$epidipride. In contrast, typical antipsychotics were reported to achieve similar occupancy in striatal and extrastriatal areas, as measured with $[^{11}C]$FLB 457 [134] or $[^{123}I]$epidipride [135]. It should be noted, however, that these very high affinity ligands do not allow accurate determination of D_2 receptor availability in the striatum. In contrast, $[^{18}F]$fallypride enables accurate determination of D_2 receptor availability in both striatal and extrastriatal areas [136], and preliminary PET experiments in primates with $[^{18}F]$fallypride indicate that clozapine and risperidone achieve similar D_2 receptor occupancy in striatal and extrastriatal regions [137]. Finally, it is important to point out that the most

robust evidence regarding the site of therapeutic effect of antipsychotic drugs in rodents points toward the nucleus accumbens [138,139], while the imaging studies reviewed above contrasted striatal versus mesotemporal D_2 receptor binding. Improved resolution of PET cameras currently allows distinguishing signals from ventral and dorsal striatum [140,141], and it is now feasible to specifically study the clinical correlates of D_2 receptor occupancy in ventral striatum in humans.

Another unresolved question is the discrepant values of D_2 receptor occupancy obtained with [11C]raclopride versus [11C]NMSP. The haloperidol plasma concentration associated with 50% inhibition of [11C]NMSP binding (3–5 ng/mL) [142] is 10 times higher than that associated with 50% inhibition of [11C]raclopride binding (0.32 ng/mL) [143]. Quetiapine, at a dose of 750 mg, decreased [11C]raclopride specific binding by 51%, but failed to affect [11C]NMSP specific binding [144]. These observations contribute to the debate regarding differences between benzamide and butyrophenone binding to D_2 receptors.

B. Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) is a noninvasive imaging modality capable of evaluating the chemistry of living tissue. Like magnetic resonance imaging (MRI) and functional MRI (fMRI), it is an application of the basic method of nuclear magnetic resonance (NMR), and as such involves no radioactivity (ionizing radiation) and generally involves the same scanning equipment and environment as MRI. The neurochemical abnormalities of schizophrenia remain an area of active investigation. New information on the neurochemistry of schizophrenia has mainly been derived from phosphorus and proton MRS.

1. Phosphorus Spectroscopy

Phosphorus MRS (^{31}P MRS) can provide an assessment of brain membrane phospholipid and high-energy phosphate metabolism. However, ^{31}P MRS is only $\sim 5\%$ as sensitive as proton MRS, primarily because of the lower gyromagnetic ratio of ^{31}P [145], requiring correspondingly greater volumes of interest (often chosen to be 15–36 cm^3). Metabolites detectable in the ^{31}P spectrum include α, β, and γ nucleoside triphosphates (NTP), phosphomonoesters (PME), phosphodiesters (PDE), phosphocreatine (PCr), and inorganic phosphate (Pi). In addition, intracellular magnesium (Mg^{2+}) and intracellular pH can be com-

puted from spectral separation of certain resonant peaks in the ^{31}P spectrum [146,147].

PME and PDE resonances arise from the precursors and breakdown products, respectively, of membrane phospholipids, as well as phospholipid bilayer itself. The observed PME spectrum is composed mainly of the metabolites phosphocholine, phosphoethanolamine, and L-phosphoserine. PDE spectra are primarily comprised of glycerol-3-phosphocholine (GPC), glycerol-3-phosphoethanolamine (GPE), and phospholipid bilayer [148].

PCr, NTP, and Pi resonances are indicators of the state of energy metabolism in the region of interest. In the schizophrenia ^{31}P MRS literature, it has generally been assumed that the predominant contribution to the NTP resonances is adenosine triphosphate (ATP). Calculation of such metabolite concentration ratios as PCr to Pi, NTP to Pi, and PCr to NTP can also offer useful information about the regional energy state.

In an early study, Pettegrew et al. [149] studied membrane phospholipid and high-energy phosphate metabolism in the dorsal prefrontal cortex of first-episode, neuroleptic-naive patients with schizophrenia and matched healthy controls. The study found reductions in PME and Pi, and increases in PDE and βATP, but no significant differences in PCr or intracellular pH in patients relative to controls. The authors proposed that their phospholipid findings may be related to an exaggeration of normal synaptic pruning during adolescence, when PME levels normally decrease [149,150)], and interpreted these findings as reflecting decreased synthesis and increased breakdown of membrane phospholipids in the patients. They interpreted the high-energy phosphate findings as consistent with hypofrontality in schizophrenia as previously found by PET and other methods [21,31,151,152] in that increased ATP and decreased Pi levels suggested decreased ATP utilization.

PME decreases have been replicated in other in vivo ^{31}P MRS studies in treatment-naive, first-episode [153] and chronic medicated patients [154–156], as well as in patients with prominent negative symptoms [157], but were not found by Volz et al. [158] or by Deicken et al. [159] in chronic patients. PDE increases have been replicated in first-episode, treatment-naive patients [153]. However, in chronic medicated patients, PDE changes have been quite variable: increases were found by Deicken et al. [159]; no changes were seen by Williamson et al. [154], Fujimoto et al. [160] or Shioiri et al. [157]; and decreases were found by Volz et al. [158]. Differing MRS methodologies (including voxel size, pulse sequences, localization method, quan-

tification of signal ratios) may account for some or all of these discrepant findings [161,162].

Taken together, the phospholipid findings of Pettegrew et al. [149], Williamson et al. [154], and Stanley et al. [153] have been interpreted as suggesting that as schizophrenia progresses to chronicity, levels of breakdown products may normalize from their early elevated levels, while the precursors of membrane phospholipids remain in deficit as in the earlier stages of illness. However, the study by Potwarka et al. [156] using ^{1}H decoupled ^{31}P MRS methods capable of distinguishing the components of the PDE resonance has suggested an alternative interpretation of the increases in that peak. Their finding in a study of chronic, medicated patients showed an increase only in the mobile or membrane phospholipid component of the PDE peak, but not in the phospholipid breakdown products GPE and GPC, suggesting abnormal membrane structure but not increased phospholipid breakdown.

High-energy phosphate metabolism findings have been inconsistent across studies, perhaps due to variability in the MRS or clinical methodology [161,162]. While Pettegrew et al. [149] and Shiori et al. [157] observed increased ATP, suggesting hypofrontality, other investigators, including Stanley et al. [153] and Volz et al. [158] found no alterations in these measures. Phosphocreatine (PCr) levels have also been variable, with both increases [155] and decreases [159] being reported.

Temporal lobe findings using ^{31}P MRS have shown considerable variation for high-energy phosphate and membrane phospholipid metabolism [161,162]. In a study of chronic patients, O'Callaghan et al. [163] found no differences in any metabolite levels in the left temporoparietal region, while the studies of Fujimoto et al. [160] and Fukuzako et al. [164] found increases in PDE, and a more recent study [165] found both decreased PME and increased PDE.

Calabrese et al. [166] investigated asymmetry of ^{31}P MRS measures in a group of chronic, mainly medicated patients, and found higher PCr/βATP and PCr/Pi ratios in the right temporal lobe, and elevation in βATP itself on the left. With improved technology, this group [167] later replicated these findings; however, they contrast in laterality to the ATP findings of Fujimoto et al. [160] and Fukuzako et al. [164], and a more recent study [165] found no changes.

2. Proton Spectroscopy

The signals of interest in proton or ^{1}H MRS are derived from protons in compounds other than

water, in contrast to MRI, where the proton signal that yields the structural image is derived mainly from water. Indeed, the protons in tissue water and lipids emit extremely intense signals that tend to obscure the ^{1}H spectra of interest. The compounds of interest typically occur in concentrations on the order of mM, or 10^4- to 10^5-fold less than water. The dominant water and lipid signals must therefore be suppressed [168] for the fine spectral structure to emerge, historically a technically demanding requirement but now a routine part of ^{1}H MRS .

The compounds of interest detected by proton MRS include N-acetylaspartate (NAA), an amino acid derivative described as a putative cell marker, found in all structural components of neurons, and found mainly but not exclusively in neurons [169]. The role of NAA in neuronal function is not fully understood; its signal strength is generally regarded as proportional to neuronal density, neuronal function, or neuronal viability, and may undergo reversible changes [170–172]. Proton MRS can also detect choline containing compounds (Cho), creatine/phosphocreatine (Cr), myo-inositol, and lactate. Glutamate (Glu), the major excitatory neurotransmitter in the central nervous system, can also be measured, particularly at shorter echo times, although it is not routinely resolvable from glutamine (Gln) and gamma-aminobutyric acid (GABA) at the clinical magnetic field strength of 1.5 tesla. Other discernible but less reliably quantified peaks are alanine, aspartate, and glucose [173]. In addition to these metabolite peaks, resonances from macromolecules have been shown to contribute to the spectrum in the range 0.9–2.05 parts per million (ppm). These overlap with metabolites in short echo time spectroscopy, complicating the process of spectral assignment and quantification [174,175]. Separation of these resonances by exploiting their differing T1 relaxation times from those of metabolites has been demonstrated [174], allowing both improved identification of metabolites at short echo times and direct investigation of macromolecule resonances in pathological conditions.

The three strongest and most easily quantifiable metabolite peaks are produced by NAA, Cr, and Cho, and these have therefore been the most studied compounds in ^{1}H MRS. Proton (^{1}H) MRS has two distinct advantages over other nuclei: hydrogen atoms are present in almost every compound in living tissue, and hydrogen has the most sensitive of the nuclei studied by MRS, allowing relatively small volumes of interest (fractions of a cm^3 to several cm^3). One difficulty arises from the narrow (10 ppm) range of chemical shifts of ^{1}H spectra [161], making

resolution of individual resonances more difficult. For example, glutamine, glutamate, and GABA are difficult to distinguish as noted at conventional 1.5 tesla magnetic field strength because of partially overlapping peaks. Resolution of these peaks is possible with more sophisticated spectroscopic editing acquisition techniques [176,177] and with higher field strengths [178]. These developments are of great interest in psychiatric research, in view of the potential significance of these compounds for the pathophysiology of psychiatric disorders.

Findings in Schizophrenia

Studies of NAA in frontal lobes in schizophrenia have produced mixed results. Stanley et al. reported an absence of NAA change in first-episode patients [179], which was replicated in a later study [180]. However, other groups have found decreased NAA in first-episode patients [181,182]. In chronic schizophrenia, results have been similarly mixed: reduced frontal lobe NAA/Cr ratio was found in some studies [183–185] while others reported no changes [186,187]. A study notable for its large size (47 patients and 66 controls) [188] included subjects of mixed chronicity and found no NAA reduction. These authors provided an effect size estimate for an even larger sample of subjects from their laboratory (103 patients and 71 controls) of ~ 0.2.

These studies have also investigated the amino acid signal (glutamate, GABA, glutamine) in frontal lobes, with mixed results. The ratio of GABA plus glutamate to creatine was found to be elevated by Choe et al. [182,189]. Stanley et al. [179] and Bartha et al. [180] reported no change in glutamate, but an increase in glutamine signal. Stanley et al. [179] interpreted their findings of unaltered glutamate with an increase in the glutamine signal as reflecting altered glutamatergic neurotransmission and suggested that glutamine may be a more sensitive marker of alteration in glutamatergic neurotransmission.

NAA reductions in temporal lobes have been found fairly reliably in schizophrenia. Reduced NAA (or NAA/Cr ratios) were reported by Deicken et al. [190], Fukuzako et al. [187], Lim et al. [191], Bertolino et al. [183,184], Maier et al. [192], Nasrallah et al. [193], and Yurgelun-Todd et al. [194] in medial temporal structures in chronic schizophrenia, but not by Buckley et al. [186] or Heimberg et al. [195]. First-episode psychosis was studied by Renshaw et al. [196], who found a reduction in the NAA/Cr ratio bilaterally.

Clinical and Imaging Correlates

Evidence for an absence of neuroleptic medication effect on NAA has been provided by the studies of Bertolino et al. [184], Choe et al. [182], and Stanley et al. [179].

No consistent correlations have been found between frontal or temporal lobe NAA and cognitive or symptom measures [186] or duration of illness [190]. Frontal lobe NAA reductions have been found in adolescent [197] and older relatives at risk for schizophrenia [188], raising the question whether NAA reductions may characterize individuals at risk for schizophrenia.

Frontal lobe NAA has been compared with other brain imaging and clinical measures in recent studies. NAA exhibited interesting correlations with amphetamine-induced DA release [86] and with a PET measure of cerebral blood flow during cognitive challenge tasks [198], suggesting a relation between frontal lobe neuronal deficits and impaired cognitive function as well as subcortical dopamine dysregulation.

The quite reproducible NAA deficits in temporal lobe and the more variable frontal lobe NAA deficits are consistent with impaired neuronal function across a distributed network already implicated in schizophrenia. The variable reports for frontal lobe, consistent with the effect size indicated by the report of Callicott et al. [188], suggest a quite small yet detectable effect in frontal lobes. The frontal NAA reduction may be substantially larger in chronic patients, as indicated by the positive findings in small samples of chronic patients reported by Bertolino et al. [183,184]. This may place limitations on the generalizability of the frontal NAA reduction and may place constraints on its interpretation, in that this regional deficit may evolve with chronicity, or may be detectable mainly in patients with illness severity sufficient to necessitate long-term hospital care.

3. Summary

Considerable progress has been made in utilizing the capabilities of in vivo MRS to study the neurochemistry of schizophrenia. The first generation of MRS studies in schizophrenia has been characterized by a marked diversity of techniques, study populations, and anatomic regions investigated. A corresponding range of results has been obtained; nevertheless, areas have emerged of reproducible findings of alterations in membrane phospholipid metabolism using ^{31}P MRS, and reduction in temporal lobe (and more variably, frontal lobe) NAA using ^{1}H MRS. These findings have both contributed to our understanding of the

neurochemistry of schizophrenia and have stimulated continued investigation.

Research into the roles in brain physiology of the metabolites detectable by MRS has been stimulated by the application of this modality; further understanding, including normal values in various regions and brain matter types, is needed to assist in interpreting MRS findings. A methodological advance that would improve data analysis and interpretation would be the establishment of a reliable method for absolute metabolite quantification [199,200], particularly in the ^{1}H case. Interpretability of MRS data would also be improved by the reporting of segmentation analyses of the MRS voxels into distinct brain matter types, since illness may modify not only the neurochemistry but also the relative amounts of brain matter types in the regions under study.

Future investigations of MRS in schizophrenia can be expected to benefit from availability of higher field strengths for human studies, permitting improvements both in spectral and in spatial resolution; application of tracer methods such as ^{13}C label to probe biosynthetic pathways [201]; and spectroscopic editing techniques which allow enhanced peak identification at a given field strength [176,177]. The potential of ^{1}H MRS to examine glutamate, glutamine, and GABA with increasing resolution suggests a future generation of direct studies of these specific neurochemicals.

V. CONCLUSION

Development of sophisticated brain imaging techniques has enabled the study of alterations in brain structure, function, and neurochemistry associated with schizophrenia. Regarding structure, studies showed that subtle morphological abnormalities are consistently observed, involving increased ventricular-brain ratios, and moderate general tissue reduction, the latter being more pronounced in the limbic regions of the mesial temporal lobe. Findings with proton spectroscopy demonstrating reductions in NAA content are generally consistent with the structural abnormalities, and indicate that these volume reductions might be associated with reduction in neuronal density or function. Functional studies are consistent with aberrations of regional connectivity in corticolimbic networks, and implicate the prefrontal cortex as a critically deficient node in these interactions. Imaging of the dopaminergic system is also consistent with the idea of dysconnectivity, as regulation of this system appears to be deficient. Combined with complementary neuropatho-

logical findings, these studies have put into images the dysconnectivity of mental processes characterizing this illness. Maybe the most fundamental contribution of brain imaging so far has been to document that neuronal fragmentation underlies the mental fragmentation experienced by the patients. The hope for the future is that refinements in imaging techniques will provide endophenotypes contributing to the elucidation of the genetic and epigenetic etiology of the illness and offer insights for new therapeutic approaches.

The Dopamine Hypothesis of Schizophrenia

PHILIP SEEMAN and MARY V. SEEMAN
University of Toronto, Toronto, Ontario, Canada

I. INTRODUCTION

The speculation that impairments in dopamine circuitry lie at the heart of the susceptibility to schizophrenia has long been debated but, recently, new evidence has arisen to support it. Dopamine mimetics such as L-dopa, amphetamine, and disulfiram are well known to produce psychotic symptoms de novo or to worsen pre-existing ones. Recent evidence shows that amphetamine causes a twofold higher release of dopamine in individuals with schizophrenia than it does in control subjects [1,2].

At the same time, dopamine-blocking drugs have long been known to reduce psychotic symptoms. It had been thought that the newer or "atypical" drugs exert their action through a different mechanism but, in fact, all antipsychotic agents block D2 receptors. Their clinical potency against positive symptoms of schizophrenia correlates with their ability to block this receptor [3–6].

The therapeutic concentrations of antipsychotic drugs used to derive the receptor occupancies have been summarized elsewhere [6–10]. The prediction that clinical efficacy requires a threshhold of 60–70% receptor occupancy is supported by PET (positron emission tomography) and SPET (single photon emission tomography) studies [11–17]. This range of D2 receptor occupancy correlates with efficacy for all clinically effective compounds.

II. IS CLOZAPINE AN EXCEPTION?

Using PET with a variety of radioligands, clozapine has been reported to occupy only between 0% and 50% of D2 receptors at clinically effective doses [11,12,15,18–25]. This is also true for studies using SPET methods [26–30]. Taken at face value, these results have been interpreted as evidence against the dopamine hypothesis since clozapine is considered one of the most (if not *the* most) effective antipsychotic agents in the treatment of schizophrenia.

The majority of these imaging studies, however, have examined schizophrenia patients at a time point that corresponds with a period of 6–12 h following the last oral dose of the drug. Importantly, recent data by Kapur and colleagues have shown that both clozapine and quetiapine occupy the requisite 60–70% of dopamine receptors as long as the patient is scanned within 2–4 h after the last administered dose [31–33].

The reason time is important is that compounds such as clozapine and quetiapine are loosely bound to the dopamine receptor. This stands in contrast to compounds such as haloperidol, chlorpromazine, remoxipride, olanzapine, raclopride, and sertindole, which are all tightly bound [34].

The loosely bound drugs are easily displaced by endogenous dopamine. A pulse of an endogenous concentration of 100 nM dopamine [35] displaces

D2-bound [3H]clozapine or [3H]quetiapine at least one hundred times faster than it does D2-bound [3H]haloperidol or [3H]chlorpromazine [34]. Thus, the rapidity with which endogenous dopamine supplants clozapine and quetiapine at dopamine D2 receptors contributes to low apparent D2 receptor occupancy.

III. EVIDENCE OF ISOMERS

The three-dimensional molecular configuration of antipsychotic agents is similar to that of dopamine itself, which explains their ability to fit snugly into the receptor and obstruct dopamine transmission. Drugs with very similar structures that do not fit into and block the receptor are not antipsychotics. As an example, the isomer of flupenthixol that blocks dopamine receptors is an effective antipsychotic whereas the isomer that does not is ineffective. Loosely bound drugs (clozapine and quetiapine) fit the receptor, but not snugly, and they are therefore easily displaced and their blockade is brief.

IV. EVIDENCE OF DOPAMINE DEPLETION

Also supporting the dopamine hypothesis are data that show that dopamine depletion by reserpine produces an antipsychotic effect and that blocking dopamine synthesis by alpha-methyl-p-tyrosine (AMPT), for instance, reduces the antipsychotic dose needed to produce an antipsychotic effect.

V. EVIDENCE OF PROLACTIN ELEVATION

All antipsychotics, including clozapine, can be shown to elevate prolactin levels by a direct block of D2 receptors in the anterior pituitary. Prolactin elevations with the loosely bound agents are, however, transient [36], mirroring striatal effects.

VI. EFFECT LAG

One time-honored objection to the dopamine hypothesis of antipsychotic action is the therapeutic time lag. Antipsychotics alter dopamine activity from the first day of treatment whereas clinical improvement does not set in until later, although some clinical effects (calming of agitation, fear reduction, disappearance of catatonic features, attenuation of suspicion/hostility) begin almost immediately, reducing scores on the Brief Psychiatric Rating Scale (BPRS). In the face of postsynaptic blockade, the reaction of a dopamine neuron is to compensate by increasing presynaptic release. This is evidenced by initial increases of dopamine metabolites—i.e., increases in levels of homovanillic acid (HVA). With time, the HVA levels in the cerebrospinal fluid decrease, as the dopamine system accommodates. In patients who respond to antipsychotics, full clinical response occurs at a time that corresponds with the plateau in HVA levels (∼ 3 weeks after initiation of treatment).

VII. WHAT CAN BE LEARNED BY THE NOVEL ''ATYPICAL'' ANTIPSYCHOTICS?

The block of D2 receptors by antipsychotic drugs elicits parkinsonism and other extrapyramidal signs. Clozapine and quetiapine, however, cause few or no extrapyramidal effects. Few extrapyramidal signs are induced by other novel antipsychotics as well, as long as the dose is kept low.

Does this mean that the D2 blockade of these agents is small relative to other receptor block, and does this undermine the hypothesis that dopamine D2 binding is the primary source of antipsychotic action? For instance, it has been suggested that the blockade of serotonin-2A receptors alleviates the parkinsonism caused by D2 block. But most data do not support this hypothesis. For example, selective serotonin-2A receptor blockade actually enhances the catalepsy of submaximal doses of raclopride in rats (Wadenberg M-LG, Hicks PB, Young KA, 1997, personal communication). Rat catalepsy is the analog of parkinsonism in humans.

Furthermore, the serotonin-2A blocker, ritanserin, (2 mg/kg SC) had no effect on raclopride-induced catalepsy in rats, whether maximal (4 mg/kg SC) or submaximal (0.2 mg/kg SC) doses of raclopride are used [37]. Additionally, in humans, a high degree of serotonin-2A receptor occupancy (95%) by risperidone (6 mg/day) does not prevent extrapyramidal signs in six out of seven patients with schizophrenia [38].

Finally, when it comes to clozapine, this drug is 20 to 50-fold more potent in blocking muscarinic acetylcholine receptors than in blocking dopamine D2 receptors. Clozapine and olanzapine are extremely potent anticholinergic drugs. Clozapine blocks muscarinic receptors between 1.5 nM and 36 nM, and this may contribute to the absence of parkinsonism by clozapine.

More importantly and more generally, antipsychotic drugs which tend to elicit little or no extrapyramidal signs are those that have dissociation constants (K_d values) > 1.5 nM, which is the K_d for dopamine at the high-affinity state of D2. This means that dopamine binds more tightly to D2 than the drugs do, so that the high endogenous dopamine in the human striatum quickly replaces loosely bound antipsychotics at the D2 receptor.

If that is the case, how can loosely bound drugs exert their effect against psychosis? Part of the explanation is that endogenous dopamine in limbic brain regions (e.g., frontal cortex, cingulate gyrus) is one-tenth that of the striatum. These low concentrations of endogenous dopamine in the synapses of limbic brain regions cannot compete against the drug. Thus, the D2 occupancy of these drugs in the limbic regions of the human brain may be high for longer periods than in the striatum. In other words, the higher output of endogenous dopamine in the striatum displaces D2-bound clozapine more quickly than does the low output of dopamine in the cerebral cortex. In corroboration of this theoretical model, Pilowsky et al. [39] have indeed found that clozapine occupies more D2 receptors in the cerebral cortex of patients than in the striatum.

It may also be possible that relatively transient D2 receptor occupancy is all that is needed in order to achieve clinical efficacy and that constant blockage of the receptor is unnecessary.

VIII. CONSEQUENCES OF LOOSE/TIGHT CATEGORIES

It appears that the rapid displacement of clozapine by dopamine is an important part of the explanation for the lack of extrapyramidal effects induced by novel antipsychotic agents. While dopamine can also displace other antipsychotic drugs such as raclopride [40] or [3H]chlorpromazine) [1,41]. such action is not sufficiently rapid to prevent parkinsonism. This is because these drugs are more tightly bound to D2 than is clozapine.

The separation of antipsychotic drugs into "loose" and "tight" D2 binding, relative to that for dopamine, is consistent with the findings by Kalkman et al. [42]. In animal models, these investigators were able to reverse catalepsy that was induced by olanzapine and loxapine (both more loosely bound than dopamine), but were not able to reverse the catalepsy produced by haloperidol (Kalkman HO, Tricklebank MD, 1997, personal communication).

Another consequence is that patients taking clozapine are at risk for quick relapse upon stopping their medication [43,44]. Because clozapine is loosely bound to the dopamine D2 receptor ($K_d = 44$ nM), it is readily displaced by any sudden pulse of endogenous dopamine arising from emotional or physical activity. In fact, both R. Conley [in 43] and Pickar et al. [45] observed that the D2 occupancy by clozapine rapidly decreased upon clozapine withdrawal. This was in contrast to the 2 weeks or more of residual occupancy of D2 by traditional neuroleptics [46]. Any sudden surge of impulse-triggered release of endogenous dopamine will quickly displace residual clozapine and may lead to a precipitate clinical relapse.

IX. FURTHER EVIDENCE FOR THE IMPORTANCE OF ENDOGENOUS DOPAMINE

Low dose clozapine [47–51] or remoxipride [52] effectively treats L-dopa psychosis in Parkinson's disease. The average dose for clozapine for this condition is 55 mg/day, while that for remoxipride is 150 mg/day, much lower doses than those used to treat schizophrenia.

The reason for the effectiveness of these very low doses is the fact that $> 95\%$ of the brain dopamine has been depleted in Parkinson's disease. Thus, there is virtually no endogenous dopamine to compete against the clozapine or remoxipride. The low dose of clozapine corresponds to a low spinal fluid concentration of clozapine and norclozapine, estimated to be of the order of 60 nM (given that the unbound clozapine is 20% of the total plasma clozapine) [53]. Under these conditions, the fraction of D2 receptors occupied would be $\sim 60\%$*.

X. IS D2 BLOCK A NECESSARY MINIMUM FOR ANTIPSYCHOTIC ACTION?

If serotonin block is not the major reason for the relative absence of extrapyramidal side effects by the novel antipsychotic agents, is it perhaps the reason for the extra efficacy attributed to these drugs, especially to

*Where $C/(C+K)$ is 60 nM/(60 nM + 44 nM) = 60% of D2.

clozapine? It seems not. Full blockade of serotonin-2A receptors occurs at doses of risperidone, olanzapine, and clozapine, which are markedly subtherapeutic, indicating that serotonin-2A block contributes little or nothing to antipsychotic action [17].

The consistent finding that all antipsychotic drugs, including clozapine, occupy 60–70% of D2 receptors when clinically effective, suggests that the blockade of D2 is an essential minimal requirement for clinical antipsychotic action in those patients who respond to neuroleptics. It is also true, however, that many schizophrenia patients may not clinically improve despite high drug occupancy ($>75\%$) of their D2 receptors.

The argument has been made that, since 30% of patients who have not responded to traditional D2 blockers such as haloperidol do respond to clozapine, then the drug must work through a different mechanism [54]. Such "treatment-resistant" patients, however, also respond (often dramatically) to remoxipride [55–57], which is extremely selective for D2. In fact, just like clozapine, remoxipride clinically improves at least 30% of treatment-resistant schizophenia patients [55–57]. The experience with remoxipride indicates that treatment-resistant patients may still improve via D2 block when using a low potency drug such as clozapine ($K_d = 44$ nM at D2) or remoxipride ($K_d = 30$ nM at D2).

XI. DO DOPAMINE RECEPTORS HAVE ANYTHING TO DO WITH SCHIZOPHRENIA?

Although it is important to recognize that the drugs we currently use to control schizophrenia symptoms all act principally through dopamine receptors, does this have anything to tell us about the etiology of schizophrenia? Does the dopamine hypothesis refer only to drug action, or to the pathophysiology of the disease itself? By using D2-blocking isotopes in a PET scanner, it is possible to image striatal dopamine receptors in psychotic patients who are drug free. Some drug-free patients manifest an increase in D2 receptors [58], suggesting a possible early indication of increased sensitivity to dopamine. Other investigators have not been able to replicate this finding [59], but these studies have used different ligands, and different assumptions and the sample sizes have been small, so no definite conclusions are currently possible. The group that finds elevations uses the ligand [11C]methylspiperone [22]; the group that does not, uses [11C]raclopride [60].

The two ligands may bind differently to the D2 receptor. Since D2 receptors exist either in the monomer or the dimer form both in rat and human tissue [61], one ligand may bind only to the monomer and the other may bind to both. There are reasons to believe that raclopride, like nemonapride, binds to both forms of the receptor [62–64] and, thus, the raclopride method may obscure a D2 monomer elevation that, at least speculatively, lies at the heart of schizophrenia susceptibility.

Why would D2 monomers be elevated in schizophrenia? In postmortem tissue, their elevation might be explained as a response to the virtual absence of dopamine in the synaptic cleft [65]. But in vivo studies throw further light on the situation. In the presence of a resting level of neuron firing, the synaptic level of dopamine in subjects with schizophrenia is at least twice that of control subjects [1,2,41]. Presumably, in living subjects, there is a faster turnover, more dopamine being synthesized in response to increased need. In other words, the more monomer-type receptors on the postsynaptic membrane, the more dopamine depletion in the synapse, the more feedback to autoreceptors on the presynaptic cell, and the more dopamine synthesis.

XII. EFFECT OF THE D1 RECEPTOR

There is the further influence of the D1 receptor, which plays a role as yet not well defined. What we do know is that D1 influences D2, possibly in the direction of reducing its high affinity states. The D1-D2 link appears to be reduced or even absent in post mortem tissues in psychosis [66]. Without the moderating influence of D1, more D2 receptors in schizophrenia may exist in their high-affinity (or physiologically active) [67] state, thus further increasing psychosis vulnerability.

XIII. THE DOPAMINE HYPOTHESIS AND MOLECULAR GENETICS

Genetic linkage with dopamine receptor subtypes has, in general, excluded dopamine receptor genes as loci of major effect in schizophrenia [68]. Association studies suggest that variation in the D3 gene may confer a small relative risk to schizophrenia [69]. Incidentally, the same review [69] underscores the important links which exist between impaired cognition in schizophrenia and dopamine pathways, too extensive a literature to include in this chapter. It is important to understand

that genetic linkage to the disease may not directly involve dopamine receptor genes but may implicate genetic defects of other proteins responsible for the regulation or modulation of these genes. The increase of D2 monomers found in schizophrenia, and the presence of relatively more D2 high-affinity states, may be a response to as yet unknown genetic variations in other systems. For instance, Kegeles et al. [70] found that ketamine, which blocks N-methyl-D-aspartate (NMDA) receptors, enhances the amphetamine-induced release of endogenous dopamine in healthy volunteers, strongly suggesting an interaction between glutamate and dopamine systems. A confounding factor, however, is that ketamine has equal affinity for NMDA receptors and the high-affinity state of dopamine D2 receptors [71]. This shows the complexity and the interaction potential of neurotransmission systems, which increases the difficulty of candidate gene searches.

Serotonergic Dysfunctions in Schizophrenia
Possible Therapeutic Implications

I. INTRODUCTION

There is considerable evidence for a role of the neurotransmitter serotonin (5-hydroxytryptamine; 5HT) in schizophrenia. Numerous studies indicate that the cortical serotonergic signal transduction system is likely to be deficient in that disorder [1–5]. Furthermore, the psychotomimetic actions of 5HT agonists like lysergic acid diathylamide (LSD) and mescaline are well documented and mimic, at least partially, psychotic symptoms seen in schizophrenia [1].

Recent interest in 5HT with regard to antipsychotic drug action has been fueled by the fact that novel antipsychotic drugs such as clozapine, olanzapine, quetiapine, risperidone, sertindole, and ziprasidone are potent $5HT_{2A}$ receptor antagonists and relatively weaker dopamine D_2 antagonists [6]. In addition, $5HT_{1A}$ and $5HT_{2C}$ receptors seem to contribute to clinical effects of some novel antipsychotics [7].

This chapter will provide a selective review of the literature with regard to evidence for serotonergic dysfunctions in schizophrenia. First, we will briefly review the evidence from genetic studies and from challenge experiments with serotonin agonists. Then we will continue with a more detailed description of the possible molecular role of several families of serotonin receptors in schizophrenia, and conclude with an overview about the relevance of serotonin for atypical antipsychotics.

II. GENETICS

While the causes for schizophrenia remain unknown, evidence from family, twin, and adoption studies clearly demonstrates that it aggregates in families. This clustering is largely attributable to genetic rather than cultural or environmental factors. Identifying the genes involved has proved to be a difficult task because schizophrenia is a complex disorder characterized by the existence of phenocopies, low disease penetrance, and an imprecise phenotype. The current working hypothesis for schizophrenia causation is that multiple genes of small to moderate effect confer compounding risk through interactions with each other and with nongenetic risk factors. These same genes may be commonly involved in conferring risk across populations, or they may vary in number and strength among

different populations. To search for evidence of such genetic loci, both candidate gene and genome wide linkage studies have been used in clinical cohorts collected from a variety of populations. Collectively, these works provide some evidence for the involvement of a number of specific genes (e.g., the $5HT_{2A}$ receptor gene [8] and the dopamine D_3 receptor gene) and as yet unidentified factors localized to specific chromosomal regions, including 6p, 6q, 8p, 13q, and 22q. These data provide suggestive, but no conclusive, evidence for causative genes. More detailed reviews of the molecular genetics [9] and epigenetics [10] of schizophrenia can be found elsewhere.

III. CHALLENGE STUDIES

Pharmacological challenge with the partial 5HT agonist m-chlorophenylpiperazine (MCPP) significantly increased positive psychotic symptoms in schizophrenic patients but not in healthy controls [11]. This effect appears to be specific for schizophrenia as MCPP has been reported to be anxiogenic but not psychotomimetic in patients with panic disorder, posttraumatic stress disorder, major depressive disorder, obsessive-compulsive disorder, alcohol dependence, or Alzheimer's disease.

IV. SEROTONIN $5HT_{1A}$ RECEPTORS

Serotonin $5HT_{1A}$ receptors are located pre- and post-synaptically. The presynaptic $5HT_{1A}$ receptor is an autoreceptor located on cell bodies of raphe neurons, and its stimulation inhibits firing of 5HT neurons. Stimulation of postsynaptic $5HT_{1A}$ receptors leads to hyperpolarization of neurons. Human autoradiography revealed the highest density of $5HT_{1A}$ receptors in temporolimbic cortex, followed by brainstem raphe nuclei, frontal cortex, and other neocortical regions, with very low or undetectable levels in the cerebellum [12]. The brainstem receptors are somatodendritic autoreceptors, while cortical receptors are mainly postsynaptic. The cortical $5HT_{1A}$ receptors are localized on axon hillocks of pyramidal cells, especially in the layers II, III and V of the cerebral cortex [12]. These receptors are involved in the inhibitory modulation of corticocortical association and corticostriatal efferent fibers [13]. Cortical $5HT_{1A}$ receptors exert inhibitory control over striatal glutamate release, and $5HT_{1A}$ antagonists increase glutamate release in the striatum via corticostriatal efferents [14]. In addition, $5HT_{1A}$ agonists increase the outflow of dopamine

in the prefrontal cortex, without a similar change in striatal dopamine release [15]. Stimulation of $5HT_{1A}$ receptors appears to produce many of the same effects as antagonism of $5HT_{2A}$ receptors [7].

Earlier efforts to quantitatively analyze $5HT_{1A}$ receptors were limited by a lack of appropriate ligands. Results obtained with the widely used agonist ligand 8-OH-DPAT were hampered by the fact that it labels $5HT_{1A}$ receptors only in their high-affinity state. This problem has recently been overcome by the discovery of WAY-100635, a selective high affinity ($K_d < 1$ nM) $5HT_{1A}$ antagonist, which labels both low- and high-affinity receptors [16].

Postmortem studies showed an elevation in cortical serotonin $5HT_{1A}$ receptor density in schizophrenia using [^{3}H]8-OH-DPAT as a ligand [17,18]. This finding was subsequently replicated by other groups using 8-OH-DPAT [19–23] and WAY-100635[12] for postmortem quantification of $5HT_{1A}$ receptors (Table 1).

To adapt WAY-100635 for human studies, it has been labeled at the [carbonyl-^{11}C] position [24] and can be used for the quantitative analysis of binding to $5HT_{1A}$ receptors in humans [25]. Using [carbonyl-^{11}C]WAY-100635 and positron emission tomography (PET), cortical $5HT_{1A}$ binding can be quantitatively analyzed using the cerebellum as input function of a simplified reference tissue model (SRTM) [26].

PET and [11C]WAY-100635 were used to show decreased $5HT_{1A}$ receptor binding potential (BP) [27] in patients with major depression, [28, 29] as compared to healthy controls. Using PET and [11C]WAY-100635, our group demonstrated an age-dependent decline of cortical $5HT_{1A}$ receptor BP in healthy volunteers, [30], consistent with postmortem studies which showed a decline in $5HT_{1A}$ receptor numbers with age [31–33].

Our group recently completed a PET study in 14 neuroleptic-naïve patients with a DSM-IV diagnosis of schizophrenia suffering from a first psychotic episode. On the basis of human postmortem studies, we hypothesized that the in vivo $5HT_{1A}$ receptor BP as measured with [carbonyl-^{11}C]WAY-100635 and PET will be higher in frontal and temporal cortex of schizophrenic patients, as compared to an age-matched control group of healthy volunteers. The $5HT_{1A}$ BP of 14 antipsychotic naïve patients were compared to 14 age-matched healthy controls [34]. PET data were analyzed using nine cortical regions of interests (ROI), which were delineated on a coregistered MRI scan and transferred to the PET image, with the cerebellum as reference region for a SRTM. Additionally, we

Table 1 Postmortem Studies of Serotonin $5HT_{1A}$ Receptors in Schizophrenia

Study	Pts. vs controls	$5HT_{1A}$ Receptors in prefrontal cortex
Hashimoto et al. [17,18]	10 vs. 11	40% increase in B_{max}[a] in Scz[b] ($P < .05$). No difference in K_d[c]
Joyce et al. [19]	10 vs. 8	20–40% increase in B_{max} in Scz ($P < .01$).
Simpson et al. [20]	12 vs. 18	20–40% increase in B_{max} in male Scz ($P < .05$). No difference in K_d
Burnet et al. [12,21]	9 vs. 8	23% increase in B_{max} in Scz ($P < .01$)
Sumiyoshi et al. [22]	10 vs. 11	79% increase in B_{max} in Scz ($P < .001$). No difference in K_d.
Gurevich et al. [23]	10 vs. 13	20–75% increase in B_{max} in Scz ($P < .05$)

[a] B_{max} = number of $5HT_{1A}$ receptors
[b] Scz = schizophrenic patients
[c] K_d = equilibrium dissociation constant (a measure for affinity)

performed a voxel-wise comparison using Statistical Parametric Mapping (SPM) [35]. The ROI-based analysis revealed a significant mean cortical $5HT_{1A}$ receptor BP increase of 7.1% ((6.4 SD) in schizophrenic patients (F = 2.975; $P = .025$); local differences were +20% in left mediotemporal cortex (MTC; F = 9.339; $P = .005$) and +13% in right MTC (F = 4.453; $P = .045$) [34]. There were no significant differences in regional R_1 values or cerebellar [11C]WAY-100635 uptake. The voxel-based analysis with SPM99 also confirmed a group difference in a small region of the left MTC. In summary, this in vivo PET study revealed a medio-temporal increase of cortical $5HT_{1A}$ receptor BP in patients suffering from a first episode of schizophrenia [34].

All patients in the postmortem studies had received several years of antipsychotic treatment, and all except five in the Hashimoto et al. study [17] were receiving antipsychotics at the time of death. In contrast, all patients in the PET study were antipsychotic naïve. Hence the noted increase in postmortem $5HT_{1A}$ receptors could be an effect of chronic drug treatment. However, there was no correlation between antipsychotic dose at death and the degree of $5HT_{1A}$ elevation, [20–22], and repeated administration of antipsychotics in animals did not alter $5HT_{1A}$ receptor number [17,18].

Another noteworthy confound of the postmortem studies is that patients had an average illness duration of ∼ 20 years. In the PET study, the sample consisted of first-episode patients with an average duration of untreated psychosis of 21 months (± 18 SD), ranging from 7 months to 5 years. There is some evidence for an abnormal persistence of $5HT_{1A}$ receptors in schizophrenia, suggesting a failure to regress rather than an abnormal upregulation during the course of the disease [36]. In line with that theory, the PET study was not able to demonstrate any significant correlation between $5HT_{1A}$ receptor BP and duration of the illness.

Most postmortem studies selected limited and often arbitrary brain regions to study. Only two groups studied samples from all cortical regions [17,18,23]. All others investigated only the prefrontal cortex, [12,20–22] or the prefrontal and temporal cortex [19]. While all the postmortem studies report "prefrontal" increases, the data came from Brodmann Areas (BA) 9 [19], 10 [17], 11 and 12 [20], 24, 9a, and 44 [23], or 46 [12,21]. To avoid an unjustified restriction to frontal brain areas in the PET study, $5HT_{1A}$ receptor BP was analyzed in cortical ROI drawn in several cortical regions. Although all ROIs were delineated on the coregistered MRI and were consecutively transferred onto the PET summation image, the process of co-registering introduces another source of error. This also contributes to anatomical inaccuracy of the ROI approach. Moreover, if any given pathology afflicts only parts of an ROI, a possible BP increase or decrease will be diluted. As a result, the chance to miss a group difference is high. With this in mind, the results of the ROI analysis were validated by applying additional voxel-wise analyses with SPM. This approach revealed an elevated $5HT_{1A}$ receptor BP in left MTC of patients, confirming the strongest result of the ROI based approach. Although the left temporal cortex is an anatomical region known to be afflicted in schizophrenia [37], the significance and functional relevance of locally elevated [11C]WAY-100635 uptake in schizophrenic patients is unclear.

V. SEROTONIN 5HT$_2$ RECEPTORS

The published studies of 5HT$_{2A}$ receptors in schizophrenic patients to date have mainly involved postmortem brain samples, and produced conflicting results. The radioligands [^{3}H]ketanserin, [^{3}H]spiperone, [^{3}H]LSD, and [^{125}I]LSD, which bind to 5HT$_{2A}$ and 5HT$_{2C}$ receptors, were used in 10 studies, and these studies have produced discrepant results: – six studies [18,21,23,38–40] found a reduction in 5HT$_2$ receptor density in the frontal cortex of schizophrenic patients, and the other four did not find significant differences compared to controls [19,41–43]. Limitations of postmortem studies in terms of inaccurate diagnosis, prior medication history, effects of concurrent illnesses and medications at the time of death, different causes of death such as suicide, differences in brain subregions investigated, as well as different radioligands used, further restrict inferences regarding the role of a possible 5HT$_{2A}$ receptor abnormality in schizophrenia. Most of these confounds can be better addressed with in vivo imaging studies.

Among numerous PET tracers developed for 5HT$_{2A}$ receptors, only [^{18}F]altanserin [44–46], [^{18}F]setoperone [47–50], and [^{11}C]MDL 100,907 [51] have demonstrated appropriate in vivo properties for a successful imaging agent in humans. In two recent [^{18}F]setoperone PET studies using ROI analysis no decreases in 5HT$_{2A}$ receptors were observed in neuroleptic-free or neuroleptic-naïve schizophrenic patients [52,53]. However, localized differences may have been diluted in these ROIs if either some areas were considerably smaller than the ROIs or some areas were not or only partially included in the ROIs. Therefore, additional 5HT$_{2A}$ PET studies have been performed using voxel-by-voxel analysis by the application of SPM [35]. One study reanalyzed data from 13 schizophrenic patients obtained in a previous study [53] but compared them with a larger group of 35 age-matched controls [54]. No substantial 5HT$_{2A}$ receptor changes were observed in the schizophrenic patients. Another [^{18}F]setoperone PET study indicated significant 5HT$_{2A}$ receptor decreases in the left and right prefrontal cortex in six schizophrenic patients versus seven age-matched controls [55].

The lack of substantial 5HT$_{2A}$ receptor BP changes observed in vivo is in contrast with the majority of postmortem studies that reported regionally localized 5HT$_{2A}$ decreases in the frontal cortices from schizophrenic patients [18,21,23,38–40]. It is conceivable that the 5HT$_{2A}$ receptor decrease observed in earlier postmortem studies in schizophrenic patients either on antipsychotic medication, or withdrawn from antipsychotics at time of death, was confounded by medication effects. Studies performed in rats suggest that 5HT$_{2A}$ receptor downregulation may be a component of antipsychotic activity not only of atypical antipsychotics (such as clozapine) but of some typical antipsychotics (such as chlorpromazine, thioridazine, and loxapine) as well.[56–59]. Receptor downregulation is less likely to have confounded the results from the in vivo studies as these were performed in neuroleptic-free or neuroleptic-naïve schizophrenic patients with an interval off antipsychotics of at least 1 month, [52], or 7 weeks [53], prior to PET imaging.

However, in one postmortem study that carefully controlled for the use of antipsychotics at time of death, nonsuicidal schizophrenic patients who had been medication free for at least 1 month showed significant 5HT$_2$ receptor decreases in the anterior cingulate and medial and superior parts of the premotor cortex, corresponding to BAs 24 and 6, more pronounced in cortical layer III than in layer VI [23]. Cortical 5HT$_{2A}$ receptors are localized on apical dendrites of pyramidal neurons [60–62] and on certain subclasses of GABAergic interneurons that provide inhibitory input to pyramidal cells [63–66]. Post mortem studies have shown that in the prefrontal cortex of schizophrenic patients selective subclasses of GABAergic interneurons are decreased [67], unchanged [68], or increased [69]. The assessment of 5HT$_{2A}$ receptor BP in vivo is not sufficiently specific or sensitive to detect selective 5HT$_{2A}$ decreases in cortical layers or selective decreases and increases in subclasses of GABA-ergic interneurons expressing 5HT$_{2A}$ receptors.

In addition, the sensitivity of the in vivo studies to detect group differences has been limited. Given the relatively small sample sizes of the schizophrenic patient groups in these studies, reductions in 5HT$_{2A}$ receptor density may not have been detected if these had been minimal, in areas of high 5HT$_{2A}$ receptor density variability, or with an variable location, leading to type 2 errors [70]. Nevertheless, a recent PET study using SPM analysis which showed significant 5HT$_{2A}$ receptor BP decreases in the left and right prefrontal cortex in six schizophrenic patients versus seven controls indicates that such a detection is feasible in vivo [55]. The discrepant findings between the in vivo studies could, similar to the discrepancies among the postmortem studies, be due to heterogeneity in the populations of schizophrenic patients studied.

VI. SEROTONIN 5HT$_3$ RECEPTORS

In one postmortem study, [^{3}H]LY278584 was used to analyze binding to serotonin 5HT$_3$ receptors in samples of amygdala from schizophrenic and matched control subjects [71]. All of the schizophrenic patients but none of the controls had been treated with neuroleptics. In a first step, the effects of short- and long-term haloperidol administration on limbic 5HT$_3$ receptors were investigated in rodents, and no effect was found. Furthermore, no differences in the maximum number of 5HT$_3$ binding sites or equilibrium dissociation constant between schizophrenics and controls were found in the amygdala. This study did not support the presence of an alteration of 5HT$_3$ receptors in the amygdala in schizophrenic patients [71].

VII. SEROTONIN TRANSPORTERS

Serotonin transporters (SERT) have been implied to play a role in various psychiatric disorders. Single-photon emission computed tomography (SPECT) and the ligand [^{123}]I](-CIT revealed a decreased SERT density in depression, [72] and in seasonal affective [73] and eating disorders [74]. However, an in vivo SPECT study investigating potential alterations of striatal dopamine transporters (DAT) and brainstem SERT density in schizophrenia did not find alterations of DAT in the striatum or SERT in the brainstem [75], although one postmortem study in schizophrenic patients had shown decreased SERT in the prefrontal cortex [43].

VIII. SEROTONIN AND ATYPICAL ANTIPSYCHOTICS

Serotonin receptors implicated in the action atypical antipsychotic agents, such as clozapine, or other recently introduced novel antipsychotics include 5HT$_{1A}$, 5HT$_{2A}$, 5HT$_{2C}$, 5HT$_3$, 5HT$_6$, and 5HT$_7$ receptors [76]. These are also of potential value for developing more effective or better-tolerated antipsychotic agents. It was initially thought that a relatively higher 5HT$_{2A}$ receptor affinity as compared to that for the D$_2$ receptor is the basis for the difference between "atypical" and "typical" antipsychotic agents, with "atypical antipsychotic" defined as an agent causing low EPS at doses with demonstrated or putative antipsychotic activity. This hypothesis contributed to the development of newer antipsychotic agents, all of which are consistent with the hypothesis of high affinity for

5HT$_{2A}$ and low affinity for D$_2$ receptors [6]. While some of the atypical antipsychotic drugs also have affinities for 5HT$_{2C}$, 5HT$_6$, or 5HT$_7$ receptors that are in the same range as those for the 5HT$_{2A}$ receptor, it has been found that this is not a common characteristic of these agents and, thus, it is not likely that affinities for 5HT$_{2C}$, 5HT$_6$ or 5HT$_7$ receptors are primary factors contributing to the low EPS profile of the entire class of agents [6,77,78]. However, the low EPS effects of specific drugs, or other actions, could still be dependent on their affinity for one or more of these 5HT receptors, including the 5HT$_{2C}$ and 5HT$_7$ receptors. Among other factors, 5HT$_{1A}$ receptor agonism has also been suggested to be able to contribute to an atypical antipsychotic drug profile [7,79]. Furthermore, there is extensive evidence for interactions among 5HT$_{2A}$, 5HT$_{2C}$, and 5HT$_{1A}$ receptors [80].

Serotonin 5HT$_{2A}$ receptors have been implicated in the genesis and treatment of psychosis, negative symptoms, mood disturbance, and EPS. The antipsychotic effect of clozapine has been attributed, in part, to its ability to block excessive 5HT$_{2A}$ receptor stimulation [81]. This is supported by the high occupancy of 5HT$_{2A}$ receptors produced by clozapine at clinically effective doses and its low occupancy of D$_2$ receptors [80].

Clinical trials of ritanserin, a potent 5HT$_{2A}$ and 5HT$_{2C}$ antagonist, were conducted to test the contribution of 5HT$_{2A}$ receptor antagonism to antipsychotic drug action. The limited data available suggest little or no beneficial effect, and 5HT$_{2C}$ receptor antagonism might even oppose the beneficial effects of 5HT$_{2A}$ receptor blockade. The bell-shaped dose response curve of risperidone, with higher doses being less effective than lower doses, [82], suggests that excessive D$_2$ receptor antagonism may diminish some of the beneficial effects of 5HT$_{2A}$ receptor blockade [78]. The potent D$_4$/5HT$_{2A}$ receptor antagonist fananserin was ineffective in acutely psychotic patients with schizophrenia [83]. Additional evidence supporting the role of 5HT$_{2A}$ receptor blockade in the action of clozapine and possibly other drugs with potent 5HT$_{2A}$ affinities is available from the several reports that the *His452Tyr* allele of the 5HT$_{2A}$ receptor, which is present in 10–12% of the population, is associated with a higher frequency of poor response to clozapine [84]. In summary, the evidence from clinical trial data suggests that 5HT$_{2A}$ receptor blockade may contribute to antipsychotic drug action.

Serotonin 5HT$_{1A}$ receptors may be of interest for the development of novel medications as there is some preclinical evidence to support a role for 5HT$_{1A}$ agonism in the antipsychotic action and extrapyramidal side

effects of drugs [7,79,85]. Results of behavioral studies in animals using the $5HT_{1A}$ agonist 8-OH-DPAT first suggested in the late 1980s that stimulation of $5HT_{1A}$ receptors might produce antipsychoticlike effects [86]. Subsequent studies demonstrated that 8-OH-DPAT enhanced the antipsychotic-like effect of the D_2/D_3 antagonist raclopride [87] and haloperidol [88], and antagonized the catalepsy induced by the D_1 agonist SCH23390 in rats [89]. It was recently demonstrated that 8-OH-DPAT inhibited the ability of clozapine and low-dose risperidone, but not haloperidol, to increase extracellular DA levels in the nucleus accumbens and the striatum of conscious rats [85]. Several atypical antipsychotic drugs are partial agonists at the $5HT_{1A}$ receptor, including clozapine, ziprasidone, quetiapine and tiospirone. The affinities of these drugs for $5HT_{1A}$ receptors were similar to their affinities at the human D_2 dopamine receptor [90]. These findings suggest that the combination of D_2 antagonism and $5HT_{1A}$ agonism may produce an atypical antipsychotic agent. S16924 is an example of such a compound. It has atypical properties very similar to those of clozapine in a variety of animal models [91]. Compounds such as ziprasidone and clozapine combine $5HT_{1A}$ agonism and $5HT_{2A}$ antagonism. Clinical studies of adding $5HT_{1A}$ partial agonists such as buspirone, ipsapirone, and tandospirone may help to clarify the possible importance of $5HT_{1A}$ agonism in the treatment of schizophrenia.

The GABA Cell in Relation to Schizophrenia and Bipolar Disorder

FRANCINE M. BENES and SABINA BERRETTA

McLean Hospital, Belmont, and Harvard Medical School, Boston, Massachusetts, U.S.A.

I. INTRODUCTION

Neurons that express the compound γ-aminobutyric acid (GABA) are broadly present throughout the central nervous system, although the cerebral cortex shows the most abundant quantities of this neurotransmitter [1]. Over the past several decades, several subtypes of GABA cell have been identified using a combination of anatomical and physiological approaches (Fig. 1). In the discussion that follows, the functional integration of various types of GABA-ergic interneuron [for a review, see 2] in the cortex and hippocampus will be related to recent postmortem studies implicating this transmitter system in the pathophysiology of schizophrenia and its treatment with neuroleptic drugs [for more comprehensive reviews on cortical and hippocampal neurons, see 3–5].

II. FUNCTIONS OF GABA-ERGIC INTERNEURONS IN THE CORTEX AND IN THE HIPPOCAMPUS

A. Feedback and Feedforward Activity

Basic electrophysiological studies have demonstrated that the action of GABA is typically an inhibitory one [6]. It seems obvious from the above discussion, however, that different interneuronal subpopulations play different and highly specialized roles in rather complex circuits. At the most basic level, most inhibitory interneurons in the cortex and hippocampus are involved in either *feedback* or *feedforward* inhibitory mechanisms which are thought to help stabilize the activity of pyramidal neurons. In *feedback inhibition*, an excitatory input activates the pyramidal neuron, which in turn excites inhibitory interneurons through recurrent collateral fibers [7]. The inhibitory interneurons thereby activated inhibit principal projection neurons, including those that directly excited them. Intracellular recordings from cortical pyramidal cells typically show a depolarization of brief duration that is followed by a longer lasting hyperpolarization [8]; it is the latter component of this complex that reflects the action of GABA on the $GABA_A$-chloride ionophore complex expressed by most postsynaptic neurons [for a comprehensive review, see 9]. Such an arrangement provides a "fail safe" mechanism that ensures pyramidal neuron do not fire excessively.

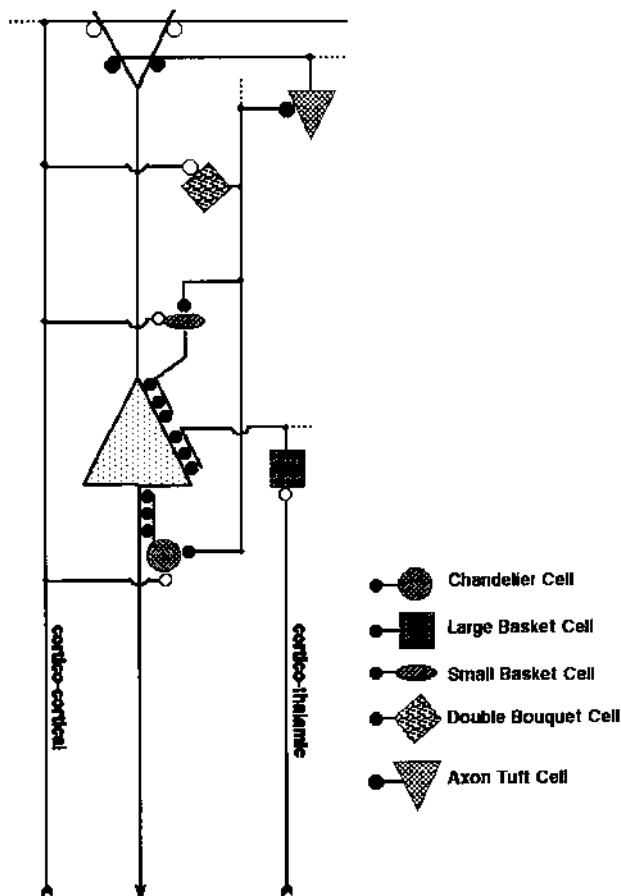
In a *feedforward* system, on the other hand, pyramidal neurons (e.g., in CA3) project downstream to other pyramidal cells in CA1 (Fig. 2, upper panel). In addition, however, these excitatory neurons also project to interneurons of CA1, and this ultimately curtails the excitability of pyramidal neurons in this latter sector [10].


Figure 1 Schematic diagram showing the relationship between various types of GABA-ergic interneurons and a pyramidal cell (black, open circles). Small and large *basket cells*, respectively, form axosomatic contacts with the cell body of the pyramidal neuron. A *chandelier cell* forms axo-axonic synapses with the proximal portion of the pyramidal cell dendrite. A *double bouquet* cell is shown forming GABA-to-GABA synapses with a small basket cell and a large basket cell and a axon tuft cell. A fourth type of interneuron, called a Martinotti cell (MC), is also found predominantly in layer VI and may be excitatory in nature. Not shown are the Cajal-Retzius neurons that are primarily found in layer I and to a lesser extent layer II of the cortex. Interneurons are depicted as receiving excitatory inputs from extrinsic afferents from other regions. (From Ref. 179).

B. Network Oscillations

In both the cortex and the hippocampus, complex interconnections between GABA-ergic interneurons and pyramidal cells have been found to establish and maintain large scale network oscillations, such as those in the theta, gamma (40–100 Hz) and ultra-fast (200 Hz) frequency ranges [3,11–23]. Studies of theta oscillations have demonstrated that both inter-neurons and pyramidal cells fire during the negative phase of the waveform; however, the interneurons discharge earlier than pyramidal cells. In the cortex, networks of inhibitory interneurons have been found to entrain pyramidal cell discharges. This results in coherent oscillations that have been proposed to "group" or "bind" features detected in different cortical areas into unified perceived objects [19]. In the hippocampus, these oscillations have been proposed to provide the "context" for the "content" coded by excitatory projection neurons [for review see [21,22]. According to this hypothesis, GABA-ergic "supernetworks" may control pyramidal neurons and provide the temporal structure needed to coordinate and maintain the function of neuronal ensembles in the hippocampus. The available evidence suggests that networks of hippocampal interneurons are capable of generating gamma frequency oscillations [24]. For the theta rhythm, basket cells have been found to have regular membrane oscillations, and the occurrence of rhythmic inhibitory postsynaptic potentials are believed to involve GABA-ergic inputs from the septal nuclei [25]. Thus, GABA-to-GABA interactions, albeit ones involving extrinsic afferents, may play a key role in the generation of some rhythmic activity generated by the hippocampus.

C. Discriminative Processing

Growing evidence supports the hypothesis that cortical interneurons can influence the discriminative properties of pyramidal neurons. For example, in the visual system, GABA-ergic interneurons play a key role in modulating geniculate inputs to the primary visual cortex and in defining the orientation selectivity of its neurons [8,26]. Support for a role of interneurons in the shaping of receptive fields has been extended to other cortical areas such as the somatosensory cortex [27–30]. For example, recordings from layer IV neurons of the somatosensory cortex in the presence of GABA receptor antagonists have shown that inhibitory receptive field properties of barrel neurons can be explained by intrabarrel inhibition and that the expansion of receptive field size during GABA blockade is due to an enhanced effectiveness of convergent, multiwhisker thalamocortical inputs [31]. Interestingly, in monkey prefrontal cortex, interneurons have similar receptive fields to those found for pyramidal neurons. This suggests that interneurons carry a specific informational signal

that helps in shaping receptive fields [32]. Furthermore, it has been shown that, in the motor cortex, intrinsic inhibitory circuits maintain and adapt motor representations [33]. Inhibitory interneurons appear to be able to unmask latent connections, so that rather than being "hard-wired" somatotopic maps, they show a marked degree of plasticity and can continually reorganize [33]. It can readily be appreciated that similar neurons located in associative cortical regions may play a similar role in defining the nature and integrity of higher cognitive functions, such as motivation, attention, learning, and object recognition. For example, recent findings suggest a role for cortical interneurons in working memory [30,34,35]. In the dorsal prefrontal cortex "fast-spiking" interneurons have been shown to play an important role in shaping "spatial memory fields" in much the same way as they have been found to shape "sensory receptor fields" [34,35]. In addition, blockade of GABA-ergic inhibition in the inferotemporal area has been associated with a disruption of the normal response of neurons selective for particular object features [36].

D. Long-Term Potentiation (LTP) and Depression (LDP)

Intrinsic inhibitory interneurons in the hippocampus have been suggested to control long-term modifications of synaptic strength induced by synaptic transmission [37–42]. Both LTP and LDP play a central role in memory and learning.

E. Phenotypical Differentiation

Of particular interest for the field of schizophrenia research is the fact that interneurons have been shown to regulate the differentiation of hippocampal neurons during development [43]. That many of these functions might involve functional (and presumably structural) neuroplasticity is strongly suggested by the observation that GABA, GAD, and the $GABA_A$ receptors are all regulated in an activity-dependent manner [44,45]. This raises the question whether phenotypic changes in the GABA system seen in schizophrenia might be related to increases or decreases in the flow of afferent activity into the cortex and hippocampus from other regions with which they are connected (see below).

III. THE GABA SYSTEM IN SCHIZOPHRENIA AND BIPOLAR DISORDER

GABA dysfunction is believed to play a role in various neuropsychiatric disorders. For example, as early as 1972, Eugene Roberts postulated that this compound might play a central role in the pathophysiology of schizophrenia [46]. Schizophrenia typically involves disturbances of cognitive functioning that include impaired attentional reponses [47], disruptions of normal information processing [48,49], and a selective impairment in declarative memory [50]. Overall, the thought pattern of schizophrenics has been described as being "overinclusive"; i.e., there is an inability to filter out extraneous information [51–53]. This has lead to the speculation that an impaired central filtering mechanism may be present in this disorder [54], as schizophrenic individuals are unable to distinguish relevant objects in the perceptual field [55]. Using physiological recordings from schizophrenics, a decreased auditory-evoked P50 response to repeated stimuli has been noted [56]. These authors concluded that such a defect may be related not only to sensory gating difficulties, but also to problems with learning efficiency and accuracy. The most consistent electrophysiological abnormalities observed in schizophrenia, however, are a reduced amplitude and increased latency of the P300 evoked potential [57]. These changes are related to a diminished ability to habituate selective attentional responses to a stimulus, and could reflect defective GABA-ergic inhibitory modulation. Consistent with this idea, a recent PET study has demonstrated an increase of basal metabolism in the hippocampal formation of schizophrenic subjects [50], and, as shown in Figure 2 (lower panel), this finding is consistent with a recent model for how the GABA system in this region may be dysfunctional in schizophrenia [58,59]. On a highly speculative level, it could be hypothesized that decreased GABA-ergic transmission in specific cortical areas could result in rearrangement, and possibly enlargement, of sensory, memory, and cognitive fields and thereby lead to overinclusive, disorganized thought processes.

To better understand the functional implications of a dysfunction of the GABA system in schizophrenia, it is necessary to have direct empiric evidence demonstrating alterations of specific markers for this neurotransmitter system. To date, such information has come largely from postmortem investigations as discussed below.

Cell-Counting Studies

CEREBRAL CORTEX. In 1991, a postmortem study in which pyramidal and nonpyramidal neurons were differentially counted in cresyl violet–stained sections revealed a decreased density of nonpyramidal cells in layers II–VI of the anterior cingulate area and layer II only of the prefrontal cortex of schizophrenic and schizoaffective subjects [60]. In the anterior cingulate cortex, however, these changes were primarily significant in the schizoaffective group, suggesting the possibility that they might show a stronger covariation with affective disorder than with schizophrenia. This finding is controversial, however, since several other groups have not demonstrated a similar change in the prefrontal cortex of schizophrenics [61–64] and the anterior cingulate cortex of bipolar subjects [65]. There are significant methodologic factors that may have contributed to these failures to replicate the reduced density of nonpyramidal cells. Not least among these are the difficulties in comparing data obtained with two-dimensional-cell counting methods with those obtained with three-dimensional techniques. Both have their strengths and weaknesses. In evaluating conflicting results, it is important to consider the type of cell counting method employed in studies of schizophrenia [for detailed review, see [66,67].

In a subsequent replication study, a 2D method was employed to study a cohort in which schizophrenics and manic-depressives were included as comparison groups. The results of this study showed a pattern similar to that previously reported [68]. The manic-depressive showed approximately a 30% decrease, while the schizophrenics showed a 16% decrease. It is noteworthy that another study in which tyrosine hydroxylase–immunoreactive fibers were analyzed [69] was found in a post hoc analysis to also show an 18% reduction in the density of non-pyramidal neurons in layer II of ACCx [70]. More recently, the findings from these three studies have been combined and the data indicate that the reduction in the density of nonpyramidal neurons in layer II of ACCx was 16% in the schizophrenics (N = 25), 25% in schizoaffectives (n = 18) and 30% in manic-depressives [71]. Taken together, these data suggest that a loss of interneurons does occur in affective disorder as well as schizophrenia.

HIPPOCAMPUS. In a recent study of the hippocampal formation, a preferential decrease in the number of nonpyramidal neurons was observed in sector CA2 (refer to Fig. 2, lower panel); however, in this region, the change occurred to an equivalent degree in both schizophrenics and bipolars [72]. Based on these

Figure 2 (continued)   CA1 (see text for details). There are inhibitory interneurons (square cells with hatched filling) providing GABA-ergic input to pyramidal cells in CA3 and CA1 and to the stratum oriens. Some GABA cells are disinhibitory interneurons (circular cells with hatched filling) that decrease the ability of the GABAergic cell to fire. **Schizophrenics:** A schematic diagram similar to that shown for normal controls, except that there is increased excitatory activity (thickened arrows) entering the trisynaptic pathway from three routes: (1) basolateral nucleus of the amygdala; (2) entorhinal projections to the stratum moleculare of the dentate gyrus; and (3) entorhinal projections to CA1 and CA3 from layers III and II, respectively, that travel along the stratum moleculare of the these subfields (see text for details). In addition, there is a defect of GABA-ergic modulation at various points along the trisynaptic pathway. First, inhibitory GABA-ergic activity appears to be decreased in sectors CA4, CA3, and CA2, but not CA1. There is also a subtle decrease of disinhibitory modulation in the stratum pyramidale of CA3 that would result in an increased inhibition of pyramidal cell firing in this sector. Although it is difficult to understand how a dual defect in inhibitory *and* disinhibitory modulation in CA3 might impact on the flow of activity along the trisynaptic pathway, it seems likely that there would be an overall increase of excitatory activity along most of the trisynaptic pathway. This is indicated as an intensification of the dark shading occurring uniformly from the area dentata through sector CA1. In the area dentata, the feedforward excitatory drive progressively increases as the conduction of impulses passes toward CA1. Since the changes in GABA-ergic integraion in CA3 are complex and the increase of disinhibitory activity may have the ability to offset some of this excitation, the arrow is missing in this sector and is replaced by a question mark (**?**). In CA1, the excitatory drive would attain its highest level of activity, particularly since a decrease of inhibitory modulation appears to be minimally present in this sector in schizophenics. Taken together, these hypothesized changes would be capable of generating an overall increase of basal metabolism in this region, but an impaired ability to selectively retrieve information when challenged with a specific task. (From Ref. 50.)

results, it has been postulated that a loss of GABA-ergic neurons might be related to a factor (such as stress) that the two disorders would share to an equivalent degree. It is not straightforward to explain why there is a greater decrease in the density of nonpyramidal neurons in ACCx of manic-depressives than in schizophrenics. Nor is it obvious why this parameter shows an equivalent change in the hippocampal formation of both disorders; however, it is conceivable that each disorder may involve region-specific alterations of neural circuitry that impact on GABA-ergic neurons to differing degrees, depending on the specific diagnostic category.

Calcium-Binding Peptides

CEREBRAL CORTEX. A variety of peptides have been found to be associated with various subtypes of nonpyramidal neurons and are being used to identify specific phenotypes of GABA-ergic inteneurons [73]. An ICC localization of the calcium binding protein parvalbumin (PVB) has demonstrated a *decrease* of cells showing this immunoreactivity in the prefrontal cortex of schizophrenics [74]. In another study, however, prefrontal areas 9 and 46 showed no differences in the distribution of neurons expressing detectable levels of immunoreactivity (-IR) for PVB [75]. In the anterior cingulate cortex, on the other hand, an increase of cells immunoreactive for this peptide has been reported in schizophrenics [76]. In attempting to interpret such disparate results, it is important to consider whether differences in the regions studied, tissue handling, and perhaps even subject populations may account for the discrepancies. All of these factors may potentially influence whether the amount of PVB-IR is either above or below the level of detection.

For calbinding (CB) 28k, an increase in the numerical density of neurons showing immunoreactivity for this peptide in the dorsolateral prefrontal cortex was observed, while there was no change in those containing calretinin (CR-IR) [77]. Unfortunately, there has not as yet been another study reporting on this peptide in the prefrontal cortex of schizophrenics.

HIPPOCAMPUS. CB expression has been shown to be increased [77] and CB-IR neurons have been reported to show a marked degree of disarray in sector CA2 [78]. Although an overt decrease in the numerical density of these cells was not detected, it is noteworthy that another study revealed a selective loss of nonpyramidal neurons in sector CA2 of subjects with schizophrenia and bipolar disorder [72].

Taking together the results of cell-counting studies using cresyl violet–stained sections with those processed immunocytochemically with antibodies against various calcium-binding proteins, there does not appear to be a definitive answer as to whether a decrease of interneurons is present in the cortex or the hippocampus of schizophrenic subjects. On the one hand, studies of cresyl violet–Stained sections suffer from significant issues regarding cell-counting methodology. On the other hand, studies that have localized PVB, CB, and CR are impeded by the factors that influence the retention of immunoreactivity in the tissue and the fact that increases or decreases of detectable levels of peptide may occur without any overt change in the actual number of neurons. Thus, the apparent changes in numerical density of such cells can be quite misleading.

2. Markers for GABA-ergic Terminals

In the 1970s, perhaps prompted by the speculations of Eugene Roberts [46], a series of neurochemical investigations focused on various markers for the GABA system in schizophrenia. The first study to appear examined the concentrations of GABA in the nucleus accumbens and thalamus of patients with schizophrenia and a group of subjects with Huntington's chorea, and found a reduction of this transmitter in the two disorders [79]. Around the same time, another study reported that the activity of glutamate decarboxylase (GAD) was significantly reduced in schizophrenics [80]. Although it began to appear that a pattern of decreased GABA-ergic activity was emerging, subsequent studies failed to show changes in either GABA levels or GAD activity [81], although one study did show a nonsignificant decrease of GAD in the prefrontal cortex [82]. Because subjects who died suddenly were less apt to show such changes, it was believed by some that decreases in the specific activity of GAD were related to the agonal state [83].

More consistent findings have come from studies of the GABA uptake site where reductions of this marker have been consistently observed in the prefrontal cortex [84], amygdala [85], and hippocampus [86] of the schizophrenic brain. A recent attempt to replicate this finding in prefrontal and temporal cortex, however, did not show any differences in schizophrenics [87].

More recently, the 65-kDa isoform of GAD, a marker for GABA-ergic terminals [88], has been localized immunocytochemically in the anterior cingulate cortex, where schizophrenic patients showed no differences (not shown). In bipolar subjects, on the

other hand, a marked decrease was detected on pyramidal neurons in layers II and III (Fig. 3). In the hippocampal formation no overall differences between normal controls and schizophrenics were detected in the density of GAD_{65}-IR terminals on either pyramidal or nonpyramidal cells in any of the subregions or sublaminae [89]. However, a small number of subjects who were neuroleptic free for at least a year prior to death showed a significant reduction on both neuronal subtypes in sectors CA4, CA3, and CA2, but not in sector CA1. The subjects treated with neuroleptics showed a dose-related increase in terminal density in these sectors, particularly in the stratum oriens of CA3 and CA2. These data suggest that there may be an intrinsic reduction of GABA-ergic terminals in the hippocampus of schizophrenics, and the therapeutic efficacy of neuroleptic drugs may involve, at least in part, a trophic sprouting of these terminals. This conclusion is consistent with a controlled study in rat medial prefrontal cortex (anterior cingulate region) in which chronic haloperidol administration was associated with a marked increase of GABA-IR terminals [90]. Whether such changes require blockade of dopamine receptors on GABA cells is not clear; however, the increase in this latter study was most striking in layer II, where the dopaminergic projections to this region are most sparse [91]. Nevertheless, antipsychotic drugs may be capable of inducing changes in GABA cells that are mediated either alone or in combination with other receptors, such as the $5HT_{2A}$ receptor [92], or possibly even by direct trophic changes in synapses [93–95].

Other cytochemical studies have employed in situ hybridization (ISH) to examine the distribution of mRNA for GAD, particularly that for the 67 kDa isoform (GAD_{67}) [88]. In the prefrontal cortex of schizophrenics, a reduction in the number of cells expressing GAD_{67} mRNA has been reported by two different groups [64,96]. More recently, a decreased expression in GAD_{67} mRNA, but not GAD_{65}, its closely related isoform, has again been noted [97]. A variety of studies have suggested that GAD_{67} is regulated through transcriptional mechanisms. For example, increased expression of mRNA for this protein has been found in relation to lesioning of the substantia nigra [98,99], climbing fibers of the cerebellum [100], and in the hippocampus in response to systemic treatment with kainic acid [101]. In contrast, expression of mRNA for GAD_{65} [102] and its translation into protein also appears to be relatively stable [103],

although its regulation may be controlled primarily through posttranslational mechanisms [104]. The postmortem findings obtained using either immunocytochemistry or ISH show decreased expression of GAD_{67}, but not GAD_{65}, as well as stable levels of immunoreactivity for GAD_{65} in terminals of the hippocampal formation [89]. Since mRNA for the two isoforms of GAD are expressed by 95% of the neurons in rat hippocampus [105], it seems likely that complex cellular mechanisms may be influencing the nature of the results observed in these postmortem studies. That changes in GAD_{67} mRNA in prefrontal cortex were observed not only in schizophrenics, but also in subjects with bipolar disorder [97] suggests that these changes may be related to a nonspecific factor associated with both disorders. Interestingly, differential expression of mRNAs associated with the two isoforms of GAD have been reported in relation to both acute and chronic stress [106], although that for GAD_{67} was increased rather than decreased. A recent study in rats has attempted to model for the effects of pre- and/or postnatal stress by injecting rats with corticosterone [107]. Within 24 hr of the last injection, a decreases of mRNA for GAD_{67}, but not GAD_{65}, was observed in the dentate gyrus, CA4, CA2, and CA1 of rats exposed both pre- and postnatally. Five days after the last injection, however, the levels of mRNA for GAD_{67} returned to normal, while those for GAD_{65} were markedly increased. These findings suggest that stress during the prodrome and/or early stages of schizophrenia or bipolar disorder could theoretically influence the regulation of both isoforms, whether or not exposure to stress has occurred early in life. Such an effect should be considered when interpreting changes in GAD mRNA expression.

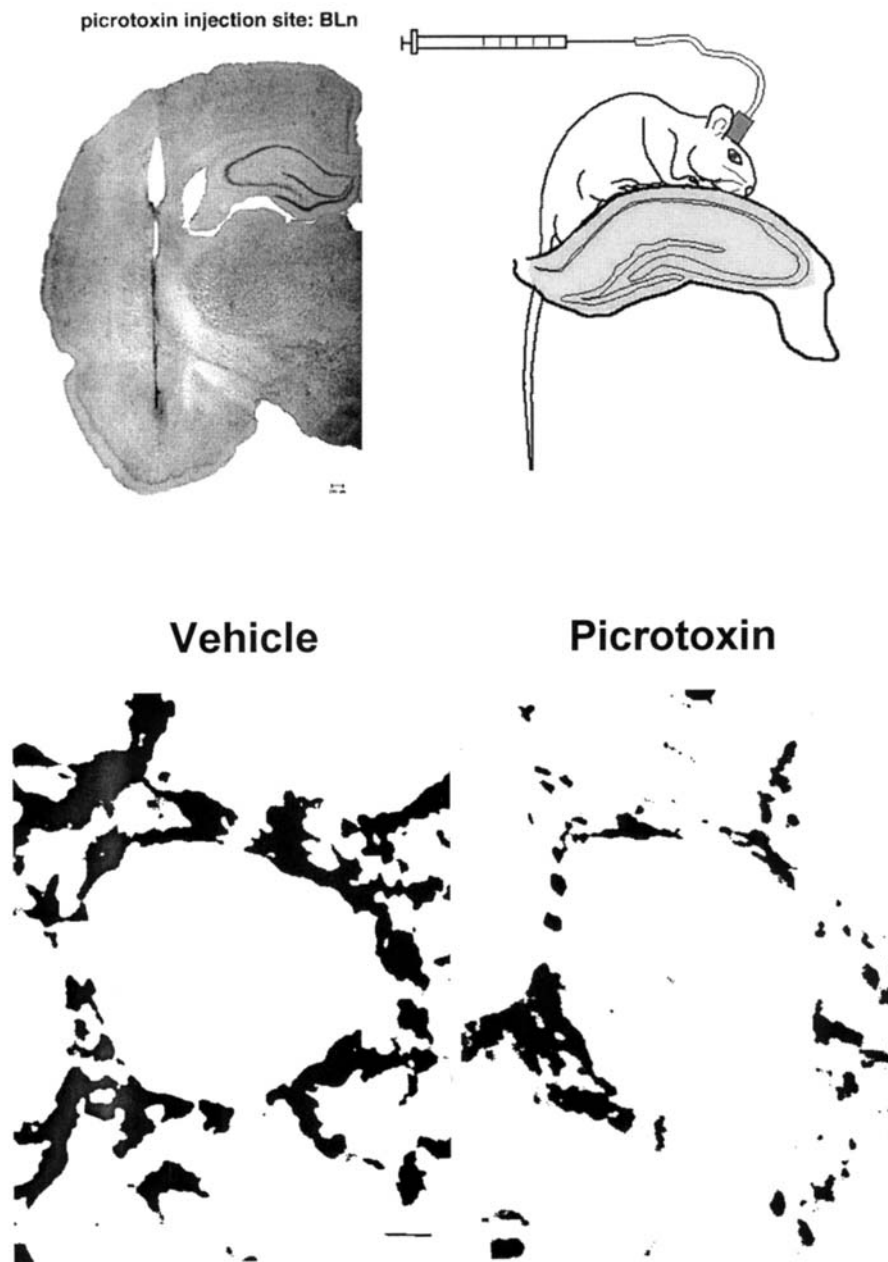
Another finding supporting the presence of disruption of GABA-ergic networks in schizophrenia is the decrease of "cartridge-like" terminals that are immunopositive for the GABA membrane transporter (GAT-1) in prefrontal cortex [108]. These "cartridges" represent axo-axonic terminations of chandelier neurons (see Fig. 1) and are strategically positioned within cortical circuitry to modulate cortical output. Thus, their decrease is likely to reflect crucial changes in information processing in the cortex. Other terminals with a more conventional punctate appearance did not show differences. This population of GABA terminals accounts for only 1% of the total. It is not known, however, whether GAT-1-containing terminations express GAD_{65}, GAD_{67} or both.


Figure 3 Stereotaxical local infusion of the $GABA_A$ receptor antagonist picrotoxin in the amygdala (needle track shown in upper left panel) of awake freely moving rats (schematic in upper right) induced significant changes in densities of GAD_{65}-positive terminals in hippocampus of picrotoxin-treated rats (lower right) when compared to vehicle-treated (lower left). These decreases, detectable around cell bodies of pyramidal neurons, were selectively observed in sectors CA3 and CA2, but not CA1 and therefore showed a subregional distribution of GABA changes remarkably similar to that seen in schizophrenia and bipolar disorder

3. GABA Receptor-Binding Activity

Binding of the selective radiolabeled agonist [³H]muscimol was evaluated in the prefrontal cortex of controls and schizophrenics matched for age, but with an average postmortem interval of 8 and

13 h, respectively [82]. The data indicated that the schizophrenics showed a 48% increase (not significant) in the B_{max}, but no difference in affinity for [³H]muscimol binding. Addition of the benzodiazepine diazepam resulted in a greater increase in binding in the schizophrenics. One limitation of this study was

the fact that GABA was used as a competitive inhibitor, rather than bicuculline, a specific antagonist of the $GABA_A$ receptor [9]. Thus, it is unclear whether the results reflect changes in this latter receptor, the $GABA_B$ receptor, GAT-1 or perhaps even other GABA transporters.

Subsequent investigations have specifically examined high affinity binding to the $GABA_A$ receptor complex. Using bicuculline as a selective antagonist, [^{3}H]muscimol binding was found to be increased in the hippocampal formation (Fig. 7) [109], anterior cingulate cortex [110], and prefrontal region [111,112] of schizophrenic subjects. It is noteworthy, however, that benzodiazepine receptor activity did not show differences in the hippocampal formation, suggesting that there might be an uncoupling in the regulation of these two sites on the $GABA_A$ chloride ionophore complex [113]. One other study had reported a decrease of benzodiazepine receptor binding in the cortex [114], but it is not clear if the subjects in this study were treated with benzodiazepine agents prior to death. It is also important to note that this pattern does not preclude the presence of an allosteric uncoupling in the regulation of the receptor.

SPECT imaging investigations have also been used to study the $GABA_A$ receptor in schizophrenia using specific ligands, such [^{123}I]iomazenil for the benzodiazepine receptor. While two such studies have found no differences in schizophrenics [115,116], two others have found a reduction in this binding activity [117,118]. In two of these studies, changes in the benzodiazepine receptor correlated with both cognitive impairment [118] and severity of illness [115]. It is important to emphasize that these studies were probably examining only the benzodiazepine site on the $GABA_A$ chloride ionophore complex so that, in the setting of an allosteric uncoupling in its regulation, the status of the $GABA_A$ site cannot be inferred from such imaging data.

A high-resolution microscopic technique has provided specific information regarding the distribution of this receptor binding activity on pyramidal neurons versus nonpyramidal cells (interneurons). In the prefrontal [119] and anterior cingulate [110] cortices, increased $GABA_A$ receptor binding activity has been preferentially found on pyramidal, but not nonpyramidal neurons, particularly in layers II and III. This pattern was thought to be consistent with the hypothesis that a compensatory upregulation of this receptor was occurring in response to a decrease of GABA-ergic neurons and/or activity. When this form of analysis was applied to the hippocampal formation, a similar "classic" pattern was observed on pyramidal neurons in sector CA1 [109]. In sector CA3, however, the increase of $GABA_A$ receptor-binding activity was paradoxically found on nonpyramidal neurons, but not pyramidal cells, suggesting that a decrease of GABA-to-GABA interactions might be occurring in this sector of schizophrenics.

Taken together, these results consistently indicate that a disruption of inhibitory GABA-ergic neurons occurs in selective regions of the cerebral cortex. In the hippocampus, however, there may be more complex alterations that involve both inhibitory and disinhibitory GABA cells along the trisynaptic pathway of schizophrenics [58,120], and these changes would likely result in disruptions of the normal feedforward activity of this region (see Fig. 2).

4. Altered Inputs to GABA Cells

The dopamine system has long been suspected of playing a role in the pathophysiology of schizophrenia [121], even though convincing empiric evidence for a primary defect in this system has been lacking [122]. Seymour Kety was the first to suggest that subtle changes in connectivity could occur in the absence of any discernible biochemical alterations [123]. To determine whether such a defect is present in schizophrenia, it is now possible to visualize dopamine fibers using antibodies against tyrosine hydroxylase (TH) [124–128]. A recent study of the distribution of TH-IR varicosities in the anterior cingulate and prefrontal cortices of schizophrenic brain has suggested that there may be a decrease of these fibers on pyramidal neurons, but an increase on interneurons in layer II of the anterior cingulate; this change was not observed in the prefrontal cortex [69]. In layers V and VI of the cingulate region, there was also a significant reduction in the density of TH-IR varicosities, and this compares favorably with an analysis of fiber length in the prefrontal cortex of schizophrenics where a significant reduction was also found in layer VI [129]. In the anterior cingulate cortex, however, this change was only found in patients treated on neuroleptics, whereas the apparent shift of TH-IR varicosities from pyramidal to nonpyramidal cells of layer II was found in all schizophrenic subjects, whether they were treated with antipsychotic medication or not [69].

A subsequent post hoc analysis in which several different working models were considered suggested that these data might best be explained by a trophic shift of TH-IR fibers from pyramidal to nonpyramidal neurons [70]. A loss of GABA-ergic interneurons

was not required for this pattern to occur, although it could coexist with such a shift. If these findings were correct, they would suggest that dopaminergic afferents might be providing a nonadaptive hyper-innervation to a subpopulation of GABA-ergic inter-neurons. Since dopamine appears to exert an inhibitory effect on cortical GABA cells [130], these findings would predict that an excessive release of dopamine would occur under conditions of stress [131,132]. This could lead to a secondary effect on GABA-ergic function and ultimately to a decompen-sation of the intrinsic circuitry in layer II of anterior cingulate cortex [133].

B.   The Neurodevelopmental Hypothesis

1.   Cell Migration

The findings of a variety of changes in layer II of the anterior cingulate and prefrontal cortices suggested the possibility that there might be a disturbance in the migration of neurons in the developing cortex of subjects with schizophrenia [134]. To investigate this possibility further, the distribution of nicotinamide adenine dinucleotide diaphorase (NADPH dia-phorase) was examined in the prefrontal cortex of normal controls and schizophrenics [135]. The results demonstrated a significantly higher density of cells positive for this marker in the subcortical white matter when compared to the cortical mantle [136]. Of significance to the current discussion is the fact that NADPH diaphorase has been colocalized to interneurons that are GABA-ergic in nature [137–145].

2.   Reelin and Cortical Lamination

Another line of investigation that has pointed to a possible neurodevelopmental mechanism playing a role in the pathophysiology of schizophrenia has come from studies of Reelin, a protein derived from the Reeler mouse mutant. Reelin is believed to be secreted by a subclass of GABA-ergic interneuron called a Cajal-Retzius cell [146,147] that are the first to appear during ontogenesis and are localized in layer I [148]. During fetal development, they interact with Martinotti cells in deeper laminae and are thought to play a role in the formation of laminar patterns [148]. In both schizophrenia and bipolar disorder, both Reelin and GAD_{67} mRNA have been found to be decreased in layer I and, to a lesser extent, layer II

[149]. These latter findings are consistent with two other studies, one in which nonpyramidal neurons were counted [150] and another using high resolution analyses of $GABA_A$ receptor binding activity [119], showing preferential changes in layer II of the pre-frontal cortex. These authors propose that a down-regulation of Reelin expression in this region of schizophrenic and bipolar brain may be due to either a genetic or an epigenetic factor. Since this protein is reduced in both schizophrenia and bipolar disorder, it seems more likely that the changes noted might be related to an environmental factor common to both. In this regard, it is noteworthy that obstetrical complications have been found to occur in both schizo-phrenia [151] and bipolar disorder [152,153], making it plausible that an insult early in life could influence the subsequent expression of this protein during adulthood.

3.   Postnatal Ingrowth of Extrinsic Afferents

Important questions regarding the role of a neuro-developmental disturbance in the induction of altered phenotypes of GABA cells are when and how such changes become manifest during the life cycle in individuals who carry the susceptibility genes for schizophrenia and bipolar disorder. One possibility is that the GABA cells are abnormal from birth; how-ever, the clinical observation that most subjects with schizophrenia are relatively normal during childhood and early adolescence argues against this possibility. It is important to emphasize, however, that studies in rat suggest that the cortical GABA system continues to develop until the equivalent of early adolescence [90,154–157]. Taking together these various observa-tions, a second possibility is that the GABA cells are relatively normal during childhood when they are also relatively immature [158], but become abnormal as their maturation process is completed. The activation of a putative gene or genes associated with schizo-phrenia and/or bipolar disorder may "trigger" the appearance of a phenotypic abnormality in GABA-ergic interneurons. In this case, it would be assumed that both disorders might share common genes and that these would be capable of altering the normal functioning of GABA cells. A third possibility is that the GABA cells are either relatively normal or abnormal during childhood, but their activity is quiescent as they await the ingrowth of a fiber system from another region. The dopaminergic afferents to the cortex are a good candidate for playing such a role, as there have been at least three studies demon-

strating an increase in medial prefrontal cortex during the equivalent of adolescence [159,160]. These fibers continue forming increased numbers of appositions with GABA-ergic interneurons until the early adult period [161].

4. Influence of Pre- and Postnatal Stress

The potential role that stress might play in the induction of changes in the cortical GABA system is an interesting issue to explore. For example, glucocorticoid hormones have the ability to bind to the $GABA_A$ receptor [162] and have been found to directly increase its activity [163,164]. It is noteworthy that the binding of [^{3}H]corticosterone is greatest in sector CA2 [165,166] where schizophrenics and bipolars both show a marked decrease of nonpyramidal neurons and the largest increase of $GABA_A$ receptor binding (see above). It is important to point out, however, that stress is believed to increase rather than decrease the activity of the GABA system [167–170], although it is possible that chronic stress, particularly when preceded by stress in utero, might result in an eventual decrease in the activity of this transmitter system. This possibility is particularly intriguing when the marked sensitivity of GABA-ergic neurons to excitotoxic injury [171] is considered. It is believed that cell death in this setting probably requires both an increase of excitatory activity and an increase of circulating levels of glucocorticoid hormone [172].

Another important component to the stress response is the increased release of dopamine that occurs in the medial prefrontal cortex (see above). By exposing rats both pre- and postnatally to stress-related doses of corticosterone , an increase of dopamine varicosities forming appositions with GABA-ergic interneurons has been induced [133]. Thus, it is possible that the postnatal maturation of GABA cells in the cortex may be normally influenced by the ingrowth of dopamine fibers, but abnormally affected when this occurs in individuals for whom pre- and postnatal stress are comorbid factors. In this latter case, it would have to be assumed that gene(s) involving the dopamine system and perhaps also cortical GABA cells would be affected by prenatal exposure to stress and would be permanently sensitized in such individuals.

IV. MODELING ACTIVITY-DRIVEN CHANGES IN HIPPOCAMPAL GABA CELLS

A conundrum that has presented itself from postmortem studies of the GABA system in schizophrenia and bipolar disorder is the following: Why are abnormalities preferentially detected in layer II of the prefrontal and anterior cingulate cortices and sectors CA3 and CA2 of the hippocampus? A potentially important clue that will help answer this question comes from studies of the connectivity of these regions. Layer II of the anterior cingulate cortex is known to receive a "massive" projection from the basolateral nucleus of the amygdala [173], while sectors CA3 and CA2 also receive a substantial input from this same complex [174]. Taken together with other evidence [59,175], it seems plausible that the changes in the GABA system described above may potentially be related to an increased inflow of activity from this key limbic region. To explore the possibility that changes in the cortical and hippocampal GABA system in schizophrenia could be related to an increased inflow of activity originating in the amygdala, a "partial" animal model has been developed [120]. When the $GABA_A$ antagonist picrotoxin is infused locally into the basolateral nuclear complex of awake, freely moving rats, within 2 hr, a marked decrease in the density of both the 65- and 67-kDa isoform of GAD-IR terminals can be detected on neuron somata in sectors CA3 and CA2, but not CA1. In anterograde tracer studies, amygdalo-hippocampal projection fibers show a similar distribution. Overall, these results suggest that activation of afferents from the basolateral nucleus is associated with the induction of significant changes in the GABA system in the hippocampus with a subregional distribution that is remarkably similar to that found in schizophrenia. Under pathological conditions, an excessive discharge of excitatory activity emanating from the amygdala could be capable of altering inhibitory modulation along the trisynaptic pathway and may contribute to disturbances of GABA-ergic function in schizophrenia. Such "partial" modeling in rodents will provide an important strategy for deciphering the effect of altered corticolimbic circuits in schizophrenia.

V. CONCLUSIONS

The cortical and hippocampal GABA systems consists of many different subclasses of interneurons, each having unique phenotypes defined by their morphology, neuropeptide content, electrophysiological properties, and synaptic connectivity (Benes and Berretta, 2001). In reviewing the postmortem investigations of schizophrenic brain, it is clear that there have been some inconsistencies, particularly with regard to cell-counting findings. There are many different confounding factors that can be invoked to explain failures to replicate and these vary according to the types of methodology that have been employed. Nevertheless, when this literature is viewed as a totality, not only cell-counting studies, but also those in which immunocytochemistry, receptor-binding autoradiography, and in situ hybridization have indicated that some form of dysfunction in the GABA-ergic system appears in the cortex of schizophrenics. That similar findings are also being reported in bipolar disorder further suggests that such a defect may be related to a common environmental factor, perhaps one that is related to obstetrical complications. Indeed, the neurodevelopmental hypothesis of schizophrenia (and by extrapolation, bipolar disorder) has received its most convincing evidence from studies of the GABA system.

An important question raised by these findings is whether the GABA-ergic interneuron might be a common site for the action of drugs that are used in the treatment of both schizophrenia and bipolar disorder. Indeed, GABA-mimetic drugs, such as mood-stabilizing anticonvulsants, show efficacy in the treatment of both schizophrenia [176] and bipolar disorder [177], although patients with affective disorder show a more striking beneficial effect. Recent studies demonstrating direct interactions between the dopamine and serotonin systems with GABA-ergic neurons in the cortex, as well as the expression of their respective receptor systems in these interneurons [for review, see 178], are also consistent with this idea.

In the years to come, continued investigations of the GABA system in rodent, nonhuman primate, and human brain will undoubtedly provide important new insights into how the integration of macro- and microcircuitry in the corticolimbic system is altered in schizophrenia and bipolar disorder. Most importantly, the use of increasingly sophisticated probes will eventually lead to a precise understanding of how neuroleptic drugs can influence the structural and functional integrity of the GABA system and other neuromodulator systems with which it interacts. Information of this type will ultimately point the way toward novel approaches to the treatment of schizophrenia and bipolar disorder.

Genetic Findings in Psychotic Disorders

MICHAEL O'DONOVAN and MICHAEL OWEN
University of Wales College of Medicine, Cardiff, Wales

I.   INTRODUCTION

Hypotheses concerning the etiology and pathophysiology of schizophrenia are legion, but the origins of this disorder remain unknown. Furthermore, as there are no objective, laboratory-based diagnostic tests for schizophrenia; diagnosis is based on patterns of symptoms, signs, and other historical variables. Given these problems, the disorder we know as schizophrenia should be thought of as a syndrome, covering a range of conditions that are heterogeneous in terms of symptoms, course, outcome, response to treatment, and probably etiology. Nevertheless, with the use of structured and semistructured interviews and explicit operational diagnostic criteria, it is possible to diagnose the disorder with a high degree of reliability, and, as we shall show below, the syndrome so defined has a high heritability thus allowing the possibility of dissection of schizophrenia by genetic investigation. However, as in all areas of schizophrenia research, the likely etiological heterogeneity of the disorder poses a formidable obstacle to progress, and disappointments abound in schizophrenia genetic research, particularly in the field of molecular genetics. Nevertheless, progress has been made and we remain optimistic that schizophrenia will succumb to the ever increasingly powerful tools available to geneticists. In this chapter, we review the current state of the field from the perspective of psychiatric geneticists, consider some of the difficulties that lie ahead, and offer our opinion on the likely solutions and the trajectory that future research is likely to follow.

II.   GENETIC EPIDEMIOLOGY

A.   Familiality and Genetic Risk

The extensive literature in genetic epidemiology contains some of the most robust findings in psychiatric research. In particular, the observation that schizophrenia tends to run in families is no longer open to serious debate. For example, Gottesman and Shields [1], based on data from $\sim$ 40 family studies spanning much of the 20th century, were able to conclusively show that the risk of schizophrenia is increased in relatives of probands with the disorder. The lifetime risk for schizophrenia in the general population worldwide is generally reported to be around 1%. This contrasts with the risk to siblings (10%) and offspring of affected probands (13%), and although the risk to parents of an affected proband is somewhat lower (6%), this reflects the reproductive disadvantage conferred by schizophrenia. Many of the studies in this analysis predate up-to-date methods, but in a review of seven methodologically modern studies, the finding of an

approximately 10-fold increase in risk of schizophrenia in first-degree relatives of schizophrenic probands remains [2].

However, it is well known that in addition to genetic inheritance, infective, cultural, and socioeconomic transmission may explain familial clustering. Fortunately, there is also an unambiguous twin and adoption literature on schizophrenia that permits genetic factors to be differentiated from other causes of familiality. The evidence here is clearcut; shared genes rather than shared environments underlie the increased risk of illness in relatives of those with the disorder [3]. Undoubtedly, unknown environmental factors play an important role in determining liability to schizophrenia, but the major determinant of individual variation in susceptibility is genetic. It is difficult to put an exact figure on the contribution made by genes, but based on the five most recent twin studies (conducted since 1995), the probandwise concordance rate for schizophrenia in monozygotic (MZ) twin pairs is 41–65% compared with 0–28% for dizygotic (DZ) twin pairs. This corresponds to heritability estimates of ~ 80–85% [4].

B. Complex Genetics

Genetic epidemiology provides clear evidence that genes are the major risk factors for schizophrenia, and therefore, if we are to understand the etiology of schizophrenia, we must understand its genetics. Ideally, before seeking a disease-related gene or genes for a given disorder using molecular genetics techniques, it is helpful to define the mode of inheritance of that disorder. Under the simplest genetic models, there is a very strong correlation between phenotype (i.e., affected status) and genotype. For example, if a disease is genetically homogeneous, under a model of simple autosomal-dominant transmission, if a person is affected, then he can be assumed to carry a mutation at the disease locus, and vice versa. Under recessive inheritance, if a person is affected, then he can be assumed to carry a disease mutation in both copies of the gene involved in disease, and vice versa. However, given the fairly high rates of discordance for schizophrenia in MZ twin pairs, it is clear that such strict correlations between genotype and phenotype are not the rule.

The risk of a disease in a defined class of relative compared to that in the general population is often called λ. The λ for siblings is called λs, and in schizophrenia this is ~ 10. The contribution of an individual allelic variant to the familiality of a disorder can be also expressed in these terms. Thus, for a given risk allele, λs is the relative risk to siblings resulting from possession of that disease allele [5]. This measure can be used to test the simplest hypothesis that risk for disease in any given family can be attributed to alleles of a single gene of large effect. By comparing expected with observed recurrence rates for a range of classes of relative, Risch [5] has calculated that the maximum λs for any schizophrenia susceptibility gene is ~ 3 and, unless extreme epistasis exists, multiple loci of $\lambda s \leq 2$ are more plausible. These calculations are based on the assumption that the population of schizophrenics is etiologically homogeneous. Under a model of heterogeneity, it is possible that genes of larger effect are operating in some subpopulations of patients. Nevertheless, these and other analyses [e.g., 6] strongly suggest that schizophrenia is neither a single-gene disorder nor a collection of single-gene disorders. Rather, the mode of transmission is complex; how complex, is unknown.

Complex inheritance implies that susceptibility in any given individual may be conferred by coinheritance of alleles in more than one gene. This may be a small number of alleles of moderate effect (oligogenic inheritance), a large number of alleles of small effect (polygenic inheritance), or a mixture of the two. However, the number of susceptibility loci, the disease risk conferred by each locus, and the degree of interaction between loci all remain unknown. It is also important to note that complex inheritance implies that not all affected individuals will carry a given susceptibility variant, and conversely, many (possibly most) unaffected individuals carry at least one susceptibility variant. This complexity is the second major obstacle faced by those whose goal is identifying genes for schizophrenia.

C. Complex Phenotype

Many of the difficulties in classifying and defining the schizophrenia phenotype have been discussed elsewhere in this book, and we will therefore mention them only briefly. While it is clear that genotype confers liability to schizophrenia, we have no clear idea what form this "liability" actually takes. That is to say, we do not understand the nature of the inherited intermediate phenotypes that predispose to schizophrenia. It follows, then, that unless it is manifest as disorder, we do not know who has inherited high liability or, more accurately, how liability should be measured and quantified.

The situation is made even more complex by the fact that we are unable to demarcate the clinical syndrome to which liability may lead. Family, twin, and adoption studies have shown that the phenotype extends beyond the core diagnosis of schizophrenia to include a spectrum of disorders including, mainly, schizophrenic schizoaffective disorder and schizotypal personality disorder [7]. However, the limits of this spectrum of disorders and its relationship with other psychoses, affective and nonaffective, and nonpsychotic affective disorders remain uncertain [8–10]. Uncertainty, then, about the nature of liability and the limits of the phenotype is the third major obstacle to genetic analysis of schizophrenia.

These difficulties are not unique to schizophrenia or psychiatric genetics, and although it is of little consolation, they are faced to varying degrees by genetic investigators of other common diseases, be it diabetes, cancer, asthma, or heart disease. In spite of the problems and uncertainties we have described and the difficulties that ensue, schizophrenia seems a compelling candidate for molecular genetic approaches. This is because genes make such a strong contribution to its etiology, and, notwithstanding improvements in neuroimaging, the brain is still difficult to study directly, and the interpretation of cause and effect is problematic.

III. MOLECULAR GENETICS

There are two main approaches for identifying disease genes in human populations: linkage, and association. In linkage studies the objective is to identify regions of the genome that are cotransmitted with the disease in families containing two or more affected individuals. Where linkage is appropriate, it can detect the presence of genes within large chromosomal regions. This means that *relatively* few evenly spaced genetic markers (~ 200–300) are required to screen the whole genome for the presence of disease genes. Therefore, linkage has the potential to locate disease genes by chromosomal position alone without regard to any prior knowledge of disease etiology.

Linkage is ideally suited to detecting genes for simple genetic disorders, but its power to detect genes of moderate to small effect is limited. In association studies, the aim is to detect alleles that are more (or less) common in a series of unrelated cases than in controls. Under most circumstances, association is more powerful for detecting genes of small effect than linkage. However, in outbred populations, many tens, or even

hundreds, of thousands of markers are required to screen the whole genome by association. This is currently impractical, and although the hope is that genomewide association screening may be possible with improved technology, the role of association to date is restricted to testing discrete hypotheses except in unusual isolated populations.

A. Linkage

The first wave of systematic molecular genetic studies of schizophrenia in the late 1980s/early 1990s focused on linkage analysis of large pedigrees containing multiple affecteds. This approach had been highly effective for identifying genes of large effect in single-gene disorders. The proponents of this method were aware it was unlikely that such genes accounted for most of the genetic risk for schizophrenia. Instead, the hope was that under a mixed genetic model, the multiplex families, or at least a sufficient proportion of them, were the result of segregation of rare genes of large effect.

This optimistic view proved to be well founded in a number of complex disorders—for example, Alzheimer's disease (AD), where mutations in three genes, APP, PS1, and PS2, are now known to cause rare forms of the disorder. In such cases, the disease is of unusually early onset and is transmitted through multiplex pedigrees as an autosomal-dominant [11–13]. Early studies of large schizophrenia pedigrees also initially produced a strongly positive finding [14]. Unfortunately, this could not be replicated. However, modest evidence for several linked loci has been reported, some of which has received supportive evidence from international collaborative studies. These include chromosome 22q11-12, 6p24-22, 8p22-21, and 6q [15–17]. There are also a number of other promising areas of putative linkage, which have been supported by other individual groups although not from larger, international consortia. These include 13q14.1-q32 [18–20], 5q21-q31 [21,22], and 10p15-p11 [21,23,24]. One other region that is notable for the strength of evidence (maximum heterogeneity LOD score of 6.5) from a single study, rather than the more important convergence of evidence from different sources is 1q21-q22 [25]. The finding on 1q21-q22 more than meets standard criteria for claiming "significant" linkage. Early experience in psychiatric genetics has, however, impressed the need for replication firmly upon the minds of most researchers, and although there have been other reports of linkage to markers on chromosome 1 [26,27], these are distal to 1q21-q22, and it is

not yet clear that these findings are consistent with the existence of a single susceptibility locus on 1q. Not surprisingly, this region is now under intense investigation by an international linkage consortium.

While the linkage data based on multiplex families are not definitive, it seems likely that one or more of the above loci are true positives. However, it should be noted that in every case there are negative as well as positive findings, and in only two cases, 13q14.1-q32 and 1q21-q22, did any single study achieve genome-wide significance at $P <.05$, that is, a linkage value that is expected less than once by chance in 20 complete genome scans.

As more linkage data from genome scans of schizophrenia and bipolar disorder have emerged, putative linkages to both disorders have been reported in the same regions of the genome, for example 13q22 and 22q11-13 [28]. The observation of common linked loci may indicate at least a partial degree of overlap in the etiologies of these two disorders. However, while we are inclined to be sympathetic to this view, there are several reasons for caution:

1. None of the linkages are as yet definitive, and therefore the strength of the evidence for joint areas of linkage is not conclusive.

2. Similarity is more noticeable than dissimilarity. Until the apparent "clustering" has been subjected to rigorous statistical analysis, the pattern may be coincidence.

3. Even if correct, the regions of linkage contain hundreds or even thousands of genes. It follows that the presence of common linked loci does not prove common genes.

4. It is possible that the joint linkages are to loci that modify the phenotype of both disorders rather than susceptibility genes common to both. An obvious example that might lead to increased ascertainment in linkage studies of both disorders is chronicity.

As an alternative to linkage based on multiplex families, some groups have advocated the use of smaller families with two or more affecteds in a single sibship. This is in the belief that such families may be more suited for the analysis of complex traits, and being much more common, may also be more representative of disease in the general population. This approach has been successful in detecting linkage to several complex diseases. Of most relevance to this readership, these include late-onset AD [29]. We have recently reported the largest systematic search for linkage yet published using a sample of 196 affected sibling pairs (ASPs) [30]. This study was designed to have

power >0.95 to detect a susceptibility locus of $\lambda s = 3$ (the maximum effect size estimated by Risch [5]) with genomewide significance of 0.05. However, no regions of the genome gave linkage results approaching genomewide significance, but we did find modest evidence (at the level expected by chance once per genome scan) for loci on chromosomes 4p, 18p, and the centromeric region of X.

Since, arguably, no definitive linkages have emerged to date from linkage analysis of schizophrenia, the results must be viewed as disappointing. However, as some of the more promising findings described above have only recently emerged, we believe that persistence with the linkage approach is justified. We must also continue to explore different models of disease definition, but also tailor our sample sizes appropriately. For example our own genome scan [30] based on sib pairs was powered predicated on a locus of $\lambda s = 3$, but only had power of 0.7 to detect significant linkage to loci of $\lambda s = 2$. Such loci are still within the detection limits of linkage, using sample sizes of 600–800 sibling pairs [31,32], and in collaboration with colleagues in Sweden, we are currently engaged in such a study. Those engaged in linkage analysis should now give priority to collecting such samples (or equivalently powered samples of multiplex families). Furthermore, clinical methodology must be, as far as is possible, comparable across all interested research groups if "failure to replicate" is to have much meaning. However, if liability to schizophrenia is entirely due to the operation of many genes of small effect, then even these large-scale studies will be unsuccessful. To detect genetic risk factors of this magnitude, we must turn to the second main gene identification strategy based on association designs.

B. Association Studies

As mentioned above, association studies offer a powerful means of identifying genes of small effect. However, because it is impractical at present to screen the whole genome by association, researchers must select specific genes or loci to be tested. This may be on the grounds that a gene is a functional candidate (i.e., it is involved in a biological process that is postulated as relevant to the disorder), because it is a positional candidate gene (i.e., it is located, or maps, to a locus that has been implicated by linkage), or a combination of the two. Because of doubts concerning the robustness of linkage findings in schizophrenia, most studies to date have focused on functional candidate genes. Before consid-

ering the most widely debated findings, it is necessary to consider some of the potential problems with association studies.

First, for disorders of unknown etiology such as schizophrenia, the potential choice of candidate genes is limited largely by the number of genes in the human genome ($\sim$ 40,000). This places a heavy burden of proof on positive results because each gene has an extremely low prior probability that it is involved in the disorder [33]. Second, many researchers believe that these studies have a significant potential to generate false positives due to unknown differences in the genetic structure of cases and well-matched control groups. This problem can be addressed by family-based association methods [34], but large enough samples with all relevant family members willing to participate are difficult to collect [35]. The next two problems relate to the interpretation of "failures to replicate" positive findings. This is often interpreted as evidence that the first study is a false positive. However, it is also possible that subsequent studies are false negatives, as to date all association studies of schizophrenia have had insufficient power to reliably detect small genetic effects. Even with larger samples, potential differences in the genetic structure of samples collected by different groups means fresh studies cannot be considered true replication experiments. For these reasons, it is difficult to draw definitive conclusions from conflicting findings [35].

The most obvious candidate genes derive from the neuro-pharmacological literature (see Chapters 0, 0, 0, 0 and 0 in this section). Thus, genes involved in dopaminergic and serotonergic neurotransmission have received a great deal of attention. With recent developments in genome analysis technology and the recent publication of the (almost) complete sequence of the human genome, these data are being rapidly extended to other systems including the glutamatergic, GABA-ergic, and genes involved in neuromodulation and neurodevelopment. It is impossible for us to present the results of the hundreds, possibly thousands, of candidate gene analyses that have been published or reported at meetings. Fortunately for the reader, this can be avoided by noting that for the reasons just outlined, the overwhelmingly negative reports cannot be considered as definitive exclusions of small genetic effects. Moreover, with perhaps the two exceptions we discuss below, no positive finding has received sufficient support from more than one group to suggest a true association with even a modest degree of probability.

C. Serotonin 5HT2a receptor

The serotonergic system is a therapeutic target for several antipsychotic drugs. The first genetic evidence for its involvement in schizophrenia was a report of association with a T > C polymorphism at nucleotide 102 in the HTR2A gene which encodes the 5HT2a receptor [36]. This association was based on a small sample of Japanese subjects. Firmer evidence for association subsequently emerged from a large, multicenter European consortium [37] and a meta-analysis of all the data available in 1997 based on > 3000 subjects [38].

Since the meta-analysis was undertaken, a few further negative reports have followed, none with the sample sizes required. If we assume homogeneity and that the association is correct, the odds ratio (OR) for the C allele is $\sim$ 1.2. Sample sizes of 1000 subjects are required for 80% power to detect an effect of this size even at $P = .05$. However, while the negative studies do not refute the putative association, the evidence presented even in the meta-analysis ($P = .0009$) is well short of genome wide significance (estimated at around $P = 5 \times 10^{-8}$ by Risch and Merikangas [39]). Admittedly, demanding genomewide significance is inappropriate for such a strong candidate gene because the prior probability that it is involved in schizophrenia is greater than a gene selected at random. However, as there is no way of quantifying how much greater the prior probability is, we have no compelling alternative to genomewide significance. Consequently, we believe that the evidence tends to indicate association between HTR2A and schizophrenia, but that the burden of proof has not yet been met. Another reason to be skeptical about the putative association is that there are no variants yet detected in the gene that clearly alter receptor function or expression. However, there is some indirect evidence for the existence of sequence variation elsewhere that alters HTR2A expression in some regions of the brain [40].

D. Dopamine D3 Receptor Gene

The dominant neurochemical hypothesis of schizophrenia involves dysregulation of the dopaminergic system, with disordered transmission at the dopamine D2 receptor widely favored. However, association analyses of DRD2 to date have essentially been negative, although recently, three groups, two Japanese [41,42] and one Swedish [43], have implicated a polymorphism in the promoter which alters DRD2 expression in vitro. Unfortunately, the biggest single study to date found no evidence for association [44]. Furthermore,

when the U.K. data from this study were combined with a large dataset from Scotland, the allele that was associated with schizophrenia in the other three studies was actually significantly less common in the patient group [45]. This finding has been interpreted as suggestive that the polymorphism tested in these studies is simply a marker for the true susceptibility variant (i.e., association due to linkage disequilibrium [LD]). While it is reasonable to attribute reversal of allelic association to LD differences between samples of different ethnic origins, the explanation would be more convincing if the same allele were associated in both the U.K. and the Swedish samples. Furthermore, if LD is the explanation, then the fact that this particular polymorphism is functional is no longer relevant. Data from more groups are required before a sensible discussion of the role of this variant can be undertaken.

The dopamine hypothesis has received somewhat stronger, although not robust, support from studies of DRD3 which encodes the dopamine D3 receptor. Association has been reported between schizophrenia and homozygosity for a Ser9Gly polymorphism in exon 1 of this gene [46]. As expected, positive and negative data have emerged, but unlike DRD2, sufficient data are available for meta-analysis. Based on all available data from > 5000 individuals, Williams and colleagues [47] concluded in favor of association although the effect size was extremely small (OR = 1.23) but nominally significant ($P = .0002$). As for HTR2A, for the reasons outlined above, the level of statistical evidence, while supportive, is not conclusive.

IV. ANTICIPATION AND TRINUCLEOTIDE REPEATS

Anticipation is the phenomenon whereby a disease becomes more severe or has an earlier age at onset in successive generations. Numerous studies have now suggested that the pattern of illness in multiplex pedigrees segregating schizophrenia and other psychotic illnesses is at least consistent with anticipation, although ascertainment biases offer an alternative explanation [48].

True genetic anticipation is a hallmark of a particular class of mutation called expanded trinucleotide repeats. The observations in families have therefore been taken as suggestive that such mutations might be involved in the etiology of psychosis [49]. This hypothesis has received support from a number of studies reporting that large but unidentified CAG/CTG trinu-

cleotide repeats are more common in patients with schizophrenia and other psychoses than in unaffected controls [e.g., 50,51]. Unfortunately, these early findings have been followed by numerous failures of replication. Also, the specific loci responsible for $\sim$ 50% of the anonymous CAG/CTG repeats detected in the previous studies have now been identified, but neither is associated with psychosis [e.g., 52,53]. These data have tempered much of the enthusiasm for the CAG/CTG hypothesis, but it is still premature to discard it. Indeed, two independent groups have recently detected the presence of proteins in a small number of schizophrenics that react with an antibody against moderate to large polyglutamine sequences [see 54]. This is of relevance here because polyglutamine sequences are often encoded in DNA by CAG repeats. It remains to be seen whether these proteins are involved in the disease rather than simply chance findings.

V. CYTOGENETIC ABNORMALITIES

A third approach by which investigators have sought to locate susceptibility genes for schizophrenia has been to identify chromosomal abnormalities in affected individuals. Cytogenetic anomalies, such as translocations and deletions, may be pathogenic through several mechanisms; direct disruption of a gene or genes; indirect disruption of the function of neighbouring genes by a so-called position effect; or an alteration of gene dosage in the case of deletions, duplications, and unbalanced translocations. It is also possible for an abnormality merely to be linked with a susceptibility variant in a particular family. Owing to the high prevalence of schizophrenia, a single incidence of a cytogenetic abnormality is insufficient to suggest causality. To warrant further investigation, a cytogenetic abnormality should either be shown to exist in greater frequencies in affected individuals, to disrupt a region already implicated by genetic analyses, or to show co-segregation with the condition in affected families.

There have been numerous reports of associations between schizophrenia and chromosomal abnormalities [55,56], but, with two exceptions, none has yet provided convincing evidence to support the location a gene conferring risk to schizophrenia. The first strongly suggestive finding is a t(1;11) balanced reciprocal translocation found to cosegregate with schizophrenia in a large Scottish family [57], and which has recently been reported to directly disrupt three genes, of unknown function, on chromosome 1 [58]. Interestingly, the breakpoint appears to be located

close to the markers implicated in the two Finnish studies mentioned previously [26,27]. However, until mutations have been identified in other families or convincing biological evidence implicating this locus has been obtained, the mechanism by which the translocation confers risk to mental illness remains obscure. The second finding of interest is the association between velocardiofacial syndrome and schizophrenia.

Velocardiofacial syndrome (VCFS), also known as DiGeorge or Shprintzen syndrome, is associated with small interstitial deletions of chromosome 22q11. The phenotype of VCFS is variable, but in addition to characteristic core features of dysmorphology and congenital heart disease, there is strong evidence that individuals with VCFS have a dramatic increase in the risk of psychosis [59–61]. There is still some dispute about the nature of the psychotic phenotype associated VCFS. Thus, the first two of these studies [59,60] suggested the association to be with schizophrenia and schizoaffective disorders, while the third [61] demonstrated a high prevalence of bipolar spectrum disorders. At least some of the differences can be attributed to differing methods of proband ascertainment, the proband age group, and the diagnostic methodology used.

To characterize the psychosis phenotype in VCFS further, we recently evaluated 50 VCFS cases with a structured clinical interview to establish DSM-IV diagnosis [62]. Fifteen individuals with VCFS (30%) had a psychotic disorder, 12 of whom met DSM-IV criteria for schizophrenia. These data strongly suggest that it is schizophrenia and allied disorders that explain the high rates of psychosis in VCFS, but studies based on sounder epidemiological principles are now required to demonstrate this beyond all doubt.

Clearly, with an estimated prevalence of 1 in 4000 live births, one can estimate that VCFS cannot be responsible for more than a small fraction (~1%) of cases, and this estimate is in keeping with empirical data (63). From the practical perspective, clinicians should be vigilant for VCFS especially when psychosis occurs in the presence of other features suggestive of the syndrome such as dysmorphology, mild learning disability, or a history of cleft palate or congenital heart disease [64,65]. However, from the perspective of the genetic researcher, the most pressing question is whether the high rate of psychosis in VCFS provides a short cut to a gene within the deleted region which is involved in susceptibility to schizophrenia in cases without a deletion. To answer this, we are currently screening all the genes that map to the deleted region. However, there are reasons to be optimistic that this

will be a route to a general susceptibility gene rather than a blind alley. As we have already seen, some linkage studies suggest the presence of a general schizophrenia susceptibility locus on 22q. While most suggest that this maps outside the VCFS region, linkage mapping in complex diseases is imprecise, and modest evidence for linkage within the VCFS region has also been reported [19,66,67].

VI. RESOLVING THE IMPASSE

The linkage studies to date have shown that genes of major effect are not common causes of schizophrenia and allied psychoses. They have also provided information concerning the *possible* location of some genes of moderate effect. Association studies have provided further mapping information, with VCFS providing fairly strong evidence for a susceptibility locus in 22q11. To a lesser degree, with the proviso that the associations in HTR2A and DRD3 are at best weak and provisional, they also suggest that the dominant neurochemical hypotheses are at least partially correct. It is clear, however, that the findings from molecular genetics are as fragile as those from genetic epidemiology are robust. How are we to make progress?

As in other common diseases, it is hoped that advances in the genetics of schizophrenia will come through the application of detailed information on the anatomy and sequence of the human genome combined with new methods of genotyping and statistical analysis. To take advantage of these developments, collection of large, well-characterized samples is a priority [68]. Samples for genetic studies of schizophrenia are generally ascertained in differing and unsystematic ways, which may be one of the explanations of failures to replicate between studies. For example, if a positive association is detected in one patient group that, by virtue of the method of ascertainment, has been inadvertently selected for chronicity, the putative "risk allele" might actually be an allele that modifies treatment response rather than predisposing to the disorder itself. Unless this is recognized, replication will be difficult except in samples with a bias toward chronicity.

Another possible route forward will be the development of suitable animal models and the possibility of identifying the disease genes in animals by genetic mapping. This may be simpler in animals because, unlike humans, they can be bred under conditions that allow optimal power for gene detection. New

technical developments also now permit us to compare the expression of thousands of different mRNAs and proteins between model and control animals, with the goal of identifying clues to novel biological pathways that can be tested in human subjects. Disorders that predominantly involve higher cognitive function such as schizophrenia are likely to prove difficult to model in animals, but there have been some developments that will be discussed in Section B, Chapter 9.

Finally, it is worth reminding ourselves that the effectiveness of molecular genetic studies depends on the genetic validity of the phenotypes studied. We therefore need to focus research on the development and refinement of phenotypic measures and biological markers, which might simplify the task of finding genes. It is possible that genetic validity may be improved by focusing on quantitative aspects of clinical variation such as symptom profiles [e.g., 69] or by identifying biological markers that predict degree of genetic risk or define more homogeneous subgroups. However, it seems unlikely that these phenotypes will provide a rapid solution to the problem. First, we will need measures that can be practicably applied to a sufficient number of families or unrelated patients; second, we will need to ensure that the traits identified are highly heritable, which will itself require a return to classic genetic epidemiology and model fitting.

Membrane Abnormalities in Psychotic Disorders

WAGNER FARID GATTAZ and ORESTES V. FORLENZA
University of São Paulo, São Paulo, Brazil

I. INTRODUCTION

Research into biochemical processes affecting membrane composition and fluidity have generated models that fit relatively well in both the neurodevelopmental hypotheses of schizophrenia and the neurodegenerative mechanisms of dementia. Data from the late 1980s suggesting increased phospholipase A_2 (PLA_2) activity in schizophrenia [1,2], and decreased in Alzheimer's disease [3,4], have been replicated by several groups [5,6]. Abnormalities of PLA_2 metabolism have also been described in other neuropsychiatric diseases such as multiple sclerosis [7] and temporal-lobe epilepsy [8,9].

 PLA_2 enzymes participate in a wide variety of physiological processes, including phospholipid digestion, remodeling of cell membranes, and host defense. They also take part in pathophysiological processes by producing precursors of various types of biologically active lipid mediators, such as prostaglandins, leukotrienes, thromboxanes, and platelet-activating factor [10]. Over the past two decades, with advances in molecular biology, numerous PLA_2 subtypes have been identified and characterized [11–16]. According to biochemical features such as their primary structure, cellular localization, requirement of Ca^{2+}, and substrate specificity, these PLA_2s are classified into several families, including low-molecular-weight secretory

PLA_2 ($sPLA_2$), Ca^{2+}-sensitive arachidonoyl-specific 85-kDa cytosolic PLA_2, Ca^{2+}-independent PLA_2, and platelet-activating factor-acetylhydrolase [13].

 Accordingly to the "phospholipid hypothesis," membrane changes play a primary role in the etiology of schizophrenia. Abnormal regulation of highly unsaturated fatty acid metabolism, mainly at the *sn*-2 position of phospholipid molecules, results in modifications of the neuronal membrane structure, affecting intracellular signalling from neurotransmitter- and ion channel-related functions [17].

A. Short Review on the Biology of Membranes

Biomembranes are major constituents of neural tissue. Membrane integrity is essential for neuronal metabolism, at both the cellular and subcellular levels. The 7-nm-thick outer membrane provides an impermeable barrier for extracellular agents and substances, as well as the ability for the cell to become electrically and chemically excitable. The biophysical and biochemical properties of the membrane are the basis for all message transmission and signal transduction in the mammalian brain. In addition, the distinct roles that organelles undertake through neuronal metabolism are notably dependent on membrane function. One

should include nuclear and mitocondrial membranes, the primarily membranous organelles such as smooth and rough endoplasmic reticula, the Golgi complex, and the container membranes required for disposal of catabolic products (lysosomes) and for enclosing intracellular stores of calcium and neurotransmitters (synaptic vesicles).

Membrane remodeling is fundamental for the long-term maintenance of neuronal function, since mammalian neurons are postmitotic from embryonic life and therefore no longer undertake cell division. All neuronal membranes are made up of lipids in which phospholipids, cholesterol, and cholesteryl esters play major roles in structure and function. In neurons, as compared to other nonneuronal cells, the importance of phospholipid metabolism is even greater, bearing in mind the profusion of axones and dendrites—which are mostly membrane-coated cytoskeleton—and the phenomenon of synaptic plasticity.

Biochemical signaling is likewise dependent on membrane function. Neuronal proteins and receptors are mostly embedded in, or attached to, phospholipid-rich membranes. Downstream on signal transduction, the release of second messengers is also highly dependent on the activity of phospholipases. Fatty acids, diacylglycerols, and inositol phosphates, which are central components of intracellular signaling systems, are released from membrane phospholipids during neuronal activation and under the catabolic action of phospholipases A, B, C, and D.

B.   Molecular Structure of Phospholipids

Membrane phospholipids are large molecules assembled on a three-carbon backbone of glycerol. The four most important membrane phosphoglycerides—phosphatidylcholine (lecithin), phosphatidylethanolamine (cephalin), phosphatidylserine, and phosphatidylinositol—have two long fatty acid chains starting from carbon atoms at positions sn-1 and sn-2, and a phosphate-bound hydrophilic "characterizing group" (choline, ethanolamine, serine, and inositol) at sn-3 (Fig. 1).

The existence of a hydrophylic head group at one end of the molecule, and two hydrophobic fatty acid tails at the other, yields the amphipathic nature of phosphoglycerides. Such biophysical properties determine the ability of phospholipids to organize themselves as lipid bilayers in the interface of two aqueous solutions, that is, between the intracellular (cytosol) and extracellular environments.
Figure 1   Schematic structure of membrane phospholipids, showing the three-carbon (C) backbone of glycerol (positions sn-1, 2, and 3) bearing two varying fatty acid tails and the phosphate- (P) bound characterizing group (phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, or phosphatidylinositol). The sites of action of phospholipases A_1, A_2, B, C and D are indicated by arrows. The catalytic activity of phospholipases originates free fatty acids and lysophospholipids (phosphodiesters) from phosphomonoester substrates.

Phospholipids differ from each other not only according to their "characterizing" heads, but also to the varying length of fatty acid chains (ranging from 12 to 20 carbons) and the nature of the bonds between every two carbon atoms within the fatty acid sequence. In other words, carbons may be linked by saturated (single) or unsaturated (double) covalent bonds. Both these features have an effect on the nature of the membrane. The shorter and more unsaturated the fatty acid tail, the greater the fluidity of the membrane, since such properties make the tails more difficult to pack compactly within the membrane's core. The interior of the membrane is thus an organic fluid in which the individual phospholipid molecules continuously exchange places with each other and seldom migrate (or "flip-flop") from one side of the membrane to another. Modifications of membrane fluidity are expected to occur during neuronal metabolism and, indeed, as a consequence of brain maturation and ageing. Indeed, recent data from our laboratory provide indications of altered membrane fluidity in postmortem brains of schizophrenic and Alzheimer's disease patients (in preparation).

C.   Role of Phospholipase A_2 in Membrane Phospholipid Metabolism

Phospholipids are substrates for the production of intra- and extracellular signaling molecules, and PLA$_2$

is one of the major phospholipid-cleaving enzymes. The PLA_2 superfamily is a heterogeneous group of enzymes, most of which display high selectivity for sn-2-arachidonoyl-containing phospholipids. Biochemically, PLA_2 enzymes are classified based on their molecular size, substrate specificity, aminoacid sequence, and disulfide bond pattern [18]. According to its site of release and action, human PLA_2 can be further classified in cytosolic (type IV or $cPLA_2$) and secretory ($sPLA_2$) phospholipase A_2, the latter group being additionally subdivided into pancreatic (type I) or nonpancreatic (type II) forms. Recently, several additional members of the PLA_2 superfamily have been identified, leading to the inclusion of class V (secretory), VI (80 kDa inducible), VII and VIII (both of which are calcium independent and specific for platelet activating factor), and IX (secretory) [19,20].

Type II $sPLA_2$ are small (13–19 kDa) secretory enzymes characterized by the presence of several disulfide bridges, being thus inhibited by sulfhydryl reducing agents. Secretory PLA_2 becomes active following extracellular release and requires micromolar calcium concentrations as a catalytic cofactor. In addition, $sPLA_2$ has no preference for arachidonic acid over other acyl groups at the sn-2 position—rather, it has a broad affinity for phospholipids with different polar head groups and fatty acyl chains [18,21,22]. At present, mammalian $sPLA_2$s are classified into five different groups (groups IB, IIA, IIC, V, and X), depending on the number and positions of cysteine residues and the localization of intramolecular disulfide bridges [14]. Among them, group IIA PLA_2 has been thought to be one of the key enzymes in the pathogenesis of inflammatory diseases, owing to its augmented expression under various inflammatory conditions including sepsis, Crohn's disease, and acute pancreatitis. Likewise, the expression of $sPLA_2$-IIA has been shown to correlate well with disease severity in rheumatoid arthritis [23].

Type IV $cPLA_2$ are very distinct enzymes in that they display no detectable sequence homology to $sPLA_2$. The mammalian 85-kDa calcium-dependent cytosolic PLA_2 ($cPLA_2$-α) is a well studied example of this class of enzyme [11,24]. It is a monomeric polypeptide of 749 amino acids containing an aminoterminal calcium-dependent regulatory domain responsible for the translocation of the enzyme to membranes of the nuclear envelope upon activation [25–27]. Thus, $cPLA_2$ are larger intracellular molecules, with a clear preference (as compared to $sPLA_2$) for the cleavage of arachidonic acid at the sn-2 position of phospholipids. Whereas some type IV ($cPLA_2$) are calcium-dependent, other forms are not. More recently, three distinct

subtypes of $cPLA_2$ have been described—α-, β-, and γ-PLA_2. Despite significant homology in both the calcium-dependent lipid-binding domain as well as in the catalytic domain, βPLA_2 is markedly less selective for cleavage at position sn-2 of phospholipids [28].

Phospholipases A_2 that reside in the cytosol are of particular interest because of their ability to interact directly with signal transduction elements such as G-proteins and kinases. Thus, $cPLA_2$ plays an essential role in neuronal membranes, not only by influencing the physicochemical properties of synaptic membranes, but also in signal transduction [29,30]. Lysophospholipids have several biological properties including membrane lysis, chemotaxy, mithogenesis, smooth muscle fiber contraction [31], and platelet activation factor (PAF) synthesis [32]. In addition, $cPLA_2$ activation leads to the downstream release of arachidonic acid and choline, respective substrates for the synthesis of major inflammatory mediators (eicosanoids) and acethylcholine [33,34] (Figure 2).

Both nonpancreatic $sPLA_2$ and $cPLA_2$ are ubiquitous enzymes and have been found in every cell line so far investigated, including neurons [35,36]. Tissue distribution is likewise wide, including platelets, neutrophils, monocytes, macrophages, skin fibroblasts, and
Figure 2 The 85-kDa intracellular enzyme $cPLA_2$ catalyzes the hydrolysis of the acyl group from the position sn-2 membrane glycerophospholipids. Both products of the reaction, fatty acids and lysophospholipids, may act as second messengers in intracellular signaling. Arachidonic acid has a central importance in generating bioactive and proinflammatory lipid components such as eicosanoids (e.g., prostaglandins, leukotrienes, and tromboxanes). The subsequent hydrolysis of lysophosphatidylcholine generates choline for acetylcholine synthesis.

cells of the brain, lung, liver, kidney, and spleen [18]. Although the importance of these enzymes in eicosanoid metabolism and signal transduction is not questioned, much of PLA$_2$ function and regulation remains to be learned. Cellular mechanisms for activation are yet unclear although 85 kDa undergoes translocation to membrane fractions in the presence of physiologically relevant changes in free calcium; an amino-terminal 140 aminoacid fragment of cPLA$_2$ shares this activity, suggesting the existence of a calcium-dependent phospholipid-binding motif [11]. PLA$_2$ activity is modulated by proteins of the PLIP (phospholipase-inhibiting protein) family, of which annexin-I, a calcium-dependent phospholipid-binding protein, has been shown to inhibit both low- and high-molecular-weight PLA$_2$ in a substrate-specific fashion [37].

Cytosolic PLA$_2$ is also a substrate for enzymes of the mitogen-activated protein (MAP) kinase cascade, and the phosphorylation at serine 505 by MAP-kinase increases the enzymatic activity of cPLA$_2$ [38]. In response to growth factors and neurotransmittters, ^{p42}MAP-kinase and protein-kinase C (PKC) activation lead to the phosphorylation of cPLA$_2$ in distinct sites, bearing the involvement of tyrosine kinase and G-protein-linked receptors in the regulation PLA$_2$ metabolism [38,39]. In fact, mechanisms of cross-talk between phospholipase A$_2$ and C have been suggested in studies with bone marrow [40] and thyroid cells [41,42].

Cytosolic PLA$_2$ expression can be influenced by tumor necrosis factor, interleukin-1, transforming growth factor beta, macrophage colony-stimulating factor, and glucocorticoids [18]. In animals, levels of calcium-independent cPLA$_2$ can be elevated by oxidative stress [43]. In the rat brain, it has been shown that PLA$_2$ expression is also developmentally regulated, being highest at embryonic day 12, gradually decreasing toward birth and retaining a constant level into adulthood [44]. This suggests that the enzyme plays an important role in the early development of the nervous system, which adds—at least theoretically—speculative interest in the neurodevelopmental models of schizophrenia.

II. PHOSPHOLIPIDS AND SCHIZOPHRENIA

A. Evidence of Relationship Extrapolated from Basic Research

In tissue culture models, it has been shown that arachidonic acid participates in pathways underlying neurite outgrowth and differentiation of neuroblastoma cells [45]. Thus, one can speculate that genetically deter-mined abnormalities of PLA$_2$ metabolism, affecting arachidonic acid availability in early stages of embryonic life, are likely to result in abnormal neuronal sprouting and differentiation, leading to cytoarchitectural changes within the brain. In vitro studies show that PLA$_2$ modulates dopamine (DA) synthesis and release [46,47]. The addition of exogenous PLA$_2$ and arachidonate to primary cultures of rat tubero-infundibular neurones has been shown to stimulate DA release; likewise, the activation of calcium channels by ionophore agents leads to increased arachidonate levels (suggesting PLA$_2$ activation), and results in enhanced DA release [47]. On the other hand, dopamine receptor sensitivity is under negative modulation of PLA$_2$, as shown by the inhibition of the activation of DA- sensitive adenylate cyclase in striatal tissue by the pretreatment with PLA$_2$ [48] and by the PLA$_2$- and lysophosphatidylcholine-induced reduction of [^{3}H]spiperone binding to DA receptors in microsomal membranes isolated from sheep caudate nucleus [49].

Animal models have granted interesting insights on the inhibition of dopaminergic function by PLA$_2$. The in vivo effects of intracerebral injections of the PLA$_2$ were investigated in the model of DA-mediated locomotion behaviour in rats under apomorphine challenge. It is well known that subcutaneous injection of apomorphine increases locomotion in rats by a direct agonism of postsynaptic DA receptors. According to the rotational model presented by Ungerstedt and Arbuthnottin 1970 [50], the direction of circling movements is ipsilateral to the hemisphere with the lowest nigrostriatal dopaminergic activity [51,52]. Both intra-nigral [53,54] and intracerebroventricular injection of PLA$_2$ [55] resulted in reduced locomotion after apomorphine challenge, as compared to saline-injected controls. The inhibiton of apomorphine-induced locomotion by PLA$_2$ was reversible within 4 weeks after stereotaxic surgery, suggesting a functional inhibition of dopaminergic postsynaptic receptors by PLA$_2$. Unilateral stereotaxic injection of PLA$_2$ into the nigrostriatal area caused an ipsilateral apomorphinein-duced rotational asymmetry, whereas intracerebroven-tricular PLA$_2$ application reduced apomorphine-induced locomotion [56]. Taken together, these data suggest that intracerebral injection of PLA$_2$ inhibits dopaminergic neurotransmission in vivo.

B. From Animal Models to Schizophrenic Patients

How could this inhibitory effect of PLA$_2$ on dopaminergic neurotransmission be involved in the patho-

physiology of schizophrenia? Because of the central role of phospholipids in neurons, one could argue that the very large number of neurotransmitter-related abnormalities in schizophrenia may be a secondary consequence of phospholipid changes [57].

In 1971 John Stevens published what is perhaps the first report describing membrane lipid pathology in schizophrenia, after studying the lipid composition of erythrocyte membranes from 101 schizophrenics as compared to 20 normal controls [58]. Of the four major phospholipids studied, he found a marked (50%) increase in the phosphatidylserine content among schizophrenics, and an associated smaller decrease in phosphatidylcholine and phosphatidylethanolamine. Stevens was foresighted in his brief discussion, in which he pointed out that "if these membrane abnormalities extended to the brain, they could change the electrostatic charge at the synapse and thus have an inflence on the threshold and transmission of impulses" [58,59].

Evidence of disturbed PLA_2 metabolism in schizophrenia was drawn from our studies at the University of Heidelberg in the late 1980s, bearing indications of increased PLA_2 activity in schizophrenic patients. The activity of PLA_2 was determined in the plasma of 20 drug-free schizophrenic patients, six nonschizophrenic psychiatric control patients, and 21 healthy controls. Schizophrenics showed significantly higher plasma PLA_2 activity than both controls (70% of the schizophrenics had enzyme activity higher than the highest value from the control group), which was reduced to the level of the controls after 3 weeks of neuroleptic treatment [1]. Such findings were subsequently corroborated by postmortem studies of schizophrenic brains, in which Horrobin and collaborators demonstrated significant differences from normal in the fatty acid composition of phosphatidylethanolamine in the frontal cortex [60].

Controversy was raised after negative measurements in the serum of drug-naïve schizophrenics [61], and the specificity of the finding was further questioned by the observation of increased plasmatic PLA_2 both in schizophrenic and nonschizophrenic psychiatric patients. Noponen and collaborators in 1993 found higher than normal PLA_2 activity not only in schizophrenics, but also in a psychiatric control group, including patients with major depression, bipolar disorder, posttraumatic stress disorder, and substance abuse [5]. Although PLA_2 activity values in the nonschizophrenic patients were not as high as among schizophrenics, the authors claimed that such increases should be viewed as nonspecific, in the same fashion

as the findings of increased circulating PLA_2 in infectious and inflammatory conditions.

Such controversies were explained by the heterogeneity of plasmatic PLA_2 and the use of methodologies that may have measured the activity of diferent molecular forms of the enzyme [3]. In view of that, Ross and collaborators in 1997 [6] compared the PLA_2 activity simultaneously by means of the distinct protocols that had been used by earlier authors [1,5,61]. Activity of PLA_2 in serum samples obtained from 24 individuals with schizophrenia was compared with serum obtained from 33 age- and sex-matched control subjects, using both fluorometric and radiometric assays with different substrates. They were able to confirm by fluorometric analysis that PLA_2 activity was significantly elevated in schizophrenic patients compared to controls, validating the previous indications of abnormal phospholipid metabolism in schizophrenia. In contrast, radiometric assay of the same serum samples resulted in PLA_2 activity not significantly different between patients and control subjects. Further investigations demonstrated that, whereas the radiometric assay measured activity of a calcium-dependent enzyme, the fluorometric assay detected a calcium-insensitive enzyme possessing an acid-neutral pH optimum [6].

Indeed, calcium-independent $cPLA_2$ activity in schizophrenic patients has been consistently reported to be increased in plasma [1,6], serum [2,5], and platelet membranes [2,62]. In platelets of schizophrenics, phosphatidylcholine concentration (a substrate of PLA_2) was found to be decreased, and lysophosphatidylcholine (a breakdown product of PLA_2 hydrolysis) elevated [63]. These data are suggestive of an accelerated systemic breakdown of membrane phospholipids. However, in a subgroup of schizophrenic patients, the concentration of arachidonic acid was found to be decreased in red blood cell membranes [64].

Further studies from our group, conducted with the University of Turku, Finland [65], compared the concentrations of types I and II PLA_2 in the serum of 43 schizophrenic patients, 32 nonschizophrenic psychiatric patients, and 41 heathy controls. No differences were found among the three groups with respect to pancreatic (type I) PLA_2, whereas nonpancreatic (type II) PLA_2 was significantly elevated in schizophrenics as compared to nonpsychiatric ($P < .05$) and psychiatric controls ($P < .05$). In addition, positive correlations were found between higher PLA_2 levels and scores on negative symptoms.

In a prospective case control study, 31 drug-free schizophrenic patients (half of whom were first-episode

and drug-naïve schizophrenics) were compared with sex- and gender-matched nonschizophrenic psychiatric patients and healthy controls [3]. Baseline and weekly determinations of platelet PLA_2 activity were respectively obtained prior to and during a 3-week 10-mg/day haloperidol course. PLA_2 activity was significantly increased both in the group schizophrenic patients as a whole and in the first-onset subgroup, when compared to nonschizophrenic patients ($P < .03$) and healthy controls ($P < .01$). No differences were found between the two control groups. In addition, haloperidol treatment resulted in decreased PLA_2 activity, abolishing the previous difference between schizophrenic cases and controls. Likewise, schizophrenic patients had decreased concentrations of the PLA_2 substrate phosphatidylcholine ($P < .006$), and increased concentrations of the metabolite lysophosphatidylcholine ($P < .005$), which reverted to control levels after neuroleptic treatment.

Membrane fluidity studies recently performed in our laboratory reinforce the assumption that enhanced PLA_2 activity is related with abnormal fatty acid metabolism in schizophrenia (data in preparation). Synaptosomal-mitochondrial membranes isolated from the frontal cortex and hippocampus of schizophrenic brains (n = 7) were compared to the respective controls (n = 8). Membrane fluidity was examined using four different fluorescent techniques, showing that frontal cortex membranes obtained from schizophrenics had a significantly higher flexibility of fatty acids in the membrane hydrocarbon core and in the hydrophilic region of phospholipid head groups than controls. Conversely, fluidity parameters in hippocampal membranes were unchanged. Taken together, these data indicate alterations of biological properties of membranes that may be specific to frontal areas of schizophrenic brains.

C. Spectroscopy Studies

In addition to biochemical studies, the examination of brain phospholipid metabolism in living patients was made possible with the aid of ^{31}P magnetic resonance spectroscopy (NMR). Several studies suggested that schizophrenic patients have lower prefrontal levels of phosphomonoesters (PME) and higher levels of phosphodiesters (PDE) compared to matched controls [66–73]. Thus, an increased concentration of membrane phospholipid breakdown products (PDE) associated with a decrease in the respective precursors (PME) is suggestive of accelerated phospholipid breakdown—in other words, increased PLA_2 cleaving activity—parti-

cularly in frontal areas. However, patients with psychotic depression also seem to show lower levels of phosphomonoesters than controls, and furher studies are needed to define whether these findings are specific to schizophrenia or part of a generalized membrane phospholipid abnormality in psychotic disorders [74].

Attempts to correlate psychopathological subtypes and *in vivo* phospholipid metabolism abnormalities suggested that negative symptoms may be associated with higher levels of saturated fatty acids and lower levels of long-chain unsaturates in red blood cell membranes, while the positive symptom patients showed the opposite picture [75]. Maras et al., [65] also described association between higher serum PLA_2 levels and negative schizophrenic symptoms. More recently, NMR spectroscopy studies demonstrated that disordered phospholipid metabolism in the prefrontal cortex of schizophrenic patients is correlated with neuropsychological dysfunction [72]. Comparing 16 chronic schizophrenic patients and 13 normal controls, Deicken et al. [72] observed that lower left frontal phosphomonoester levels in the schizophrenics were associated with fewer categories achieved, lower percent conceptual level, and greater total errors in the Wisconsin Card Sort Test. No significant correlations between frontal phospholipid measures and performance on the test were noted in the controls. The results suggest a relationship between altered left frontal phospholipid metabolism and a specific measure of frontal lobe neuropsychological functioning. Since a reduced dopaminergic activity in the prefrontal cortex has been postulated in the hypofrontality hypothesis of schizophrenia [76], increased PLA_2 activity may be hypothesized as one of the causes of hypodopaminergic function in the prefrontal system in schizophrenia.

D. Genetic Studies

Few studies have addressed the genetic basis for disordered phospholipid metabolism in schizophrenia. The 85 kDa $cPLA_2$ gene has been sequenced and mapped to the chromosome 1q25 in humans [11,77]. Two simple sequence repeats, i.e., the poly(A) or (dA)n mononucleotide repeat and the (CA)n dinucleotide repeat, were reported at the human PLA_2 locus. The poly(A) simple sequence repeat is located at the 5′ end of an inverted Alu repeat near the promotor region, and its predicted DNA fragment should contain the (dA)43 repeat sequence. The analysis of length polymorphism within this marker, using a polymerase chain reaction (PCR) method, showed 10 individual alleles with $\sim$ 76% of heterozygosity due to the

poly(A) repeat among unrelated individuals [77]. Hudson and collaborators examined the association of the poly(A) simple sequence repeat in the human PLA_2 gene with the schizophrenic phenotype, and described a genetic variant near the $cPLA_2$ locus in 65 schizophrenics, as compared with a matched normal control population [78]. Out of 10 alleles (A1–A10), the frequency of A1–A6 was significantly lower in patients with schizophrenia than in control subjects. A follow-up haplotype relative-risk study of 44 triads (mother, father, affected offspring), confirmed the results seen in the association study. Such findings suggest that a genetic variant near the promotor region of the gene for $cPLA_2$ may be associated with schizophrenia. However, a similar study was conducted in 58 patients with schizophrenia and 56 control subjects, but the authors failed to demonstrate the allelic association of the poly(A) repeat polymorphism with schizophrenia [79].

More recently, Peet and collaborators [80] identified a dimorphic site on the first intron of the cPLA2 gene, by using a long PCR combined with restriction length fragment polymorphism analysis. Schizophrenic subjects were found to have a significant excess of the A2/A2 homozygote relative to healthy control subjects.

In addition, PLIP genes are located in chromosome 6, not far from major histocompatibility complex (HLA) genes. Evidence of linkage between HLA antigens and schizophrenia [81–83] leads to the speculation that PLIP genes might be involved in the pathogenesis of the disease. Genetic alteration in the $cPLA_2$ gene may be manifested as a membrane abnormality throughout the body. Since a major proportion of neuronal membrane is made up of unsaturated fatty acids, this abnormality will be most pronounced in the brain.

III. CONCLUSIONS

Cytosolic PLA_2 catalyzes the hydrolysis of membrane phospholipids to release cytotoxic products, such as lysophosphatidylcholine. In schizophrenia, increased PLA_2 activity and an accelerated breakdown of membrane phospholipids have been reported. In neuronal membranes, PLA_2 modulates DA release and receptor sensitivity, and has been shown to reduce dopaminergic neurotransmission. Spectroscopy data suggest disorderd phospholipid metabolism in the prefrontal cortex of schizophrenics, which correlates with the occurrence of negative symptoms, consistent with the hypofrontality hypothesis of schizophrenia.

I. INTRODUCTION

Animal models of human disorders can be invaluable tools for investigating the etiology and underlying pathophysiology of clinical syndromes, including psychiatric disorders. For example, as epidemiological, genetic, or biochemical studies identify a particular factor (e.g., gene, protein, developmental insult, change in the social milieu) that may be causal or contributory for the incidence of a disease such as schizophrenia, animal models can be employed to evaluate the possibility that manipulation of the factor may plausibly result in the occurrence of relevant psychopathology. The contribution of particular biological substrates to symptomatic components of the human disorder can be evaluated in animals with perturbations of discrete physiological functions.

Psychotic disorders have been particularly difficult to model in nonhuman species because the array of affected functions includes processes that are difficult to evaluate in animals, if they are present at all. For example, the objective measurement of animal beha-

viors thought to model formal thought disorder or hallucinations is abstruse, and other symptoms, such as verbal dysfunction, exist within domains that likely are not reproducible in any nonhuman species. In addition, schizophrenia and related disorders are characterized by spectra of impairments that implicate complex, multivariate dysfunctions. This pathophysiology may be difficult to model using selective, experimental manipulations.

Despite these limitations, important information regarding the pathophysiology of schizophrenia has been developed in animals via two parallel courses of investigation. First, researchers have examined the neurobiological consequences of perturbations that are thought to *evoke* psychotic reactions in otherwise normal humans or to provoke symptoms in schizophrenia patients. As will be discussed below, a variety of approaches have been employed in an attempt to induce schizophrenialike behavior in animals, and despite the disparateness of some of these approaches, it is hoped that understanding what common, vulnerable brain systems are affected by all these psychosis-

producing conditions will result in greater insights regarding the pathophysiology of the idiopathic disorder.

Second, analyses of the mechanisms of action of therapeutically antipsychotic drugs in animals have contributed to conceptual hypotheses regarding the neurochemical and structural bases of schizophrenia. The hypothesis here is that the brain substrates targeted by antipsychotic drugs are the systems that are primarily dysfunctional in the diseased condition. Ultimately, these two approaches (studies of pro- and antipsychotic manipulations) may be successfully combined to more fully examine mechanisms underlying effective treatment of the dysfunctional brain [1].

In this chapter we will focus on animal models designed to evoke schizophrenia-like phenotypes. For descriptions of models designed primarily to predict the effects of antipsychotic drugs, the reader is referred to other reviews [2,3]. The use of psychotomimetic drugs (agents that provoke psychotic reactions), neurodevelopmental insults, and genetic manipulations will be reviewed. Ultimately, we will try to go beyond simple description of multiple models and provide some insight into the brain systems that are affected by each of these manipulations. In the end, we expect that understanding the areas of overlap among otherwise etiologically diverse animal models will contribute to understanding the pathophysiology of idiopathic psychotic disorders.

II. WHAT PSYCHOPATHOLOGY SHOULD AN ANIMAL MODEL OF PSYCHOSIS REFLECT?

Schizophrenia is a psychiatric disease that probably involves pathological function in many brain areas and systems (Table 1) [4–8], and the complexity of the syndromatic spectrum reflects that pervasiveness. Nevertheless, for simplicity, the symptoms of schizophrenia have been subdivided into three functional categories: positive, negative, and cognitive symptoms (Fig. 1) [9]. These categories are not arbitrary but are meant to classify symptoms into relational groups. Positive symptoms include motor stereotypy, formal thought disorder, delusions, and hallucinations (psychopathology that otherwise does not appear in normal individuals). Negative symptoms include normative functions that are lost in the disorder, e.g., avolition and flattened affect. In addition, neurocognitive dysfunction is likely to be at the core of the schizophrenic disease process [10,11], and cognitive

symptoms include dysfunction of working memory and alterations of attention and executive function. Other symptoms are more difficult to definitively categorize; impaired latent and prepulse inhibition may reflect deficits of attention, stimulus filtering, and motivation, while impairments of social function may reflect subtle cognitive loss as well as decreased desire to engage the social network. The particular symptoms and features of psychotic disorders exhibited in Figure 1 have been provided as examples because they are ones that have been investigated in animal models most fully, and this is discussed in some detail below. Again, these diverse impairments probably point to dysfunction of multiple brain structures and circuits, including (but not limited to) the frontal and temporal cortices and the basal ganglia (Fig. 1, Table 1).

III. DRUG-INDUCED MODELS OF PSYCHOSIS

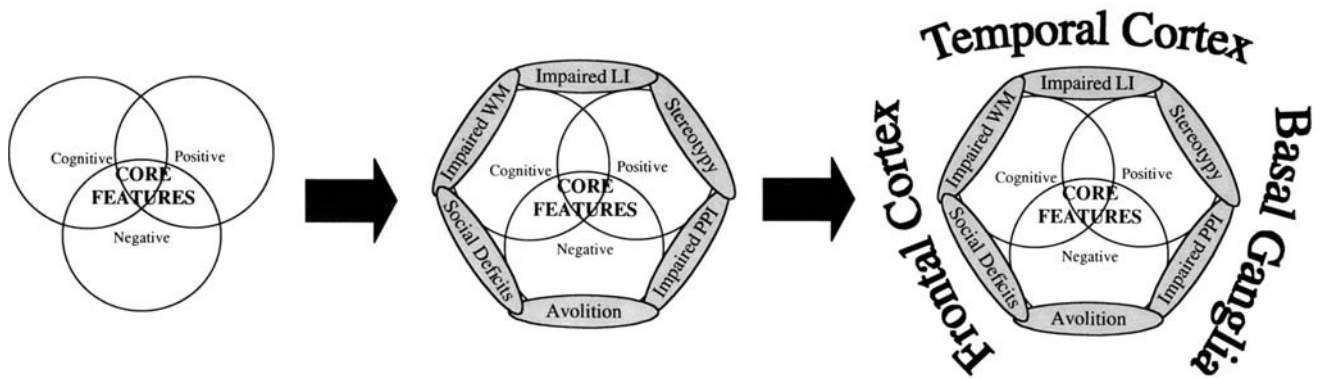
Certain classes of drugs, including stimulants such as d-amphetamine, serotonin receptor agonists, and noncompetitive N-methyl-D-aspartate (NMDA)/glutamate receptor antagonists, provoke psychoticlike reactions in otherwise normal humans or schizophrenia patients. Though a variety of pharmacological classes of compounds are able to elicit psychotomimetic reactions, the effects of different agents have been interpreted to provide evidence for alterations of different neurotransmitter systems in schizophrenia. d-Amphetamine, which strongly increases the release of dopamine and other monoamines in brain, can induce transient psychotic states in normal humans that strongly resemble the positive symptoms of schizophrenia [12], and these results were interpreted to suggest that a hyperdopaminergic state may underlie some components of the schizophrenic disease process. In addition, most serotonin type-2 ($5HT_2$) receptor agonists, including lysergic acid diethylamide (LSD) and mescaline, produce hallucinations in human beings [13], providing support for a serotonergic component to schizophrenia. Finally, noncompetitive NMDA/glutamate receptor antagonists, such as phencyclidine and ketamine, can evoke the positive, negative, and cognitive components of schizophrenia in normal humans, evidence for hypoglutamatergic function in psychosis [14–16]. For each of these agents, their psychotomimetic effects were first observed in humans; however, animal studies quickly followed. The animal studies were supported by two primary expectations: (1) that the agents would induce repre-


Figure 1 The psychopathology of schizophrenia can be categorized roughly into positive, negative, and cognitive subsyndromes. These groupings are not exclusive, and many symptoms can be considered to fall within more than one grouping. Nevertheless, a variety of behaviors including stereotypy, impaired prepulse inhibition (PPI), avolition, deficits of social function, impaired working memory, and latent inhibition are key to the disorder and can be modeled with some success in animals. These impairments map onto dysfunction of corticostriatal circuits originating in the frontal and temporal cortices and having outputs via the basal ganglia.

Table 1 Variables Currently or Potentially Useful for Assessng Isomorphism of Animal Models with Schizophrenia

Type of evidence	Specific dependent variables	Change in schizophrenia	Refs
Neuropsychological	Working memory tasks	Deficits	69
	Reversal learning	Retarded	70
	Perseverative responding	Increased	70
	Latent inhibition	Impaired	30
	Attention tasks	Impaired	10
Sensorimotor gating:	Prepulse inhibition	Decreased	24
Neurological:	Spontaneous oral dyskinesias	Increased in patients with frontal lobe pathology	90 111
Brain Morphometric:	Brain volume	Normal or decreased	86
	Cerebral cortical size	Normal or decreased	
	Hippocampal/parahippocampal size	More markedly and reliably decreased	
	Medial frontal cortical size	Slightly decreased	
Cellular:	Cerebral cortical neuronal density/ neurophil	Increased/decreased in multiple regions	129
	Cerebral cortical neuronal:		
	size	Decreased	130
	shape	Altered	
	distribution	Altered	
	Number of neurons in thalamus	Decreased anterior, limbic-related thalamus	131
	Expression of genes related to synaptic transmission and plasticity	Decreased in prefrontal and parahippocampal cortices, but also in other cortical regions	132,133

sentative psychopathology that would model key characteristics of the idiopathic disease. and (2) that subsequent, systematic neurobiological studies would reveal the causes for these behavioral abnormalities, and thus indirectly, for the human illness.

A. *d*-Amphetamine

A variety of psychomotor stimulant drugs, including *d*-amphetamine and cocaine, can induce psychotomimetic responses in humans, particularly after high dose or repeated administrations [17]. Progressive augmentations in the behavioral and neurochemical effects of stimulant drugs (termed "sensitization") have been argued to serve as a basis for the induction of psychopathology [17–19], though repeated treatments are not necessary for amphetamine-induced psychosis [12].

Amphetamine produces a number of behavioral abnormalities in animals that are thought to be relevant to schizophrenia. These include motor stereotypies, disruption of latent and prepulse inhibition and abnormalities of social interactions. As described above (Sect. II), these are principal components of the schizophrenia syndrome, and the validity of an animal model of psychosis is dependent upon reflecting some or all of these symptoms.

Motor stereotypy is the perseverative repetition of motor behaviors, particularly those that are very short and/or that require no external feedback [20]. One of the most classically studied effects of amphetamine is the induction of multiple forms of stereotypy [20–25], and the attenuation of amphetamine-induced stereotypy is a common effect of antipsychotic drugs [e.g., 25,26], many of which act as dopamine receptor antagonists [27].

Other behavioral effects of amphetamine may represent more complex forms of psychopathology. Latent inhibition describes a process wherein repeated, noncontingent exposures to a neutral stimulus retard the ability of subjects to subsequently learn a Pavlovian relationship between that stimulus and a contingently paired reinforcer. Schizophrenia patients have been reported to exhibit abnormal latent inhibition in that noncontingent preexposure to the neutral stimulus does not affect subsequent conditioning in psychotic individuals [28, but see 29]. This possible impairment is thought to implicate deficits of selective attention during the noncontingent preexposure period. Amphetamine administration to animals produces impairments of latent inhibition, and these effects are blocked by coadministration of either typical or atypical antipsychotic drugs [reviewed in 30].

Another paradigm that involves attentive processes, as well as subattentional components, is prepulse inhibition [24,31–33]. This measure of sensorimotor gating in humans and animals is assessed in a paradigm in which the delivery of a stimulus that normally causes startle in animals or humans (an air puff or very loud sound) is preceded by a neutral stimulus. In normal subjects, the delivery of the neutral stimulus gates or attenuates the subsequent startle reflex. In contrast, schizophrenia patients exhibit a reduced attenuation of the startle response with the presentation of the neutral "warning" stimulus. The face validity of the prepulse inhibition paradigm for modeling schizophrenic sensorimotor-gating deficits has been well established [24]. Amphetamine administration dose-dependently reduces prepulse inhibition of the startle reflex in rats [34], and both atypical and typical antipsychotic drugs block the amphetamine-induced impairment of prepulse inhibition [32].

Amphetamine produces behavioral abnormalities in socially living nonhuman primates and rodents [35–37]. These drug-induced behavioral alterations are characterized by stereotypy/hyperreactivity together with social withdrawal and anxious responses to social interactions, a behavioral profile similar to that observed in many patients suffering from schizophrenia. The amphetamine-induced changes in social behavior have thus been argued to model some processes relevant to schizophrenia, and to constitute an animal model with face validity for schizophrenia that encompasses both positive (e.g., stereotypy) and negative (e.g., social withdrawal) symptoms. In addition, pharmacological experiments using known antipsychotics have suggested that this model also have some degree of predictive validity [37]. However, it is not clear that social functions in rats and humans bear any relationship to one another (in terms of either the form of the behavior or the motivation to engage in such interactions). Moreover, there is strong evidence that social impairments in schizophrenia may be secondary, for instance, to cognitive dysfunction. Thus, the "face validity" of amphetamine-induced disruptions of social behavior may be misleading.

Above, the evidence that amphetamine administration can produce a spectrum of behavioral abnormalities in animals that are thought to model components of schizophrenia symptomatology was reviewed. The face validity of some of these behavioral effects is supplemented by the modulation of these responses by antipsychotic drugs (predictive validity). However, there are also several key limitations to this model. Perhaps most importantly, amphetamine has variable

effects on cognitive functions. At low to moderate doses, amphetamine improves cognition in schizophrenia [38] while exacerbating psychotic symptoms [39]. Therefore, the amphetamine model of psychosis may not provide good insights into the neurocognitive component of schizophrenia.

Morever, the equivalent effects of typical and atypical antipsychotic drugs on amphetamine-induced behaviors have led many to assume that the amphetamine model may not be particularly useful in terms of predicting the unique qualities that are essential in next-generation antipsychotic drugs. Other pharmacological models, including those discussed below, may be more useful in that regard.

B. Serotonin 5HT$_2$ Agonists

Certain 5HT$_2$ receptor agonists (e.g., LSD and mescaline) produce hallucinogenic effects in human subjects [13]; these drug-induced consequences have inspired researchers to use these substances to examine neural mechanisms relevant to psychosis and schizophrenia. These experiments are supported by observations demonstrating 5HT neurotransmission abnormalities in schizophrenic patients [40], as well as evidence indicating that actions at brain 5HT$_2$ receptors contribute to the clinical efficacy of atypical antipsychotic drugs [41]. Although the psychoactive effects produced by 5HT$_2$ agonists in humans in some respects are similar to the symptoms of schizophrenia, there are also important differences. For example, the 5HT$_2$ receptor agonists primarily produce visual hallucinations whereas auditory hallucinations dominate in schizophrenic individuals. Although such differences may limit the usefulness of this animal model for studying schizophrenia, it has been stressed that the use of 5HT$_2$ agonists could yield important information about specific components of the schizophrenia syndrome [24].

One such line of investigation is in the study of prepulse inhibition. As discussed above, schizophrenia patients exhibit disruptions of sensorimotor gating [33], and treatment of experimental animals with hallucinogenic drugs can reproduce this impairment [42]. New research utilizing transgenic murine models has begun to implicate particular serotonin receptor subtypes that contribute to normative prepulse inhibition [43]. Future investigations utilizing these techniques may yield insights into either pathophysiology of schizophrenia or the receptors critical to antipsychotic efficacy.

C. N-Methyl-D-Aspartate/Glutamate Receptor Antagonists

Nearly forty years ago, it was first reported that acute administration of the noncompetitive NMDA-sensitive glutamate receptor antagonist phencyclidine to normal humans induced a psychopathology with "impressive similarity (to) . . . certain primary symptoms of the schizophrenic process" [44]. In addition, acute phencyclidine treatment exacerbates the primary symptoms of chronic schizophrenia patients [45]. The pharmacological specificity of these effects is supported by the observations that ketamine, which, like phencyclidine noncompetitively blocks NMDA receptors, also simulates schizophrenic psychopathology in normal humans [46] and exacerbates symptoms in schizophrenic patients [47].

Phencyclidine is distinguishable from both *d*-amphetamine-like stimulant drugs and serotonin receptor agonists in that it can produce both positive and "negative" or deficit state symptoms of schizophrenia, such as emotional lability and social withdrawal [14,15]. In addition, phencyclidine/ketamine administration can lead to substantial cognitive dysfunction [14,15,44], including impaired performance of the Wisconsin Card Sort Test and continuous performance vigilance tasks and deficits in delayed recall, free recall, recognition memory, and verbal fluency [46].

Many attempts have been made to draw parallels between the behaviors exhibited by phencyclidine-treated animals and schizophrenia symptomatology [see 24,15]. The quantified behaviors examined occur within several different domains, including locomotor behavior, sensorimotor gating, latent inhibition, social interactions, and cognitive functions. As mentioned previously, each of these behavioral domains has proved useful to investigating the neural circuitry underlying both psychotomimetic and antipsychotic drug responses.

The ability of phencyclidine, or its congeners, to stimulate locomotor behavior and induce motor stereotypy in animals has been evaluated as a model of some components of schizophrenia psychopathology [48–50]. It is not clear that locomotor behavior in rats bears any relationship to schizophrenic symptomatology; however, dysfunction within corticostriatal circuitry, which may be manifest as locomotor abnormalities in rodents, has been postulated to be a critical pathophysiological substrate of the disease [4,8,51]. Moreover, the modification of phencyclidine-induced locomotion and motor stereotypy by drugs is one classical assay for putative antipsychotic efficacy

because these effects are differentially sensitive to atypical versus typical antipsychotic drugs (e.g., clozapine is more potent than haloperidol in terms of preventing phencyclidine-induced hyperlocomotion in rodents) [48,52].

Similarly to amphetamine or serotonin receptor agonists, phencyclidine administration disrupts prepulse inhibition in rats [31]. The face validity of the phencyclidine-induced impairment of sensorimotor gating is strengthened by the manifestation of similar deficits by patients suffering from idiopathic schizophrenia [32,33]. Though stimulant drugs and serotonin receptor agonists likewise disrupt prepulse inhibition of the startle reflex (see above), it is argued that unlike amphetamine-induced alterations of prepulse inhibition, the effects of phencyclidine on startle gating are differentially affected by typical, atypical, and putative antipsychotic drugs [53]. For this reason, phencyclidine-induced disruption of prepulse inhibition may represent an important measure of the therapeutic efficacy of new-generation antipsychotic drugs.

Phencyclidine administration reduces social interactions in rats, and as discussed above, this impairment is thought to model the alterations of social interactions exhibited by schizophrenia patients [49]. In addition to the "face validity" of these effects, the social deficits produced by phencyclidine are amenable to treatment with atypical antipsychotic drugs [54]. However, as discussed above, construct validity for this sort of model is far from assured.

Attempts to study cognitive functions in phencyclidine-treated animals may yield the more informative results for several reasons. The performance of cognitive tasks by animals and patients may depend on similar neural and psychological constructs, and the validity of the particular tasks employed cross-species may be directly assessed. In addition, schizophrenia has been described by some as a fundamentally neurocognitive disorder [10,11], and therefore, the examination of cognitive processes in animals may tap more directly into the core features of the disorder.

Administration of phencyclidine, ketamine, or MK-801 (another noncompetitive NMDA receptor antagonist) to rats produces performance impairments on a variety of tests of learning and memory, including passive avoidance, acquisition of the Morris water maze task or a conditional discrimination, tests of spatial working memory and performance of a spatial continuous-recognition memory task [reviewed in 15,55]. However, administration of noncompetitive NMDA receptor antagonists impairs even simple behavioral measures, evidence for impairments of simple sensory

processes and associative learning [15,55]. For this reason, the specificity of "cognitive" deficits in animals acutely treated with phencyclidine/ketamine/MK-801 is questionable.

The effects of chronic, rather than single-dose, exposure to phencyclidine may better represent some facets of schizophrenia. Though both regimens can induce psychosis, thought disorder, delusions, flattened affect, and withdrawal, with the effects of chronic exposure being generally more persistent [44,56,57], there are qualitative differences between the effects of these two dosing regimens. Acute ketamine administration to humans produces delusions and hallucinations, typically within the visual domain [46], similar to LSD intoxication [13] but not schizophrenia [24]. More consistent with symptoms observed in schizophrenia patients, phencyclidine-abusing humans present with religious and paranoid delusions and auditory hallucinations [56,57]. These findings provide support for the argument that long-term phencyclidine abuse is associated with a psychopathology that is remarkably similar to schizophrenia and which may be more isomorphic to the chronic symptoms of schizophrenia (e.g., cognitive and negative symptoms) than those induced by acute phencyclidine exposure.

Long-term phencyclidine treatment may also closely model the cerebral metabolic dysfunction of schizophrenia. Chronic phencyclidine intake by humans has been associated with reduced frontal lobe blood flow and glucose utilization [58,59], a finding consistent with the observation that some components of the cognitive dysfunction of schizophrenia is associated with reduced frontal blood flow, so-called hypofrontality [60]. By contrast, acute ketamine administration markedly increases frontal blood flow [61]. Therefore, there are biological indices that suggest chronic, rather than acute, phencyclidine administration may be a superior model of schizophrenia.

Though less explored, there are a number of behavioral impairments that appear to be as a persistent/long-lasting consequence of single or repeated doses of phencyclidine. These behavioral effects are likely not to be complicated by the "acute" effects of phencyclidine intoxication, and may therefore be more selective and hence relevant to schizophrenia. Augmentations of the locomotor response to stress or d-amphetamine is a persistent consequence of single-dose or chronic phencyclidine administration [62,63], and subchronic ketamine administration leads to greater apomorphine-induced stereotypy [64]. Impaired social interactions have also been reported in rats after cessation of repeated phencyclidine administrations [54,65].

Finally, impaired latent inhibition, but not prepulse inhibition, has been reported to be a long-term consequence of phencyclidine exposure [66,67]. These long-term behavioral effects of phencyclidine exposure may be indicative of corticostriatal dysfunction relevant to schizophrenia.

The cognitive effects of long-term phencyclidine treatment in rats and monkeys have also been investigated. Long-term phencyclidine administration delay-dependently impairs performance of a variable-delay spatial T-maze alternation task (a test of spatial working memory) [68], and these impairments are similar to those observed in schizophrenia patients using analogous tasks [69]. Pronounced deficits of reversal learning (a measure of cognitive control over reward-related behavior) have also been reported in schizophrenia [70] and in rats after repeated phencyclidine treatments [71]. Finally, prolonged administration of phencyclidine to monkeys produces cognitive dysfunction [72], effects that are associated with altered corticostriatal dopaminergic function [73]. Though this is a developing line of investigation, the results suggest that prolonged treatment with phencyclidine produces a pattern of neuroadaptive changes that may ultimately produce behavioral impairments with superior similarity to the primary psychopathology of schizophrenia.

An additional issue pertains the predictive validity of any of these effects. As noted above, many of the "acute" behavioral effects resulting from phencyclidine administration are differentially sensitive to atypical versus typical antipsychotic drugs, and for this reason, the phencyclidine model is hoped to be a mechanism for predicting the efficacy of next-generation antipsychotic drugs with superior therapeutic effects. Recent studies of the cognitive consequences of long-term phencyclidine administration also bear out these differences. For example, the enduring deficits of cognitive control over motor behavior produced by phencyclidine administration to monkeys is attenuated by systemic administration of the atypical antipsychotic clozapine but not the classical neuroleptic haloperidol [72,74]. Similar effects have been observed in rats [75].

The degree to which phencyclidine administration to animals may model the primary symptoms of schizophrenia undoubtedly requires further exploration, and it is likely that both acute intoxication with and chronic administration of phencyclidine will provide important insights into the pathophysiology of psychotic disorders. Much new research has begun to focus on the neural mechanisms that are enduringly affected by phencyclidine exposure [15,76,77], and insights from these studies may ultimately be integrated with observations of clinical pathophysiology in the idiopathic disease.

D. Common Mechanisms Among Pharmacological Models?

What can pharmacological models tell us about the pathophysiology underlying schizophrenia if otherwise pharmacologically diverse compounds produce similar behavioral effects? Do these drug effects indicate that NMDA/glutamatergic, dopaminergic, and serotonergic systems are all dysfunctional in schizophrenia? Or do they indicate that the subtle (and difficult to measure) interactions between these systems, at the neurochemical and physiological levels, are impaired? These questions are made even more challenging when one considers that several other classes of drugs also exhibit psychotomimetic effects, including cannabinoid receptor agonists [78], antidepressant drugs [79], and antiparkinsonian agents [80].

Otherwise different pharmacological classes of psychotomimetic drugs may share among themselves common downstream alterations of corticostriatal circuitry. In the most simplistic sense, almost all psychotomimetic drugs either directly or indirectly affect frontal and temporal cortical and/or striatal metabolic activity [81,82], as well as the impulse-dependent or -independent release of neuromodulatory transmitters within these structures [15,83]. However, the neural mechanisms that are targeted by psychotomimetic drugs are undoubtedly very complex. For example, O'Donnell and Grace [84] have provided evidence that phencyclidine acts, in part, to attenuate the drive of limbic striatal neuron activity by excitatory corticostriatal afferent inputs, and amphetamine is known to likewise reduce the excitatory influence of cortical inputs on striatal neurons [85]. Therefore, further exploration of the common actions of psychotomimetic drugs on corticostriatal functioning, determined both behaviorally and physiologically, seems warranted.

IV. DEVELOPMENTAL MANIPULATIONS AS MODELS OF SCHIZOPHRENIA

Developmental models share the strategy of using manipulations early in brain development in order to produce an adult phenotype that is isomorphic with schizophrenia in critical aspects. These models are based on growing epidemiological, behavioral, and neuroanatomical evidence for abnormal brain,
Figure 2 Schematic representation of the spectra of psychopathology reflected by three principal pharmacological models of schizophrenia. Each model mimics components of psychotic disorders, yet the phencyclidine model is considerably more comprehensive in terms of mimicking the negative, positive, and cognitive components of idiopathic schizophrenia. Dark gray ovals represent symptoms that are successfully modeled by the drug, with white ovals indicating areas in which the models do not accurately represent schizophrenia. Intermediate shades indicate no data or insufficient studies.

especially cerebral cortical, development in a large number of schizophrenia patients. This evidence includes ventricular enlargement and reduced cerebral, especially parahippocampal, volume occurring in the absence of gliosis. The cytoarchitectural abnormalities in cerebral cortex are also consistent with abnormal neuronal differentiation and migration and/or genesis or maintenance of synapses [86,87]. There is also evidence for subtle neurological, neuropsychological, or craniofacial abnormalities in children who later develop schizophrenia, and a significant association of obstetric complications or perinatal stress with severity or age of onset of schizophrenia [88–90]. Importantly, of the hundreds of research findings in schizophrenia, many are difficult to replicate or appear to have a elatively weak association with the risk for the disease. However, hypotheses proposing an early disruption of brain development that initiates a process that retards the development of limbic and prefrontal cortices and/or renders them significantly more vulner-

able to environmental stressors most successfully accounts for the plethora of findings and the variance among them.

Thus, whereas as pharmacological models in adult animals model key aspects of the fully manifested behavioral (and, where information is available, neurochemical) phenotypes within schizophrenia, developmental models emphasize other aims, roughly falling into three categories. The first is to make a developmental manipulation, usually directed at limbic forebrain regions, that will model the age of onset of the behaviors and neurochemical changes believed to be closely related to the "positive" symptoms. Another aim is to model a developmental process that leads to the neuroanatomical abnormalities evidenced in the brains of schizophrenia patients. The third, perhaps ultimate, aim is to also model a pathodevelopmental process that, while leading to marked dysfunction prefrontal cortex, limbic-related cortex, and subcortical and cortical dopamine systems in the

adult, also leads to the anatomical and neurochemical phenomena that are isomorphic with schizophrenia. To assess the usefulness of these models in understanding schizophrenia, an array of dependent variables have been measured. These variables, shown in Table 1, are considered to be isomorphic with brain and behavioral indices that are altered in schizophrenia. In this section, we describe a number of different experimental methods used to disrupt brain development and evaluate how they address the general aims described above. Genetic manipulations designed to specifically affect cortical development will be included here, while those based on the role of the gene in the mature brain will be covered in the *Genetic Models* section, below.

A. Early Limbic Lesion Models

The use of neonatal lesions of limbic structures to model schizophrenia was pioneered by Lipska and Weinberger [87,91]. The effects of excitotoxic lesions of the ventral hippocampus (VH) on postnatal day 7 in the rat have been most carefully characterized and extensively reviewed. Lesioned rats are tested before puberty (PD 32) and in adulthood (after PD 56). Around PD 32, lesioned rats show few small behavioral differences from controls when psychostimulant or stress-evoked locomotion or prepulse inhibition is assessed. However on or after PD 56, neonatal VH-lesioned rats show increased psychomotor activity evoked by indirect and direct dopamine agonists and psychotomimetic NMDA receptor antagonists, as well as exaggerated effects of these drugs on PPI (relative to control littermates). The hippocampus is largely absent in adult rats having received neonatal lesions; however, lesions of the hippocampus in adulthood do not reproduce the same effects. This has led to the hypothesis that neonatal VH lesions produce consequent dysregulated development of other forebrain structures, most probably the prefrontal cortex [91].

This hypothesis is supported by various findings [91]. Firstly, neonatal VH lesions result in altered N-acetylasparate levels (a measure of neuronal integrity) in prefrontal cortex (similar effects are found in schizophrenia patients). Moreover, subtle alterations of dendritic morphology of prefrontal cortical neurons results from VH lesions; these effects are very similar to that found in schizophrenia. The hypothesis that the alteration of prefrontal cortex is tangibly manifest in the abnormal behaviors exhibited by these rats is supported by the observation that destruction of the prefrontal cortex in adulthood reverses many of the abnormal behaviors produced by neonatal VH lesions. Thus, although a near-complete lesion of the hippocampus is clearly not present in schizophrenia patients, nearly all of the known effects of neonatal hippocampal lesions in rats and primates appear to be highly relevant for the psychopathology of schizophrenia and may be mediated by abnormal prefrontal cortical development and function.

Other early limbic lesions have also been shown to lead to abnormalities in prefrontal structure and function and DA system activity. For example, electrolytic or excitotoxic lesions of the amygdala 2–7 days after birth also increase locomotor sensitivity to DA agonists and produce morphometric changes in the temporal and frontal lobes that are to some extent consistent with morphometric abnormalities in schizophrenia patients [92,93]. Another technique, infusion of a low dose of kainic acid into the ventricles of rats on PD 7, produces a delayed, relatively subtle cell loss in the dorsal hippocampus [94]. However, loss of cortical neurons is not a consistent finding in schizophrenia. It remains to be determined whether intraventricular infusions of kainic acid or amygdala lesion models will show the range of effects observed in neonatal VH lesion model. Though intriguing, it remains to be tested if these other limbic lesion models can model as many aspects of schizophrenia as the Lipska-Weinberger model.

The effects of early developmental limbic lesions have also been characterized in primate by Bachevalier and colleagues [95]. Monkeys with early hippocampal and/or amygdalar lesions display a progression of abnormality in social behaviors that have face validity with the social withdrawal that precedes and progresses through the onset of psychosis in schizophrenia [95]. Neonatal limbic-lesioned monkeys also show decreases in NAA in the prefrontal cortex and altered prefrontal cortical regulation of mesostriatal dopamine [96], findings that are isomorphorphic with the neurochemical phenotype of schizophrenia (Table 1) [97]. However, these monkeys also display cognitive deficits that are not prominent in schizophrenia, resembling hippocampally rather than prefrontally mediated neuropsychological deficits [98]. Taken together, however, all of these models support the notion that early developmental lesions of limbic cortex or amygdala lead to abnormalities in behaviors normally regulated by the prefrontal cortex, limbic cortex, or mesolimbic dopamine in the adult. Moreover, some of these deficits appear to be isomorphic or consistent with behavioral phenotypes in schizophrenia.

B. Perinatal Distress Models

Given the small but significant association with early-life "psychological" stressors and later expression of schizotypal symptoms [88], a number of studies have examined the effect of perinatal or neonatal stress in rats on brain systems implicated in schizophrenia. Repeated stress and nutritional deprivation [99,100] of the dam during gestation have each been shown to lead to delayed and persistent changes in hippocampal neuron morphology and catecholamine systems in the offspring. Similarly, 24-hr isolation of pups at PD 3, 6, or 9 leads to deficits in PPI and enhanced apomorphine-induced motor stereotypy in the adult rat, indicating delayed changes in hippocampal and mesolimbic dopamine circuits [37,101]. Moreover, although the effects of maternal separation on the behavioral response to psychostimulants appear to be inconsistent, these rats show increased amphetamine-evoked striatal DA efflux as adults [102]. Whereas neonatal maternal separation imposes substantial *physiological* stress on rats, social isolation of weanlings is arguably a more *psychological* stressor. This stressor also leads to persistent deficits in prepulse inhibition and amphetamine-evoked striatal dopamine efflux, but has no effect on latent inhibition [103]. Taken together, studies of gestational or early postnatal stressors indicate that striatal dopamine systems are exquisitely sensitive to early-life stressors.

C. Developmental Viral Infections or Evoked Immune Responses

As with early-life stressors, there is a small but significant association between viral infection during gestation and the risk for schizophrenia [88]. Thus, researchers have investigated the effects of perinatal infection or maternal immune responses on brain development and behavior of the offspring. These models are not as widely used as other perinatal manipulations, perhaps because of the indirect relationship between schizophrenia risk and viral infection. Moreover, because of differences in rodent and human gestational periods, viruses would be expected to affect more stages of brain development in rodents than in humans. Accordingly, influenza or Borna infections in rodents cause gross morphological abnormalities in the brains of the offspring that are unlike the relatively subtle morphologic and histologic abnormalities found in brains of schizophrenia patients. Nevertheless, the available studies indicate that gestational exposure to viral infection can result in cyto-

chemical abnormalities in the cerebral cortex [104], as well as deficits in frontal lobe–mediated behaviors [105] and enhanced responsiveness to psychostimulants [106] in the adult offspring. Moreover, it has recently been shown that offspring of dams treated with polyribocytidilic acid, a compound that induces release of cytokines, show a delayed onset of latent inhibition [107]. It has been hypothesized that the cytokines released during the response to viral infection may significantly affect brain development and plasticity and, thus, may be more directly relevant to schizophrenia [108].

D. Genetic Factors

Given the evidence for developmental abnormalities, especially in limbic-related and frontal cortical regions in schizophrenia patients, genes known to regulate cortical development are considered candidates in creating animal models of schizophrenia. The possible roles of some of these genes in schizophrenia have been proposed [109,110]. One fact that may become important in focusing on particular genes in developmental models is that schizophrenia is considered to involve maldevelopment of the cerebral cortex and/or abnormal plasticity within cortical circuits in the adult. Therefore, genes known to play a role in both of these processes may be of the most relevance. Moreover, given that a subset of these genes is preferentially expressed in the cortical regions most affected in schizophrenia, the search could be narrowed further. Alternatively, given the overwhelming evidence that schizophrenia is a "polygenic" disorder, it has been proposed that genes that regulate processes such as methylation which, in turn, regulate multiple chromosomal sites and, thus, multiple genes, may be highly relevant [111]. This argument would be especially important if manipulation of such genes is shown to have a relatively greater impact on development and plasticity of limbic-related and frontal cortices. An example of a genetic model that achieves a subset of the aims described above is genetic manipulation of *reelin*, a protein involved in neuronal migration that is localized in the dendritic spines of mature. *Reelin* is decreased in schizophrenia [112]. Furthermore, mutations of the genes regulating *reelin* expression or function result in decreases in size of the hippocampus and cytoarchitectural changes, mainly neuronal disorganization. However, mutation of *reelin*-related genes also results in marked deformation of the hippocampus, cerebellum, thalamus, and brainstem [113], unlike the subtle structural changes in schizophrenia. More generally, in fact, knockouts of many of the "candi-

date" genes described above, when not fatal, result in severe brain deformation and/or mental retardation [e.g., 114]. Thus, genetic strategies that are more temporally and anatomically selective than knockouts are likely to be necessary to achieve valid models of schizophrenic phenotypes.

E. Epigenetic Manipulations That Alter the DNA of Developing Neurons

A key issue in animal models of schizophrenia is to be able to understand how a unitary etiological process can produce diffuse histopathological and variable morphological changes in the cerebral cortex coexisting with relatively localized and severe dysfunction of limbic and paralimbic cortical circuits. A recent model employing the neuronal DNA-methylating agent methylazoxymethanol acetate (MAM) addresses this issue [111]. In this model, MAM is administered to pregnant Fischer 344 rats on gestation day (GD) 17, a period during which neuronal proliferation is continuing in limbic-related cortical regions, slowing in other cortical regions, and paused or completed in most other brain regions. Similar to other developmental models the offspring of dams treated with MAM on GD17 show a delayed onset of an enhanced locomotor response to amphetamine [111], indicative of increased amphetamine-evoked DA release in striatum. MAM GD17 offspring also show abnormal spontaneous and drug-induced orofacial behaviors, and deficits in reversal learning and PPI, indicating dysfunction of medial prefrontal cortical, hippocampal/parahippocampal and related dopaminergic circuits (see Table 1).

Single-cell recording in the PFC, ventral striatum, and ventral tegmental area have revealed marked alterations in neurophysiological activity regulated by the limbic or paralimbic afferents to these neurons. Importantly, however, these relatively prominent functional abnormalities occur in the presence of small to moderate reductions in cross-sectional thickness and increases in neuronal density in the cerebral cortex, especially limbic-related regions. Moreover, while medial limbic thalamic regions were also reduced in size, the sizes of nonlimbic thalamus and anterior cerebellum are not affected. Thus, the pattern of anatomical, neurophysiological, and behavioral abnormalities resulting from the disruption of neuronal DNA methylation on GD 17 in the rat is isomorphic with schizophrenia in several critical aspects and may model the pathophysiology subserving a core set of behavioral abnormalities in this disorder.

The effects of MAM administration at earlier time points also appear to be relevant to schizophrenia. Administration of MAM at GD 12–15 affects the fetal brain during the neurogenesis of the majority of neurons destined for the forebrain, including basal ganglia and thalamus, thus producing less selective and more severe hypoplasia than MAM exposure at GD 17 [111]. However, there are some characteristics shared by offspring of dams treated with MAM at GD 12, 15, or 17 that are highly relevant to schizophrenia, including a greater reduction in the size of hippocampal or parahippocampal regions, relative to other cortical regions [115] and behavioral abnormalities such as increased responsiveness to amphetamine [111] and PPI deficits [116]. Thus, the effects of exposure to MAM at one of several points of rat gestation indicate that disruption of DNA methylation can disrupt cortical development, but that limbic cortex is the most affected morphologically. Other methods of disrupting DNA structure, such as radiation exposure, can have similar effects when timed appropriately [115]. Moreover, irradiation can be used in primates to affect DNA structure during specific stages of brain development, in order to produce primate models of thalamic or cortical maldevelopment [117].

In summary, as with nearly all other developmental models, this disruption of DNA methylation or structure results in prefrontal cortical and limbic cortical dysfunction, as well as abnormal cortical regulation of forebrain DA systems in the adult. Importantly, the MAM GD 17 model shows that a pathodevelopmental process can produce these functional abnormalities while causing relatively subtle anatomical abnormalities similar to those observed in the brains of schizophrenia patients.

F. Implications

There is considerable evidence to support the hypothesis that the etiology of schizophrenia begins early in brain development. Developmental models have revealed common etiologic pathways for some of the key neuroanatomical, neurochemical, and behavioral abnormalities observed in schizophrenia. Moreover, there is converging evidence from these models that normal development of limbic cortex is critical to the normal development of the prefrontal cortex and cortical regulation of dopamine transmission. Other commonalities among the models support the notion that the limbic-related cortical neurons are significantly more vulnerable to developmental disruptions than neurons in other cortical regions. This may relate to

unique patterns of gene expression in limbic-related regions, or may relate more generally to the stability of expressed regions of the chromosome in these neurons. The findings generated from developmental models do not disprove a degenerative component to the etiology of schizophrenia or negate the possibility that chronic drug administration can induce changes in cortical circuits similar to those resulting from abnormal development. Moreover, the effects of epigenetic manipulations used in these models are not inconsistent with the evidence that the majority of the risk for schizophrenia is inherited.

V.   GENETIC MODELS OF SCHIZOPHRENIA

As discussed in the previous section, considerable evidence suggests that schizophrenia depends on a relatively large heritable component [118–121]. Despite this, very little progress has been made in determining candidate polymorphisms or mutations that have a significant load factor associated with them; therefore, it seems likely that schizophrenia is a polygenic disorder that significantly interacts with nongenomic factors [120].

With the advent of transgenic technologies, it is increasingly possible to induce specific genomic effects in animals and to subsequently evaluate the validity of the line as a putative model of psychosis, or other psychiatric disorders [122]. Genetic models have been chiefly targeted toward neurotransmitter systems widely theorized to subserve the behavioral phenotypes within schizophrenia (e.g., alpha 7 nicotinic acetylcholine receptor and sensory gating; catechol-O-methyl transferase [COMT] and working memory) or be involved with neural systems thought to be abnormal in schizophrenia (e.g., dopamine system manipulations, NMDA receptors). Moreover, some experimental genetic manipulations have additional construct validity, given the fact that the targeted gene is located in chromosomal regions that are significantly linked with increased risk for schizophrenia. For example, the alpha 7 nicotinic receptor and COMT protein are located on chromosomes 15 and 22q, respectively, at loci known to be linked with increased risk for schizophrenia [119–121].

The gene for the alpha 7 subunit of the nicotinic cholinergic receptor has been the subject of intense study, since it has been revealed that the expression of this subunit is strongly associated with suppression of the P50 component of a sensory-evoked EEG potential. The decrease in P50 is a phenotype reliably observed schizophrenia patients and their relatives [123]. Freedman and coworkers have selectively bred mice with sensory gating deficits and have found this phenotype to be significantly associated with abnormal nicotinic receptor binding in the hippocampus [124]. Moreover, in the same mouse strains, the deficits can be rescued by selective alpha 7 nicotinic receptor agonists [125].

Based on the observation that there may be hypoglutamatergic function in schizophrenia [14,16,126], Mohn et al. [127] explored the behavioral consequences of knockdown of NR1, an obligatory subunit of the N-methyl-D-asparate/glutamate receptor, in mice. Mice expressing only 5% of normal levels of NR1 display behavioral abnormalities, including increased motor activity and stereotypy and deficits in social and sexual interactions. The responsiveness of the phenotype to administration of the antipsychotic drug clozapine further evidences the usefulness of transgenic models of this type.

In fact, schizophrenia and other disorders characterized by psychosis and pervasive attentional and executive dysfunction may be characterized by at least two sets of "genetic" abnormalities. The first set would involve genes that regulate the maturation of synaptic transmission and plasticity in cortical, especially limbic cortical, circuits. In the mature system, however, a second set of abnormally regulated genes could be associated with schizophrenia: those involved in the real-time pathophysiology underlying the psychopathology of schizophrenia. Dysregulation of the second set of genes could result from developmental pathology mediated by the first set of genes, but could also be secondary to alterations modeled, for example, by the effects of phencyclidine. Whereas prevention of schizophrenia will depend on revelation of the first set of genes and finding ways to normalize the relevant developmental processes, treatment will depend on therapeutic regulation the second set of genes.

VI.   FUTURE DIRECTIONS FOR ANIMAL MODELS OF SCHIZOPHRENIA

One advantage of having validated animal models of schizophrenia, particularly etiologically distinct models, is the ability to then test directly whether particular biological mechanisms may be realistically implicated in psychopathology. For example, quantitative trait loci are being developed for schizophrenia, and candidate genes are on the horizon [120]. Having a validated

model in hand, we can again utilize behavioral pharmacological approaches, or even transgenic techniques, to question whether the candidate(s) may be *plausibly* related to impaired function. In turn, we can use the same techniques to question whether direct manipulation of these same factors may yield antipsychotic effects.

For example, a substitution mutation in the COMT gene, which putatively results in reduced cortical catecholaminergic function because of *increased* catabolic activity, has been implicated in the neurocognitive component of schizophrenia [128]. Animals with pharmacological or transgenic manipulations of cortical COMT activity can be utilized to [1] evaluate the plausibility that alterations of enzyme activity could produce neurocognitive dysfunction, and [2] to determine the potential antipsychotic effects of directly manipulating COMT activity. This two-pronged approach depends critically on the use of validated and well-understood animal models. It is also strongly supported by the utilization of behavioral procedures in animals with strong construct validity for the symptomatology of schizophrenia.

Undoubtedly, future research will focus on the generation of new animal models and the refinement of behavioral techniques for modeling symptoms of schizophrenia. In addition, the integration of multiple models (to reflect etiological heterogeneity of idiopathic schizophrenia) may assist in the production of more comprehensive reproductions of primary symptomatology. And ultimately, as with any debilitating disease, it is hoped that animal models will generate useful information that will improve the functional outcome of patients with schizophrenia.

Affective Disorders
Imaging Studies

WARREN D. TAYLOR and RANGA R. KRISHNAN

Duke University Medical Center, Durham, North Carolina, U.S.A.

I. INTRODUCTION

The development of new imaging technology, able to more fully visualize the structure and function of specific brain regions, has enabled us to better understand the biological basis of psychiatric disorders. Specific brain regions, including the frontal lobe, the basal ganglia, and the limbic system, are all involved in the regulation of emotions, and injury to these areas can increase the risk of developing a mood disorder. Functional imaging studies demonstrate that mood disorders are associated with impairment in their normal function.

Computed tomography (CT) scans were used for earlier research, but magnetic resonance imaging (MRI) provides several advantages over CT. These higher-resolution images allow for more accurate measurement of structure volumes, which is facilitated by the MRI's ability to distinguish gray and white matter. Additionally, the MRI can discern smaller abnormalities not visible on CT. Further, this work in structural imaging is complementary to research utilizing functional imaging, which can measure regional blood flow or glucose utilization. This chapter will review this research and highlight specific brain regions implicated in mood disorders. When possible,

we will attempt to correlate these findings with clinical outcomes.

II. IMAGING STUDIES IN DEPRESSION

Structural imaging research in depression has typically focused on two types of studies: research on structural volumes, and research on the presence, severity or volume of high-intensity lesions (hyperintensities) reflecting pathology. Unlike neuroimaging research in many other psychiatric disorders, imaging research in depression has typically focused on the elderly. This may limit the generalizability of this research, as geriatric depression is often clinically different than depression in younger individuals, but it also allows us to correlate psychiatric findings with injury to specific regions.

Functional imaging studies have mostly examined younger cohorts with smaller numbers of subjects. Many research findings using these techniques appear contradictory, which emphasizes the heterogeneity of disorders that may result in a clinical diagnosis of depression. Regardless, this body of work is highly important as it documents alteration in function of specific regions.

A. Structural Imaging Studies in Depression

1. Global Brain Abnormalities and Normal Aging

Clinically, these studies also have limited utility, as there are no well-established age- and sex-specific normal values [1]. In general, whole-brain volume data are less informative than data on specific regions that distinguish between gray and white matter.

Research clearly demonstrates that the brain's volume decreases with normal aging [2–4], but atrophy may not occur at the same rate in various regions [5]. Both cortical and subcortical regions, such as the caudate, putamen, and thalamus, are affected [6,7]. There are also gender differences, as men exhibit more atrophy with normal aging than women [2,3,5]. These data emphasize the need for age- and sex-matching when performing controlled neuroimaging studies, particularly in the elderly.

The majority of studies comparing whole-brain volumes between elderly depressed subjects and controls showed no significant difference between the two groups. There was no difference between elderly subjects with late-onset depression and controls, [8–12] nor was there a difference between late- and early-onset depressed subjects [8], but these results are not universal [13]. Studies exclusively of depression in women have also demonstrated no total brain volume difference from age-matched controls [14,15]. Also, neither depression severity [9] nor age of depressive symptom onset, after controlling for the subjects' current age [4], exhibited a significant association with total brain volume.

Another persistent finding in depressed elders is increased ventricle size. Subjects with late-onset depression have increased whole-brain CSF fluid volumes, larger ventricle-to-brain ratios, [10,13,16] and larger lateral and third ventricles than controls [10,13,16,17]. These findings have been interpreted as "atrophy" in depressed subjects, but this conclusion conflicts with studies of total brain volume. As CSF is typically easier to measure, this may be a more precise estimate but is also affected by overall head size; longitudinal studies are needed.

2. Regional Brain Measurements

Frontal Lobe

The frontal lobe has long been implicated in the regulation of both emotion and executive functioning. Multiple studies have demonstrated a reduced frontal lobe volume in depressed elders compared with controls [7,18,19], and smaller frontal lobes have also been observed in familial depressed subjects [20]. Only one study found no significant difference in frontal lobe volume between late-onset depression and controls, [13] but these researchers defined late-onset as after age 50, while other studies used an older age. The cause of this reduced volume may be decreased asymmetry in the frontal lobes of depressed subjects. Kumar et al. [21] demonstrated a significant right greater than left volume asymmetry in the frontal lobe of controls and subjects with minor depression. This asymmetry decreased (by diminishing right-sided volume) with increasing depression severity. The group with major depressive disorder did not exhibit a significant difference in volumes of the two lobes.

As the frontal lobe comprises almost a third of the brain, efforts have been made to examine specific regions, particularly the prefrontal cortex (PFC). Late-onset depressed subjects have a smaller PFC volume than controls [9], with an inverse correlation between depression severity and odds ratio for acquiring major depressive disorder, and PFC volume [9,10,21]. The absolute volume of the PFC may also be smaller in subjects with psychotic depression compared with nonpsychotic depression [22]. Specific regions of the PFC have also been studied, noting a decreased volume of gray matter in the subgenual PFC in familial depressed subjects; this finding correlated with decreased blood flow by PET [23]. Depressed subjects also exhibit a decreased orbitofrontal cortex volume compared with controls in imaging studies [24], correlating with atrophy of this region found in postmortem studies [25].

Temporal Lobe

The temporal lobe exhibits no statistically significant reduction in volume when late-onset depressed subjects are compared with controls [10,13]. There are reports of small, statistically insignificant differences in temporal lobe volumes of elders when both major and minor depression are compared with controls [9,26], however, when the small effect size is coupled with the negative studies, the relevance of this observation must be questioned. Although the temporal lobe's total volume may not be associated with late-onset depression, there may be contributory regional atrophy; a comparison of elderly late-onset depressed subjects to early-onset depressed subjects showed the late-onset group had more left medial temporal atrophy [27]. Another study demonstrated

greater left sylvian fissure size and greater bilateral temporal sulcal enlargement when compared with controls [28].

Hippocampus and Amygdala

In depression research, the hippocampus has been primarily studied in two populations-women and the elderly. The studies in women intentionally excluded men to eliminate brain differences related to gender [15], and demonstrated smaller hippocampi bilaterally in women with recurrent major depressive disorder [14, 15] and smaller amygdala core nuclei volumes bilaterally [14]. These changes were not associated with age or age of depression onset, but were associated with lifetime duration of depression [14,15]. Other studies of mixed-gender cohorts found a significant 19% decrease in left hippocampal volume in depressed subjects, and a similar insignificant trend on the right hippocampus; there was no correlation with hippocampal volume and duration of depression [29].

Several investigators have hypothesized that the association between hippocampal volume loss and depression duration may be explained by episodes of hypercortisolemia during depressive episodes [15,30]. Animal studies that found the hippocampus to be sensitive to the neurotoxic effect of elevated cortisol levels [31]. One study correlated reduced hippocampal volumes with specific changes in cortisol concentration [32].

Studies in the elderly have been less conclusive. Several research groups failed to demonstrate a significant difference in the amygdala/hippocampal complex volume between late-onset depressed subjects and controls [13,18,32,33], or between late-onset compared with early-onset depressed subjects [33]. One study did find that depressed elders had significantly smaller right hippocampal volumes than controls, with a trend toward smaller left volumes [34]—a finding similar to Bremner et al.'s study in a younger population [29]. These apparently contradictory data are difficult to interpret owing to the amygdala/hippocampal complex's small size and the different techniques used to measure it; many studies measured the amygdala and hippocampus together, which could be a partial explanation of this discrepancy.

If reduced hippocampal volume is confirmed in other depressed, elderly populations, does this mean glucocorticoid toxicity is also responsible? Possibly, but that is not the only conceivable etiology, as neurodegenerative processes may also be involved. Late-onset depression can precede the onset of Alzheimer's dementia, which is itself associated with hippocampal degeneration [35]. Further research is needed to clarify this issue.

Subcortical Gray Matter Structures

Studies examining the basal ganglia's role in depression were initially driven by early observations about the increased frequency of depression seen in diseases that affect the basal ganglia, like Parkinson's disease. Smaller caudate nuclei are consistently found in late-onset depression when compared with controls [6–8] or early-onset subjects [8], although this finding may be specific to the left caudate [27]. The putamen is also smaller in late-onset depressed subjects than controls, and younger age at the first depressive episode correlated with smaller putaminal volumes [6,7]. Thalamic volumes are not different between controls and depressed subjects [6,8]. These findings are not consistent across all ages, as younger individuals may not exhibit volume abnormalities [36].

3. Cerebral Hyperintensities in Depression

General Associations

Hyperintensities, or high-intensity lesions, are bright areas in the brain parenchyma on T2-weighted magnetic resonance images that have strongly been associated with late-onset depression. They are traditionally classified into three major groups based on their location: periventricular hyperintensities (PVH), deep white matter hyperintensities (DWMH), and subcortical gray matter hyperintensities (SCH) (Fig. 1). Large, irregular hyperintense lesions > 5 mm are considered to represent actual infarcts.

Hyperintensities are associated with increased age [4,37] and are seen in normal aging [38]. They are also associated with medical comorbidity, appearing in neurologic diseases such as Alzheimer's dementia [16] and multiple sclerosis. Increased hyperintensity severity also correlates with cerebrovascular risk factors [37,38], including hypertension, diabetes, history of smoking, low cerebral blood flow velocity, carotid artery disease, and prior episodes of cerebral ischemia. However, hyperintensities can occur in many subjects without obvious risk factors. A recent study using diffusion tensor imaging, a MRI variant sensitive to ischemic disease, concluded that hyperintensities had diffusion characteristics similar to ischemic lesions, supporting a cerebrovascular etiology [39].
Figure 1 Axial slices exhibiting severe confluent deep white matter (DWMH) and periventricular hyperintensities (PVH) in the left image. PVH tend to hug the ventricle border, while DWMH are further from the ventricles in the white matter. The right image demonstrates smaller, punctate subcortical hyperintensities (SCH) in the basal ganglia and thalamus. (From the Neuropsychiatric Research Imaging Laboratory, Duke University Medical Center, Durham, NC)

Hyperintensity Location

Hyperintensities are more common and more severe in late-onset depressed subjects than in age-matched controls [16,17,40–42]. This is not true for younger depressed individuals.

Does hyperintensity location matter in the development of depression? Evidence is strongest for a contributory effect of SCH, particularly basal ganglia hyperintensities, which are more common in late-onset depressed subjects than controls [17,41,43–45], although this finding is not universal [46]. Results for PVH are more mixed. Although more common in depressed elders [18, 47], there may not be a correlation between PVH and depression [17,43]. The relationship between DWMH and depression is more promising. Late-onset depressed subjects exhibit more significant DWMH disease than do controls [17,26] or early-onset subjects [8,47–49]. Increased DWMH severity is associated with increased depression risk [26], but this finding is not universal [43].

Frontal lobe hyperintensities may be particularly important, as one study found that left frontal hyperintensities predicted assignment into the depressed group [44]. Another study found that increased lesion density in the medial orbital PFC and a region of the left internal capsule correlated with depression severity [45].

4. Clinical Significance of Neuroimaging Findings

Volumetric studies are difficult to translate into clinical relevance, as there are no well-defined "normal volumes" for specific structures. Clinical correlates of hyperintensity presence have been bettered studied. Increased SCH and DWMH severity are associated with poor treatment response to both pharmacotherapy and ECT [50–52]. One author, having previously coined the term "silent cerebral infarction" (SCI) in referring to hyperintensities [53], retrospectively found that individuals with more severe SCI had sig-

nificantly longer hospitalizations for depression [54]. Lesion severity in younger depressed subjects is not so significantly correlated with outcome as it is in elderly depressed subjects [55].

More severe SCI is also associated with a higher occurrence of adverse central nervous system reactions to antidepressants [54], a finding replicated elsewhere that demonstrates an association with a higher risk of delirium from both antidepressant drug therapy [56] and electroconvulsive therapy [57]. Specifically, caudate hyperintensities are associated with increased risk of antipsychotic-induced parkinsonism [58].

Increased hyperintensity severity, particularly PVH and DWMH, is also associated with neuropsychological deficits [37], including impaired psychomotor speed, executive dysfunction [47,50,51], and impairment in verbal and nonverbal memory [47]. Caudate lesions are specifically associated with impairment on tasks requiring planning and sequencing. Increased severity of gray matter hyperintensities is also associated with the subsequent development of frank dementia [59].

5. Vascular Depression

Because of these findings, various authors have proposed that vascular disease is more than a cause of depression—rather a distinct subtype. Initially coined "arteriosclerotic depression" [60] this described a syndrome of vascular changes associated with depressive symptoms, including apathy, psychomotor retardation, cognitive impairment, functional disability, and lack of a family history of mood disorders [50,60,61]. Later, to be more consistent with the concept of vascular dementia, the term was changed to "vascular depression" [61,62]. Authors have used varying definitions of this syndrome: Krishnan et al. [61] defined it by MRI findings, while Alexopoulos et al. [63] used a broader definition which included depressed patients with any vascular disease. Diagnostic criteria for this subtype, utilizing both MRI findings and clinical symptoms, have been proposed [1].

6. Conclusion

Both volumetric studies and hyperintensity measurements correlate with depression. The frontal lobe, particularly the PFC, and the basal ganglia are most associated not only with depression, but also with neuropsychological deficits and functional impairment. It is very likely that hyperintensities and atrophy in these regions represent two separate pathways to a common clinical syndrome.

B. Functional Imaging Studies in Depression

Functional imaging studies, many examining younger cohorts than do structural studies in depression, demonstrate that the metabolic rate of frontal, striatal, and limbic regions is altered in depression. When results are compared across studies there are occasionally conflictual data, with some studies reporting hypometabolism and others hypermetabolism for the same structure in similar depressed states. It is likely these findings represent the heterogeneous pathogenesis of depression, which is associated with multiple pathophysiological states and subsequent assortment of distinct functional imaging abnormalities [64]. Although specific regional metabolic changes are not yet associated with distinct clinical syndromes, the fact that these regions exhibit an altered metabolism in depression supports their involvement in the pathogenesis of mood disorders. The most implicated regions include the prefrontal cortex (PFC), the cingulate and hippocampus, and the basal ganglia.

1. Resting Studies

Specific PFC regions consistently exhibit metabolic changes in depressed individuals. Most studies examining the dorsolateral PFC found a left-sided decrease in metabolism and blood flow in depressed subjects compared with control subjects [65–67]; a few studies reported bilateral hypometabolism [68,69]. Other studies have found relative dorsolateral PFC hypermetabolism [70]. The ventrolateral PFC, adjacent to the dorsolateral PFC, may also be involved, exhibiting a hypermetabolic rate in depression [66,70,71].

The medial OFC demonstrate hypermetabolism—increased blood flow and glucose metabolism—in depression [64–66, 72]. Studies in older depressed subjects found an opposite result; older subjects had decreased cerebral blood flow in the orbital frontal cortex, in the context of globally reduced cerebral blood flow and glucose metabolism [73,74].

The cingulate gyrus, a limbic structure, also has regional metabolic changes in depression. The anterior cingulate gyrus ventral to the genu of the corpus callosum exhibits decreased blood flow and metabolic rate [23,67,75,76]. This is also seen in older subjects [74], although recent data in a group of young male subjects found a higher metabolic rate in the right pregenual anterior cingulate in depressed subjects than control subjects [77]. Experimentally induced sadness may result in increased blood flow to the sub-

genual cingulate [78]. Basal ganglia structures also involved, particularly the caudate, which consistently exhibits metabolic changes, either a lower [71,72,74, 75,77,79] or higher metabolic rate [65,70].

2.   Studies of Antidepressant Response

These studies examined metabolic changes in depressed individuals compared with controls. What about comparing regional metabolic rates before and after treatment? Most research demonstrates that successful antidepressant therapy results in metabolic rate normalization in the dorsolateral PFC [68,70,77,78], but these findings are not universal [76,80]. This is also noted in the ventrolateral PFC [70,76] and medial orbital frontal cortex [76]; decreases in ventrolateral metabolism correlate with decreased depression severity [76].

Changes in the cingulate or basal ganglia are not so clear. Some data demonstrate that specific regions of the cingulate's metabolism may decrease with treatment response [78,81,82], but other research suggests that it may not normalize with treatment [23,76]. The dorsal anterior cingulate may experience an increased metabolic rate with successful antidepressant therapy [77]. The caudate's metabolic rate may normalize, but some studies have found this specific to the right side [70,83]. Other research shows that caudate metabolism may decrease with successful treatment, while putaminal metabolism initially increases, then decreases after several weeks of treatment [81].

Unfortunately, many of these studies provide limited information on neural circuitry that may mediate or predict antidepressant response. There is some evidence that baseline metabolism may predict response to antidepressant therapy; a study of the rostral anterior cingulate found that subjects with hypermetabolism in this region responded better to therapy than did hypometabolic subjects [69]. A recent EEG study utilizing brain electrical tomographic analysis replicated this finding [84]. Lower baseline metabolism of the ventral anterior cingulate may also be associated with better response [76]. Clearly more research into how neuroimaging findings may influence treatment response and ultimately guide clinical treatment is needed.

3.   Conclusions

Although the heterogeneity of findings in functional imaging makes these results difficult to interpret, this research supports the role of specific regions in the pathogenesis of depression. Although different depressive syndromes and different antidepressant therapies may result in different metabolic changes, the dorso-

lateral and ventrolateral PFC, the anterior cingulate, the medial orbital frontal cortex, and the basal ganglia continue to be specifically implicated. Functional imaging also has the potential to identify prognostic features supportive of treatment response, but more work is clearly needed.

III.   IMAGING STUDIES IN BIPOLAR DISORDER

Historically there has been less structural neuroimaging research of bipolar disorder than depression. Also, in contrast to the research in depression, most neuroimaging studies in bipolar disorder have focused on younger populations, with several recruiting first-episode manic subjects.

There are several confounders when examining this research. Substance abuse is more common in this group than the general population, and bipolar patients more frequently have smoking histories, which qualifies as a cerebrovascular risk factor; both may affect neuroimaging results. Beyond this, there is also the potential confounder of treatment, as chronic lithium use has been associated with an increased volume of certain cortical regions, including the hippocampus [85].

A.   Structural Imaging Studies in Bipolar Disorder

1.   Volumetric Studies in Bipolar Disorder

There is no evidence of whole brain or cortical atrophy in subjects with bipolar disorder [86–92], but studies examining ventricular enlargement are more mixed, with some studies finding increased ventricle-to-brain ratios [48,89,93,94], and others not [95,96]. Specific cerebellar regions may also be atrophic in bipolar patients with multiple past affective episodes [92].

Bipolar subjects generally exhibit no frontal or parietal lobe volume abnormalities, even when specific regions such as the PFC are measured [1,97], although one study did find a significantly smaller PFC in bipolar subjects than controls [86]. Most research has also shown no difference in temporal lobe volumes [94,98], although this finding is not universal [1]. Late onset bipolar subjects may be different from early-onset or control subjects, as they exhibit increased volume of the left sylvian fissure and bilateral temporal sulcal enlargement [28].

As in depression, the hippocampus is smaller than in controls [97,98], particularly the right hippocampus

[98]. There is a suggestion of increased amygdala volumes in bipolar subjects [90,97], but there was no correlation between amygdala volume and duration or severity of illness [97]. Others have not found significant differences in amygdala volumes [98], or found smaller left amygdala volumes [91].

Data regarding subcortical structure volumes are also mixed. Some studies have reported enlarged thalami and basal ganglia [97]. One report demonstrated larger caudate volumes exclusively in male bipolar patients compared with controls [87]. Other studies have not found increased volumes of the caudate [98], putamen [87,98], or globus pallidus [87].

2. Hyperintensities in Bipolar Disorder

There are significantly fewer studies examining the presence and severity of hyperintensities in bipolar disorder than in depression. Most research shows that hyperintensities are increased in bipolar patients compared with controls, are more common in bipolar patients of all ages [99], and that hyperintensities are stable over time [48,87,96,100–102]. These trends are also true in treatment-naïve subjects [93], but other studies did not find increased hyperintensity frequency in bipolar subjects but did find that the risk of bipolar disorder was significantly greater in those with focal signal hyperintensities [96].

In the studies that reported increased hyperintensity severity in bipolar patients, the most commonly reported region was the deep white matter of the frontal and parietal lobes [48,87,100,102]. Younger bipolar subjects may have an increased frequency of PVH [96,101,102]. Unlike hyperintensities seen in older patients, these hyperintensities are not located in watershed zones, but rather in the deep white matter of the frontal and frontoparietal regions of both hemispheres [88]. Hyperintensities in young bipolar patients are not related to any vascular risk factors, but may be familial [88]. One study examining a family with a strong history of bipolar disorder reported that the majority of family members had MRI hyperintensity findings, including all those individuals with bipolar disorder [103]. Elderly bipolar patients also have increased SCH and DWMH when compared with controls [102].

3. Clinical Significance of Structural Findings in Bipolar Disorder

The clinical correlations of neuroimaging abnormalities have not been as extensively studied as in depression. The presence of hyperintensities is related to the presence of psychosis, the likelihood of rehospitalization in 2 years [102], and the total number of psychiatric hospitalizations [100]. One study classified bipolar subjects as poor outcome or good outcome, and found that poor outcome subjects had a greater number and more severe subcortical hyperintensities than did good outcome or control subjects [104].

As in depression, hyperintensities in bipolar subjects may also correlate with neuropsychological impairment: in this case, deficits on tests of fluency or recall [100], although some research has been unable to correlate white matter lesions in bipolar subjects with cognitive deficits [105]. This area of research desperately needs further study: several studies demonstrate that neurocognitive deficits observed in young bipolar subjects do not fully reverse with remission of mood symptoms [17], and that elderly bipolar patients with cognitive deficits may experience progression of their cognitive impairment [106]. These findings have not been correlated with neuroimaging, nor have they been correlated with treatment options.

4. Conclusion

Given the limited research, it is more difficult to reach firm conclusions about neuroanatomical substrates of bipolar disorder. As in depression, hyperintensities are more common, but unlike depression, are more common at earlier ages. There may be a familial component to hyperintensities in bipolar subjects, and they also appear related to worse treatment outcomes, although data for this conclusion are sparse. Volumetric studies are mixed, and the findings complicated by recent discoveries of the potential neurotrophic effects of mood stabilizers.

B. Functional Imaging in Bipolar Disorder

There have been limited number of studies utilizing functional imaging to study bipolar disorder, however even these preliminary studies may provide insight into involved brain structures. One complication of research utilizing these methods is the current mood state of the subjects; regional brain activity may differ in depression and mania.

Specific regions exhibit changes in glucose metabolism in bipolar disorder. Frontal metabolism is decreased in depressed bipolar subjects compared with controls [23,71,79], and one study has demonstrated reduced metabolism and regional blood flow specifically in the subgenual prefrontal cortex [23]. Manic subjects may exhibit increased glucose metabo-

lism in this region [23]; however, other investigators have not replicated this finding [68,79]. One study examining temporal cortical regions also demonstrated decreased metabolism during depression and increased metabolism during mania [107], but these results have not been replicated. There are also reports of decreased caudate and thalamic metabolism in depressed subjects [79], and decreased metabolism of the left amygdala in manic subjects [108].

Although far from conclusive, this research further supports the involvement of frontal, striatal, and limbic structures in the pathogenesis of both bipolar depression and mania. Further research is needed to examine how the functioning of these regions may change with treatment or with repeated mood episodes and treatment resistance.

IV. CONCLUSIONS

This body of literature clearly demonstrates, in both studies of regional injury (atrophy and hyperintense lesions) and regional metabolism and functioning, that frontal, limbic, and striatal regions are involved in both depression and mania. Further, depression research demonstrates that injury to specific regions is associated with poor or delayed treatment response and increase frequency of adverse events to antidepressant therapies.

This research has started to be applied to therapeutic interventions, but more work is needed. Using neuroimaging techniques to identify individuals who will exhibit a poorer treatment response is the first step, but future use of this research may guide the development of new, more effective interventions. This critical research, along with future work, can help improve treatment outcomes and thus the quality of life for our patients.

Role of Acetylcholine and Its Interactions with Other Neurotransmitters and Neuromodulators in Affective Disorders

DAVID S. JANOWSKY and DAVID H. OVERSTREET
University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, U.S.A.

I. INTRODUCTION

Most mood disorder hypotheses are limited to focus on a single neurotransmitter, neuromodulator, or postsynaptic messenger. There are viable hypotheses proposing that norepinephrine (NE), dopamine (DA), gamma amino butyric acid (GABA), serotonin, (5HT) acetylcholine (ACh), and/or their respective receptors, as well as postsynaptic mechanisms including G proteins, cyclic AMP, and the inositol system predispose to or regulate mania and depression. Why single-factor hypotheses have dominated the literature is probably due in part to their conceptual simplicity, the relative ease by which they can be pursued, and the rewards an investigator derives from focusing on a specific neurochemical. However, there is considerable evidence that the various neurotransmitters/neuromodulators and related neurochemicals actively interact with each other. Virtually all perturb other systems, leading to the strong possibility that a cascade of neurochemical events, rather than a single neuroactive compound, is related to the mood disorders.

Although neurotransmitter interactions have been found for Parkinson's disease and for a variety of autonomic phenomena such as heart rate, pupillary size, and bowel motility, prior to 30 years ago no widely accepted balance or interactive hypothesis existed for an emotional disorder. In 1972, Janowsky and colleagues proposed the adrenergic-cholinergic balance hypothesis of affective disorders [1]. With an interactive perspective in mind, in this paper we will utilize ACh and its muscarinic receptor effects as a prototype to illustrate how it and its interactions and perturbations may lead to affective phenomena. We will describe the proposed relationship of ACh as such to mood disorders (i.e., a unitary hypothesis). We will also demonstrate how a more complete and complex picture can be obtained by considering how other candidate neurochemicals (i.e., 5HT, DA, GABA, G proteins, cyclic AMP, etc.) can be affected by ACh and/or influence ACh and hence mood.

II. CHOLINERGIC-BEHAVIORAL EFFECTS IN ANIMAL MODELS

Several preclinical animal models of depression have been developed, including the self stimulation model, the hypoactivity model, the learned helplessness model, the chronic stress model, and the behavioral despair or forced swim model [2,3]. Such models are useful in investigating neurochemical hypotheses of affective disorders. When central cholinergic activity is increased with centrally acting cholinomimetic drugs,

such as the direct cholinergic agonists arecoline and oxotremorine, and with cholinestrase inhibitors which inhibit the breakdown of ACh, such as physostigmine, the animal behavioral concomitants of depression occur. Thus, centrally acting cholinergic drugs consistently cause lethargy, hypoactivity, decreases in self-stimulation, increases in behavioral despair and decreases in preference for the reinforcing effects of sugar as swell as activation of the hypothalamic pituitary axis [3–6].

A very productive strategy for studying depression has been the development of genetically derived animal models which show enhanced or diminished responses to a given neurochemical perturbation. Such genetically derived animal stains can represent animal analogs of depression. For example, the Roman Low Avoidance rats (RLA) have been bred to ineffectively learn avoidance responses. Interestingly, these animals are relatively more sensitive to cholinergic agonists [7], and are considered to be an animal model for anxiety and depression [8]. Similarly, the Flinders Sensitive Line (FSL) of rats, developed by co-author David Overstreet, were selectively bred to have increased muscarinic responses to the anticholinesterase agent diisopropylfluorophosphate (DFP), an agent which blocks the central and peripheral breakdown of ACh [9].

FSL rats were bred to show increased behavioral toxicity and an exaggerated decrease in temperature after exposure to DFP, and in later generations to the cholinergic agonist oxotremorine. They were developed in parallel with the Flinders Resistant Line (FRL) rat, which does not show such sensitivity to cholinergic drugs. Overstreet and colleagues have proposed that the FSL rat is an animal model of depression, and an increasing and impressive body of evidence supports this contention. Among the many similarities between FSL rats and depressed humans, FSL rats have lower body weight, decreased activity, and decreased locomotion. Very significantly, they have increased REM sleep and reduced REM sleep latency, and given cholinergic stimulation, they have an exaggerated release of cortisterone [9]. FSL rats also demonstrate less interest in drinking saccharin than do controls when exposed to chronic mild stress [3]. This suggests that the FSL rats may have stress-induced anhedonia, another parallel to the symptoms of depression. Very importantly, FSL rats have exaggerated immobility in the forced swim test, a test is considered to be an excellent animal model for depression and for detecting antidepressant drug effects [10]. This phenomenon parallels the increased immobility induced by centrally

acting cholinergic agonists, as recently confirmed by Hasey and Hanin [11].

III. MOOD-DEPRESSING EFFECTS OF CHOLINOMIMETICS IN MAN

One of the most dramatic effects of centrally acting ACh-enhancing drugs is their ability to rapidly induce depressed moods. In the early 1950s, Rowntree et al. [12] observed depression in a number of affective disorder patients and in several normals that he treated with DFP. Furthermore, Gershon and Shaw [13] and Bowers et al. [14] and others have reported induction of anxiety and depression by nerve gases and related cholinomimetic insecticides. Building on the above information, Janowsky and colleagues, in 1972, found induction and intensification of depressive symptoms in bipolar manic patients given physostigmine [1]. They also found that depression increased significantly when unipolar depressed patients and schizoaffective depressed patients were given physostigmine. The noncentrally acting cholinesterase inhibitor neostigmine did not cause any such behavioral effects, nor did the noncentrally acting anticholinergic and antimuscarinic agent, methscopolamine. Significantly, the centrally acting anticholinergic and antimuscarinic agent, atropine, did reverse the mood depressing effects of physostigmine [15–17]

This work has been replicated by a number of authors including Davis et al. [18] and Modestin et al. [19,20], who found an increase in depression in manic patients given physostigmine. Risch et al. [21] and Nurnberger et al. [22,23] gave depressed patients the direct-acting cholinergic agonist arecoline and noted that their patients developed increased depression, as well as anxiety and hostility. Oppenheimer et al. [24] also noted that depression was also caused by physostigmine in a majority of euthymic bipolar patients who were receiving lithium. Furthermore, Risch et al. [21,25,26] found a significant increase in negative affect on the Profile of Mood States (POMS) mood rating scale in normals receiving physostigmine or arecoline. Mohs et al. [27] also noted induction of severe depression in an Alzheimer's patient receiving oxotremorine. El-Yousef, Janowsky, and colleagues [28] reported that physostigmine induced extreme depression in individuals who had recently smoked marijuana. This apparently was a central effect, since it was reversible with atropine.

In addition to eliciting depressed mood, physostigmine and other cholinomimetic agents induced a psy-

chomotor depression which was very similar to that occurring in endogenous depression. This observation was consistent with the anergic and behavioral inhibitory effects noted by Rowntree et al. [12], Gershon and Shaw [13], Modestin et al. [19,20], and Janowsky et al. [29]. Indeed, these anergic behavioral-inhibitory effects crossed diagnostic lines, and were not selective for affective disorder patients.

Choline is a precursor of ACh and it or its precursors' administration increases ACh levels. Tamminga et al. [30] and Davis et al. [31] observed an increase in depressive symptoms in a subgroup of schizophrenic patients receiving choline, a phenomenon that was atropine reversible. Similarly, a subgroup of Alzheimer's disease cases developed depressed mood as a side effect of choline and lecithin (a choline precursor) treatments [30]. Furthermore, the choline precursor deanol caused a depressed mood [32].

A growing body of information suggests not only that can muscarinic cholinomimetic drugs induce depression, but that patients with mood disorders are more vulnerable to the depressing effects of these agents than are normals or individuals with other psychiatric diagnoses. Thus, Janowsky et al. [15,16,33] observed that patients with an affective component to their illness (i.e., patients with depression, mania, or schizoaffective disorders), when compared to schizophrenics without a mood component, were vulnerable to becoming depressed or more depressed after receiving physostigmine. Similarly, Oppenheimer et al. [24], giving physostigmine to lithium-treated euthymic bipolar patients, observed a significant percentage who became depressed, while noting that normal controls receiving physostigmine showed anergia, but not depression.

Janowsky et al. [33,34] replicated the above findings using self-rated and observer-rated scales. They showed that greater increases in the anxiety, depression, and hostility and decreases in the elation subscale of the POMS occurred in mood-disordered patients compared to other psychiatric patients or normals following physostigmine infusion. Using the acetylcholine precursor deanol, Casey [32] also found selectively increased depressive symptoms in affective-disorder patients compared to non-affective-disorder patients who had tardive dyskinesia.

In related studies, Steinberg et al. [35] found that patients who had affectively unstable personalities (often Borderline Personality Disorder patients) were more vulnerable to increases in negative affect caused by physostigmine than were individuals who were affectively stable or who had predominantly impulsive personality disorders. Significantly, such individuals

with affectively unstable personalities did not show negative affect following noradrenergic, serotonergic, or placebo challenges. Also, Fritze et al. [36,37] noted that behavioral and cardiovascular sensitivity to physostigmine correlated with baseline irritability and emotional lability, and with the degree to which an individual showed habitual passive stress coping strategies. Thus, stress sensitivity and coping profiles, rather than specific affective diagnostic disorders as such, may determine sensitivity to a cholinomimetic agent.

IV. CHOLINOMIMETIC EFFECTS ON SLEEP PARAMETERS

Major depression is associated with such sleep changes as decreased rapid eye movement (REM) sleep latency and increased REM sleep density. Significantly, muscarinic cholinergic agonists such as arecoline, physostigmine, RS86, and pilocarpine shorten REM latency and increase REM density [38–40]. Sitaram et al. [41,42] and Gillin et al. [43] demonstrated that individuals receiving arecoline who had a history of an affective disorder or a family history of affective disorder showed exaggerated shortening of REM latency following arecoline infusion.

Further replication of the phenomena of exaggerated REM latency shortening in affective disorder patients was noted by Berger et al. [44]. These authors found that supershortening of REM latency occurred in patients with endogenous depression following administration of the oral muscarinic agonist RS86. The control group, which showed less shortening, were normals and eating-disorder patients. Significantly, Berger et al. [39] also found that physostigmine-induced arousal and awakening from sleep predominated in affective-disorder patients.

In an extension of the above studies, Gann et al. [45] administered placebo and RS86 to patients with major depression, anxiety disorder patients, and healthy control subjects. RS86 selectively increased the number of REM episodes, the shortening of REM latency, and the increasing of REM density and duration. Riemann et al. [46,47] found that to a lesser extent, schizophrenics showed parallel findings to the affective disorder patients. However, patients with anxiety disorders did not show the degree of cholinomimetic-induced REM or behavioral abnormalities noted in the affective-disorder patients [48,49].

There is evidence, as was noted in the FSL rats [9], that hypersensitivity to cholinomimetics of REM sleep

parameters is genetically determined. This relationship has been confirmed in monozygotic/dizygotic twin studies, in which twin pairs received arecoline [50], and in which monozygotic twins showed increased concordance of effects on REM parameters after administration of the cholinomimetic drug compared to dizygotic twins.

Similarly, Schreiber et al. [51] evaluated first-degree relatives of patients with a DSM-III diagnosis of major depression and found enhanced shortening of REM latency and increased sleep-onset REM periods following RS86 administration. Furthermore, early results by Holsboer (personal communication, 1998) suggest that nondepressed relatives of depressives who initially showed prominent decreases in REM latency following RS86 are more likely to become depressed at a later point in time.

V. GROWTH HORMONE SUPERSENSITIVITY IN MOOD DISORDER PATIENTS

There is considerable evidence that centrally acting ACh activation increases growth hormone levels [33,52. With respect to affective disorders, O'Keane et al. [52] evaluated growth hormone release following administration of the peripherally acting cholinesterase inhibitor pyridostigmine in depressed patients and normals. Their depressed patients, especially males, showed relatively higher serum levels of growth hormone following pyridostigmine infusion. This finding was also observed in manic patients [53], in obsessive-compulsive patients [54], and in schizophrenics [55,56]. However, Cooney et al. [56] observed that schizophrenics with panic disorder and low depression scores did not differ from a control group in their pyridostigmine induced levels of growth hormone.

VI. INCREASED CENTRAL CHOLINE IN IMAGING STUDIES

Clinical in vivo proton magnetic resonance spectroscopy and other techniques including PET scanning offer a relatively direct way of observing cholinergic function in the living individual. These technologies can be used to measure choline-containing substances in the brain, and the amount of measured central choline may reflect central ACh activity, since choline is an ACh precursor. Charles et al. [57] observed an increase in choline in the brains of patients with major depression compared to controls. Significantly, choline levels were state dependent and decreased to those of normal controls after successful drug treatment of the depression. In another study, Renshaw et al. [58] studied the basal ganglia of depressed and control subjects. These authors noted alterations in cytosolic choline in the basal ganglia in depressives, particularly of those who responded to fluoxetine. Similarly, Hankura et al. [59] found higher subcortical choline containing compounds in depressed bipolar disorder patients than in normals. More recently, Moore et al. [60] found that in the left cingulate cortex, bipolar subjects' depression ratings correlated positively with MRSI measures of choline Cr-PCr. In the right cingulate cortex, the choline Cr-PCr ratio was significantly higher in subjects with bipolar disorder than in control subjects. In addition, bipolar subjects not taking antidepressants had a significantly higher right cingulate cortex choline Cr-PCr ratio than patients taking antidepressants or controls. No clinical or drug-related changes were observed for the inositol Cr-PCr ratio. The results of the study suggest that bipolar disorder is associated with alterations in the metabolism of cytosolic, choline-containing compounds in the anterior cingulate cortex.

All of the above imaging studies offer indirect evidence in support of a role for ACh in the phenomenology and/or etiology of mood disorders. However, it must be mentioned that choline has many other functions along with serving as a precursor to ACh. Therefore, proof of a direct relationship between the choline findings and affective disorders awaits further research.

Furthermore, in contrast to the above results, a preliminary study by Soares et al. [61] found no difference in choline/Cr-PCr ratio in the anterior cingulate of depressed patients, compared to controls. Also, they found that depressed subjects had lower rather than higher initial choline levels than normal controls. Therefore, as Moore et al. [60] note, increases and decreases in choline/Cr-PCR have been associated with depressed state or response to therapy. Significantly, however, where inconsistencies occur, they often were in studies of unipolar rather than bipolar subjects.

VII. CENTRALLY ACTING ANTICHOLINERGIC AGENTS AS ANTIDEPRESSANTS

Several studies have pointed out that antiparkinsonian drugs with centrally acting antimuscarinic properties may cause euphoria, feelings of increased well-being,

sociability, and a reversal of depressed mood in schizophrenic patients. These compounds are generally quite complex in their effects, and probably affect DA and other neurotransmitters, as well as obviously affecting ACh receptors. Kasper et al. [61] observed that the centrally acting antimuscarinic drug biperiden had antidepressant effects, especially in patients with endogenous depression. However, several studies have shown a lack of antidepressant efficacy for anticholinergic drugs. Thus, Fritze et al. [37] could not demonstrate an advantage to the addition of biperiden over noncentrally acting anticholinergic drugs, where study drugs were added to ongoing antidepressant medications. Similarly, Gillin et al. [62] could find no antidepressant effects for biperiden in depressives. Also, there is little or no evidence that the centrally acting antimuscarinic agent scopolamine is useful in the treatment of depression.

VIII. SUPERSENSITIVE PUPILLARY RESPONSES TO PILOCARPINE

Sokolski and DeMet [63] studied the pupillary miotic response to the muscarinic cholinergic agonist pilocarpine. They found that this response was exaggerated in patients with major depression. This exaggeration represents a shifting in balance to a cholinergic predominance, since the pupil is controlled by reciprocal noradrenergic and cholinergic mechanisms. Sokolski and DeMet [63] suggest that the supersensitive pupillary response may be mediated by M3 muscarinic receptors, working through the G protein-phosphatidyl inositol system. These data support the notion of both peripheral and central muscarinic supersensitivity and noradrenergic hyposensitivity in depressives. In a related study, Fountoulakis and colleagues [64], comparing depressed patients and normal controls, found that depressed patients with melancholic features manifested shorter ACh-induced latency to constriction than did control subjects. These authors suggest that there is NE hypoactivity in melancholic depression and that therefore relatively smaller changes in ACh are needed to balance the NE. Conversely, Sokolski and DeMet [65] found that patients with more severe mania required relatively higher concentrations of pilocarpine in order to effect a 50% decrease in pupillary size. Presumably, the resistance to pilocarpine-induced pupillary constriction represents an overbalancing of cholinergic activity by adrenergic activity, since the mania ratings were linearly related to the effective dose of pilocarpine needed to cause pupillary constric-

tion. Furthermore, DeMet and Sokolski [66] observed that improvements in mania after treatment with valproic acid were closely correlated with a decrease in the amount of pilocarpine needed to cause a 50% reduction in pupillary size, and this relationship was indistinguishable from one previously observed after lithium treatment.

IX. CHOLINERGIC MECHANISMS AND THE HYPOTHALMIC-PITUITARY-ADRENAL AND ADRENOMEDULLARY AXES

In humans, a major characteristic of depression is activation of the hypothalamic-pituitary-adrenal (HPA) axis. Indeed, depression has been considered to be a form of stress. Several studies have shown that increased cortisol, ACTH, and β-endorphin levels exist in depressed patients, and that endogenously depressed patients often fail to suppress cortisol after administration of dexamethasone. A variety of studies have suggested that cholinomimetic drugs and ACh as such can release corticotrophin-releasing factor (CRF), and subsequently a cascade follows in which elevation, activation, and release of ACTH, cortisol, and β-endorphin occurs [33]. In separate studies, physostigmine has been shown to reverse dexamethasone-induced suppression of cortisol in normals and in depressives [67]. Therefore, an HPA axis analog of depression is created by cholinomimetic agents such as physostigmine, and this can be reversed by centrally acting antimuscarinic agents [16].

In addition to effects on the HPA axis, patients with major depressive disorder have been reported to have increased epinephrine excretion and some increases in NE excretion. As with the HPA axis, physostigmine has been found to cause epinephrine release, and to a much lesser extent to cause norepinephrine release. This effect is centrally mediated, being effectively blocked by centrally acting scopolamine but not by noncentrally acting methscopolamine [16]. This represents central muscarinic stimulation leading to the adrenal release of epinephrine. Furthermore, both physostigmine and arecoline have been shown to increase pulse rate and blood pressure in subjects treated with peripherally acting antimuscarinic drugs, probably secondary to epinephrine and norepinephrine release. These physiological effects, almost certainly mediated by sympathetic outflow, can be antagonized by the centrally acting antimuscarinic drug scopolamine but not by the noncentrally acting drug methscopolamine [16].

It is likely that ACh is an important moderator of the body's stress responses, and conversely, that stress activates ACh. Stress is multidimensional and includes gastrointestinal, cardiovascular, behavioral, analgesic, immunological, endrocrinological, psychological-behavioral, and psychopathological changes [33]. Information from animal studies suggests that stress is likely to be mediated by complex alterations of a variety of central neurotransmitters, mostly almost all depression relevant, such as ACh, NE, 5HT, GABA, and DA. A dramatic demonstration of a stress-ACh linkage is the work of Gilad et al. [68] showing increased ACh release and downregulation of muscarinic receptors after exposure to stress, a phenomenon much exaggerated in stress-sensitive rats. Furthermore, Mizuno and Kimura [69] found hippocampal ACh release and cortisol release were increased following stress in young rats, and Mark et al. [70], using microdialysis, showed that inescapable stress caused selective ACh release in rat hippocampus and prefrontal cortex, a phenomenon which was further exaggerated when the stress was lifted. Likewise, Day et al. [71] showed that prenatally stressed rats, as adults, showed greater hippocampal ACh activity when exposed to a mild stress or when given corticotrophin-releasing factor.

X.   NICOTINIC AND MUSCARINIC INTERACTIONS AND DEPRESSION

Although the major focus of this chapter has been on muscarinic mechanisms, a number of studies have suggested that there is a relationship between depression and nicotine consumption. Glassman et al. [72] reviewed this information in depth and suggested that tobacco smoking was associated with current major depression and current depressive symptoms. Furthermore, a lifetime history of major depression increases the chances of a person trying nicotine and becoming addicted to it, even if the individual is not depressed at the time of exposure. Furthermore, there is evidence in people with a history of major depression that attempts to stop smoking may precipitate severe depression. Also, Kendler et al. [73], using monozygotic and dyzgotic twin pair data, found that smoking and depression appear to be linked genetically.

Nicotine's stimulating effects on dopaminergic reward systems have been offered as a popular explanation as to why people smoke, and why depressives might be more likely to smoke and/or have trouble stopping smoking. However, it is possible that a rela-

tionship or interaction between muscarinic and nicotinic mechanisms may underlie nicotine addiction, since ACh naturalistically stimulates both muscarinic and nicotinic receptors. It is conceivable that stress and/or depression, causing ACh release and activating muscarinic mechanisms, leads to an overall muscarinic predominance. This could be overcome by nicotinic activation via smoking, possibly via the release of dopamine. However, if nicotinic activation ceased owing to acute abstinence, there could be a rapid decrease in dopaminergic activity, leading to a muscarinic predominance and to dysphoria and depression. Furthermore, there is some evidence that activation of nicotinic receptors such as occurs with cigarette smoking leads to muscarinic outflow [74]. Therefore, it is possible that if nicotinic stimulation leads to muscarinic activation, this muscarinic activation remains a predominant effect when nicotine is stopped, leading to depression, anxiety, and other symptoms of nicotine withdrawal.

Paralleling the above possibilities, it should also be pointed out that nicotine has also been reported to have antidepressantlike effects in animal models [75–77]. Importantly, the control strain of rat that was treated chronically with nicotine exhibited a withdrawal depression when observed 2 days after cessation of treatment [75]. Thus, evidence in animal models supports the hypothesized muscarinic basis for humans taking nicotine for its antidepressant effects.

XI.   NEUROTRANSMITTER/ NEUROMODULATOR/ACETYLCHOLINE INTERACTIONS

Although much information suggests a strong role for ACh in the phenomenology and/or etiology of the affective disorders, there is information that is not supportive of acetylcholine directly effecting depression. As described above, one would expect centrally active antimuscarinic agents such as scopolamine and atropine to be effective antidepressants, but the evidence for this is equivocal at best. Furthermore, many effective antidepressant medications, such as the selective serotonin reuptake inhibitors, lack muscarinic receptor blocking properties.

Thus, there is strong evidence both for cholinergic supersensitivity and for the induction of depression in human depressives by cholinomimetic agents, yet there is also the inability of muscarinic antagonists to ameliorate depression and the lack of effect of several antidepressants on muscarinic receptors. One scenario that

might explain the above paradox is as follows: The basic abnormalities underlying depression could be located in serotonergic, dopaminergic, GABA-ergic, or other systems, initially effected by ACh, but later assuming a life of their own. Thus, administration of cholinergic agonists and other cholinomimetic agents might perturb or induce these other systems, resulting in depression, but once perturbed, these systems would be unlinked from muscarinic receptors. Anticholinergic agents would then be unable to counteract depressive symptoms, yet stimulation by ACh would cause an increase in effects.

A second possibility is that the basic abnormalities underlying depression are located in a second-messenger cascade that is downstream from the muscarinic receptor itself. An abnormality in the cascade that amplifies the cholinergic signal could promote supersensitive responses to cholinergic agonists. However, because this abnormality would be beyond the receptor, muscarinic antagonists would not affect its actions and therefore, could not alleviate symptoms of depression. The plausibility of this model is enhanced by recent studies suggesting abnormalities in second-messenger systems in human depressives [78,79].

As a prelude to discussing the clinical and biochemical interactions that occur between ACh and other neurotransmitters, neuromodulators, and second messengers, especially in the mood disorders, it is illustrative to discuss the nature of altered neurochemicals in the brains of the cholinergically derived FSL rats. As mentioned earlier, these rats were developed to be supersensitive to muscarinic cholinergic drugs. They show supersensitivity with respect to vulnerability to the behavioral and hypothermic effects of cholinergic agents. The FSL rats also show decreased persistence in the forced swim test, an animal analog of depression used to screen for antidepressant drugs [9].

In recent years, Overstreet and collaborators have begun to look at secondary neurotransmitters and neuromodulator effects of this primarily hypermuscarinic rat line. They have found that differences in central catecholamines exist between FSL rats and control FRL rats. In a study by Zangen and colleagues [80], NE levels were two- to threefold higher in nucleus accumbens, hippocampus, and median raphe, and DA levels were six times higher in the nucleus accumbens and two times higher in the striatum, hippocampus, and hypothalamus of FSL rats. After administration of antidepressants, catecholamine levels were normalized. Furthermore, Serova et al. [81] observed that catecholamine biosynthetic MRNAs for tyrosine hydroxylase and dopamine beta-hydroxy-

lase were markedly elevated in the FSL rats. Interestingly, Yadid et al. [82] reported that when FSL and control rats were stressed in a forced swim test, DA levels decreased initially in FSL and control rats, but subsequently increased only in control rats. Also, Zangen et al. [83] found that extracellular dopamine levels in the nucleus accumbens of FSL rats were 40% lower than in control rats, and that FSL rats did not respond with an expected release in DA following 5HT administration, a lack of reactivity reversed by antidepressant drug treatment. Thus, FSL rats appear to have more stored catecholamines but to have less that is available.

Like the catecholamine system, 5HT sensitivity is altered in FSL rats. Overstreet et al. [84] found that the FSL rat is hypersensitive not only to cholinergic agents, but to 5HTlA receptor stimulating agents. Supersensitive responses to the 5HTlA agonist 8-OH-DPAT were observed in the FSL rats, and these were not blocked by anticholinergic agents. Conversely, Zangen et al. [85] observed that levels of 5HT and its metabolite 5-hydroxyindolacetic acid (5HIAA) were two- to eightfold higher in the nucleus accumbens, prefrontal cortex, hippocampus, and hypothalamus of FSL rats, an effect which normalized with antidepressant drug treatment. Also, the 5HIAA/5HT ratio was lower in FSL rats, meaning that less metabolism was occurring and more 5HT was stored. The lower ratio was increased after chronic desipramine treatment, while the high tissue levels decreased. Therefore, with respect to DA and 5HT, the observations suggest that there is more intracellular and less extracellular monoamine neurotransmitter in the FSL rats, suggesting a relative cholinergic predominance.

XII. CATECHOLAMINE/ACETYLCHOLINE INTERACTIONS

As suggested in the original 1972 article proposing the adrenergic-cholinergic balance hypothesis of mood disorders [1], considerable information suggests a role for monoaminergic-cholinergic balance in the pathogenesis of mood disorders. In the original hypothesis, the coauthor of this paper, Janowsky, and colleagues [1] proposed that depression was a manifestation of central cholinergic predominance, whereas mania, conversely, was due to a relative monoaminergic (i.e., catecholaminergic) predominance. The original conceptualization of this hypothesis was based on the observation that centrally active cholinergic agonists and cholinesterase inhibitors possess antimanic proper-

ties. At the time that the hypothesis was developed, mania was considered, as conceptualized in the catecholamine hypothesis, to be a disease of excessive NE and/or DA. Therefore, turning off mania with a cholinomimetic drug would suggest a shifting of catecholaminergic-cholinergic balance, such as occurs with heart rate, pupillary constriction, and bowel motility [86]. To this end, Rowntree et al. [12] gave the centrally acting cholinesterase inhibitor DFP to several patients who were manic or hypomanic. The manics studied improved with DFP, and one who became less manic relapsed upon DFP withdrawal. Subsequently, Janowsky et al. [1,29,87] in the early 1970s conducted a controlled experiment in which the centrally acting cholinesterase inhibitor physostigmine was compared with placebo, as well as the noncentrally acting cholinesterase inhibitor neostigmine. Neither placebo nor neostigmine produced any behavioral changes, but physostigmine administration caused the manics to become less talkative, active, active, happy, friendly, grandiose, or euphoric, and to effect a decrease in their flight of ideas. These results were replicated by Modestin et al. [19,20], who reported a diminution of manic systems following physostigmine, but not neostigmine infusion. Likewise, Davis et al. [18] reported that physostigmine caused antimanic effects, and these results were replicated by Carroll et al. [88] and Shopsin et al. [89], as well as Berger et al. [44], who used RS86, a relatively specific muscarinic (M_1) receptor agonist.

Several studies have demonstrated antimanic effects using ACh precursors including the choline precursor lecithin [30,90]. The antimanic efficacy of phosphatidyl choline was also demonstrated by Leiva [91]. Most recently, Burt et al. [92] found that the cholinesterase inhibitor and anti-Alzheimer's drug, donepezil (Aricept) was useful in treating 6 of 11 treatment-resistant manic patients who had been maintained on antimanic therapy.

The converse of the above studies is found in the mood effects of antiadrenergic agents. Sympatholytic-antihypertensive medications, including α-methyldopa propranolol, clonidine, and reserpine, can cause depression. These drugs appear to have ACh-releasing/activating properties as well as antiadrenergic properties. They can cause mood depression as well as vivid nightmares, lethargy, and sleeplessness, symptoms very similar to those caused by physostigmine or other cholinomimetic agents, and to those occurring in naturalistic depression and in Parkinson's disease [1,93]. Furthermore, antipsychotic agents, which block central DA receptors, also increase ACh turn-

over and are quite capable of causing depression [94]; and depression is a frequent concomitant of Parkinson's disease, in which decreased DA and increased ACh activity coexist [95].

There is also evidence that when the central ACh system is activated using cholinesterase inhibitors, ultimately a compensatory antagonistic activation of the noradrenergic/dopaminergic system occurs. To this end, Fibiger et al. [96] demonstrated that the increase in acetylcholine activity caused by the administration of physostigmine initially caused a decrease in locomotion in rats, and eventually led to exaggerated locomotion. This activating effect occurred as physostigmine's effects were wearing off, and was exaggerated when the centrally acting anticholinergic agent scopolamine was given at the onset of the hyperactivity phase. Thus, it would appear that cholinomimetic agents can simultaneously both antagonize and activate central catecholaminergic mechanisms.

The work of Fibiger et al. [96], described above, is paralleled by results in humans. "Rebounding" into a mania after DFP was given was reported by Rowntree et al. [12]. Similarly, Shopsin et al. [89] demonstrated rebounding into hypermania following physostigmine infusion in two of three manic patients, and more recently, donepezil has been observed to cause manic episodes [92]. Thus, Jacobsen and Comas-Diaz [97] observed that donepezil (Aricept), given to nongeriatric affective-disorder patients to treat psychotropic drug-induced anticholinergic symptoms, caused antagonism of these symptoms. In addition, the donezepil caused nausea, vomiting, diarrhea, and mania within hours of starting it in two bipolar patients. Similarly, Benazzi reported donepezil induced mania [98].

A behavioral pharmacological model for naturally occurring adrenergic-cholinergic balance in the regulation of mood may be found in the interaction of psychostimulants and cholinomimetics. Methylphenidate-induced psychostimulation, including increased locomotor activity, stereotyped movement behavior, and stereotyped self-injurious gnawing behavior in rats is antagonized by physostigmine [99]. Furthermore, there is strong evidence that dopaminergic agents stimulate the reward processes [100,101] and that cholinergic agonists inhibit it [102,103]. These findings may have particular relevance to mood disorders, because a cardinal symptom of depression is anhedonia. Thus, it is possible that anhedonia could arise by either an underactive dopamine system or an overactive cholinergic system. Alternatively, the anhedonia associated with an overactive cholinergic system might be overcome by activating the dopaminergic system.

In human studies paralleling the above animal studies, methylphenidate-induced hypertalkativeness, euphoria, and increased thinking is rapidly antagonized by physostigmine but not by noncentrally acting neostigmine [104]. Conversely, physostigmine's inhibitory and mood depressant effects in man are rapidly reversed by methylphenidate administration. This type of reversal is also reflected in the observation that physostigmine can cause a dramatic decrease in 3-methyoxy-4-hydroxphenylglycol (MHPG), a NE metabolite [105]. This decrease was associated with a tearful, depressed state, and a decrease in manic symptoms.

With respect to sleep, we have previously described the central cholinomimetic-muscarinic effects on REM density, frequency, and latency. However, REM parameters appear to reflect a balance between monoaminergic and cholinergic factors. Dopamine and norepinephrine (and serotonin) all increase REM latency and decrease REM density, in marked contrast to the effects of acetylcholine. Related to the above, Schittecatte et al. [106] noted that human depressives are subsensitive to the REM-suppressing effect of the noradrenergic agent clonidine. This would suggest that β-adrenergic (i.e., noradrenergic) subsensitivity might exist in depressives along with cholinergic hypersensitivity.

A reciprocal relationship appears to exist between a subject's response to a psychostimulant and his or her separate response to a cholinomimetic agent. A negative correlation was noted between amphetamine-induced behavioral excitation and the ability of arecoline, given on another occasion, to decrease REM latency [107]. Similarly, Siever et al. [108] showed that in a mixed group of affective-disorder and normal subjects, those with the most dramatic physostigmine- or arecoline-induced anergy and negative affect showed a blunted growth hormone response to the noradrenergic agonist clonidine. This was presumably a reflection of decreased noradrenergic responsiveness. Unfortunately, Siever et al. [108] did not measure growth hormone responses to cholinergic challenges, so a direct comparison of the adrenergic and cholinergic systems in regulating growth hormone could not be made.

Several more direct biochemical studies also suggest that the dopaminergic and cholinergic systems oppose each other. Ikarashi et al. [109] found that DA D2 receptor stimulation in the striatum led to an inhibition in ACh release. In contrast, Downs et al. [110] demonstrated that depletion of brain DA caused a supersensitive ACTH response following physostigmine administration, a finding paralleling the exaggerated ACTH response to physostigmine found in affective-disorder patients [111,112]. There is also evidence that chronic treatment with antipsychotic drugs, which produce dopamine supersensivity, also produces a cholinergic subsensitivity [113]. Thus, several studies suggest opposite changes in dopaminergic and cholinergic systems following specific manipulations. These findings raise the possibility that the cholinergic supersensitivity observed in depressed patients could be due to an indirect consequence of dopamine deficiency, as well as to an innately supersensitive cholinergic system.

Consideration of the second-messenger cascades of the two primary DA and ACh receptors may help understand the mechanisms involved in depressive disorders. The m_1 and m_2 ACh receptors are positively and negatively coupled to the phosphatidyl inositol and adenyl cyclase cascades. A similar arrangement appears to exist for the D_1 and D_2 DA receptors [114]. This information seems paradoxical, because the D_2 and m_2 receptors would be expected to operate in parallel if they operate through the same second-messenger cascade. However, one must also consider neuroanatomy. For example, DA terminals innervate cholinergic interneurons in the striatum and inhibit these neurons via D_2 receptors. The cholinergic neurons in turn disinhibit GABA inhibitory neurons, which then inhibit the dopamine neurons in the substantia nigra. Also, a recent study has also indicated the involvement of GABA-ergic neurons in the effects of cholinergic modulation of locus coeruleus noradrenergic neurons. The direct stimulation of cholinergic neurons projecting to the locus coeruleus inhibits the REM-off neurons, an effect that can be blocked by GABA antagonists [115].

XIII.   ACETYLCHOLINE-SEROTONIN INTERACTIONS

At this time, the most widely accepted etiological hypothesis of depression is the 5HT hypothesis, as described elsewhere in this volume. Convincing evidence of the importance of 5HT comes from the fact that selective 5HT reuptake inhibitors have little effect on muscarinic receptors. However, there is considerable information suggesting that there are important interactions between the serotonergic and cholinergic systems, which do not involve their respective receptors as such.

Interactions between the cholinergic and serotonergic systems have been described for a variety of situations, including global interactions at the clinical level,

more discrete interactions for specific physiological and behavioral functions, and synaptic and/or molecular interactions that have been observed in vitro as well as in vivo. The current section will present evidence for cholinergic/serotonergic interactions in these three broad categories.

Clinically, there are two major areas where an interaction between the two systems have been demonstrated. These are sleep regulation and hormonal regulation, both of which are abnormal in depressive disorders. With regard to sleep, there is a long history of cholinergic stimulation leading to REM sleep and serotonergic stimulation being associated with slow-wave sleep [38,43,44,46,47,116]. It appears, however, that serotonergic stimulation, via 5HT1A receptors, can also suppress REM sleep [116], suggesting that the cholinergic and serotonergic systems are opposing systems in the regulation of REM sleep. One implication of this balance model is that the apparent cholinergic supersensitivity of REM sleep in depressed individuals [43,116] could be the consequence of a subsensitivity of the serotonergic balancing system. However, no evidence for a reduced inhibitory effect of the 5HT1A receptor agonist ipsapirone on REM sleep in depressed individuals could be found [117].

It has been well established that levels of specific hormones, such as cortisol, prolactin, and growth hormone, can be modified by cholinergic and serotonergic agents [53,54,118,119]. In general, the levels of these hormones are raised by the appropriate agonists. As far as we can tell, there is no information about how these two systems interact in the control of these hormones. No study has given probes from both systems to the same group of subjects.

The literature cited above indicates that the serotonergic and cholinergic systems are opposing systems in the regulation of sleep. However, there is evidence from other sources for parallel systems being involved in other functions. It has been shown that memory can be impaired by the disruption of either system, but the impairments are more severe if both systems are damaged [120]. Similarly, both muscarinic and 5HT1A receptor agonists induce hypothermia in rats [84,121,122].

Although the selective serotonin reuptake inhibitors do not appear to block muscarinic receptors as such, Saito et al. [123] have shown that ACh release appears to be regulated by inhibitory 5HT1B heteroreceptors located on cholinergic nerve terminals. Similarly, Crespi et al. [124] found that 5HT3 receptor agonists decrease ACh release by affecting 5HT3 hetero-receptors located on cortical cholmergic nerve endings.

Consistent with the above, the 5HTIA agonist 8-OH-DPAT turned off cholinergic REM-on neurons which activate REM sleep [125]. Conversely, 8-OH-DPAT enhanced ACh release from rat hippocampus and cerebral cortex [126], and MKC-242, another 5HT1A agonist, likewise increased extracellular ACh [127]. Thus, it is at least possible that the selective 5HT reuptake inhibitors, such as fluoxetine, may in part exert their effects by decreasing ACh availability in some brain regions while increasing it in others.

The studies described above indicate that 5HT could interact positively or negatively with ACh through release mechanisms. However, another mechanism by which the two systems could interact is via postreceptor cascades. The fact that there are at least five muscarinic receptors and at least 20 5HT receptors makes defining such a task daunting. We propose, therefore, to consider the postreceptor cascades for the 5HT1A and 5HT2A and the m_1 and m_2 ACh receptors only in this discussion.

Current evidence suggests that the 5HT1A receptor is negatively coupled to an adenyl cyclase cascade, while the 5HT2A receptor is positively coupled to the phosphatidyl inositol cascade [128]. Likewise, the m_2 and m_1 ACh receptors are negatively and positively coupled to adenyl cyclase and phosphatidyl inositol cascades, respectively [114,128]. Therefore, stimulation of the 5HT1A and m_2 ACh receptors could have a similar effect in those brain regions where these receptors are located postsynaptically on the same neurons. It must be remembered, however, that both 5HT1A and m2 receptors are located on axon terminals as well as on postsynaptic neurons and that their function in those locations is normally to inhibit release of the transmitter. It is also possible that responses mediated by 5HT2A and m_1 receptors could have additive effects. Unfortunately, there are hardly any data to support these ideas at present. However, one study has suggested that 5HT1A and m_2 receptor stimulation may have their effects via different G proteins [119]. This study suggests that it might be possible to develop pharmacological agents that selectively stimulate the serotonergic cascade.

XIV. SECOND-MESSENGER/ ACETYLCHOLINE INTERACTIONS

In the past decade, a number of studies have suggested that second-messenger alterations are linked to the affective disorders and possibly are causative of them. These include alterations in the phosphatidyl

inositol system (with evidence that administration of inositol leads to antidepressant and antiobsessional effects), alterations in the cyclic AMP system, and alterations in G proteins. However, what is often not stressed in these papers is that the very neurotransmitters which have been implicated as moderating depression are those which moderate the activities of second messengers, including 5HT, DA, NE and ACh. Thus, ACh activates the phosphatidyl inositol system, turns on cyclic GMP (which antagonizes cyclic AMP), and has effects on G proteins. It is thus quite possible that an interaction between ACh and other neurotransmitters, impacting on appropriate receptors, and leading to second-messenger activation may be significant in inducing a cascade leading to depression. Conceivably, this might explain why activation of such receptors appears important, but blockade of them leaves them in a quiescent phase, and therefore they are not relevant to the treatment or phenomenology of depression. More specifically, Manji and Chen [128] have suggested that guanine nucleotide binding protein coupled signal pathways are regulatory in mood states. Avissar and Schreiber [129] have found that lithium inhibited the coupling of both muscarinic and β-adrenergic receptors, suggesting alterations of G proteins . These results suggest that antidepressant and mood stabilizing treatments attenuate β-adrenergic receptor coupled G protein function [129]. In these studies, m_1 receptors appear especially sensitive to carbamylcholine effects and to the effects of guanine triphosphate (GTP) binding. Similarly, the phosphatidylinositol system, a second-messenger system used by noradrenergic, serotonergic, and cholinergic receptors, has been implicated in unipolar depression and bipolar disorder [78,130], and it would appear that for lithium to exert its effects on the phosphatidyl inositol system, acetylcholine is essential [131].

XV. SUMMARY

As reviewed above, considerable evidence suggests that the cholinergic nervous system, alone or acting in concert with other neurotransmitters, may have an important role in the regulation of affect. Nevertheless, as with all currently proposed biological hypotheses of the etiology of affective disorders, there exist alternative explanations, as well as some data that are inconsistent with the cholinergic hypothesis.

One question concerns the specificity of the cholinergic alterations: Are they confined to patients with affective disorder only or are they also present in other disorders such as schizophrenia, chronic fatigue, or multiple chemical sensitivity? A number of studies have failed to detect any evidence for cholinergic supersensitivity among patients with anxiety disorders [49]. In contrast, several studies suggested an involvement of cholinergic mechanisms in schizophrenia. Early investigators used cholinesterase inhibitors to treat schizophrenia. Others proposed a dopaminergic/cholinergic balance and/or interactive model for schizophrenia [31], and it has been suggested that cholinergic over activity may underlie the negative symptoms of schizophrenia, such as affective flattening, anhedonia, asociality, and apathy [132]. Reduced REM sleep latency has also been observed in schizophrenics [133]. Thus, symptoms of schizophrenia that bear some similarity to key symptoms of depression may also be mediated by cholinergic overactivity.

As described above, it is possible that pharmacologically induced changes in acetylcholine may cause perturbations in depression-relevant systems other than the cholinergic nervous system. Pharmacologically induced acetylcholine alterations could cause a "model depression" by perturbing other potential governing neurotransmitters (e.g., GABA, serotonin, dopamine, or norepinephrine) or second messengers in affect-disordered patients. Furthermore, obviously, the fundamental biochemical changes in depression could be due to a relatively low level of central norepinephrine or serotonin activity, a situation that could explain all of the above observations under the scope of a balance hypothesis. It is also conceivable that the cholinergic supersensitivity observed in many depressives may be a reflection of altered second messengers, including G proteins [93,129,134].

However, even if cholinomimetics can only cause a "model depression" (with such components as low mood, psychomotor depression, elevated ACTH, cortisol, β-endorphin, and epinephrine levels, as well as sleep architecture changes and increased pulse rates and blood pressure), understanding how this pharmacological phenomenon occurs may ultimately offer a window into understanding the pathophysiology of affective disorders and may have useful treatment implications. Thus, at the least, understanding the implications of the mood-depressant and other depressionlike effects of cholinomimetics may give clues as to the actual neurobiology of affective disorders. Alternatively, it is not beyond possibility that acetylcholine actually is directly involved in the etiology and the expression of the affective disorders, alone or acting through other relevant neurotransmitters and/or second messengers.

GABA and Mood Disorders
A Selective Review and Discussion of Future Research

FREDERICK PETTY, PRASAD PADALA, and SURENDER PUNIA

Creighton University and Omaha Veterans Administration Medical Center, Omaha, Nebraska, U.S.A.

I. INTRODUCTION

Gamma-amino butyric acid (GABA) is a neurotransmitter which is ubiquitous in mammalian brain. About 30–50 % of neurons in the central nervous system use GABA as a neurotransmitter. Thus, a role for GABA in the molecular and neuronal etiopathology of mental illnesses and behavioral disorders is expected. In fact, GABA is thought to be involved in a variety of psychiatric disorders, including personality disorders, anxiety disorder, schizophrenia, addictive disorders, and mood disorders. This review will focus on mood disorders.

II. BACKGROUND

GABA is considered to be an ''inhibitory'' neurotransmitter. Sometimes this causes confusion regarding its relationship with mental illnesses and behavioral disorders. First, the word inhibitory relates to physiology, not to behavior, in the context of neurotransmitter function. Most GABA neurons are small interneurons which synapse upon other GABA interneurons. Thus, physiological disinhibition is often the net or end result of activation of GABA. From a behavioral perspective, drugs that act to increase GABA activity or func-

tion, such as alcohol or benzodiazepines, tend to have a disinhibitory effect, particularly at low doses. Of course, higher doses lead to physiological and behavioral inhibition, such as sedation. Thus, while at a particular receptor, the action of GABA molecules may be inhibitory, at the systems level the effects are much more complex. Additionally, it is worth noting that at some biogenic amine nerve terminals GABA actually facilitates release of norepinephrine and dopamine, adding another level of complexity [1].

The general topic of GABA and mood disorders has been recently, well, and thoroughly reviewed [1–4]. Thus, we will not provide an exhaustive or comprehensive review of the data, rather, we will attempt to highlight and synthesize the most important and provocative features of this work. Also, we will analyze some interesting inconsistencies in the data, and suggest plausible explanations and hypotheses for further exploring the field. Finally, we will attempt to provide an overall theoretical framework and suggest potentially fruitful areas for future further exploration.

Initial interest in GABA in the etiopatholoqy of mood disorders derived from clinical observations made in the 1970s that valproic acid (valproate) was useful in treatment of *both* depression and mania in bipolar patients. In fact, the first published announcement of a ''GABA Theory of Affective Illness'' was

provided by Emrich [5], based on a case series of observations in manic-depressive patients.

Valproate exerts its primary neurochemical effects by increasing GABA in the brain. Hence, the original idea was that low GABA caused, or was related to, bipolar disorder, since the therapeutic effects of valproate were assumed to occur by rectifying this deficit. Subsequently, other agents that increase GABA levels or function were found useful in the treatment of bipolar patients. Interestingly, these medications are effective across a remarkably wide range of symptomatology, including anxiety, depression, irritability, aggression, and mania. In other words, these medications do not just provide symptomatic relief for a particular clinical state, such as mania, but appear to have beneficial action across the broad spectrum of psychopathological manifestations we observe in persons with symptomatic bipolar disorder [6].

III. DEPRESSION

In addition to its role in manic depressive disease, a role for GABA in depressive disorders was also first suggested in the early 1980s by findings from several studies of cerebrospinal fluid (CSF). Most of these studies reported that patients with depression had low GABA, compared to controls. While not all the studies were statistically significant, a meta-analysis revealed an overall high level of statistical significance [2]. Only one study included patients with mania [7]. Manic patients had CSF GABA lower than controls, though this did not achieve statistical significance. Generally, neurotransmitters measured in CSF are thought to originate from brain, though the contributions from spinal cord should not be ignored. Studies with GABA in spinal fluid are complicated by the rostrocaudal gradient of GABA concentration in CSF, and by the fact that GABA levels in CSF are artifactually elevated if samples are not collected on dry ice, because of breakdown of conjugated GABA.

GABA can also be measured in plasma, where its levels are comparable to those in CSF. Our group has studied plasma GABA in mood disorders for two decades. Naturally, the measurement of neurotransmitters in plasma is very controversial, since a presumption is that peripheral sources contribute to most of what is measured in peripheral tissues, such as blood. This, of course, is true for the biogenic amine neurotransmitters, since brain levels of these compounds are relatively low and peripheral sources are prominent in total body metabolism. Serotonin, for example, is the

neurotransmitter for only a few hundred thousand neurons, but has high concentrations in platelets. Similarly, norepinephrine is the neurotransmitter for relatively few neurons, but is synthesized by the adrenal. In the case of GABA, however, the largest concentrations are in brain, which accounts for perhaps 98% of total body GABA. It has been thought that GABA does not cross the blood brain barrier. However, like most neutral amino acids, GABA indeed does cross the blood brain barrier if ingested or given intravenously in large doses. Also, it certainly crosses the brain CSF barrier, and the CSF blood barrier, and most GABA measured in plasma is likely to have an origin in brain, judging from experiments performed in laboratory animals [8]. Nevertheless, even a peripheral marker of mental illness can be useful [9].

IV. PLASMA GABA

A consistent and well replicated finding of this research is that GABA levels are low in plasma in patients with primary, unipolar, major depressive disorder [10]. Further, low GABA in depression does not normalize with treatment or with clinical recovery [11]. Nor does low GABA in depressed patients correlate with severity of illness [12]. Taken together, these features suggest low GABA in depression may be a trait marker for the illness. We do not know whether low GABA in depression is an antecedent of illness, or a consequence or "scar." However, we do know that low GABA characterizes only adult depression, since levels of GABA in children and adolescents with mood disorders are not different from controls [1]. Further research should clarify the important question of whether low GABA in adults precedes the onset of depression and represents a vulnerability marker, or is a long-term consequence of depression. Possibly, the neurobiology of the disease process in adolescents and children is different from that in adults.

Low GABA in depression characterizes a subset of patients, about 40%. We have not done a detailed examination of what behavioral, symptomatic, or psychological features differentiate patients with low, versus normal, GABA levels. A post hoc analysis suggested that low-GABA patients had higher levels of endogenicity, based on items from the Hamilton Rating Scale for Depression [10]. Also, a post hoc analysis of data obtained from a family study suggested that GABA levels were inversely correlated with hostility in first-degree relatives of persons with primary unipolar depression who were not themselves

depressed [13]. Further research is needed to elucidate whether low GABA in depression has any value in characterizing the illness according to behavioral subtypes, or in selecting treatments.

It is worth emphasizing that plasma GABA will never serve as a diagnostic test for depression, simply because low GABA is not specific for depression and within depression characterizes only a subset of patients. Thus, as a diagnostic test, plasma GABA lacks both sensitivity and specificity. We do not consider this to be a problem. Depression is a heterogeneous illness, with multiple causes, multiple features, multiple treatments, and multiple responses to treatment. The diagnosis of depression is a clinical diagnosis, with an arbitrary cluster of symptoms and no truly pathognomonic features. Hence, we should not expect, and in fact should be skeptical of, any marker which purports to identify all, or even most, depressed patients, and to differentiate them from other mental illnesses. Nevertheless, as a marker for depression, low plasma GABA has some selectivity. Plasma levels of GABA appear normal in patients with anxiety disorders and in patients with eating disorders [14–16]. Both these conditions are associated with high rates of comorbid depression. Mean plasma GABA levels in patients with schizophrenia are similar to control, though with a larger standard deviation [16]. There has not been a detailed study with a large cohort of plasma GABA levels in schizophrenia.

V. SPECIFICITY

Plasma GABA levels are low in patients with alcohol dependence [17]. In patients with alcohol dependence, GABA levels remain low for several months after cessation of drinking and maintenance of sobriety. GABA levels after withdrawal and detoxification predict outcome, in that patients with lower levels are more likely to maintain sobriety at 6-month follow-up. This seems counterintuitive, if a GABA "deficit" corresponds to a feature of illness that alcoholics are "self-medicating" with alcohol, which has its primary action via the GABA-A receptor, by facilitating GABA transmission. On the other hand, one might speculate that higher GABA levels, which are associated with conduct disorder in children and adolescents, may be associated with disinhibition. Thus, persons with higher GABA may be more predisposed to impulsive actions, and a greater likelihood of return to drinking.

Brain GABA levels are inversely correlated with symptom severity, in biopsies from patients under-going psychosurgery [18]. Brain GABA levels are low in patients with major depressive disorder, as measured by magnetic resonance spectroscopy (MRS) [4,19]. Unlike plasma GABA, brain GABA as measured by MRS levels do seem to increase and return toward normal with treatment and clinical improvement (Sanacora, personal communication, 2001). An interesting facet of the brain GABA research with MRS is that, for technical reasons, levels are measured in the occipital cortex. Generally, our conceptualization of the anatomy of mood disorders involves the limbic system, specifically the frontal cortex, hippocampus, amygdala, hypothalamus, cingulate cortex, and so forth. Thus, finding low GABA in occipital cortex in depression suggests that the GABA deficit in depression is global. Plasma GABA, if we accept that this originates from brain, must reflect some global, probably cortical GABA level. This suggests that the "lesion" involved in low GABA states is not anatomically specific, but occurring throughout much, if not most, of brain, and perhaps in the periphery as well. Thus, the low GABA observed in depression and in bipolar disorder may be due to low activity of an enzyme which regulates GABA levels, rather than a specific receptor.

A small number of neuroendocrine challenge studies with GABA agonists have been reported, mostly with the GABA-B receptor agonist baclofen. These studies are mixed in their results, but the largest and best study reported a positive finding [20]. To our knowledge, no challenge studies with GABA-A agonists, or with valproate, or GABA itself, have been reported.

VI. PHARMACOLOGY

Further support for a "GABA deficit" in depression was provided by the provocative findings that the GABA agonists progabide and fengabine were efficacious in the treatment of major depressive disorder [21]. These medications never achieved widespread clinical use, owing to problems associated with hepatotoxicity. However, the benzodiazepine alprazolam did achieve wide spread clinical use, with an indication for anxiety disorders. About 20 clinical trials of alprazolam for major depressive disorder were conducted, with consistently positive results [22]. Though alprazolam remains the best-studied benzodiazepine in the treatment of major depression, some preliminary studies suggest that the high-potency benzodiazepines lorazepam and clonazepam may also have antidepressant efficacy [23,24]. Since the primary mechanism of action

of these compounds involves facilitating the GABA-A receptor, these findings are compatible with a GABA deficit in patients with depression.

We have further tested the GABA deficit hypothesis in depression by treating depressed patients with valproate. In an open-label trial with patients with primary, unipolar depression, valproate led to significant improvement over 8 weeks of treatment [25]. In a recently completed double-blind, placebo-controlled trial, valproate was no different from placebo in symptom reduction in patients with unipolar depression. In patients with bipolar depression, valproate treatment was better than placebo at the trend ($P < .1$) level [26].

Further research with GABA agonists in the treatment of depression is certainly needed, and the newer anticonvulsants, vigabatrin and tiagabine, should be tested as antidepressant (and antimanic) agents.

VII. ANIMAL MODELS

Recently, techniques of molecular biology have been applied to research in GABA and mood disorders. Table 1 summarizes findings to date. Needless to say, the results of these studies are preliminary, and in need of extension and replication. It is worth noting that no

Table 1 Molecular Genetics of GABA System and Mood Disorders

Author	Year	Study	Finding
De bruyn[a]	1996	Linkage study between bipolar and genes involved in dopaminergic and GABA-ergic neurotransmission	Excluded linkage for DAT1, DRD2, DRD3, DRD5, DBH, GABRA 1 and GABARB1 genes
Duffy[b]	2000	Linkage sudy of candidate genes in GABA-ergic transmission in lithium-responsive bipolar disorder	Significant association between Lithium response and GABA RA3,RA5 and RB3
Oruc[a]	1997	Association between GABRA5 and unipolar recurrent major depression	Positive association of GABRA5 gene in unipolar recurrent major depression
Papadimitriou[d]	2001	Association between GABA-A receptor beta-3 and alpha-5 subunit gene cluster in chromosome 15q11-q13 and bipolar	No difference between bipolar and controls
Papadimitriou[e]	1998	Association GABA-A receptor alpha-5 gene locus and bipolar	Presence or absence of 282-bp allele does not influence the age of onset or severity; More in manic episodes than depression
Puertollano[f]	1997	Association between MDD and a highly polymorphic marker from the GABR-beta-1 gene	No association; significant difference between patients and controls in women subpopulation
Serretti[g]	1999	D2 and D4 genes,GABA A alpha-1 subunit genes, and response to lithium prophylaxis in mood disorders	No association

study to date has attempted to study both the phenotype of low plasma, or CSF, or brain GABA, and genotypes in the same patient cohort.

Research with animal models of depression tends to support a role for GABA in depression. Curiously, to our knowledge, no studies have been done with plasma or brain GABA levels in animal models of depression. Thus, an exact extrapolation or comparison with the clinical data is difficult. An interesting finding of early research with the learned helplessness model and olfactory bulbectomy models was that GABA-B receptors were downregulated in the "depressed" rats, and that chronic treatment with a variety of antidepressants upregulated the GABA-B receptor. "Depressed" rats that received chronic antidepressant treatment had normal density of GABA-B receptors [27]. These findings are provocative, but have proved difficult to replicate. Whether GABA-B agonists have antidepressant properties is not clear. GABA agonists are active in the learned helplessness model, reversing "depressed" behavior [28].

Our research with GABA in the learned-helplessness model has shown decreased GABA release from synaptosomes from hippocampus of helpless rats. This decrease was normalized by repeated treatment with tricyclic antidepressant in a time course which paralleled normalization of helpless behavior [29]. Interestingly, helpless behavior could be prevented by intracerebral microinjection of GABA into frontal cortex and hippocampus, and normalized by injection of GABA into hippocampus of helpless rats [27]. Bicuculine, a GABA-A receptor antagonist, caused helpless behavior in naïve, nonstressed rats when injected into hippocampus [27]. We have recently completed an extensive study of GABA-A and GABA-B receptors in learned helplessness using quantitative receptor autoradiography. Results were surprising, since we found no changes in either GABA-A or GABA-B receptors in frontal cortex, hippocampus, hypothalamus, or amygdala. In lateral septum, GABA-A receptors were upregulated in both helpless rats and rats that received inescapable stress but did not become helpless, but more so in the helpless rats. Also in lateral septum, GABA-B receptors were downregulated in the stressed, nonhelpless rats, but similar to control in helpless rats [30]. Parenthetically, in another study, lateral septum was also the only brain region where expression of the immediate early gene c-fos was decreased in helpless rats exposed to brief stress [31]. This brain region deserves additional study, since it serves as a relay between hippocampus and hypothalamus, two regions of the limbic system

clearly implicated both in learned helplessness and in human depressive disorders. Thus, research with animal models supports an important role for GABA in regulating "depressive" behavior, but not a clear "deficit" hypothesis.

However, we should be cautious regarding acceptance of simplistic "neurochemical deficit" theories of mental illnesses. Just because something is found to be low in some patients with depression doesn't mean that this is etiologically related to the cause of illness, or that rectifying the deficit will correct the illness. Also, GABA has known interactions with all other neurotransmitters. The low GABA may not, therefore, be the "primary" lesion. For example, a primary disturbance in, say, glutamate function might lead to a secondary decrease in GABA.

VIII. BIPOLAR DISORDER

Low plasma GABA is found in patients with bipolar disorder, in both the manic and depressed phases of the illness. This means that low GABA is not a "state" marker for illness, since if it were, levels in persons with bipolar disorder would be different in mania from these in depression. "Bipolar disorder" is now widely recognized as a spectrum of related conditions. This spectrum includes psychiatric illnesses, personality disorders, and temperamental variants, ranging from classic Bipolar I (manic-depressive disease), through Bipolar II, Cyclothymia, Recurrent Brief Depression, Borderline Personality Disorder, and Hyperthymic Temperament. These conditions can be manifest by inappropriate, fluctuating mood, disturbed biorhythms, compromised social function, and impulsive aggressive behavior. Notably, when persons with a bipolar spectrum condition are not "symptomatic," they appear normal to most observers; indeed, a hallmark of bipolar disorder is its episodic nature, with good prognosis and interepisode recovery. While the vulnerability for bipolar disorder is clearly genetic, and known to involve several genes, the precise onset, severity, expression, and pattern of illness are influenced by developmental, environmental, toxic, and other factors. Hence, the concept that the phenotype of bipolar disorders will naturally range across a spectrum of clinical syndromes and behavioral manifestations, is coherent and rational.

With this developing knowledge of bipolar disorders has similarly evolved an increasing appreciation for neurotransmitter regulation of the dimensions of temperament and behavior, initially prompted by the

clinical utility of selective serotonin reuptake inhibitors across a wide variety of clinical syndromes. Similarly, valproate appears to have beneficial effects for persons with impulsivity and aggression across diagnoses. At the molecular level, alterations in genes regulating biogenic amine transporters and receptors correlate more with dimensions of behavior, such as harm avoidance, novelty seeking, or high anxiety, than with arbitrarily defined syndromes or psychiatric diagnoses. Similarly, further research with GABA may well show low levels in patients across the bipolar spectrum. Thus, concurrent with the conceptualization of bipolar disorders as a spectrum, evolves an understanding that neurotransmitter alterations may influence a variety of temperaments or behaviors across psychiatric diagnoses.

IX. GABA AND MOOD DISORDERS

Hence, the theory that alterations in the neurotransmitter GABA are reflected in several "mental illnesses," as well as in related behaviors that are not clearly pathological, seems intuitive and plausible. The primacy of GABA as a neurotransmitter, regulating most if not all brain synapses, supports an important role for GABA regulation of behavior.

A logical hypothesis derived from these clinical observations is that low GABA represents the phenotype, or expression, of a genetic trait marker of bipolar disorder. Indeed, our laboratory has reported that low GABA is a trait marker for bipolar disorder in a subset of patients. Low GABA is not unique to bipolar disorder, since, as mentioned, a subset of patients with primary unipolar disorder also have low GABA. Since bipolar disorder and unipolar disorder share both symptomatic features and a genetic diathesis, finding a commonality in neurochemical abnormalities in these two conditions is, in fact, to be expected. Not surprisingly, low plasma GABA also occurs in about one-third of males with primary alcoholism. Again, a strong relationship has repeatedly been demonstrated between alcohol dependence and mood disorders, in both clinical and family studies. In addition to the extensive comorbidity between these diagnostic categories, it is of particular importance to the GABA theory of bipolar spectrum that episodes of alcohol abuse frequently precede the onset of first mania in persons with bipolar disorder, particularly males.

An interesting and seemingly counterintuitive observation we have made, in several studies, is that treatments which improve clinical state, in other words, treatments which improve depression and mania,

tend to decrease, rather than increase, plasma levels of GABA [32]. In fact, in bipolar patients in the manic phase of the illness, we found an inverse correlation between plasma GABA levels and clinical response to valproate [33]. Again, this seems counterintuitive, since if valproate is rectifying a GABA deficit, one would predict that the patients with low GABA levels should be preferential valproate responders. Superficially, this seems to contradict to the hypothesis that low GABA correlates with psychopathology. However, if low GABA is represent a trait, rather than a state, biomarker of illness, indeed, treatments that improve overall clinical function might well be expected to revert GABA levels toward their premorbid and psychopathologically neutral state, which in a subset of persons with mood disorders is low. Hence, finding that antimanic and antidepressant treatments lead to a decrease in GABA in some symptomatic individuals, in synchrony with clinical improvement, provides an independent confirmation that low GABA is a trait, not a state, biomarker of illness.

X. A GABA THEORY OF MOOD
DISORDERS

From these and other observations, we have developed a "GABA theory of mood disorders." This theory postulates that low GABA is a genetically determined trait which creates a vulnerability to development of symptoms of either depression or mania. Then, other factors, such as stress or heavy alcohol use, increase GABA over its baseline, creating an instability in the neuronal circuits of the limbic system. Though elevated above baseline, the levels are still lower than population norms. This instability in the limbic GABA system is accompanied by symptoms and behavioral features characteristic of the state of illness, and described clinically as depression or mania. Then, with mood-stabilizing treatment, cessation of heavy drinking, relief of stress, or with the passage of time, the GABA levels decrease back to the lower, premorbid baseline, in synchrony with clinical recovery and return to euthymia.

This theory is testable. Recently, we found that plasma GABA levels are under genetic control, with an autosomal-recessive, single-gene model [34]. Levels of GABA in brain are regulated by a relatively small number of enzymes, and by the GABA transporter. Thus, the number of candidate genes responsible for low GABA in mood disorders is small. Research in progress will attempt to identify the specific identify

mutations that underlie the genetic basis of bipolar disorder.

Finally, we will comment regarding an interesting and probably important discrepancy in the data. Our earliest (1980–84) research studies on plasma GABA in psychiatric patients used a gas chromatography (GC) assay, which measured total GABA levels. In plasma, and in CSF, and, presumably in brain, most ($\sim 80\%$) of GABA is conjugated with other amino acids, and exists as di- and tripeptides. Thus, the GC assay measures both free and conjugated GABA in plasma. In these studies, we found that bipolar disorder in the manic phase had elevated levels of GABA, and patients with bipolar depression had levels similar to controls. Patients with primary, unipolar depression, and with alcoholism, had low levels, compared to control. Since 1984, our laboratory has used a high-performance liquid chromatography (HPLC) assay which is specific to measuring free, unconjugated GABA. Of course, the absolute levels reported are about one-fifth those found with the GC assay. Also, with the HPLC assay, we find low GABA in bipolar patients in both the manic and depressed phase of the illness, and in primary unipolar depression. Interestingly, with MRS measuring brain GABA levels, low levels are found in primary unipolar depression and in alcohol dependence, but not in bipolar depression. This suggests that the brain MRS measurements correspond to total GABA, with findings similar to those obtained with the GC assay. Future research should investigate the role of conjugated GABA in mood disorders.

XI. SUGGESTIONS FOR FUTURE RESEARCH

1. Clinical trials of new GABA agonists, and GABA-mimetic compounds, such as gabapentin and pregabalin, in depression and bipolar disorder.
2. Brain imaging with specific ligands for the GABA-A and GABA-B receptors.
3. Molecular genetic analyses of glutamate decarboxylase isoforms in mood disorders, coupled with measures of plasma and/or brain GABA.
4. Animal research measuring plasma or whole brain GABA in learned-helplessness and/or olfactory bulbectomy animal models of depression.
5. Development of a valid animal model for bipolar disorder.
6. Plasma and/or brain GABA measurement in bipolar spectrum conditions, such as borderline personality disorder.

Signal Transduction Abnormalities in Bipolar Disorder

YAREMA B. BEZCHLIBNYK and L. TREVOR YOUNG

McMaster University, Hamilton, Ontario, Canada

I. INTRODUCTION

There is compelling evidence of neurobiological impairment in patients with bipolar disorder (BD). Although the exact biochemical abnormalities underlying this disorder have not been conclusively identified, the multiple neurotransmitter systems involved in regulating mood have directed many researchers to consider the functional balance among these complex, interacting systems. The temporal discrepancy between the pharmacological and clinical effects of mood stabilizers has implicated cellular and molecular processes that occur over time in the mechanism of mood stabilizer action. In the CNS, intracellular signal transduction pathways are uniquely able to mediate the downstream activities of these multiple neurotransmitter systems. They affect both the levels and function of these systems, and link them together to coordinate complex neurobiological events [1,2]. Indeed, higher-order brain functions implicated in BD, such as behavior, mood, and cognition, are critically dependent on signal transduction processes for their proper functioning. Furthermore, post-receptor signaling systems connect immediate synaptic stimuli with long-term changes in gene expression. Consequently, it has been suggested that the dys-regulation of one or more intracellular signal trans-duction processes leads to episode specific alterations in gene expression, and a periodic loss of homeostasis via the activation of existing physiologic feedback mechanisms which may be crucial to the clinical manifestation of BD [3]. Therefore, signal trans-duction molecules have presented researchers with a wide range of compelling targets for investigating the biological basis of BD and its treatment. In the following sections, we present a brief overview of these intracellular signal transduction pathways, and review some of the major clinical findings implicating these processes in BD.

II. SIGNAL TRANSDUCTION SYSTEMS

Extracellular "first" messengers, which include neuro-transmitters, modulators, hormones, growth factors, and ions, activate various neuronal receptors. In turn, these receptors are coupled to diverse intracellu-lar second-messenger systems via different mechan-isms, including the activation of receptor-linked guanine-nucleotide binding proteins (G-proteins) [4]; the direct activation of ligand-gated receptor/ion chan-nel complexes [5]; and the stimulation of tyrosine receptor- and nonreceptor-kinase activity [6]. The result is the integration, amplification, and transmis-sion of the extracellular signals to specific intracellular effector enzymes or ion channels, which catalyze the production of an extensive array of cascading

"second" messengers that act on various protein kinases [1]. These protein kinases are ultimately responsible for modulating and regulating a diverse set of biologically essential intracellular responses, including gene expression.

A. G-Proteins

Guanine-nucleotide binding proteins (G-proteins) are an integral part of the intracellular signaling pathway, with $\sim 80\%$ of all known first messengers eliciting cellular responses through receptors coupled to these molecules. G-proteins are heterotrimers, consisting of an α subunit, which binds and hydrolyzes guanosine triphosphate (GTP), and a tightly but noncovalently linked dimer composed of the regulatory β and γ subunits [7]. The functional diversity of G-proteins is primarily conferred by the α subunits, which form an extensive family consisting of four main classes that selectively regulate different effector enzymes: $G\alpha_s$, $G\alpha_i$, $G\alpha_q$, and $G\alpha_{1/2}$ [8,9]. This functional heterogeneity allows for the coupling of a wide variety of receptors to the same or different signal transduction systems, leading to near-infinite combinations. Recent evidence has also suggested important roles for the $\beta\gamma$ subunits in intracellular signal transduction. Aside from modulating GDP/GTP exchange and serving to anchor the α subunit to the plasma membrane [4], the $\beta\gamma$ subunit has been shown to activate K^+ channels, negatively regulate calcium ion channels, and possibly activate the mitogen activated protein kinase (MAPK) pathways through Ras [10–12]. Furthermore, it has been shown that these molecules variously affect certain members of the adenylyl cyclase (AC) family [13], and directly activate phospholipase C (PLC) [10,14]. Thus, even modest changes in the levels and/or function of the G-proteins have the potential to markedly alter the signal generated by various receptor ligands.

B. Cyclic AMP–Generating Pathway

Following receptor activation, G-proteins interact with a number of effector enzymes. In particular, coupling of either the stimulatory or inhibitory G-protein subunits (α_s or $\alpha_{i1/2}$, respectively) to AC has been extensively characterized (Fig. 1) [7]. There are multiple isoforms of AC which catalyze the production of cyclic adenosine monophosphate (cAMP), a ubiquitous second messenger, from ATP. These can be broadly grouped into three subfamilies depending on whether they are stimulated, inhibited, or unaffected by $Ca^{2+}/$ calmodulin (CaM) binding [15]. Furthermore, these

enzymes are differentially susceptible to regulation by the $\beta\gamma$ G-protein subunits [13], as well as phosphorylation by both PKC and PKA [16–18]. The production of cAMP by this enzyme is balanced through rapid degradation by cyclic nucleotide phosphodiesterases, which also exist as multiple subtypes [19]. Cyclic AMP second messengers in turn regulate many cellular functions, such as metabolism and gene transcription by acting through several intracellular targets. Chief among these is AMP-dependent protein kinase, also known as protein kinase A (PKA) [20,21].

The inactive PKA tetramer consists of two catalytic subunits, coupled to a dimer of regulatory subunits. When cAMP levels rise within the cell, the binding of this factor to each of the regulatory subunits induces the dissociation of the holoenzyme, thereby releasing the monomeric catalytic subunits. Once released, these subunits are free to regulate the activity of a number of substrate proteins (including receptors, ion channels, cytoskeletal proteins, phosphatase inhibitors, and transcription factors) by phosphorylating them at specific serine and threonine residues [22,23]. This action continues until the level of cAMP in the cell diminishes, causing the regulatory subunits to regain their high affinity for the catalytic monomers.

C. Phosphoinositide Pathway

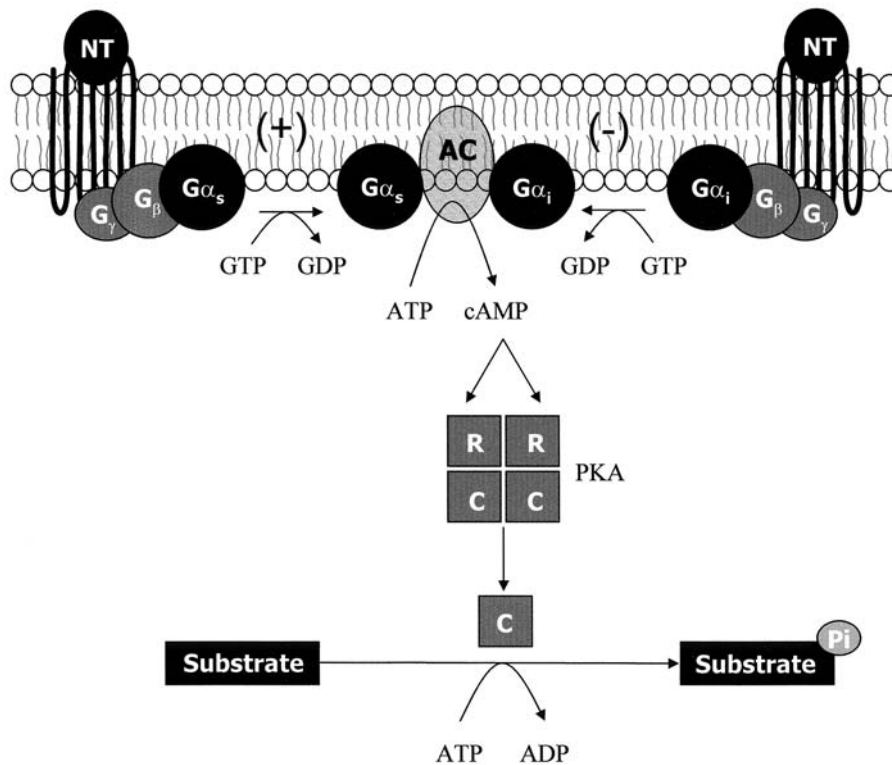
The G-protein isoforms G_q/G_{11} couple many neurotransmitter receptors to yet another signaling pathway, via the phosphatidylinositol-specific phospholipase (PLC) enzyme (Fig. 2) [24]. The activation of these receptors stimulates PLC, which in turn induces the hydrolysis of the inositol-containing phospholipid phosphatidylinositol 4,5-bisphosphate (PIP_2) to two second messengers—1,2-diacylglycerol (DAG), and inositol 1,4,5-triphosphate (IP_3) [25]. IP_3 stimulates the release of intracellular stored calcium from the smooth endoplasmic reticulum (ER) into the cytosol, by binding to an IP_3-specific receptor on the ER surface [26]. Metabolism of IP_3 then proceeds either by dephosphorylation to $Ins(1,4)P_2$, or phosphorylation to 1,3,4,5-inositol terakisphosphate (IP_4) by PI3-kinase. This latter isoform may mediate slower and more prolonged responses by enhancing the entry of calcium into the cell from external sources [27]. DAG, on the other hand, typically in conjunction with calcium, activates protein kinase C (PKC), which comprises another family of kinases [25]. Furthermore, because inositol crosses the blood brain barrier poorly, cells must maintain a sufficient supply of myo-inositol for the resynthesis of PIP_2, and the maintenance and


Figure 1 G-protein-coupled cyclic AMP system. Neurotransmitters (NT) bind to G-protein-coupled transmembrane receptors, which interact with G-proteins composed of α, β, and γ subunits. Receptor activation induces a conformational change in receptor associated G-protein, resulting in the exchange of GDP for GTP on the a subunit. The Gα subunit then stimulates (Gα_s) of inhibits (Gα_i) adenylyl cyclase (AC). Activation of AC converts ATP to cAMP. As a second messenger, cAMP activates cAMP-dependent protein kinase A by binding to the regulatory (R) domains and inducing the dissociation of the catalytic (C) domains. The free C moiety in turn phosphorylates various substrates.

efficiency PI-mediated signal transduction. This supply of myo-inositol thus depends on the dephosphorylation of inositol phosphates. The enzyme which catalyzes this reaction, inositol monophosphatase (IMPase), thus plays a crucial role in the PI signaling pathway [28].

PKC is a ubiquitous enzyme that is involved in a diverse array of cellular responses [29]. Together with other kinases, it appears to play a major role in the regulation of synaptic plasticity, learning, and memory [30]. Molecular cloning of this enzyme indicates that it exists as a family of closely related subspecies heterogeneously distributed in the brain, organized into subfamilies based on domain homology and biochemical properties: conventional PKC isozymes that require calcium for activation and are sensitive to phorbol esters; those that are sensitive to phorbol esters but not to calcium; and PKC, which is not responsive to either [29]. Activation involves the binding of DAG (or certain hydrophobic esters) to a specific regulatory site

on the enzyme, and the translocation of the enzyme from the cytosol to the particulate fraction of both neuronal tissue and platelets [25,31]. Interestingly, several isoforms of PKC may be co-expressed in a single cell, which together with their differential tissue distribution suggests that each isozyme may exert specific and distinct cellular functions [32]. In addition, PKC negatively regulates the activity of various phospholipases, which along with the degradation of IP$_3$ by activation of IP$_3$ phosphatase, serves to control signaling through the PI and calcium cascades [33].

D. Intracellular Calcium Signaling

Although the importance of the calcium ion in synaptic transmission and neurotransmitter release is well established, it has become increasingly apparent that calcium has a critical role in mediating diverse intracellular events. These include synaptic plasticity, cell survival, and excitotoxic cell death. Increased intracel-
Figure 2   Phosphoinositide-generated second-messenger system. The binding of a ligand activates receptors coupled to a G-protein (G_q) composed of α, β, and γ subunits. The $G\alpha_q$ subunit dissociates and activates PLC, which catalyzes the hydrolysis of phosphatidylinositol 4,5-biphosphate (PIP_2) and generates two second messengers—diacylglycerol (DAG), and 1,4,5-inositol triphosphate (IP_3). IP_3 releases calcium from the endoplasmic reticulum (ER), which increases levels of intracellular calcium. IP_3 is metabolized by either phosphorylation to IP_4 or dephosphorylation to IP_2. Subsequently, PI3-kinase dephosphorylates IP_4. Finally, IMPase dephosphorylates these substrates, producing inositol, which replenishes the phospholipid content of the membrane. DAG, on the other hand, activates PKC (synergistically with Ca^{2+} in most cases), which is then free to phosphorylate various substrate molecules.

lular Ca^{2+} has also been shown to affect protein phosphorylation [34], neuronal periodicity [35], neurotransmitter synthesis and release [36], and the formation of new functional associations [37]. Consequently, the mechanisms by which changes in intracellular calcium levels can lead to diverse, long-lasting biochemical alterations have been a target of directed investigation.

Cells have two major sources of calcium—the extracellular milieu, and the endoplasmic reticulum. Calcium influx from either of these stores into the cytosol is controlled by ion channels, which are regulated in turn by voltage changes or by the binding of various ligands such as NMDA (Fig. 3) [38]. With respect to the stores in the ER, we have already discussed Ca^{2+}

release via IP_3 binding to specific ion channel–coupled receptors in the ER. Experiments have also shown that certain calcium ion channels may be regulated by the $\beta\gamma$ G-protein subunit [39,40], and that calcium can autoregulate its own release through the process of Ca^{2+}-induced Ca^{2+} release (CICR) [41]. This process, which occurs upon neuronal excitation, generally involves regional increases in Ca^{2+} concentration providing a triggering pulse of Ca^{2+} that diffuses throughout the cell in a regenerative manner to recruit neighboring Ca^{2+}-sensitive channels, such as the IP_3 receptor in the ER membrane [41]. In any case, with cellular stimulation the concentration of calcium in the cytosol rises rapidly, from approximately 100 nM to values in the mM range [42]. At high intracellular con-
Figure 3 Intracellular calcium signaling. Calcium influx into the cytosol is stimulated by the binding of a ligand to a G-protein-coupled receptor, or by the direct activation of a transmembrane ion channel. In the first case, activation of the receptor frees α and $\beta\gamma$ G-protein subunits, which are variously able to stimulate Ca^{2+} signaling in different tissues and conditions. Both mechanisms open Ca^{2+} ion channels, allowing Ca^{2+} to enter along its gradient, and rapidly increase intracellular Ca^{2+} levels. At low concentrations, Ca^{2+} triggers the activation of ER and transmembrane ion channels. However, when Ca^{2+} concentrations become too high, Ca^{2+} negatively regulates these same channels. Intracellular calcium is bound to calmodulin, which transduces the ionic currents to enzymatic actions on specific substrates. In particular, Ca^{2+}/calmodulin is able to potentiate PKC, PKA, PLC, and various CaM kinases. The calcium concentration gradient is reestablished by Ca^{2+}- and Na^+/K^+-ATPases.

centrations however, Ca^{2+} downregulates its signaling by inhibiting IP_3 receptor sensitivity [26], and stimulating the hydolysis of IP_3 [43]. Return of intracellular free calcium to resting levels terminates many of its cellular effects. This gradient is reestablished and maintained by the action of membrane-associated Ca^{2+} ATPases (Ca^{2+} pumps), which drive Ca^{2+} against a steep concentration gradient either out of the cell or into intracellular stores [42], or through energy-dependent Na^+/Ca^{2+} exchange, which pumps Ca^{2+} out of and Na^+ into the cytosol of the cell [44,45].

After entering the cytosol, Ca^{2+} interacts with a number of regulatory proteins. One of these is calmodulin, a small Ca^{2+}-binding protein which acts as an intracellular Ca^{2+} sensor and is critical in the regulation of diverse cellular events [46]. Following Ca^{2+} binding, the Ca^{2+}/calmodulin (CaM) complex regulates a number of other enzymes. These include the CaM-dependent protein kinases (CaMKs), other Ca^{2+}-sensitive kinase isozymes, certain protein phosphatases, and some members of the adenylate cyclase and PLC families [46]. In addition, CaMK I, IV, and certain CaMK II isoforms may be specifically involved in mediating transcriptional activation of gene expression in response to changes in Ca^{2+} fluctuations in the cytosol [47,48].

E. ERK/MAP Kinase Signaling Pathway

The MAPK cascade is an evolutionarily conserved signaling pathway that plays a crucial role in cell growth and survival in diverse organisms. In vertebrates, at least six MAPK cascades have been identified, each of which transduces signals to a specific serine-threonine kinase subfamily. These subfamilies include ERKs 1 and 2, c-Jun-N-terminal kinases (JNKs), p38 MAPKs, ERK5, ERK7, and MOK [49–51]. The activation of these diverse kinases proceeds from a wide range of extracellular stimuli, of which the growth factors are the most extensively characterized. Growth factors such as nerve growth factor (NGF) exert their cellular effects by binding to a family of receptors known as receptor tyrosine kinases (trks) [52]. Analogous to the G-protein coupled pathways, stimulation of receptor trks by growth factor binding recruits and activates members of the ras family of low-molecular-weight GTP-binding proteins. The ras-signaling pathway subsequently involves the recruitment of a serine-threonine kinase (or MAPK kinase kinase) such as Raf-1 or B-raf, which then phosphorylates MAPK kinase (MEK). In turn, MEK activation results in the phosphorylation and activation of its target, the ERK1/2 members of the MAPK family of serine-threonine kinases [53]. Interestingly, one substrate for these ERKs is the ribosomal protein SG kinase family (RSK1–3), the activation and nuclear translocation of which play an essential role in the inducible expression of many genes [53,54]. However, alternative pathways leading to activation of MAPKs have been uncovered, and each MAPK pathway has its own unique set of related enzymes responsible for transducing signals from the receptors to the effector molecules.

F. Integration of Intracellular Responses

It is increasingly apparent that the various second messenger systems can be markedly influenced by the activity of other transduction pathways. Intracellular signaling is refined at multiple levels by an extensive cross-regulatory network, whereby second messengers linked to one receptor modulate the effector responses at another. For example, the $\beta\gamma$ subunit released upon activation of $G\alpha_i$-coupled receptors may augment the production of cAMP [55]. Furthermore, intracellular calcium balances the production and degradation of cAMP by stimulating or inhibiting AC activity [15], and potentiating Ca^{2+}/CaM-dependent phosphodiesterases (PDEs) [56]. Other studies suggest that Ca^{2+}

may affect PKA activity [57] and stimulate the PI-signaling pathway by potentiating PLC and PKC activation. In turn, cAMP regulates intracellular Ca^{2+} by decreasing the sensitivity of IP_3 receptors [58], stimulating the phosphorylation of voltage-dependent ion channels [59], opening receptor-activated Ca^{2+} channels [60], increasing Ca^{2+} removal by stimulating Ca^{2+}-ATPase [61], and inhibiting the activity of $PLC\beta_2$ [62]. Additionally, cAMP inhibits agonist-stimulated hydrolysis of membrane phophoinositides, thus reducing the production of the PI-generated second messengers. In turn, PKC has been shown to stimulate cAMP accumulation by acting on certain ACs [16], and possibly by inhibiting $G\alpha_s$ and $G\alpha_{i2}$ mRNA transcription [63].

A fairly extensive body of research also recognizes the intricate cross-communication between these signal transduction pathways and the MAPK system. In particular, the ras-mediated activation of both Raf-1 and B-raf is inhibited by PKA [64,65], whereas this same enzyme serves to activate B-raf through the GTPase Rap1 [66]. Evidence also suggests interaction with the calcium and PI signal transduction cascades. Upon GTP binding, Rap1b recruits PLC-γ to the cell membrane, where it can act on inositol phosphates [67]. Therefore, phosphorylation of Rap1b by PKA or CaMK results in the inhibition of PLC-γ, reducing PI-generated signaling [67,68]. In turn, both second messengers generated by PLC activation, calcium and DAG, are able to induce Rap1 activation [69,70]. PKC is also able to stimulate the ERK/MAPK pathway, by activating MEK1 and ERK1 via raf [71]. Alternatively, Ca^{2+} is able to activate the MAPK pathway through ras, ostensibly via CaMK stimulation of GTP binding and activation of various tyrosine kinases [72,73].

G. Regulation of Gene Expression

The propagation of extracellular stimuli to the nucleus of the cell may result in long-term changes at the genomic level. These changes occur through differential expression of a broad assortment of genes. One way to regulate the expression of these genes is to control the rate of mRNA transcription initiated by RNA polymerases. This action is mediated by *trans*-acting proteins known as transcription factors, which bind to specific *cis*-acting regulatory elements on specific target genes. These transcription factors are a major target for intracellular second messengers and their related protein kinases, which can alter their activity through changes in phosphorylation state, or concentration within the cell [74]. In particular, researchers

have focused intensively on two such factors—CREB and activating protein 1 (AP-1) (see Fig. 4).

Cyclic AMP–responsive element–binding (CREB) protein is intimately involved in the regulation of numerous genes, including other transcription factors and key members of the signal transduction pathways [75,76]. The CREB family of transcription factors includes CREB itself, the CRE modulator (CREM), the activating transcription factors (ATF), and the inducible cAMP early repressor (ICER). CREB is expressed constitutively in an inactive form, with activation requiring phosphorylation at Ser-133 by a variety of protein kinases [76,77]. These include PKA, MAPKs (such as RSK1–3), and Ca^{2+}/calmodulin-dependent kinases (CaMKs), which are regulated by the major signal transduction pathways described above. Active phosphorylated CREB (pCREB) proteins then free to regulate gene transcription by binding to a regulatory consensus region in the promoter of certain target genes, known as the cyclic AMP-response element (CRE) [78].

AP-1 is of a collection of homodimeric and heterodimeric complexes composed of the transcription factors Fos and Jun. Each of these is the product of a separate family, and is induced rapidly and transiently by a wide variety of extracellular stimuli—the induction of c-fos is rapid and transient, reaching its maximal levels within 30 min and lasting for 1–2 h [79], while the induction of c-jun, which positively regulates its own transcription, is longer lasting and varies from a few hours to several days in a cell type – and stimulus-dependent manner [79]. Both Fos and Jun are translocated to the nucleus, where they form the dimeric AP-1 complex. AP-1 proteins then bind to a common nucleotide sequence, known as the AP-1 site or the TPA response element (TRE), which is found in
Figure 4 Regulation of gene expression. Signal transduction systems transmit extracellular events to intracellular responses by modulating the activation state of key protein kinases. These protein kinases, which include Ca^{2+}-calmodulin-dependent protein kinases (CaMK), cAMP-dependent protein kinase (PKA), PKC, and elements of the MAPK cascade, in turn modulate the activity of transcription factors such as CREB and AP-1. For example, when CREB is phosphorylated at serine-133, it may bind to a cAMP-response element (CRE) in various target genes. This in turn regulates the transcription of c-fos, which combines with c-jun to form the AP-1 class of transcription factors. AP-1 may then bind to its own consensus sequence, the TRE site. Concomitantly, c-jun and CREB are both regulated by GSK3β.

the regulatory domain of many important genes [79]. These include various neuropeptides, neurotrophins, receptors, transcription factors, enzymes involved in neurotransmitter biosynthesis, and a number of cytoskeletal-binding proteins [79]. Activation and binding of the AP-1 complex can negatively or positively regulate transcription at this site [80,81].

Recently, experiments have revealed another modulator of both pCREB and AP-1 DNA binding activity—glycogen synthase kinase 3β (GSK3β). GSK3β is a highly conserved serine-threonine protein kinase which is regulated by at least three signal transduction cascades including the PI3-K cascade [82], the Wnt cascade [83], and the MAP kinase cascade [84], and plays a critical role in regulating long-term nuclear events. It phosphorylates c-jun at three sites adjacent to the DNA-binding motif, thereby reducing AP-1 binding activity [85]. As for CREB, phosphorylation at Ser-133 may make it a substrate for GSK-3β mediated phosphorylation at Ser-129, which could contribute to CREB activation under certain conditions [77]. In addition, it may regulate diverse brain proteins, such as microtubules [86], neurofilaments [87], myelin-basic protein [88], nerve growth factor [89], and tau [90]. As such, GSK3β further refines the complex patterns of gene expression in the CNS.

III. SIGNAL TRANSDUCTION ABNORMALITIES IN BIPOLAR DISORDER

Among the first studies to implicate disturbances in postreceptor signaling in the pathophysiology of BD revealed attenuated β-adrenergic receptor-activated AC activity in peripheral cells (platelets and lymphocytes) from patients with unipolar and bipolar depression [91–94]. Studies confirmed that such changes were not accompanied by changes in βAR density or affinity [95,96], which led these investigators to suggest reduced responsiveness or desensitization rather than diminished number of β adrenergic receptors, perhaps as a result of a defect distal to the receptor complex [95,97]. As a result, a wide variety of techniques and methodologies have been utilized to ascertain the locus of these postreceptor changes. Additionally, research has identified a number of signal transduction molecules as targets of medications that are most effective in the treatment of mood disorders (for review see [30]). In order to determine whether or not these treatments correct an underlying signal transduction abnormality, a number of studies have examined the

state of various intracellular transduction molecules in patient samples. These include studies in blood cells (such as platelets and leukocytes) and postmortem brain samples. As will be seen, these studies have generally complemented those drawn on the effects of mood-stabilizing medication, and supported theories of signal transduction abnormalities in the pathobiology of BD.

A. G-Proteins

Numerous independent laboratories have examined G-proteins in patients with BD, in light of their critical role in transducing signals from extracellular events to effectors with the cell (Table 1). Interest in these proteins was stimulated by studies in molecular pharmacology, which suggested that the mood stabilizer lithium attenuates the function of stimulatory G proteins [33,98,99]. In two postmortem brain studies, Young et al. [100,101] described increased immunoreactivity of the G-protein a subunit $G\alpha_s$ (but not $G\alpha_i$, $G\alpha_o$, or $G\beta$) in frontal, temporal, and occipital cortex of subjects with BD. Furthermore, they described increased forskolin-stimulated AC activity in BD temporal and occipital cortices, which was significantly correlated with the elevated $G\alpha_s$ measures. These findings were supported by a more recent postmortem study [102], which also reported elevated immunoreactivity specific to $G\alpha_s$, as well as increased agonist-activated $[^{35}S]GTP\gamma S$ binding to $G\alpha$ subunits in the frontal cortex of BD subjects. These investigators also suggest that the proportion of G-proteins in the trimeric state is significantly increased in bipolar brain, as observed through increases in both pertusis toxin (PTX)- catalyzed ADP ribosylation (a measure dependent on the heterotrimeric state of the substrate G-protein), and coprecipitation of $G\beta$ with $G\alpha$ [102]. Both of these measures were significantly reduced relative to controls upon receptor activation, indicative of enhanced receptor–G-protein coupling. Interestingly, there is also evidence of increased PTX-catalyzed ADP-ribosylation in platelet membranes of lithium-treated BD subjects [103].

Complementary observations in peripheral blood cells have largely confirmed the above findings, and explored the relationship between G-protein signaling and mood state. Indeed, Schreiber and associates [104] first reported enhanced agonist-stimulated binding of a tritiated nonhydrolyzable analog of GTP ($[^3H]Gpp(NH)p$) in mononuclear leukocytes (MNLs) of manic BD patients, implicating increased G-protein levels and/or enhanced receptor-mediated

Table 1 G-Protein Abnormalities

Tissue	Patient group	Physiological change	Ref.
Postmortem cerebral cortex	BD	↑ $G\alpha_s$; ↔ $G\alpha_i$, $G\alpha_o$, and $G\beta$ levels	100, 101
	BD	↔ $G\alpha_s$ mRNA levels	119
	BD	↑ coupling of 5-HT receptors to membrane G-proteins; ↑ $G\alpha_s$ levels; ↔ $G\alpha_i$, $G\alpha_o$, $G\alpha_z$, $G\alpha_{q/11}$, $G\beta$; ↑ ADP-ribosylation of $G\alpha_i$ and $G\alpha_o$; ↑ $G\beta$ coprecipitation with $G\alpha$	102
	BD	↓ $G\alpha_s$ levels in Li-treated subjects;	110
MNLs	BD (depressed)	↑ $G\alpha_s$ and $G\alpha_i$ levels	96
	BD (depressed)	↓ agonist-induced Gpp(NH)p binding; ↓ $G\alpha_s$ levels	109
	BD (manic and depressed)	mania – ↑ agonist-induced Gpp(NH)p binding; depression – ↓; mania – ↑ $G\alpha_s$ and $G\alpha_i$ levels; depression – ↓; ↔ $G\beta$	105
	BD (euthymic)	↓ $G\alpha_s$ levels in Li-treated patients; ↔ in Haloperidol-treated subjects	112
	BD (Type I Li-treated euthymic)	↔ $G\alpha_s$ levels	111
Platelets and MNLs	BD (mostly manic, Li-treated euthymic)	↑ $G\alpha_s$ levels in leukocytes; ↓ $G\alpha_{q/11}$ and ↑ ADP ribosylation in platelets from Li-treated patients	103
	BD I and II (euthymic on medication)	↑ $G\alpha_s$ levels in platelets of BD types I and II, irrespective of treatment; ↑ in MNLs	106
Granulocytes	BD (depressed and Li-treated euthymic)	↑ $G\alpha_s$ levels	108

activation of G-proteins in patients with BD. A large body of data strongly suggests an increase in both level and function of G-protein a stimulatory and inhibitory subunits in the manic and euthymic states [103–106], using immunoreactivity and/or [^{3}H]Gpp(NH)p binding assays.

Somewhat conflicting results have been observed in the depressed state, however. Young and associates [107] initially observed elevated $G\alpha_s$ and $G\alpha_i$ levels in MNLs from unmedicated depressed bipolar patients, a finding which was recently confirmed in granulocytes by another group [108]. In contrast, a number of studies conducted by Avissar et al. [105,109] show significantly decreased $G\alpha_s$ and $G\alpha_i$ levels and function in MNLs from bipolar as compared to manic patients or controls, and a concomitant negative correlation between $G\alpha_s$ protein function and severity of depression. These observations strongly suggest that changes in G-protein α subunits are a state-related abnormality.

Although the literature has been quite consistent with respect to elevated $G\alpha$ subunit levels and/or function in patients with BD, recent studies in both postmortem brain [110] and transformed lymphoblasts [111] have not been able to confirm these findings. By way of explanation, it has been suggested that differences in the level and function of this G-protein may be influenced by differences in mood state [105,111]. As a number of studies indicate that lithium treatment [99,103,108,112], antidepressants [113], and ECT [114] may modulate G-protein-a subunit activity, treatment history may also be informative to the G-protein response [110,111,115]. It should also be noted that it has proved more difficult to identify the mechanisms responsible for the observed G-protein abnormalities. Linkage studies of BD with the gene coding for $G\alpha_s$ have yielded negative results [116–118], and $G\alpha_s$ mRNA levels do not appear to be altered in postmortem brain from subjects with BD [119]. In any case, the transcriptional and posttran-

scriptional regulation of G-protein subunits is likely to be complex, and it has yet to be determined whether G-protein abnormalities are directly involved in BD or if they represent a secondary manifestation of dysfunction in some as yet uninvestigated mechanism. On the whole, studies in G-proteins suggest that altered Gα levels and function, perhaps through increased receptor-G-protein coupling, play important roles in the pathophysiology of bipolar disorder, by way of their pivotal roles as an amplifiers, integrators, and transducers of extracellular signals to diverse effector pathways in the CNS.

B.   Cyclic AMP Signaling Pathway

As has been described, a substantial body of literature suggests that increased basal and receptor-activated AC activity in BD brain and peripheral cells is linked to disturbances in the G-protein a subunits [91–93,100,101,104,105,109,120]. Furthermore, these changes correlate significantly with treatment or mood state, with a number of studies demonstrating decreased AC activity in depressed [105,109) or lithium-treated euthymic BD patients

[120]. As disturbances in activated AC, which catalyzes the formation of cAMP from ATP, may lead to further disturbances in the cAMP second messenger system, several groups have undertaken to determine whether these observations are attended by abnormalities downstream in the cAMP signaling cascade (Table 2).

The cellular effects of cAMP are mediated through cAMP-dependent protein kinase A (PKA). As such, investigations have examined this enzyme extensively. A postmortem study of [3H]cAMP binding to the PKA regulatory (R) subunits [121] was the first to suggest that the proportion of these subunits is reduced in brains of bipolar patients, possibly as a result of altered synthesis or protein degradation stemming from increased cAMP signaling [reviewed by 122]. As the activation state of PKA depends on the dissociation of R subunits following cAMP binding from the catalytic (C) moiety, a more recent postmortem brain study demonstrating increased basal and stimulated cAMP-dependent PKA activity in temporal cortex of patients with BD, as well as increased PKA sensitivity to cAMP, suggests a relative reduction in R subunit levels in BD [123]. Subsequent examination of the

Table 2   Cyclic AMP Signaling Pathway Abnormalities

Tissue	Patient group	Physiological change	Ref.
Postmortem cerebral cortex	BD	↑ forskolin-stimulated cAMP production;	100, 101
	BD	↔ AC levels	202
	BD	↓ [3H]-cAMP binding	121
	BD	↑ maximal and basal cAMP dependent PKA activity; ↓ PKA EC50 for cAMP	123
	BD	↓ forskolin-stimulated AC; ↓ CREB levels in anticonvulsant-treated subjects	110
MNLs	Depressed (including BD)	↓ Isoproterenol-stimulated cAMP production	95, 97
	BD (manic)	↑ agonist-induced Gpp(NH)p binding	104
	BD type I	↑ basal and NaF stimulated ↓ isoproterenol induced cAMP formation in subjects with high Ca^{2+} levels	156
Platelets	Depressed (including BD)	↓ PGE1-stimulated cAMP; ↓ NE inhibition of PGE1-stimulated cAMP production	203
	BD (unmedicated to Li-treated)	↓ forskolin-stimulated AC activity subsequent to Li-treatment in vitro	93
	BD (Li-treated euthymic)	↓ basal and stimulated AC activity	94
	BD (euthymic)	↑ cAMP dependent protein phosphorylation	125, 126
	BD (euthymic untreated—pre and post Li-treatment)	↑ basal and cAMP-stimulated protein phosphorylation following 15 days of Li-treatment in BD; ↔ in controls	127
	BD (unmedicated)	↑ PKA catalytic subunit levels vs. untreated euthymic BD and controls; ↔ PKA regulatory subunit (type I and II) levels; ↑ Rap1 levels	124

PKA subunits, while failing to uncover changes in R subunit levels, revealed significantly elevated PKA C immunolabelling in both manic and depressed BD patients, suggesting that elevated PKA activity in BD is a state-related abnormality resulting from an imbalance in the PKA subunits [124]. In assessing the functional measures of PKA activation, this group showed significantly increased cAMP-dependent phosphorylation of the MAPK-linked GTPase Rap1b in platelets of both lithium-treated and untreated euthymic BD subjects [125,126,127]. However, subsequent analyses of Rap1 immunoreactivity showed that the levels of this protein were significantly higher in platelets from BD patients irrespective of mood state [124,126], sug-

gesting that changes in Rap1 phosphorylation may be due to preexisting changes in Rap1 levels. This highlights the importance of further studies to clarify the relationship between PKA levels and cAMP-dependent phosphorylation.

C. Phosphoinositide Pathway

Studies in peripheral cells and postmortem brain have generally supported the notion of PI abnormalities in bipolar disorder (Table 3). However, initial investigations of free inositol levels failed to uncover significant changes in unmedicated BD patients [128,129], although one study observed reduced incorporation

Table 3 Phosphoinositide Signaling Pathway Abnormalities

Tissue	Patient group	Physiological change	Ref.
Postmortem occipital cortex	BD	$\uparrow$ G$\alpha_{q/11}$ and PLC-β immunoreactivity; $\leftrightarrow$ Gβ	142
	BD	$\downarrow$ GTPγS and NaF-stimulated [^{3}H]PI hydrolysis in BD vs. Li treated and controls; $\leftrightarrow$ Ca^{2+} stimulated PLC activity	143
	BD	$\downarrow$ inositol levels in frontal cortex; $\leftrightarrow$ IMPase activity	130
Postmortem frontal cortex	BD	$\uparrow$ PKC activation; $\uparrow$ PMA and phorbol-ester induced PKC translocation; $\uparrow$ cytosolic α and membrane associated γ- and ε-PKC isozyme levels; $\downarrow$ cytosolic ε-PKC levels	148
	BD (depressed)	$\leftrightarrow$ IMPase activity	28
Platelets	BD (Li treated euthymic)	$\downarrow$ PLC activity	94
	BD (manic—pre and post Li treatment)	$\uparrow$ membrane-bound vs cytosolic PKC activity; $\uparrow$ 5-HT elicited PKC translocation; $\downarrow$ basal and 5-HT elicited PKC activity following 2 weeks of Li treatment	144
	BD (manic)	$\uparrow$ PIP$_2$ levels	133
	BD (single case study)	$\uparrow$ PIP$_2$ levels manic vs. untreated euthymia; $\downarrow$ Li treated vs. manic; $\leftrightarrow$ between Li treated vs. untreated euthymic	135
	BD (Li-treated euthymic)	$\downarrow$ PIP$_2$; $\leftrightarrow$ in other phospholipids	136
	BD (manic and depressed)	$\uparrow$ basal PKC activity in manic BD; $\downarrow$ PKC responsiveness to PMA/thrombin in depressed BD; $\uparrow$ PKC responsiveness to 5-HT; $\leftrightarrow$ in PMA induced translocation	145
	BD (type I unmedicated and Li-treated)	$\leftrightarrow$ PKC-α levels	204
	BD (euthymic untreated—pre and post Li treatment)	$\downarrow$ PIP$_2$; following Li treatment; $\leftrightarrow$ in other phospholipids	137
	BD (Li-treated euthymic)	$\downarrow$ PIP$_2$; $\downarrow$ cytosolic PKC-α levels; no correlation between PLC and PIP$_2$ measures	138
	BD (depressed)	$\uparrow$ membrane PIP$_2$ levels; $\leftrightarrow$ in other phospholipids	134
Erythrocytes	BD (unmedicated and Li-treated)	$\downarrow$ inositol 1-phosphatase activity in Li treated BD	131

of tritiated inositol to PI intracellular pools [128]. Subsequent studies in postmortem brain did observe a significant decrease in free inositol levels in the frontal cortex of BD patients, but found no change in IMPase activity [130]. This finding supports an earlier study which found no significant difference in IMPase activity from erythrocytes of unmedicated BD as compared to controls [131]. However, this same study did confirm an inhibitory effect of lithium, consistent with preclinical observations. In addition, recent findings from MRI studies indicate a temporal dislocation between lithium-induced myoinositol depletion and clinical improvement [132]. As the mechanism of lithium therapy does not appear to involve inositol depletion in vivo, this effect may be seen as at best an initiating event. To further evaluate these findings, researchers examined the relative content of membrane phosphoinositides, with a particular emphasis on the major PLC substrate PIP_2, under various mood and treatment states. Brown et al. [133] were the first to show increased levels of PIP_2 in the manic state of BD, a finding that was recently observed in platelets of patients with bipolar depression as well [134]. Since PIP_2 is the precursor of IP_3 and DAG, the authors suggested increased PI signaling as a possible outcome of their findings [133,134]. A subsequent study by the same group reported on a patient whose PIP_2 membrane levels increased in the course of cycling from unmedicated euthymia to mania, and normalized with a return to euthymia subsequent to lithium treatment [135]. This finding was explored further in a number of subsequent studies, which together show significant and specific reduction in platelet PIP_2 levels in lithium treated euthymic BD patients as compared to controls [136–138]. While mood normalization cannot be discounted as a contributing factor, these studies suggest that lithium may blunt PI signaling, at least in part by diminishing the relative abundance of PIP_2 [136].

Regulation of PLC, which hydrolyzes membrane inositol phospholipids (chiefly PIP_2) to yield IP_3 and DAG, is mediated primarily by the G-protein G_q and G_{11} isoforms [24,139,140], although one or more G_i or G_o isoforms may also play a role [4,141]. However, there are few direct analyses of the primary PI-coupled G-proteins in clinical samples. Indeed, while one postmortem study reported increased abundance of both $G\alpha_{q/11}$ and $PLC\beta$ specific to the occipital region of subjects with BD [142], a second study observed decreased PI-coupled G-protein activation in the same region, as determined by GTPγS-stimulated [^{3}H]PI hydrolysis [143]. In an attempt to explain

these findings, the authors suggest an adaptive increase in $G\alpha_{q/11}$ expression as a result of deficient PI signaling activity in BD, although long-term lithium treatment could also have confounded the results [143]. Of relevance, an earlier study in peripheral blood cells found no significant differences in $G\alpha_{q/11}$ levels in unmedicated BD subjects, although the levels of these proteins in lithium-treated samples were decreased relative to controls [103]. Together with the observed changes in AC-coupled G-proteins, the data from PLC-coupled $G\alpha_q$ and $G\alpha_{11}$ may be indicative of a functional imbalance between abnormally decreased PI-signaling and elevated cAMP-signaling systems [143].

PKC, the effector molecule in the PI-signaling pathway, is an important intracellular enzyme that has stimulated much interest in recent years. A number of studies published by Friedman and coworkers [144,145] demonstrated increased membrane-bound platelet PKC activity in the manic state of subjects with BD. These findings were seen as further confirmation of impaired PI signaling, as PKC is activated directly in response to intracellular DAG levels. In addition, the earlier study, which assessed platelets obtained from BD patients before and during lithium treatment, showed increased serotonin-stimulated PKC translocation (a measure of stimulated PKC activity) from the cytosolic to the particulate fraction in the manic state [144]. This measure, along with basal PKC activity, was reduced following lithium treatment for 2 weeks [144], and in platelets from euthymic lithium treated BD patients [137,138], similar to preclinical findings [31,146,147]. More recently, investigators from the same laboratory examined the PKC enzyme in postmortem brain from subjects with bipolar disorder [148]. They observed increased PKC activity and translocation to membrane fractions, as well as increased levels of cytosolic α- and membrane-associated γ- and ζ-PKC isozyme levels in frontal cortex from BD subjects relative to tissue from controls. Additional studies by this same laboratory and others suggest that these findings may be specific to BD [144,145,149,150] and may be related to changes in the enzyme protein per se, or to increased expression of membrane RACK (receptor for activated C-kinase) protein, which anchors the enzyme to the membrane [151,152].

Given the relatively consistent findings of elevated PKC activity in bipolar disorder, and related studies showing attenuating effects of lithium treatment on PKC activity, Manji and coworkers have recently suggested that PKC inhibitors may be efficacious in the clinical treatment of this disorder [30]. As such, they

have initiated pilot studies with tamoxifen, a synthetic nonsteroidal antiestrogen widely used in the treatment of breast cancer, which was recently found to be a selective PKC inhibitor as well. Interestingly, preliminary findings from a small sample are so far promising, and provide evidence of some antimanic qualities for this medication [153]. However, these results must be interpreted with caution, and conclusions must await results of large-scale, randomized double-blind placebo-controlled studies.

D. Intracellular Calcium Signaling

The calcium signaling system has increasingly been the focus of investigation in mood disorders research. Evidence supports the notion that Ca^{2+} channels may be coupled to $G\alpha_s$ in some tissues [154,155], suggesting that the relatively robust findings of increased $G\alpha_s$ levels associated with BD may result in increased cytosolic Ca^{2+} concentrations. A recent study by Emamghoreishi et al. [156] indicates that trait-dependent disturbances with respect to βAR sensitivity and G-protein-coupled AC activity may occur in conjunction with high concentrations of Ca^{2+}. Specifically, they described decreased isoproterenol-stimulated, and increased basal and NaF-stimulated cAMP formation in β lymphocytes from BD type I patients who had high intracellular Ca^{2+} levels, compared to BD patients with normal Ca^{2+} concentration and controls. As βAR sensitivity is subject to regulation by a number of factors, including PKC and PKA activity (which are in turn sensitive to either direct or indirect modulation by Ca^{2+}), dysfunction at the level of one pathway may disrupt the intricate crosstalk between various signal transduction systems [156].

Furthermore, calcium communicates directly with the primary effector molecules of the PI-signaling pathway, and increased PI signaling might be expected to be accompanied by increased levels of intracellular calcium. As such, although investigators have maintained a long-standing interest in calcium signaling irrespective of these other second-messenger systems, the findings in these two postreceptor signaling systems may be relevant for future and current study. Initial studies in calcium signaling by Carman et al. [157] uncovered a significant relationship between transient increases in serum Ca^{2+} levels and the switch into mania. Direct measurement of intracellular free calcium has largely supported and extended these observations, with Dubovsky and colleagues [158] describing increased baseline Ca^{2+} concentration in platelets and leukocytes from unmedicated bipolar patients in both

manic and depressed states (Table 4). Indeed, given that Ca^{2+} is necessary for PKC activation, many of the previously described findings with respect to elevated PKC activity and translocation in patients with BD may be at least partly a consequence of increased affinity of certain PKC isozymes to Ca^{2+} [145]. However, while the aforementioned Ca^{2+} studies are intriguing in that they complement previously described studies in the PI-signaling pathway, other investigators have not been able to confirm these findings [159–163].

On the other hand, treatment of blood cells with various agents has generated more robust observations. Stimulation of platelets from unmedicated depressed and manic BD patients with platelet-activating factor and thrombin significantly increased calcium response relative to euthymic BD, MDD, and controls [164–166]. Likewise, agonist-induced stimulation of serotonin 5HT$_{2A}$ receptors produced consistent elevations in Ca^{2+} response in both depressed bipolar and unipolar subjects, as reported in a number of studies by diverse laboratories [159,163,167–169]. These findings were also confirmed in a very recent study including a wide range of psychiatric disorders, although in this case they were found to be specific to platelets from BD patients from a sample [162]. By way of explanation, the authors suggest that some patients classified as MDD in previous studies from their group [163,166,169] have recently been reclassified on follow-up diagnoses, with significantly increased 5HT-induced mobilization over the other "unipolar" patients that may have inadvertently skewed the results in favor of significance [162]. Another study of both unmedicated manic and euthymic bipolar patients further confirms an increase in 5HT-stimulated Ca^{2+} responses in the manic state [170]. While some of these studies suggest that elevated Ca^{2+} concentration and/or response may be a state-dependent variable that normalizes with remission of mood [158], others indicate that the persistence of these findings in euthymia suggests it to be a trait-dependent variable [161,167,169,171,172), and at least one study could not discern a correlation between severity of depressive symptoms and Ca^{2+} response [169]. Finally, while the involvement of the calcium/calmodulin activated kinases in regulating other signal transduction pathways and gene transcription has been well documented in preclinical samples, only one clinical study has been published on this family of enzymes to date. This study, conducted in postmortem cerebral cortex, was unable to associate changes in CaMK immunoreactivity with BD [173].

Table 4 Calcium Signaling Pathway Abnormalities

Tissue	Patient group	Physiological change	Ref.
MNLs	BD types I and II	↑ basal Ca^{2+} concentration; ↓ percent change in phyto-hemagglutinin stimulated vs. basal Ca^{2+} levels in BD type I	172
	BD type I	↑ basal and NaF stimulated and ↓ isoproterenol stimulated cAMP formation in BD subjects with high basal Ca^{2+} levels;	156
Platelets and MNLs	BD (manic and depressed)	↑ basal and stimulated Ca^{2+} levels in manic and depressed states	158, 205, 206
	BD types I and II, unmedicated and Li-treated	↑ basal and stimulated Ca^{2+} concentration; ↔ between types or med state in BD; no correlation between Ca^{2+} and severity	207
Platelets	BD (unmedicated)	↑ basal and stimulated Ca^{2+} levels in manic and depressed states vs. euthymic and control	165, 164
	BD (manic and depressed)	↑ 5-HT stimulated Ca^{2+} response	159
	BD (Li-treated)	↑ basal Ca^{2+} levels; ↑ thrombin-stimulated Ca^{2+} response; ↑ thrombin-stimulated Ca^{2+} response with Li treatment in vitro	171
	BD (depressed)	↑ 5-HT-stimulated Ca^{2+} response	163
	BD (manic and depressed, Li-treated euthymic)	↑ PAF and thrombin stimulated Ca^{2+} response in unmedicated states	166
	BD (depressed)	↑ 5-HT stimulated Ca^{2+} responses	167, 168
	BD	↔ basal or stimulated Ca^{2+}; ↑ serum and 5-HT stimulated intracellular Ca^{2+} levels in Li treated group	160
	BD (depressed)	↑ 5-HT-stimulated Ca^{2+} response	169
	BD (depressed)	↔ basal or 5-HT/thrombin induced Ca^{2+} response with either in vitro or chronic Li treatment	208
	BD (eythymic)	↔ basal Ca^{2+}	161
	BD (manic)	↑ 5-HT stimulated Ca^{2+} responses	170
	BD (manic and depressed)	↔ Ca^{2+} uptake; ↓ Ca^{2+} uptake following in vitro Li treatment in all samples	209
	BD (depressed to Li treatment—longitudinal study)	↑ 5-HT-stimulated Ca^{2+} response correlated with response to treatement with mood stabilizers	210
	BD	↔ basal or 5-HT induced Ca^{2+}	162
Platelets and Erythrocytes	BD	↔ Ca^{2+} response; ↑ Ca^{2+}-ATPase levels in manic and depressed BD	175
Erythrocytes	BD (depressed)	↓ Na^+/K^+-ATPase activity	177, 178, 211
	BD (manic and depressed)	↑ Ca^{2+}-ATPase activity	174
Neutrophils	BD (depressed and euthymic; Li-treated euthymic)	↑ fLMP-stimulated Ca^{2+} responses in BD vs. controls; ↓ fLMP-stimulated Ca^{2+} responses in Li treated BD	212
	BD (Li-treated euthymic)	↓ fLMP-stimulated Ca^{2+} responses	213

In accounting for the mechanisms behind disrupted calcium signaling, further confirmation of calcium-signaling abnormalities in BD was provided by reports of elevated Ca^{2+} extrusion ATPase activity in red blood cells from manic and depressed [174,175], as well as lithium-treated [176] BD patients in comparison to matched controls. These findings suggest either a compensatory change in Ca^{2+}-ATPase activity as a result of—or a primary change leading to—increased levels of intracellular free Ca^{2+}. As well, some groups have described significantly lower Na^+-K^+-ATPase activity, which regulates Na^+/Ca^{2+} exchange, in red blood cells of depressed patients with BD [177–180].

E. Regulation of Gene Expression

Gene expression is critical to the maintenance of cellular viability and function, and has also been strongly implicated in the neuronal changes thought to underlie the pathobiology as well as pharmacotherapy in subjects with BD. Recently, studies have attempted to associate diagnosis or treatment with changes in gene expression, using a variety of techniques with the ability to simultaneously analyze expression of thousands of genes. These powerful new tools thus hold out the exciting prospect of screening large numbers of genes for differential regulation of factors which may be relevant to the underlying disease process or pharmacotherapy. Differential display, serial analysis of gene expression (SAGE), and cDNA expression arrays are three such techniques which have produced promising results in both clinical and preclinical samples [181–185], including a possible decrease in the inhibitory cytokine transforming growth factor beta in the frontal cortex of subjects with BD [181].

The protein kinases regulated by postreceptor signal transduction pathways have among their targets several transcription factors which are essential to maintaining responsive and accurate gene expression. The observation of signal transduction abnormalities thus suggests that downstream consequences at the level of these transcription factors may play a role in the neuronal changes thought to underlie BD. To this end, many studies have examined the effects of pharmacotherapy on transcription factor activity in cell lines and animal models. It has repeatedly been observed that therapeutic concentrations of both lithium and valproate regulate AP-1 binding activity in these systems [182,186–188]. Likewise, Nibuya et al. [189] demonstrated that chronic AD treatment increased rat hippocampal CREB protein and mRNA levels as

well as its binding to the CRE, a finding which was confirmed in postmortem brain samples from subjects with MDD [190]. However, the status of these enzymes in subjects with BD has not been extensively explored. The sole clinical study to this end, by Dowlatshahi et al. [110], measured the levels of CREB in temporal and occipital cortices of subjects with BD, MDD, SCZ, and controls. While they were unable to observe any significant association of CREB levels with BD, decreased levels were observed in subjects who died as a result of suicide, and those treated with anticonvulsants at the time of death. This later finding, which is opposite of that observed with AD treatment, supports studies in both rat brain and cultured cells [187,191,192]. Furthermore, it is consistent with the effects of lithium treatment on the signal transduction pathways (see above) and the clinical effects of ADs and ACs in different states, such as mania and depression.

IV. DISCUSSION

The above data provide convincing evidence of signal transduction abnormalities associated with BD. In summary, the findings supporting cAMP-signaling abnormalities in BD are extensive and suggest increased levels of $G\alpha_s$, at least in the manic state. These reports are supported by observed abnormalities further downstream, in elevated AC-mediated cAMP production and PKA activation. In the PI pathway, a set of findings including increased PIP_2 levels and PKC activity has generally implicated increased signaling along this pathway as well. Indeed, experiments currently in progress are attempting to ascertain the efficacy of PKC inhibitors as antimanic agents. However, the few studies on G-protein-coupled PLC activity have been less conclusive. Finally, increased Ca^{2+} responses have been observed by a number of independent laboratories in both peripheral blood cells and postmortem brain tissue of subjects with BD, broadly supporting the findings in PI signaling. However, in spite of attempts to control for the use of medications, the possibility that treatment with antidepressants and/or mood stabilizers may be at least partly responsible for some of the observed changes cannot be discounted [110]. Furthermore, extensive crosstalk between the AMP and the phosphoinositide- and calcium-signaling pathways confounds the elucidation of clear loci of major effect in this pathway.

Given the complexity of intracellular communication, more recent studies have implicated the involvement of other signal transduction pathways in BD,

including the ERK/MAPK cascade. The last few years have witnessed the growth of considerable interest in this pathway, in light of the extensive crosstalk between this and the other signal transduction systems, and the recent focus on neurodevelopmental and kindling models as etiologically relevant in mood disorders research [3,193–196]. Studies by Perez et al. have revealed that the levels of Rap1b are increased in subjects with BD, with a concomitant increase in its active phosphorylated state [124–127]. However, the exact mechanism of Rap1 regulation, and its place in the intracellular milieu in reference to these other signaling pathways, remains highly speculative. In addition, studies of gene expression have directed research to consider novel targets, such as GSK-3β. In 1973, a team of researchers first demonstrated that therapeutic concentrations of lithium inhibit the phosphorylation of glycogen synthase by acting on an enzyme subsequently identified as GSK-3β [197,198]. More recently, VPA has been shown to have a similar effect on GSK-3β activity, further suggesting that this enzyme may play a role in the pathophysiology of BD [199]. Lesort and associates [200] examined the immunoreactivity of GSK-3β and two proteins shown to be modified by this enzyme—tau and β-catenin—in prefrontal cortex from subjects with BD and matched controls. Although no change in any of these measures reached statistical significance, the tau profile was modified in subjects with BD. Similarly, a recent study could find no change in GSK-3β protein levels in frontal cortical samples from subjects with BD [201]. Therefore, these studies suggest that mood stabilizer–mediated GSK-3β regulation may correct pathobiological dysfunction at other loci. However, further study is needed to establish the role of GSK-3β in pharmacotherapy.

V. CONCLUSION

Aggregate findings from a diverse array of clinical samples strongly implicate dysregulation of second-messenger systems in the pathophysiology of BD. In particular, altered levels and function of Gα subunits and effector molecules such as PKA and PKC have consistently been associated with BD in both peripheral cells and postmortem brain, suggesting that these systems may be involved in the complex neurobiological changes believed to underlie this disorder. On the other hand, the continuing inability to establish direct links between clinical abnormalities and specific

biochemical insults has recently been attributed to the complex interactions between many, if not all, of these signal transduction systems. Intracellular signaling is refined at multiple levels by an extensive cross-regulatory network, whereby second messengers linked to one receptor modulate the effector responses at another. The integration and modulation of these responses ensure the fidelity of signal transduction, and finely attune signaling to conditions both within and without the cell. This process also ensures that the initiation, timing, and termination of cellular responses are coordinated so as to maintain the functional integrity of the system. Likewise, BD exhibits a marked variability in the symptoms and course of the illness across patients, who also respond differently to pharmacotherapy. As it is unlikely that a single defect could account for these observations, BD may be due to the interaction of many interacting abnormalities. Thus, more recent studies have implicated novel second-messenger systems, such as the ERK/MAPK cascade, in the progression of mood disorders. With the fortuitous advances in molecular techniques such as DD, SAGE, and cDNA array hybridization, it is now possible to visualize the end result of these diverse abnormalities within the nucleus. While the published findings from these studies have for the most part been limited to cell culture and animal models, we have recently published a cDNA array study in postmortem brain samples of subjects with BD [181]. These results, in combination with work in progress at many different research centers, promise to further our understanding of signal transduction abnormalities in the context of a complex, multifactorial disease such as BD.

Molecular Genetics and Mood Disorders

DANIEL SOUERY and JULIAN MENDLEWICZ
Erasme Hospital, Brussels, Belgium

I. INTRODUCTION

Advances toward the understanding of the etiological mechanisms involved in mood disorders provide interesting yet diverse hypotheses and promising models. In this context, molecular genetics has now been widely incorporated into genetic epidemiological research in psychiatry. Affective disorders and, in particular, bipolar affective disorder (BPAD) have been examined in many molecular-genetics studies which have covered a large part of the genome, specific hypotheses such as mutations have also been studied. Decades of research into the genetic etiology of mood disorders provide evidence in favor of complex mode of inheritance unlikely to be determined by single-gene dysfunction, and appear to have non-Mendelian patterns of inheritance. Most recent studies indicate that several chromosomal regions may be involved in the etiology of BPAD. These include genes on chromosomes 18, 21, 4, 5, 12, 11, and X. Genetic heterogeneity and polygenic inheritance may explain the large number of potential genes involved.

This chapter will review the current methodologies and study tools used to search for molecular genetic factors in mood disorders and the chromosomal regions of interest already investigated for bipolar (BPAD) and unipolar (UPAD) mood disorders.

II. GENETIC EPIDEMIOLOGY

The various strategies available to investigate genetic risk factors in psychiatric disorders belong to the wider discipline of genetic epidemiology. This combines both epidemiological and genetic investigations and has the primary objective of identifying the genetic and nongenetic (environmental) causes of a disease. Genetic epidemiological data in affective disorders has come mostly from family, twin, adoption and segregation (within-family) studies. Family, twin, and adoption studies are the mainstay in establishing the genetic basis of affective disorders. These methods first demonstrated that genetic factors are involved in the etiology of these disorders. Twin and adoption data may also be used to investigate the relative contributions of genetic and environmental factors to the etiology of a disease [Vieland et al., 1995]. The exact contribution of these factors is not yet firmly understood for affective disorders, but some recent studies provide contributing findings. The study of adoptees separated from their biological parents has consistently favored the gene-environment hypothesis in the etiology of diverse psychiatric disorders. One study [Cadoret et al., 1996] shows that major depression in females is predicted by an alcoholic diathesis only when combined with an environmental factor that is characterized by a psy-

chiatrically ill adoptive parent. Other possible environmental factors were identified, such as fetal alcohol exposure, age at the time of adoption, and a family with an adopted sibling who had a psychiatric problem. These findings confirm the importance of the gene-environment interactions in the understanding of etiological mechanism in mood disorders. The adoption study design is also used to validate clinical entities throughout the understanding of the gene-environment interactions as etiologic factor. The concept of depression spectrum disease has originally been developed from family studies [Winokur et al., 1971] and further validated in adoption studies. In this model, depressions were divided into pure depressive disease (only depression in the family) and depression spectrum disease (characterized by a family history of alcoholism or antisocial personality). Different adoption studies confirmed this hypothesis, showing that daughters of alcoholics who where not adopted away showed significantly greater depression than control subjects and their female siblings who had been adopted away [Goodwin et al., 1977]. An excess of biological mothers with substance abuse was found among adoptees with depression [Van Knorring et al., 1983], and more alcoholism was observed in the biological relatives of depressed adoptees than in the biological relatives of nondepressed adoptees [Wender et al., 1986]. These results confirm the significant role of gene-environment interactions in depression spectrum disease and further validate the concept.

The diagnostic validation and the structure of the genetic and environmental risk factors in mood disorders are also approached in twin studies. Using a prospective, epidemiologic, and genetically informative sample of adult female twins, Kendler et al., [1996] were able to identify and validate a typology of depressive syndromes characterized by mild typical depression, atypical depression (increased eating, hypersomnia, frequent, relatively short episodes, and a proclivity to obesity), and severe typical depression (comorbid anxiety and panic, long episodes, impairment, and help seeking). The members of twin pairs concordant for depression had the same depressive syndrome more often than expected by chance, and this resemblance was greater in monozygotic than in dizygotic pairs. To clarify the interactions between genetic factors and stressful life events in the etiology of depression, a population-based sample of female-female twin pairs including 2,164 individuals were analyzed in regard to stressful life events and onset of major depressive episodes in the past year [Kendler et

al., 1995]. For severe stressful events, the best-fitting model for the joint effect of stressful events and genetic liability on onset of major depression suggested genetic control of sensitivity to the depression-inducing effects of stressful life events. The authors concluded that genetic factors influence the risk of onset of major depression in part by altering the sensitivity of individuals to the depression-inducing effect of stressful life events. In a more complex analysis of comorbidity among different psychiatric disorders, a large epidemiological survey of 1030 female-female twin pairs [Kendler et al., 1995] investigated the influence of major genetic and environmental risk factors (separated into different domains: genes, family environment, and individual-specific environment) on comorbidity between different psychiatric disorders (phobia, generalized anxiety disorder, panic disorder, bulimia, major depression and alcoholism). Each major risk factor domain influenced comorbidity, but in a distinct manner according to the disorders investigated and most of the genetic factors that influence vulnerability to alcoholism in women do not alter the risk for development of other common psychiatric disorders.

Segregation analysis is used to determine the mode of genetic transmission of a disorder by describing the distribution of phenotypes in affected families. The two principal hypotheses that have emerged from these complex analyses in affective disorders are the Single Major Locus (SML) model and the Polygenic Model (PM) involving possible interaction between two or more loci. The exact mode of inheritance is not yet clear [Smeraldi et al., 1995]. The situation is further complicated by the possible presence of anticipation in families with mood disorder [McInnis et al., 1993; Nylander et al., 1995; Engström et al., 1995]. This mode of transmission, which involves dynamic mutations, fits better with the twin and family epidemiological data available in affective disorders and may explain their non-Mendelian pattern of inheritance.

III.   LINKAGE METHOD

The initial molecular genetic studies of BPAD, considered the core phenotype of affective disorders, involved the parametric linkage studies of large families. Linkage examines the cosegregation of a genetic marker and disease in affected individuals within families—that is, the nonrandom sharing of marker alleles between affected members of each family

[Smeraldi and Macciardi, 1995]. Two genetic loci are linked if they are located closely together on a chromosome. In linkage analysis, the distance between a marker locus and the gene under investigation is used for gene mapping. This method was originally designed to explore a major single genetic transmission and to evaluate the extent of cosegregation between genetic markers and the phenotype investigated in pedigrees. After initial localization, additional markers in that chromosomal region are typed, and the location of the disease gene may be determined more precisely by further linkage analysis. Linkage studies use Lod score analysis which require the specification of genetic parameters such as gene frequencies, mode of transmission and penetrance [Ott, 1991]. A limitation of this approach is that for affective disorders, the mode of inheritance in unknown, so that a variety of genetic models must be tested. Thus, multiple testing is required which may increase the risk of type I errors. Since the true mode of inheritance is not known, an appropriate model may not be tested at all, so there is a risk of type II errors as well. Furthermore, the linkage approach fails to detect minor gene effects that contribute to genetic susceptibility to the disorder [Propping et al., 1993]. Another limitation in linkage studies is that broad-spectrum phenotypes are often employed, which may be less stable over time and less likely to have the a homogeneous genetic etiology.

Large pedigrees with high density of affected status are often used in linkage studies. Genetic heterogeneity may be present is such large densely affected pedigrees. These supposedly homogeneous groups of individuals are not necessarily sufficient to overcome the possibility that different genes may lead to the disease for different people. Moreover, large pedigrees are rare and thus difficult to collect. Furthermore, since these pedigrees are rare, it is questionable that they actually represent the etiology of the disease in the population at large.

The sib-pair method provides advantages over classical linkage analysis in that specific parameters need not be specified. The sample size, on the other hand, must be relatively large owing to decreased power.

High Lod scores have been observed in single pedigrees but are generally not replicated in others, which may be due to genetic heterogeneity. Even if genetic heterogeneity is present, one should find consistently positive, if not significant, linkage results in other families. Linkage may be present in some families and not in others, and these families may in fact be rare.

IV. ASSOCIATION METHOD

Given the difficulties inherent in detecting genes of small to modest effect using linkage approach, the candidate gene association method offers an alternative strategy of studying genetic factors involved in complex diseases in which the mode of transmission is not known. Association between diseases and marker may be found if the gene itself, or a locus in linkage disequilibrium with the marker, is involved in the pathophysiology of the disease [Hodge, 1994]. Thus, an association may imply a direct effect of the gene tested, or the effect of another gene close to the marker examined. Linkage disequilibrium between the disease locus and the marker tested occurs when the level of concordance between the two loci is higher than that would be expected by chance, the reason for this being their proximity on a chromosome. The major advantage of association studies is that they can detect genes with minor effects. The association method is therefore appropriate for examination of a disorder that may be caused by genes that augment susceptibility but are neither necessary nor sufficient for the development of the disease [Greenberg, 1993; Plomin et al., 1994]. The major limitation is that spurious associations between a genetic marker and a disorder may result from variations in allele frequency between cases and controls if the two populations are ethnically different (population stratification). It is important in this case to test populations that are comparable in ethnic background.

The Haplotype Relative Risk (HRR) strategy uses parental data for the control sample and reduces this type of bias. The HRR method selects nontransmitted alleles from parents of the probands for the control population [Terwilliger and Ott, 1992]. Another limitation encountered in association studies is that small sample sizes do not provide enough statistical power to detect minor gene effects. Caution must be used in the interpretation of the association observed. The result may be interpreted as linkage disequilibrium between the disease locus and the associated marker allele(s), the associated marker may be a susceptibility factor which is directly involved in the disease, or the association may be due to chance. The association method alone cannot determine which interpretation is correct [Hodge, 1994]. Once a positive association is observed, exploration of the allele occurring more frequently with the disease must be carried out to ascertain if it represents a change in gene functioning that might be implicated in the pathophysiology of the disorder. If the observed disease allele leads to reduced function or transcription of an enzyme or receptor

involved in neurotransmission, the result would truly enhance our understanding of the etiology of the disease.

The candidate gene approach is a useful method to investigate association between markers and disease. A candidate gene refers to a region of the chromosome which is potentially implicated in the etiology of the disorder concerned. The possibility of false-positive results must be taken into account, as a very large number of candidate genes now exist. The probability that each of these genes is involved in the etiology of the disorder is relatively low.

The candidate gene approach can be extended to phenotypes not directly linked to the diagnoses of mood disorders. The therapeutic effect of psychotropic drugs may be considered to investigate genetic polymorphisms (psychopharmacogenetics). In recent years, research in psychopharmacogenetics has focused on evaluating functional polymorphisms both in genes coding for drug-metabolizing znzymes and in genes coding for other enzymes or receptors involved in the mechanism of action of psychoactive drugs. In this context, the use of new technologies is rapidly evolving. Gene expression patterns in response to drug treatments can be investigated by new techniques such as DNA microarrays. Microarrays are powerful tools for investigating the mechanism of drug action by measuring changes in mRNA levels in brain tissues before and after exposure to treatment [Debouck and Goodfellow, 1999].

V. CANDIDATE CHROMOSOMAL REGIONS AND CANDIDATE GENES

A. Chromosome X

A systematic review of the literature on linkage studies in BPAD (Turecki et al., 1996) indicated that the proportion of positive DNA findings is higher for X markers compared to other chromosomal regions. Mendlewicz et al. (1987) first reported possible genetic linkage between BPAD and coagulation Factor IX (F9) located at Xq27 in 11 pedigrees. The same genetic marker was also tested in a French pedigree where linkage was confirmed [Lucotte et al., 1992]. Linkage with DNA markers on the X chromosome has been excluded, however, in other pedigrees [Berrettini et al., 1990, Gejman et al., 1990, Bredbacka et al., 1993]. A study published in 1987 by Baron et al. [1987] demonstrated positive linkage for glucose-6-phosphate deshydrogenase (G6PD), but later results

from the same author did not support this finding [Baron et al., 1993], though G6PD was slightly positive for linkage in one family. In a more recent study [De Bruyn et al., 1994] several DNA markers in the Xq27-28 region were tested in nine bipolar families. Results suggestive of linkage were found in four bipolar I families with the markers F9, F8, and DXS52. Pekkarinen et al. [1995] evaluated 27 polymorphic markers on the X chromosome (Xq25-28 region) in one large Finnish family, and found the highest Lod scores when using a narrower phenotype definition (BPI and BPII only). Linkage was found between a marker located on Xq26 (AFM205wd2) and BPAD. This marker is located ∼ 7 cm centromeric to the F9 locus. The initial genome screen for BPAD in the NIMH genetics initiative of 97 pedigrees also revealed positive though small Lod-scores on the X chromosome (Xp22 and Xq26-28) [Stine et al., 1997]. All these results are extremely suggestive of X linkage; in particular, the Xq26-28 should be considered a strong candidate region for genetic studies in BPAD.

The association between BPAD and polymorphic DNA markers in the pseudoautosomal region of the X chromosome have also been investigated. Yoneda et al. [1992] reported an association between the A4 allele of the marker DXYS20 in this chromosomal region in Japanese BPAD patients. This has not been replicated in European populations, however [Nothen et al., 1993; Parsian et al., 1994].

The MAOA and MAOB genes which code for the enzymes that degrade biogenic amines, including neurotransmitters implicated in the pathophysiology of affective disorders such as norepinephrine, dopamine and serotonin, are both located on the X chromosome and tightly linked to each other (Xp11.12–Xp11.4). Lim et al. [1994a, 1995] reported a weak but significant association for 3 different polymorphisms of MAOA, but not for MAOB, in a sample of 57 BPAD patients compared to population controls not assessed for psychiatric status. A weak association was found for MAOA and bipolar disorder by Kawada et al. [1995], but different alleles were more frequent in the patient population compared to the previous report. A series of negative reports followed, leaving the question open as to the usefulness of the MAO genes in psychiatric genetics research [Craddock et al., 1995a, Nothen et al., 1995; Muramatsu et al., 1997).

B. Chromosome 18

Berrettini et al., [1994] first reported linkage of BPAD to chromosome 18 DNA markers in a systematic gen-

ome survey of 22 families including 156 subjects with bipolar disorder. Though the overall Lod score for the pedigree series was negative, results of two-point linkage analysis in individual families indicated possible linkage with some marker loci in the 18p11 region. Nonparametric analysis (affected pedigree member and affected sib-pair analysis) of this sample confirmed the observation of linkage [Gershon, 1996]. These results suggested the existence of a susceptibility gene in the pericentromic region that can not be fully evaluated by classic linkage analysis. These results may be of interest because genes coding for the alpha unit of a GTP binding protein involved in neurotransmission, a corticotrophin receptor gene, and RED-1-containing triplet repeats have been mapped to this region. Stine et al. [1996] studied 28 nuclear families for markers on chromosome 18 and also found evidence for linkage and allele sharing between sib-pairs at 18p11.22–p11.21. This study replicated the findings of Berrettini, yet also demonstrated evidence for linkage and parent-of-origin effect in a region located on the long arm of chromosome 18, a sex-averaged distance 30 cm away. An excess of paternally but not maternally transmitted alleles from the D18S41 was observed.

In a study of five rigorously defined, high-density German families, no robust evidence for linkage for the pericentromeric region could be found, though one family showed slightly elevated lod scores under a recessive mode of inheritance for D18S40 [Maier et al., 1995]. Linkage to the pericentromeric region of chromosome 18 was excluded in three large Old Order Amish families [Pauls et al., 1995], and in two large Belgian pedigrees [De Bruyn et al., 1996]. In the Belgian pedigrees, while negative Lod scores were found for a marker located in the pericentromeric region, linkage and segregation analysis in one family suggested that the 18q region of the chromosome (18q21.33–q23) might contain a susceptibility locus for BPAD [De Bruyn et al., 1996]. Freimer et al. [1996], using both linkage and association strategies, reported evidence of linkage with markers in this region (18q22) in a Costa Rican pedigree with a common founder. A subsequent study further supported the interest of the 18q23 region showing linkage among six pedigrees [Coon et al., 1996]. An additional study of 173 affected subjects using the multilocus affected-pedigree member method, demonstrated a susceptiblity gene in the pericentromeric region, and multilocus analysis by affected sib-pair method also showed evidence for linkage [Berrettini et al., 1997]. Yet despite slight allele sharing with two markers on

chromosome 18 (D18S40 on 18p and D18S70 on 18q) in the NIMH genetics initiative BPAD pedigrees, linkage to chromosome 18 was not confirmed in this large genome scan [Detera-Wadleigh et al., 1997]. Furthermore, Knowles et al. [1998] found no evidence for significant linkage between bipolar disorder and chromosome 18 pericentromeric markers in another large sample (1013 genotyped individuals) using 10 highly polymorphic markers.

C. Chromosome 5

Preliminary linkage data including three DNA markers on this chromosome (D5S39, D5S43, and D5S62) suggested linkage with BPAD [Coon et al., 1993]. Two of these markers, D5S62 and D5S43, are located on the distal region of the long arm of chromosome 5 (5q35-qter). This region contains candidate genes for affective disorders such as the alpha-1 protein subunit of the GABA A receptor (GABRA1) and the 5HT1A receptor (5HTR1A). These two markers, however, had exclusion Lod scores in a previous study of 14 families [Detera-Wadleigh et al., 1992]. Similarly, strongly negative Lod scores were found in a linkage study covering the 5HTR1A locus in five pedigrees [Curtis et al., 1993]. The dopamine transporter gene (DAT1) is located in a different region of chromosome 5 (5p15.3). This marker has been investigated in association studies with BPAD, yet no association has been found [Souery et al., 1996a; Gomez-Casero et al., 1996; Manki et al., 1996]. Kelsoe et al. [1996] reported possible linkage, however, between a locus near the dopamine transporter (DAT) and BPAD, under a dominant transmission model giving a modest Lod score of 2.38. Replication of this finding was subsequently shown in another linkage analysis [Waldman et al., 1997].

D. Chromosome 11

Chromosome 11 has been thoroughly investigated in affective disorders because of the presence of candidate genes involved in catecholamine neurotransmission such as tyrosine hydroxylase (TH, 11p15), tyrosinase (11q14-21), dopamine receptor D2 (DRD2, 11q22-23), Dopamine receptor D4 (DRD4, 11p15.5), and tryptophan hydroxylase (TPH, 11p15). Overall, results of linkage studies indicate that the TH gene does not contribute a major gene effect to BPAD [Souery et al., 1996b]. A possible role for the TH gene was also examined in BPAD association studies, all on moderate to small sample sizes. Meta-analysis of the results [Furlong et al., 1999] do not support the TH gene

having a major role in the etiology of BPAD, while data suggest that this candidate gene should be examined in larger samples of UPAD for which this marker may confer susceptibility to the disease.

Linkage to the dopamine 2 receptor (DRD2) has been excluded in a number of studies [Ewald et al., 1994; Nanko et al., 1994; Kelsoe et al., 1993; Holmes et al., 1991, Byerley et al., 1990]. Most association studies have similarly showed no association between the gene for this receptor and BP [Craddock et al., 1995b; Souery et al., 1996a; Manki et al., 1996].

Linkage to the DRD4 receptor gene has not been definitively excluded [Nanko et al., 1994; Sidenberg et al., 1994], and a few association studies have found positive results. For unipolar patients alone, an excess of short exon III repeats (two to four repeats) has been found to be significantly more frequent than controls [Manki et al., 1996]. The No. 7 repeat allele was associated to bipolar disorder, and an excess of allele 3 among controls in another study, yet negative results were then found in a larger sample by the same group [Lim et al., 1994b]. Serretti et al., [1998] recently reported an excess of allele 7 among affective disorder patients with delusional features, suggesting its importance in psychoses, not necessarily affective disorders.

VI. SEROTONIN MARKERS AND AFFECTIVE DISORDERS

Dysfunction of the serotoninergic system has long been suspected in major depression and related disorders. Depression can be successfully treated with selective drugs which target serotonin receptors. The serotonin transporter may also be involved in susceptibility to affective disorders and in the response to treatment with these drugs. Allelic association has been suggested between the serotonin transporter gene (located on chromosome 17q11.1-12) and UPAD [Ogilvie et al., 1996]. The presence of one allele of this gene was significantly associated with a risk of UPAD. This study also included a group of BPAD patients although no associations were found with this marker in this patient group compared to normal controls. This preliminary finding may add to our understanding of the possibility of polygenic inheritance in affective disorders. These findings were replicated in two different samples, again showing an association between this marker and UPAD (major depression with melancholia) [Gutierrez et al., 1998a] and no association with a group of BPAD patients [Gutierrez et al., 1998b]. A higher frequency of the 12-repeat allele of the Variable

Number Tandem Repeat (VNTR) polymorphism has been associated to affective disorders in a number of studies [Collier, 1996; Rees, 1997; Battersby, 1996], with results being the most significant for bipolar subjects. On the other hand, the No. 9 repeat allele has been shown to be significantly associated with unipolar depression, (Battersby, 1996, Olgilvie, 1996).

A linkage study with the functional variant of the serotonin transporter gene in families with BPAD could not exclude linkage [Ewald et al., 1998a]. More interestingly, a polymorphism within the promoter region of the serotonin transporter gene has been associated to treatment response to fluvoxamine, a typical selective serotonin rehuptake inhibitor (SSRI) in major depression with psychotic features [Smeraldi et al., 1999]. This promising preliminary finding remains to be confirmed. The tryptophan hydroxylase (TPH) gene, which codes for the rate-limiting enzyme of serotonin metabolism, is also an important candidate gene for affective disorders and suicidal behavior. Bellivier et al., [1998] reported a significant association between genotypes at this marker and BPAD, but no association was found with suicidal behavior. In a previous study in depressed patients suicidal behavior was associated with one variant of this gene [Mann et al., 1997].

A. Chromosome 4

Possible candidate genes on chromosome 4 include the dopamine receptor D5 (DRD5) and the alpha-adrenergic 2C receptor (ADRA2C) genes. Using both linkage and sib-pair methods to evaluate six families, postive results have been found for the loci for DRD5 and ADRA2C [Byerley et al., 1994], though this was not fully replicated in a later study with a larger sample size [Blackwood et al., 1996]. Linkage was found between a locus on chromosome 4p (D4S394, 4p16) and BPAD in the latter study, yielding a robust two-point Lod score of 4.1 under a model that allowed for heterogeneity. Though the region of 4p16 contains the genes for both DRD5 and ADRA2C, specific markers for these genes were not significant for linkage in this study. Though linkage was not found in the NIMH initiative for any region on chromosome 4, modest elevation of allele frequencies was found for markers on both arms of the chromosome, D4S2397 and D4S391, on 4p and DS1647 4q [Detera-Waldeigh et al., 1997].

Other possible candidate genes mapped to chromosome 4 include those coding for protein subunits of the heteromeric GABA A receptor: the alpha-2 protein

subunit (GABRA2) and the beta-1 subunit (GABRB1), located at 4p13-12. This region was exluded for linkage in a large family in Blackwood's [1996] study, but perhaps could be examined more fully.

B. Chromosome 21

Straub et al. [1994] detected linkage with the locus for liver-type phosphofructokinase enzyme (PFLK) on chromosome 21 (21q22.3) in one large, multigenerational bipolar family. Initial results from 47 families assessed in this genome survey did not support linkage with this marker, however. Follow-up linkage analysis of an extended sample of 57 families on the 373 most informative individuals, using markers < 2 cm apart, found evidence of linkage (Lod score 3.35) at marker D21S1260, which is 5 cm proximal to PFKL [Aita et al., 1998]. Linkage between bipolar disorder and the PFLK region has also been confirmed in other studies [Ewald et al., 1996; Smyth et al., 1997], though negative results have also been reported [Byerley et al., 1995, Vallada et al. 1996]. Further confirmation of linkage to this region with a large sample size, and a later report of excess allele sharing of a cluster of markers within a 9 cm interval on 21q (D21S1254, D21S65, D21S1440 and D21S1254), were found in the NIMH Genetics Initiative bipolar pedigrees [Detera-Waldeigh et al., 1996, 1997]. Linkage to a larger region proximal to the gene for PFKL, 21q21-22, has also been reported by a number of groups [Kwok et al., 1999; LaBuda et al, 1996]. Taken together, these results indicate that the region of interest on 21q remains large, though no discrete locus or obvious candidate gene has been identified as of yet.

C. Chromosome 12

Darier's disease (keratosis follicularis), a rare autosomal-dominant skin disorder associated with increased prevalence of epilepsy and mental retardation, whose gene has been mapped to chromosome 12q23-24.1, was found to cosegregate with bipolar disorder in one pedigree [Caddock, 1994]. The Darier's disease region has been investigated in several family studies in BPAD, suggesting a possible linkage [Craddock et al., 1994; Dawson et al., 1995; Barden et al., 1996; Ewald et al., 1998]. Two of these studies have been able to report significant Lod scores > 3 [Barden et al., 1996; Ewald et al., 1998b]. To further test the hypothesis that genes containing expanded trinucleotide repeats may contribute to the genetic etiol-

ogy of BPAD, loci within this region containing CAG/CTG repeat expansions have also been investigated, but no association was found with BPAD [Franks et al., 1999].

VII. ANTICIPATION AND EXPANDED TRINUCLEOTIDE REPEAT SEQUENCES

Anticipation implies that a disease occurs at a progressively earlier age of onset and with increased severity in successive generations. This may explain deviations from Mendelian inheritance observed in some inherited diseases. This phenomenon has been observed in several neurological diseases including myotonic dystrophy, fragile X syndrome, Huntington's disease, and spinobulbar muscle atrophy [Trottier et al., 1995; Paulson and Fischbeck, 1996]. Anticipation has been found to correlate with a new class of mutations, expanded trinucleotide repeat sequences. An expanded repeat sequence is unstable and may increase in size across generations, leading to an increased disease severity of the disorder. CAG repeats are detected by the Repeat Expansion Detection (RED) method. Such unstable mutations could also be an alternative explanation in addition to environmental factors for discordance between monozygotic twins for affective disorders, where the repeat amplification might be different during mitosis in each of the two twins. A shortcoming of anticipation studies involves ascertainment bias. Earlier age of onset and/or increased severity in successive generations may be related to increased sensitivity to diagnosis in offspring of affected parents. It may appear that parents have a later age of onset than children, but perhaps parents with an earlier age of onset were not able to reproduce at all. That social and environmental factors in the younger generation may favor earlier detection and expression of the disease, is not necessarily related to observed repeats. Cohort effects can be controlled for in statistical analyses, however, such as examining age at onset in an entire generation compared to the difference observed between probands and parents.

Most unstable nucleotide repeat diseases showing anticipation also demonstrate imprinting, or parent-of-origin effect. Affective disorders have not yet unequivocally shown such an effect, though this does not necessarily exclude the possibility that anticipation occurs.

Evidence for anticipation has been observed in BPAD [McInnis et al., 1993; Nylander et al., 1995;

Lipp et al., 1995] and in UPAD [Engström et al., 1995]. Correlation between anticipation observed at the phenotypic level with the number of dynamic mutations may be the only way to confirm the implication of this phenomenon in affective disorders. One study highlighted an association between the number of CAG trinucleotide repeats and severity of BPAD illness in Swedish and Belgian patients [Lindblad et al., 1994]. This study, replicated subsequently in a different sample [O'Donovan et al., 1995; Oruc et al., 1997], showed for the first time in a major psychiatric disorder that the length of CAG repeats were significantly higher in BPAD than in normal controls. These molecular genetic findings may indicate a genetic basis for anticipation in BPAD. This hypothesis has recently been tested in a sample of two-generation pairs with BPAD. Globally, no significant differences were found in the mean number of CAG repeats between parent and offspring generations. A significant increase in CAG repeats between parents and offspring was observed, however, when the phenotype increased in severity, i.e., changed from major depression, single-episode or unipolar recurrent depression to BPAD [Mendlewicz et al., 1997]. A significant increase in CAG repeats length between generations was also found in female offspring with maternal inheritance, but not in male offspring. This is the first evidence of genetic anticipation in BPAD families and should be followed by the identification of loci within the genome containing triplet repeats. CTG 18.1 on chromosome 18q21.1 and ERDA 1 on chromosome 17q21.3 are two repeat loci recently identified [Lindblad et al., 1998] which can be investigated in such study.

VIII. ETHICAL POINT OF VIEW

Ethical questions arise from genetic research on complex diseases, such as AD, as well as clinical management of a complex disorder, involving both genetic and environmental components. The approaches and rules on genetic studies vary between countries; informed consent must be obtained (Shore, 1993). That was not the case a few years ago when the Department of Health and Human Services Office for Protection from Research Risks (OPRR) released an evaluation on human subject issues in a study at the University of California at Los Angeles involving outpatients with schizophrenia. Several problems were found with the informed consent documents. In particular, some investigators estimated that people who have mental disorders should be considered incapable of providing

valid informed consent. This opinion is not currently accepted in many countries. In a NIMH consensus, it has been established that consent documents, and the process by which informed consent is obtained, are state of the art (Shore, 1996). Parker (2002) recently summarized the difficulties in the enrollment of patients with BPAD. The study of bipolar disorders presents particular challenges due to the uncertainty and stigma that surrounds the disorders and because some of the relevant subjects may have diminished capacity to consent to participation. During a severe manic or depressive episode, the subject will not be able to correctly judge the cost and benefits of the study. Therefore, investigators must wait to approach the patient when his symptoms are controlled by medication. Furthermore, genetic studies do not offer direct benefit to the patient. This point must be taken into account and explained to the patient. The disclosure of familial genetic information has been widely discussed. The clinician has often to decide when or whether an ethical duty to inform at-risk family members about an increased genetic risk overrides the duty to maintain patient confidentiality (Lehmann et al., 2000). Recently, the American Society of Human Genetics argued that confidentiality can be breached in situations in which "serious and foreseeable harm" is highly likely to occur to the at-risk relative, assuming that the relative is identifiable and the disease is preventable, treatable, or can be detected in its early stages (American Society of Human Genetics, 1998). In BPAD, some individuals who have never considered themselves as affected may be found to fit the diagnostic criteria. From our experience, it appears that the clinician must be aware that the disclosure of such information has psychosocial implications for the patient and their family. More generally, the clinicians must take time to explain the nature of the genetic risk, the virtual risk within the family and the consequences in terms of the possibility of pregnancy to avoid miscomprehension and suicide ideation or attempt, present by virtue in BPAD.

IX. CONCLUSIONS

The physical mapping of the human genome provides an immense factory providing thousands of genes which will accelerate the identification of genes responsible for mood disorders and will contribute to significant advances in the awareness of diagnosis (diagnostic process and early recognition), pathophysiology, epidemiology, and treatment issues. During the past two

decades, the search for genes for mood disorders has mainly contributed to better understanding and confirmation of the genetic complexities inherent in these disorders. The large amount of results available and the difficulty to digest them corroborate this observation. The major contribution of these findings should be integrated in the context of the worldwide efforts to identify the thousands of genes of the human genome. The majority of these genes will be identified within the next few years. Several consistent hypotheses are currently being tested and will, hopefully, speed up the process of narrowing the important regions when the complete genome map will be available. The most promising chromosomal regions have been localized on chromosomes 4, 5, 11, 12, 18, 21 and X. A number of candidate genes have also been investigated, some of which are directly linked to neurobiological hypotheses of the etiology of affective disorders. In parallel, specific hypotheses have been implicated, such as anticipation and dynamic mutations. Further research should concentrate on these hypotheses and confirm positive findings through interdisciplinary and multi-center projects.

Biological Distinction Between Unipolar and Bipolar Disorder

XIAOHONG WANG and CHARLES B. NEMEROFF

Emory University School of Medicine, Atlanta, Georgia, U.S.A.

I. INTRODUCTION

The DSM-IV and the International Classification of Diseases, 10th revision (ICD-10), provide clear diagnostic criteria for distinguishing bipolar disorder from unipolar disorder. The clinical signs and symptoms of unipolar disorder include loss of interest or pleasure, reduced energy, poor sleep, decreased appetite and weight loss, hopelessness or worthless feeling, and suicidal thoughts. Whereas bipolar disorder includes all of the clinical symptoms of major depression during a depressive episode, it also obviously is characterized by a number of symptoms during the manic phase including an elevated, expansive, or irritable mood as well as grandiosity, decreased sleep and appetite, pressured speech, racing thoughts, and excessive involvement in pleasurable but potentially dangerous activities. Moreover, manic and depressive symptoms often occur together in the so-called mixed state. Although clinicians and investigators concur that these two syndromes are surely distinct entities, in terms of both clinical course and response to treatment, it is not clear what the definitive neurobiological distinctions are between these two disorders. During the last decade, extraordinary advances in both neuroscience and psychopharmacology have provided the field with the tools to further understand the differences between these mood disorders.

II. NEUROENDOCRINE HYPOTHESIS

It has been recognized for many years that certain endocrine disorders are associated with a higher than expected frequency of a wide spectrum of psychiatric symptoms and syndromes, e.g., glucocorticoid-induced depression, mania and psychotic symptoms; hypothyroidism-induced depression, etc. The excessive secretion of cortisol in Cushing's syndrome is also well known to be associated with both anxiety and depressive symptoms. Specific neuroendocrine alterations in response to stressors or pharmacological challenge tests have been shown to be highly associated with certain neuropsychiatric disorders. The majority of studies have scrutinized the hypothalamic-pituitary-adrenal (HPA) and -thyroid (HPT) axes as well as growth hormone and gonadal hormone secretions.

A. Hypothalamic-Pituitary-Adrenal Axis

There are extensive data available on the activity of the HPA axis in patients with mood disorders. A sizable subgroup of patients with unipolar depression exhibits hyperactivity of the HPA axis, characterized by hypercortisolemia, increased urinary free cortisol concentrations, and nonsuppression of cortisol after administration of the synthetic glucocorticoid dexa-

methasone. Patients with mixed mania exhibit similar HPA axis hyperactivity including elevation of CSF cortisol concentrations [16]. In contrast, patients with euphoric mania have normal HPA function.

Many studies have supported the hypothesis that CRF hyperactivity may contribute to the pathogenesis of depression. CRF is released from neurons in the paraventricular nucleus (PVN) of the hypothalamus and is transported to the anterior pituitary through the hypothalamo-hypophyseal-portal circulation. ACTH is released from the anterior pituitary gland by CRF, and is carried in the peripheral circulation to the adrenal cortex where it releases cortisol.

In drug-free unipolar depressed patients, CSF CRF concentrations are increased. This increase is likely due to the increased activity of CRF-secreting neurons in the hypothalamus, as well as extra-hypothalamic brain regions [1,2]. Interestingly, electro-convulsive therapy (ECT) or treatment with anti-depressants such as fluoxetine, desipramine, and venla-faxine reduce CRF concentrations in CSF in depressed patients [3,4]. Normal controls and nonhuman primates with euphoric mania do not exhibit elevation in CSF CRF concentrations.

Assessment of the activity of the HPA axis in depressed patients has been intensively scrutinized. Two tests are widely used, either alone or in combination. The dexamethasone suppression test (DST), though much maligned, has documented HPA axis hyperactivity in patients with unipolar depression and in those with mixed or dysphoric mania [5,6]. The CRF stimulation test is a more sensitive test of HPA axis function. In this test, CRF is administered intravenously (usually in a 1 μg/kg or 100 μg dose), and blood samples are obtained for ACTH and corti-sol assay at 30-min intervals over a 2- to 3-hr period. When compared to normal subjects, the ACTH response to exogenous CRF is blunted in drug-free depressed patients, but not in patients with euphoric mania [7–12]. Mixed mania has not yet been studied. The pathophysiology of the blunted ACTH response may be due to chronic hypersecretion of CRF with resultant CRF receptor downregulation and/or the feedback of hypersecreted cortisol on ACTH secretion.

The combination of the dexamethasone (DEX) sup-pression test and the CRF stimulation test (DEX/CRF test) has the promise of being an even more sensitive measure of HPA axis activity. In the DEX/CRF test, a single dose (1.5 mg) DEX is given to patients at 23:00 hr, and 100 mg CRF is given intravenously at 15:00 hr the following day. In depressed patients, the release of ACTH and cortisol was significantly higher than in nondepressed controls—evidence of the HPA axis hyperactivity. Rybakowski and Twardowska [13] reported that in bipolar depressed patients, DEX/CRF induced much higher elevations of cortisol than in unipolar depressed patients and normal controls. A separate report indicated that bipolar patients in remis-sion had higher baseline and peak ACTH concentra-tion after a single dose of CRF (100 μg) [14]. Acutely manic patients have higher basal cortisol levels as opposed to controls, and DEX challenge showed that these patients had lower DEX-induced growth hor-mone responses than did controls [15]. Finally, Swann and colleagues [16] have reported elevated CSF cortisol concentrations in patients with mixed, but not euphoric, mania.

B. Hypothalamic-Pituitary-Thyroid Axis

Alterations in the HPT axis have long been associated with higher than expected prevalence rates of all forms of mood disorders. Hypothyroidism has repeatedly been demonstrated in patients with depression, includ-ing symptomless autoimmune thyroiditis [17,18]. In clinical studies, T_3 augments the effects of antidepres-sants in treating depression [19]. Many studies have focused on the potential role of thyrotropin-releasing hormone (TRH), discovered in 1970. Similar to CRF, TRH is released from the hypothalamus and acts on the anterior pituitary via the portal system. TRH binds to the pituitary TRH receptor and induces the release of thyroid-stimulating hormone (TSH). TSH then enters the systemic circulation and binds to TSH recep-tors on the thyroid gland which causes the release of the two major thyroid hormones (T_3 and T_4). The activity of the HPT axis is controlled through the nega-tive feedback of thyroid hormones on both TSH and TRH secretion.

In addition to its role in the HPT axis, TRH also acts as a CNS neurotransmitter in both hypothalamic and extra-hypothalamic brain areas. Thyroid hormone is well known to be essential for normal neuronal development in the CNS. Primary hypothyroidism is associated with many behavioral symptoms also observed in primary depression including depressed mood, fatigue, decreased sexual drive, psychomotor retardation, increased sleep, and weight gain. In con-trast, hyperthyroidism is associated with increased autonomic function, anxiety, psychomotor agitation, and emotional lability. There are two reports of elevated TRH concentrations in CSF in depressed patients, both bipolar and unipolar [20,21]. This elevation may be due to the hypersecretion of TRH

in response to relative hypothyroidism. This explanation is supported by the report of low CSF concentrations of the thyroid transport globulin transthyretin in treatment-refractory depressive patients [22,23] and the increased size of the pituitary gland in depressed patients [24], which might be partly due to TRH hypersecretion. Symptoms of depression in patients with primary hypothyroidism do not respond to antidepressant treatment unless thyroid function is normalized. Several studies have found that the addition of T_3 (25–50 µg/day) is effective in converting antidepressant nonresponders to responders [19,25–27].

One of the most sensitive measures of HPT axis is the TRH stimulation test, in which TSH is measured at baseline and at 30-min intervals after IV injection of TRH (200–500 µg). In primary hypothyroidism an exaggerated TSH response is observed, and in primary hyperthyroidism the TSH response is attenuated. Multiple reports have demonstrated that both unipolar and bipolar depressed patients exhibit a blunted TSH response to TRH [18,28–33]. The pathophysiology of this blunted TSH response may well be due to chronic hypersecretion of TRH and the resultant downregulation of the TRH receptor in pituitary thyrotrophs. Other sensitive methods of measuring HPT axis function include the measurement of maximal circadian secretion of TSH between 23:00 hr and 01:00 hr [34,35], and performance of a standard TRH stimulation test at both 08:00 hr and 23:00 hr that was developed by Duval [36]. The differential response at 08:00 hr and 23:00 hr were compared, designated the $\Delta\Delta$TSH. The depressed patients, both unipolar and bipolar, had a significantly lower $\Delta\Delta$TSH than normal controls. Recently, two reports revealed higher TRH-stimulated TSH levels in lithium-naive bipolar II [37] and in bipolar mixed patients [38].

In contrast to the evidence for TRH hypersecretion in depression is the hypothesis that TRH acts as endogenous antidepressant. A recent report, for example, reported that TRH exhibited acute antidepressant effects when injected directly into CSF [39]. In addition, pharmacological doses of T_4 are reportedly effective in treating both the depression and mania in rapid-cycling bipolar disorder [40]. In a recent report of a 3-year treatment study of bipolar disorder with lithium or carbamazepine, a lower mean serum level of free T_4 was associated with more affective episodes and greater severity of depression. This suggests that the lower level of free T_4 may be a causal factor in mood instability, and T_4 replacement may warrant further study [41].

C. Hypothalamic-Growth Hormone Axis

Alterations in the HGH axis have also been reported in patients with mood disorders. Growth hormone is secreted from the basophilic cells of the anterior pituitary. Its secretion is regulated by two hypothalamic peptide hormones, growth—hormone–releasing hormone (GHRH) and somatostatin. GHRH induces GH release whereas somatostatin inhibits GH release. The main function of GH is to promote body growth via the release of insulinlike growth factor 1 (IGF-1) and somatomedins from the liver. GH also directly counteracts insulin's effects. The secretion of GH has a unique circadian pattern, with a peak during stage 4 sleep. GH secretion is also responsive to other factors including stress, exercise, hypoglycemia, and other neurotransmitters, e.g., dopamine, norepinephrine, and acetylcholine.

In depressed patients, nocturnal GH secretion is decreased [42], whereas daytime GH secretion is increased in both unipolar and bipolar patients [43]. GHRH-induced GH release has been reported to be diminished in depressed patients [44–47]. It would be fair to say, however, that the standardized GHRH stimulation test to evaluate HGH axis function in patients with mood disorders has not yet been developed and results obtained thus far are not consistent [48].

To further assess the integrity of HGH axis, several studies using standardized provocative pharmacological challenge tests either with clonidine (an α_2 adrenergic receptor agonist) or apomorphine (a dopamine D_2 receptor agonist) have been utilized. A blunted GH response has repeatedly been obtained in depressed patients [49–52]. In addition, a blunted GH response to other challenges such as insulin-induced hypoglycemia and L-dopa have also been noted in depressed patients [53]. Because depressed patients have repeatedly shown to have decreased CSF somatostatin concentrations [54], which would likely increase GH secretion, alternative mechanisms to explain the blunted response must be involved.

In bipolar patients, blunted GH responses to both noradrenergic stimuli and dexamethasone stimulation has been reported [15,55]. The GH response to baclofen, a GABA-B receptor agonist, was reported to be enhanced in bipolar patients, suggesting upregulation of GABA-B receptors [56]. A blunted GH response in depressed but not bipolar patients to sumatriptan, a $5HT_{1D}$ receptor agonist that stimulates GH secretion, has also been observed [57].

D. Hypothalamic-Pituitary-Gonadal Axis

A significant role for HPG axis alterations in mood disorders has been postulated to explain the inordinately high rate of depression in women, and also its higher incidence during pregnancy and in the puerperium. Similar to the HPA and HPT axes, the HPG axis is also regulated hierarchically, in this case by a releasing hormone secreted from hypothalamus, gonadotropin-releasing hormone (GnRH). This decapeptide, released from hypothalamus, acts on the anterior pituitary to release both luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Both of these gonadotropins are important for sexual development and maintenance of normal sexual function in males and females. Together they are responsible for estrogen and progesterone secretion in women and testosterone in men. GnRH secretion is positively regulated by noradrenergic agonists and negatively regulated by endogenous opioids. Postpartum depression and premenstrual dysphoric disorder (PMDD) may be in part due to disturbances of gonadal steroid regulation and secretion. One recent report revealed that androstenedione, testosterone, and dihydrotestosterone levels are increased in hypercortisolemic women with severe major depression. This study suggested that HPG axis alterations may be associated with hyperactivity of the HPA system [58,59]. In contrast, another study reported that daytime, nighttime, and 24-h mean testosterone levels are significantly lower in depressed men than in normal controls [60]. Leuprolide is a GnRH agonist and is widely used in the treatment of endometriosis and prostate cancer by inducing a "chemical gonadectomy." It is effective in the treatment of PMDD. However, leuprolide has been reported to induce depression, and concomitant sertraline treatment improved these depressive symptoms [61–63]. Plasma levels of LH and GnRH-induced LH secretion have been reported to be increased in mania, but unchanged in depression [64–66].

III. THE IMMUNE SYSTEM AND MOOD DISORDER

Numerous studies have documented that the immune system and the CNS interact and regulate each other. Dysfunction of one system may cause dysfunction in the other. Evidence has accrued that patients with a variety of psychiatric disorders, particularly those that are stress related, cause a wide range of immune alterations including decreased NK cell counts and reduced mitogen-stimulated lymphocyte proliferation. Moreover, agents that alter immune function such as the exogenous use of cytokines or immunosuppressive agents (glucocorticoids) cause significant mood alterations.

A. Interaction Between the CNS and the Immune System

Interactions between the immune and CNS systems have been extensively studied. Immune cells express receptors for a wide spectrum of neurotransmitters, hormones, and neuropeptides. These include monoamines, prolactin, GH, CRF, ACTH, and opioids [67–69]. The immune system is also regulated by the autonomic nervous system, especially the sympathetic division [70]. Limbic and cortical regions may also be involved in the modulation of immune activity. In the rat, CRF, administered intracerebroventricularly, causes activation of the central sympathetic pathway and significantly decreased NK cell number in the spleen [71]. To understand this complex, multidirectional communication, Ader proposed a term, psychoneuroimmunology, to study brain-immune interaction [67]. The advances in neuroscience and related areas suggest that this term, psychoneuroendoimmunology, may more accurately describe the interaction among the CNS, endocrine, and immune systems. Stress and medical or psychiatric illness are associated with neurobiological alterations in certain brain areas. These changes may, as noted above, trigger HPA axis alterations or changes in other hypothalamus–pituitary–end organ axes and/or descending autonomic pathways. The endocrine and sympathetic signals are sent to target immune organs such as the spleen or thymus and further trigger immune responses in vulnerable individuals. Because the interaction is multidirectional, alterations in immune or endocrine system may also induce responses in the CNS and precipitate psychiatric or medical illness.

B. Stress and the Immune Response

In 1977, Bartrop and coworkers reported that stressful life events such as bereavement have exhibited a reduction in mitogen-stimulated lymphocyte proliferation [72]. This finding was replicated in a prospective study by Schleifer et al. [73], who collected lymphocytes from individuals before and after bereavement. Mitogen-stimulated lymphocyte proliferation (MSLP) assays were performed using phytohemagglutinin (PHA), concanavalin A, and pokeweed mitogen.

MSLP was significantly lower during postbereavement when compared with the prebereavement samples. Another immune parameter, NK cell activity, has also been used to study the impact of stress on immune response. Glaser and colleagues have conducted a series of studies in this area [74]. Examination stress in medical students was found to be associated with a decreased in T-cell number, decreased MSLP, and decreased interferon production. NK cell activity was decreased during the final examination period when compared to preexamination [75]. Life stresses also caused alterations in lymphocyte subpopulation, an impaired antibody response to influenza vaccine, and prolonged latency of wound healing [76–78].

C. Mood Disorder and the Immune Response

Similar to the impact of stress on the immune system, depression has also been reported to be associated with decreased MSLP in several studies [79,80] and decreased NK cell activity as well [81]. Subsequent studies have reported discordant results. A variety of factors likely contribute to these discrepancies. One such significant variable is that circulating lymphocyte subpopulations exhibit different circadian rhythms [82]. In one report, NK cell number and activity in depressed patients and normal controls were studied at both diurnal peak (8 AM) and nadir (4 PM) [83]. In depressed patients, a significantly lower diurnal variation in NK cell number and NK activity was noted. Antidepressant treatment reportedly augments NK cell activity both in vivo and in vitro [84]. Depressed patients treated with fluoxetine (20 mg/day) for 4 weeks as outpatients exhibited increased NK cell activity in patients who had low pretreatment NK cell activity, but produced no effects on patients who had normal or high NK cell activity at baseline. Interestingly, treatment of mononuclear cells with fluoxetine and paroxetine in vitro also enhanced NK cell activity. In a separate study [85] 10 depressed cancer patients were treated with fluvoxamine, an SSRI antidepressant, for 28 days; one-half of the patients responded to the treatment with significantly improved HAM-D scores, and the mean NK cell number increased 53%. There was a significant correlation between the change in HAM-D score of the responders and the change in NK cell counts. The specificity of the action of SSRIs on NK cell activity and number was highlighted by Mizruchin and coworkers who confirmed the effects of SSRIs in reversing low NK cell activity in depressed patients associated with concomi-

tant clinical improvement; D_2 receptor antagonists or agonists were without effects [86].

There are a limited number of studies evaluating immune responses in patients with bipolar disorders. Several reports revealed hyperactivity of the immune system. In a recent study of 23 bipolar patients and 23 matched normal controls, the MSLP and serum soluble IL-2 receptor (sIL-2R) levels were significantly higher during acute mania than in remission. There was no difference in the immune measures between normal controls and remitted bipolar patients [87]. In a separate study, lithium treatment normalized the elevation of sIL-2R and sIL-6R in rapid-cycling bipolar patients [88]. Euthymic bipolar patients or those medicated with lithium have normal sIL-2R levels, antithyroid antibody levels, mitogen stimulation responses, and circulating lymphocyte phenotype profiles [89].

D. Mechanism of the Effects of Stress and Mood Disorders on the Immune System

As discussed above, the HPA axis and the autonomic nervous system, two major stress-responsive elements, exert immunoregulatory effects. Corticosteroids, the final product of the HPA axis, produce major effects on immune systems. Immune cells and tissues possess corticosteroid receptors and represent the substrate by which the immune system is regulated by glucocorticoids. Obviously corticosteroids are widely used clinically as immunosuppressive and antiinflammatory agents. Such actions may be mediated through the inhibition of the synthesis of cytokines and other mediators of inflammation [90]. Corticosteroids also produce a shift of immune reaction from primarily a cell-mediated to an antibody-mediated response by the action of certain cytokines [91,92]. In addition to a role for the HPA axis and sympathetic nervous system in regulating immune responses, CRF itself is immunomodulatory. CRF regulates the immune system response not only via the HPA axis but directly as well. CRF-overproducing mice exhibit immune defects with a profound decrease in the number of B-cells and severely impaired primary and memory antibody response [93] though this may be explained by HPA axis hyperactivity. CRF can also increase release of cytokines, specifically IL-1α and IL-2 [94,95]. Taken together, the impact of the HPA axis, sympathetic nervous system, and CRF on immune system responses is indeed very complex.

IV. CYTOKINES AND MOOD DISORDERS

The cytokines, considered as hormones of the immune system, are a group of large peptides/small proteins of low molecular weight that communicate between immune cells and mediate inflammatory or immune response to stress, injury, and infection. A growing body of literature supports the fact that cytokines act not only as immunomodulators but also as neuromodulators. Cytokines are classified into three large groups based on function: proinflammatory (IL-1, IL-6 and TNF), anti-inflammatory (IL-4, IL-10, IL-13), and hematopoietic (IL-3, IL-5, colony-stimulating factor) cytokines. Cytokines not only exist in the immune system, but also within the CNS, where they are secreted from astrocytes and microglia, and perhaps neurons. IL-1 has been found in several brain regions and its function in brain has been studied extensively [96]. Moreover IL-1 is able to stimulate the production of itself, IL-6, TNF-α, and colony-stimulating factor from astroglial cells [97,98]. Intraperitoneal injection of IL-1β into mice increases MHPG (the major norepinephrine metabolite) and 5HIAA (the major serotonin metabolite) in the hypothalamus [99,100]. Injection of IL-1β and TNF-α intracerebroventricularly (icv) causes an elevation of 5-HIAA in the nucleus raphe dorsalis [101]. IL-1 treatment was also associated with increases in CRF, ACTH, and corticosteroids [102,103]. IL-6, TNF, and interferon were reported to produce similar effects on the HPA axis [104].

CRF, administered intravenously in humans, causes a marked increase of plasma IL-1α and IL-2 concentrations [95]. Plasma concentrations of proinflammatory cytokines, IL-1, and IL-6 have been reported to be increased in depressed patients [105–107]. A recent study with a small sample replicated the increased IL-1 concentrations in CSF in depressed patients, but IL-6 concentrations were reduced and TNF-α concentrations unchanged [108]. Plasma soluble IL-6 receptor and soluble IL-2 receptor were reportedly higher in manic patients than in normal controls [109] and a recent report confirmed the latter finding in mania [87]. Interferon-α (IFN-α), an important cytokine in the early immune response to viral infection has both antiproliferative and antiviral properties [110]. IFN-α has been successfully used in the treatment of melanoma and hepatitis C. The treatment with IFN-α has been associated with a high rate of CNS side effects similar to depression (anhedonia, fatigue, anorexia, poor concentration, and sleep disturbance) [111,112]. A recently published study from our group demon-

strated that antidepressant treatment with an SSRI prevents IFN-α-induced depression [113]. In a double-blind, placebo-controlled study of 40 patients with malignant melanoma, paroxetine treatment (2 weeks prior to the initiation of IFN-α) significantly decreased the severity of depressive symptoms and the percentage of patients who fulfilled criteria for major depression induced by IFN-α treatment. Paroxetine treatment also significantly reduced the incidence of major depression during IFN-α treatment. Interestingly, several case reports demonstrated that treatment with IFN-α may also cause mania [114–118]. The mechanism of cytokine-induced mood instability may either be a direct effect on the CNS or via stimulatory effects on the HPA axis via CRF as described in Section III.D.

V. ROLE OF NEUROTRANSMITTERS AND NEUROPEPTIDES

Considerable advances in understanding of neurotransmitters and their receptors have occurred over the last decade. Many in psychoneuroendocrinoimmunology research have suggested that neurotransmitter systems function in various CNS sites and in the periphery in a concerted harmonious manner. For example, CRF responds to psychological or physical stresses and stimulates the HPA axis ultimately increasing glucocorticoid secretion and also exerts target immune organs as well. CRF also acts on extra pituitary sites to cause a wide range of biological and behavioral effects. Molecular biology, human genetics, and other research technologies have provided novel information on receptor subfamilies and their differential functions, alternate splicing of pre-prohormones in various physiological states, intracellular signal transduction and related gene transcription, genetic polymorphism of certain neurotransmitter transporters and receptors, and *in vivo* studies by remarkable new functional imaging technologies. The roles of several neurotransmitters in the pathophysiology of depression and bipolar disorder are described below.

A. Norepinephrine

The catecholamine hypothesis of affective disorders originally conceptualized by Schildkraut [42] suggested a relative deficiency of one or more catecholamines within the CNS in depression, and a relative excess in mania. The sympathoadrenal system consists of the adrenal medulla and the sympathetic nervous

system (SNS). As early as the 1960s, 3-methoxy-4-hydroxy-phenylglycol (MHPG), a major norepinephrine metabolite, was reported to be elevated in the CSF of a subgroup of patients with mood disorder [42]. Significant elevation of plasma and urinary norepinephrine and its metabolites was also reported in a subgroup of depressed patients by many research groups [119–121]. Results in patients with bipolar disorder were equivocal, probably due to their disease state, i.e., manic, depressed, or euthymic. The excretion of norepinephrine and epinephrine in urine of bipolar depressed patients was consistently lower when compared with unipolar depressed patients [122–124]. Plasma MPHG concentrations were also reported to be lower in bipolar depressed patients than in unipolar depressed patients [125]. Elevated plasma and urinary norepinephrine and epinephrine concentrations were reported in bipolar manic patients [126]. The major difference between bipolar depressed and unipolar depressed patients was the greater urinary MPHG levels in unipolar depressed patients. No significant differences in CSF norepinephrine and its metabolites were noted between bipolar and unipolar patients. Treatment with fluoxetine normalized CSF norepinephrine in depressed patients [4]. A recent study indicated that pretreatment levels of urinary MPHG correlated with improvement of mania [127]. In a recent report, Johnston et al. [128] used plasma norepinephrine levels to predict the outcome of major depressive disorder (MDD). Forty patients with MDD were followed for 8 years. The results revealed that the higher the plasma norepinephrine concentrations, the better the outcome for MDD, and the longer the time to first recurrence.

Reboxetine, the first selective norepinephrine reuptake inhibitor, has provided additional opportunities to evaluate the role of the noradrenergic system in mood disorders. Although controlled data are scant, there is a general consensus among clinicians that antidepressants that block norepinephrine, but not serotonin, reuptake are more likely to cause a switch into mania in depressed bipolar patients.

B. Serotonin

The serotonin hypothesis of depression proposed that a relative deficiency of serotonin in the CNS renders individuals vulnerable to affective illness. Reduced concentrations of CSF 5-hydroxyindoleacetic acid (5HIAA), the major metabolite of serotonin (5-hydroxytryptamine, 5HT), has repeatedly been reported in depressed patients [129–131] as well as in patients with

suicidality, increased aggression, and poor impulse control [132]. The significant efficacy of the selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine, sertraline, paroxetine, citalopram, and fluvoxamine) in the treatment of depression strongly supports a serotonergic deficiency in CNS, though some SSRIs affect norepinephrine and dopamine uptake as well. A recent study [133] using the tryptophan depletion paradigm in 55 drug-free depressed patients treated with either fluoxetine or desipramine revealed that 53% relapsed in the fluoxetine group vs. only 6% in the desipramine group. The results indicate that antidepressant response to fluoxetine (and probably other SSRIs) appears to be dependent on serotonin availability.

Other serotonergic alterations have been reported in both bipolar and unipolar depression. Platelet $5HT_2$ receptor number is increased in depressed patients and significantly decreased after antidepressant treatment [134]. Increased platelet serotonin concentrations have been reported in bipolar depressed patients [135]. Unaffected bipolar relatives were found to have lower platelet serotonin transporter function and reduced serotonin transporter-binding sites, and diminished platelet serotonin levels [136]. Levels of urinary 5HIAA were not different in bipolar and unipolar depressed patients [122]. Brain imaging studies, largely using SPECT, have confirmed the reduction in raphe serotonin transporter binding in drug-free depressed patients [137].

C. Dopamine

There are relatively few reports concerning the role of dopamine (DA) in the pathophysiology of mood disorders. Elevation of CNS DA activity may play an important role in the etiology of psychotic depression. However, the effects of some medications with primary actions on DA circuits suggest that DA may still play a pivotal role in the etiology of mood disorders. Although concentrations of urinary and CSF homovanillic acid (HVA), a metabolite of DA, were found to be no different in bipolar and unipolar depressed patients [122] others have noted that CSF HVA levels are decreased in depressed patients [138–141] and increased in agitated or manic patients [142–144]. The purported efficacy of methylphenidate, a psychostimulant which releases DA from presynaptic terminals, in the treatment of depression particularly in depressed patients with medical illness, also supports a role for DA system in mood disorder. For example, treatment of depressed post-stroke patients with methylphenidate caused significant improvement (70–

80%) and a relatively rapid response when compared to nortriptyline [145–147]. Moreover, nomifensine, a selective DA reuptake inhibitor, was shown to be an effective antidepressant, but was withdrawn from the market because of untoward effects on the hemato-poietic systems.

Postsynaptic DA agonists also possess antidepressant properties, e.g., pramipexole [148]. A recent report suggests that a deficit of brain DA and norepinephrine occurs in refractory depressed patients [149]. This study, using a catheter placed in the patients' internal jugular vein to estimate the release of brain norepinephrine and DA, showed a significant decrease of the brain venoarterial norepinephrine and DA gradient in the depressed patients compared with normal controls.

Increased dopaminergic activity has been implicated in the pathophysiology of bipolar disorder. An amphetamine challenge to euthymic bipolar patients produced a significant behavioral response as assessed by the Brief Psychiatric Rating Scale, but functional brain imaging (SPECT) failed to demonstrate increased striatal DA release after amphetamine challenge in these bipolar patients [150]. The investigators suggested that their data were consistent with enhanced postsynaptic DA responsiveness in bipolar patients.

D. γ-Aminobutyric Acid (GABA)

GABA plays an important role in the CNS as a major inhibitory neurotransmitter. It interacts with biogenic amine neurotransmitters, including norepinephrine and serotonin. Dysfunction of the GABA system has been postulated to play an important role in mood disorders. Both preclinical and clinical studies suggest that a GABA deficit may occur in depression, whereas elevated GABA activity may occur in mania [151]. Several reports of decreased CSF and plasma GABA concentrations in depressed patients [152–154] have appeared; higher GABA levels were found in bipolar manic and euthymic patients compared with unipolar depressed patients [154]. Using magnetic resonance spectroscopy, medication-free depressed patients exhibited a 52% reduction in occipital cortex GABA concentrations compared with normal controls [155].

Manic patients have been reported to exhibit enhanced growth hormone responses to baclofen, a GABA-B receptor agonist, suggesting elevated hypothalamic GABA-B receptor function in bipolar disorder [56]. In addition, pretreatment plasma GABA levels were related to severity of manic symptoms, especially in women [127]. However, several anti-

manic agents (valproic acid, carbamazepine, and lithium) have been reported to exert complex effects on GABA-ergic activity. Thus, valproic acid, carbamazepine, and lithium decrease GABA turnover in the frontal cortex [156] and increase GABA-B receptors in hippocampus after chronic administration [157,158]. Post noted that the GABA-B agonist baclofen exacerbated depression and its discontinuation was associated with mood improvement [159].

E. Glutamate

Glutamate is the major excitatory neurotransmitter in pyramidal neurons. Its postsynaptic signals are mediated through several receptor subtypes (i.e., N-methyl-D-aspartate, quisqualate, and kainate). The well-documented excitatory and neurotoxic effects of glutamate can occur by actions on both NMDA or non-NMDA receptors. A growing body of preclinical research suggests that brain glutamate systems may be involved both in the pathophysiology of mood disorders and the mechanism of action of antidepressants. In one placebo-controlled, double-blind study, a single dose of an NMDA receptor antagonist, ketamine, caused significant improvement in depressed patients after 72 hours [160]. Two recent reports used *in vivo* proton magnetic resonance spectroscopy to study the role of glutamate in both depression and bipolar [161,162]. In severely depressed patients, levels of glutamate and glutamine (Glu/Gln) were decreased in the anterior cingulate, whereas Glu/Gln levels was elevated in both frontal lobes and basal ganglia in bipolar patients. In a separate study, CSF glutamate levels were elevated in depressed patients compared with controls [163].

F. Vasopressin

Vasopressin is a peptide hormone cleaved from a pre-prohormone synthesized in the hypothalamus and other brain regions. Its main function is to conserve water and concentrate urine by activation of V_2 receptor on the basolateral surface of the renal conducting duct. High concentrations of vasopressin can also act on the V_1 receptor and cause vasoconstriction. In addition, considerable evidence suggests that vasopressin may play a critical role in learning and memory. Research from many groups demonstrated that vasopressin may also play an important role in the pathophysiology of affective disorders, and contribute to the well-documented hyperactivity of the HPA axis. Plasma vasopressin levels are higher in depressed

patients than in controls and also higher in melancholic patients than nonmelancholic patients [164]. Levels of AVP were also positively correlated to severity of psychomotor retardation [165]. Muller recently reported a case of a depressed patient with chronically elevated plasma vasopressin levels due to paraneoplastic vasopressin secretion by an olfactory neuroblastoma [166]. Interestingly, the patient's depressive symptoms were markedly improved after surgical resection of the tumor, and subsequent normalization of plasma vasopressin levels.

G. Substance P

Substance P is a neuropeptide that acts upon the neurokinin-1 (NK-1) receptor. Neurons containing substance P are found in many brain regions that regulate affect, including many of the stress circuits [167]. Preclinical studies indicate that psychological stressors caused rapid downregulation of substance P receptors, presumably due to stress-induced release of substance P [168]. In a recent study, an NK-1 antagonist, MK-869, was shown in a double-blind, controlled study to possess antidepressant properties [168]. MK-869 was equivalent in antidepressant effect to paroxetine. Although these findings need to be replicated, they hypothesized that increased substance P availability in CNS may be related to depression, whereas decreased substance P availability may contribute to mania. Lithium and carbamazepine, when administered chronically, cause an increase of substance P concentrations in the striatum, nucleus accumbens, and frontal cortex of rat brain, suggesting that substance P may play a role in the action of mood stabilizers [169,170].

H. Somatostatin

Somatostatin is a hypothalamic tetradecapeptide noted previously to be involved in the regulation of growth hormone release, and perhaps in the regulation of the HPA axis. Somatostatin has been shown to regulate affect, sleep, ingestive behavior, locomotor activity, memory, and cognition. Its role in mood disorders has been supported by the reports of decreased CSF concentrations of somatostatin in depressed patients [171–173]. In Rubinow's seminal study, 49 bipolar and unipolar depressed patients matched with 49 normal controls were found to have a significant reduction in CSF somatostatin levels [174]. The values during depression were significantly lower than in the improved state. In manic patients, a markedly eleva-

tion of CSF somatostatin was reported [175]. Treatment with carbamazepine significantly reduces CSF somatostatin [174] whereas nimodipine (a calcium channel blocker, perhaps effective in treating some rapidly cycling affective disorders) was found to increase CSF somatostatin levels [176]. Alterations in CSF somatostatin concentrations are not specific to mood disorders. Other neuropsychiatric disorders also show such changes: decreased levels in schizophrenia, Alzheimer's disease, Parkinson's disease, and multiple sclerosis; increased levels in post-traumatic stress disorder, compression injuries, meningitis, and the encephalopathies.

VI. CONCLUSION

It is clear that patients with bipolar and unipolar affective disorders share several biological findings but also exhibit a number of differences. The above discussion reviewed such differences based on recent advances in neurobiology, endocrinology, and immunology research. Clearly, advances in molecular biology, brain imaging, and psychopharmacology, as well as novel genetic discoveries, will allow unprecedented advances in a field that has unfortunately languished over the past two decades—namely, the pathophysiology of bipolar disorder. Surely more effective treatment strategies will come available with the further understanding of the pathophysiology of these devastating mood disorders.

Neurobiology of Obsessive-Compulsive Disorder

BAVANISHA VYTHILINGUM
University of Stellenbosch, Cape Town, South Africa

DAN J. STEIN
University of Stellenbosch, Cape Town, South Africa, and University of Gainesville, Gainesville, Florida, U.S.A.

I. INTRODUCTION

Obsessive-compulsive disorder (OCD), thought to be the fourth most common psychiatric disorder [1], is one of the most incisive exemplars of how a disorder that was once viewed as secondary to unconscious conflict is now known to be the result of specific neuropathological processes. Recent research has shown that OCD is mediated by specific abnormalities in both neuroanatomical and neurochemical systems. Current theories of the neurobiology of OCD can be divided into those emphasizing the role of dysfunction of specific corticostriatal pathways (neuroanatomical models of OCD) and those emphasizing the role of dysfunction in the serotonergic and to a lesser extent dopaminergic systems (neurochemical models of OCD).

II. NEUROANATOMICAL MODELS OF OCD

The current neuroanatomical model of OCD emphasizes the role of corticostriatothalamocortical (CSTC) circuitry. Alexander et al. [2,3], described multiple, parallel segregated circuits, which project from the cortex to corresponding striatal subterritories, from there to the basal ganglia, and via the thalamus back to the prefrontal regions from which they originated. To understand a CSTC model of OCD, it is necessary to first understand the relevant normal neuroanatomy.

A. Relevant Normal Neuroanatomy

1. Prefrontal Cortex

The prefrontal cortex is responsible for several cognitive functions, including response inhibition and planning, organizing, controlling, and verifying operations [4]. The prefrontal cortex can be subdivided in several functional subterritories: the dorsolateral prefrontal cortex which subserves memory, learning, and other executive functions, the posteromedial orbitofrontal cortex, a component of the paralimbic system, which plays a role in mediating affective and motivational functions [5]; and the anterior and lateral orbitofrontal cortex, which acts as an intermediary between the lateral prefrontal and posteromedial orbitofrontal zones.

2. Paralimbic System

This is an area of cortex which forms a functional link between other areas of cortex and the limbic system

proper. It includes the posteromedial orbitofrontal cortex, cingulate, anterior temporal, parahippocampal, and insular cortex [5]. This system is believed to be important in mediating intense emotional states; in particular, it has been implicated in anxiety [6] and in the modulation of autonomic effects associated with intense anxiety [5].

3. Striatum

The striatum is composed of the caudate nucleus, putamen, and nucleus accumbens. Recent work has shown that it not only modulates motor functions, but cognitive and affective functions as well [7]. It has been theorized that the function of a healthy striatum is to process information automatically, without conscious representation. Hence a healthy striatum could be seen to act as a filter at the level of the thalamus, ensuring that stereotyped processes can be carried out with reaching consciousness.

4. Corticostriatothalamocortical Circuits

CSTC circuits can be divided in two major branches: the corticothalamic branch, and the corticostriatothalamic branch. The corticothalamic branch is a reciprocal monosynaptic communication between the cortex and the thalamus that mediates consciously accessible and consciously mediated information. The corticostriatothalamic branch modulates transmission at the level of the thalamus and, as discussed earlier, is involved in the regulation of information reaching consciousness. Modern imaging studies confirm the role of CSTC circuitry in OCD.

B. Structural Studies

Several volumetric studies of the caudate have shown structural abnormalities. The nature of the abnormalities described has been inconsistent. Scarone et al. [8] in a mixed-gender cohort found increased right caudate volume in the OCD group, whereas Robinson et al. [9], also studying a mixed gender cohort, found bilaterally decreased volumes in the OCD group. In an all-female cohort, Jenike et al. [10] found rightward shift in caudate volume as well as a trend toward overall reduced caudate volume. However Stein et al. [11] found no change in caudate volume between patients with OCD and a control group. It is possible that caudate volume changes over time, with increased volume in the aftermath of streptococcal infection [12], and later shrinkage.

Volumetric changes in the orbital frontal and anterior cingulate regions have been less well studied. Of three studies reported so far, only one [13] found structural abnormalities (reduced bilateral orbital frontal and amygdala volumes). More impressive evidence for involvement of these structures has been provided by functional imaging studies (see below).

White matter reductions in OCD have been reported and a subsequent replication study confirmed overall white matter reduction but increased opercular volume, which correlated with both severity of OCD and nonverbal immediate memory [14].

Studies using magnetic resonance spectroscopy (MRS) have also demonstrated striatal abnormalities. Two studies have found decreased N-acetyl-aspartate (NAA) levels in the striatum [15,16], suggesting decreased density of healthy neurons in this region. Furthermore, one of these studies failed to find significant differences in striatal volumes [16], underscoring the purported greater sensitivity of MRS-NAA over current morphometric MRI methods.

Rosenberg's group has also demonstrated abnormalities in a pediatric population. Decreased NAA levels were found in right and left medial thalami, with the decreased levels in the left medial thalamus correlating with increased severity of disease [17]. In addition, caudate glutamatergic levels were found to be increased in children with OCD [18], but this was found to normalize after treatment with paroxetine, perhaps suggesting that paroxetine treatment is mediated by a serotonergically modulated reduction in frontostriatal glutamatergic concentration.

C. Functional Studies

Neutral state studies have implicated hyperactivity in the prefrontal cortex and, less consistently, striatal and cingulate involvement [19–25]. Pre/posttreatment studies also point to involvement of these areas. Decreased activity after medication was found in the medial frontal cortex [26] and orbitofrontal cortex [23,27], with one study correlating treatment response to activity in the right frontal cortex. Changes in the caudate and cingulum have also been reported [23].

Interestingly, Baxter et al. found decreased right caudate activity in a group receiving medication as well as a different group receiving behavior therapy [28]. This was subsequently replicated in a second study of behavior therapy, which also confirmed a correlation between orbitofrontal and caudate activity pretreatment that disappeared posttreatment [29]. These studies confirm that effective treatment of

OCD, whether pharmacotherapeutic or psychotherapeutic in nature, is associated with reduced activity in the orbitofrontal cortex, caudate, or cingulate cortex; i.e., effective treatment of OCD is associated with changes in CSTC circuits.

These results may suggest that behavioral and pharmacotherapeutic modalities work via a specific therapeutic mechanism of action. However, Brody et al. [30] found differing patterns of cerebral metabolism in patients who responded to behavior therapy than in those who responded to fluoxetine, with higher normalized metabolism in the left orbitofrontal cortex being associated with good outcome in the behavior therapy group but worse outcome in the fluoxetine group. Furthermore, thalamic volumes normalize after treatment with paroxetine but not behavior therapy [31]. It may be that the changes observed represent the differences between a symptomatic and symptom-free brain rather than any therapeutic mechanism of action.

Why should dysfunction in CSTC circuits lead to OCD symptoms? There is mounting evidence that striatal function is associated with the development, maintenance, and selection of motoric cognitive and procedural strategies; this has been variously described as "habit system," "response set," and "procedural mobilization." Thus, it may be argued that striatal lesions can lead to the inappropriate release of genetically programmed sequences (such as hand-washing, hoarding, etc.).

The "striatal topography model," an early heuristic model [32], postulated that different circuits may be involved in the mediation of different kinds of OCD symptoms. Accordingly, the cognitive symptoms of OCD are mediated by the caudate, motoric symptoms by the putamen, and affective symptoms by paralimbic CSTC circuits. More recent evidence shows involvement of a range of CSTC circuits in OCD; nevertheless, it may still be suggested that projections to specific fields or cells mediate different kinds of OCD symptoms.

Rauch has suggested that failure of thalamic filtering of information may be a key element in producing the intrusive phenomena that are a hallmark of OCD [33]. Information can be processed in two ways—explicitly (i.e., consciously), and implicitly (i.e., unconsciously)—with implicit operations being primarily processed via corticostriatal systems. Rauch postulates that in OCD, pathology in the corticostriatal pathways may allow this information to gain access to consciousness, presenting as intrusive phenomena. Indeed, his team has shown that the striatum is usually recruited during an implicit sequence learning task, but that in patients with OCD, this fails to occur; instead, medial

temporal structures, usually associated with conscious information processing, are recruited [33,34].

In this model repetitive behaviours (compulsions and tics) are viewed as compensatory mechanisms, possibly serving to recruit viable corticostriatalthalamic circuits, thereby facilitating filtering at the level of the thalamus. The repetitions required would reflect the inefficiency of such mechanisms. This is also consistent with clinical observation that patients often suddenly no longer experience the urge to perform a behavior—"as if a switch were turned off." Presumably, once sufficient repetitions have been performed, a threshold level of filtering is reached and the intrusive stimuli no longer reach consciousness. Rauch et al. have also demonstrated in functional imaging studies a characteristic pattern of thalamic deactivation with striatal recruitment [35].

III. AUTOIMMUNE PATHOLOGY IN OCD

Sydenham's chorea is a manifestation of acute rheumatic fever that is often accompanied by neuropsychiatric symptoms, including symptoms of OCD. In a series of landmark studies [36,37], Swedo and colleagues confirmed these earlier observations and also showed that OCD symptoms often preceded motor manifestations of the disease. Follow-up of children with OCD [38] demonstrated that a subgroup had OCD symptoms of abrupt onset, and showed exacerbations that often were associated with demonstrable group A β-hemolytic streptococcus infection. In addition, a subset of children with OCD have antineuronal antibodies.

Together, these finding have led to the designation of Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal infections (PANDAS) [38]. Specific criteria include (1) presence of OCD and/or a tic disorder, (2) prepubertal onset, (3) episodic course of symptom severity, (4) association with group A β-hemolytic streptococcus infection, and (5) association with neurologic abnormalities.

Autoimmune basal ganglia damage has been identified as an important pathogenic mechanism in Sydenham's chorea [39]. It is thought that basal ganglia damage is mediated by antineuronal antibodies that occur as a part of an autoimmune response to group A β-hemolytic streptococcal infection. In addition acute changes in striatal volume parallel the clinical course of PANDAS [40]. These findings therefore strengthen the case for striatal damage as a pathogenic mechanism for OCD.

The B-lymphocyte antigen D8/17 has been identified as a possible marker for susceptibility to rheumatic fever, occurring in 100% of rheumatic fever sufferers [41], with significantly higher expression in the rheumatic fever patients than in either unaffected first-degree relatives or normal controls. As increased D8/17 has not been reported in post streptococcal glomerulonephritis, it may indicate specific vulnerability to developing rheumatic fever and related complications. Elevated D8/17 expression has been described in patients with childhood-onset OCD, Tourette's syndrome, and autism, but not in trichotillomania [42–46].

The role of autoimmune pathology in adult OCD remains less well known. A few studies. however, suggest that in some adults, autoimmune pathology may play a role in the development of OCD. Bodner et al. [47] describe the case of a 25-year-old male who developed OCD after an episode of severe, antibiotic-resistant pharyngitis. Apart from age, he fufilled all criteria for PANDAS. Lougee et al. [48] also report that rates of OCD and tic disorders in first-degree relatives of pediatric probands with PANDAS are higher than those of the general population. The exact role of autoimmune pathology in the development of adult OCD, however, is still uncertain.

The possibility of an autoimmune mechanism in the pathogenesis of OCD suggests that immunological therapies may represent a new treatment modality. However, results of trials using antibiotic prophylaxis and plasmapheresis have so far shown mixed results [49,50], and more work in is needed in this area.

IV. NEUROCHEMISTRY AND NEUROPHARMACOLOGY

A number of neurotransmitter systems appear to play a role in mediating OCD symptoms. These include serotonin, dopamine, and neuropeptide systems.

A. Serotonin and OCD

It was the observation that serotonergic reuptake inhibitors (SRIs) were more effective in alleviating the symptoms of OCD, that first prompted a serotonergic hypothesis of OCD [51,52]. The mechanism of action of SRIs in OCD is not yet fully elucidated—whether they work by correcting some fundamental abnormality or whether they modulate an intact system to compensate for underlying abnormalities in OCD is not yet known. One postulated mechanism of action of the SRIs is that by blocking the reuptake pump, they

lead to increased synaptic serotonin and a resultant increased stimulation of the postsynaptic $5HT_2$ and $5HT_{1A}$ receptors. However, inhibition of the reuptake pump occurs in 24 h whereas clinical improvement may only be seen 8–12 weeks later. One possible explanation is that the delay may represent the time needed to desensitize the autoreceptor.

An interesting set of preclinical studies has found that in order to desensitize the $5HT_{1D}$ autoreceptor in orbitofrontal cortex, the administration of relatively high doses of SRIs for relatively long periods is required (low doses, short duration, and ECT do not have an effect) [53]. Furthermore, Mansari et al. [54] showed that changes in serotonergic transmission occurred more quickly in the lateral frontal cortex than the medial frontal cortex following SRI administration. This work is reminiscent of clinical findings in OCD, where it is observed that up to 12 weeks of treatment at higher doses is needed to produce a therapeutic response, and that depressive symptoms tend to remit earlier than OCD symptoms. It also corresponds with current models which postulate the lateral frontal cortex to be important in depression and the medial frontal (or orbitofrontal) cortex to be important in the pathophysiology of OCD. Together, these findings suggest that this receptor may therefore have a particularly important role in the pathogenesis of OCD.

There is also work suggesting that $5HT_2$ receptors are important in OCD. Case reports suggest that certain hallucinogens (psilocybin and LSD), which are potent stimulators of the $5HT_{2A}$ and $5HT_{2C}$ receptors, can decrease OCD symptoms [55]. Conversely, administration of ritanserin, a $5HT_2$ antagonist, results in the exacerbation of OCD symptoms [56]. Arguably, enhancement of neurotransmission through $5HT_{2A}$ or $5HT_{2C}$ receptors may be a common pathway for drugs with therapeutic effect in OCD.

Studies of indirect measures of central serotonergic function (such as platelet receptor binding and CSF concentrations of 5HT metabolites) in OCD have been inconsistent. In addition, these measures are not necessarily accurate representations of serotonergic function within the brain. There is somewhat more consistency in studies of serotonergic agonists; OCD symptoms are exacerbated by mCPP (a $5HT_{1A}$ and $5HT_{2C}$ agonist) [57–59] and sumatriptan (a $5HT_{1D}$ agonist) [60]. Administration of sumatriptan during functional imaging demonstrated a significant association between symptom exacerbation and decreased frontal activity, arguably consistent with a role for the $5HT_{1D}$ receptor in OCD [60]. Nevertheless, findings with both mCPP [61–63] and sumatriptan [64]

have not always been consistent, and sumatriptan has poor blood-brain barrier penetration, so additional work in this area remains necessary.

B. Dopaminergic Systems and OCD

Preclinical studies demonstrate that stereotypic behavior can be elicited by the administration of dopamine agonists, and decreased by dopamine blockers. Similarly, stereotypic, repetitive behaviors have been described in stimulant abusers [65,66]. Furthermore, cocaine, a dopamine reuptake blocker, has been reported to exacerbate symptoms in patients with OCD and to induce obsessive-compulsive behavior in subjects with a family but not personal history of OCD.

Tourette's syndrome (TS) is a disorder for which a dopaminergic basis is well elucidated. For example, the principal dopamine metabolite homovanillic acid (HVA) is decreased in the CSF of patients with TS [67], and dopamine blockers are a standard form of treatment in TS. Recent imaging studies have demonstrated a significant increase in the number of striatal presynaptic dopamine carrier sites in the caudate and putamen in TS patients [68–70]. Overlap between TS and OCD has been well documented, further pointing to a dopaminergic basis for OCD.

Pharmacologic studies in OCD support a potential role for the dopamine system. Forty percent to 60% of patients with OCD are treatment resistant, and patients with comorbid tics are particularly likely not to respond to SRIs [71]. However, augmentation of SRIs with dopamine blockers has been shown effective in both open [72,73] and controlled trials [71,74]. Typical neuroleptics are particularly effective in OCD patients with comorbid tics [71], while the atypicals appear useful in OCD patients both with and without tics [74].

C. Neuropeptides and OCD

Preclinical evidence has linked neuropeptides to repetitive behavior in animals, and initial clinical investigations in OCD patients suggest that they may play a role in modulation of the disorder. Neuropeptides implicated in OCD include arginine vasopressin (AVP), oxytocin, adrenocorticotropic hormone (ACTH), corticotropin-releasing factor (CRF), somatostatin, and the opioid system.

In animals, AVP is associated with enhancement of memory acquisition and retrieval and with grooming behaviors. Grooming behaviors in animals are often viewed as analogous to human washing and cleaning behavior, and excessive grooming is often viewed as an animal correlate of a washing or cleaning compulsion. AVP may also inhibit extinction, decreasing the likelihood of changing a behavioral pattern once it has been established. It can thus be seen that AVP is a likely candidate for involvement in the pathogenesis of OCD. Studies in humans, however, have been inconsistent. One study found that OCD patients had significantly elevated basal levels of AVP and secreted more AVP into plasma in response to hypertonic saline [75]. However, this has not been replicated [76]. Nevertheless, in children and adolescents with OCD, a negative correlation between symptom severity and AVP levels was found [77].

As with AVP, oxytocin administration in animals is associated with changes in grooming behavior, with marked increases in grooming. Oxytocin has also been shown to induce maternal behavior in female rats, but only in animals primed with estrogen [78]. Elevated levels of oxytocin (and estrogen) may be postulated to induce OCD symptoms in a vulnerable subgroup of women, explaining the increased risk for development of OCD in the pregnancy and puerperium, and the higher incidence of washing and cleaning compulsions in this subgroup of patients. Higher CSF oxytocin levels have been found in adult patients with no family or personal history of tic disorders, and oxytocin levels were significantly correlated with Y-BOCS scores [79]. In children, the AVP/oxytocin ratio was negatively correlated with symptom severity [77]. Administration of oxytocin to adults with OCD, however, has had no consistent therapeutic effect [80].

ACTH and CRF are both noted to increase self grooming in animals. In humans, both basal plasma ACTH and the increase following CRF administration was found to be less in adults with OCD than controls [81]. Studies of CRF levels have been inconsistent, with initial reports of elevated CRF in OCD patients not confirmed in replication studies. In children, no correlation has been found between CSF, ACTH, or CRF levels and symptom severity [77]. As both ACTH and CRF are released in response to stress, it is possible that any elevations found may be a nonspecific response to the stress of a chronic illness.

In animals, somatostatin delays the extinction of active and passive avoidance behaviors (which may be similar to the persistent repetition of OCD) and can also produce stereotypic behaviors [82,83]. Studies of both adults and children with OCD have found higher CSF somatostatin as compared to healthy adults and conduct-disordered children [84,85].

Opioids mediate reward signals and it has been postulated that they may be involved in mechanisms that

signal successful task completion. Deficiencies in these mechanisms may potentially explain the "self-doubt" experienced by many patients with OCD. OCD patients have elevated serum antibodies for the dynorphin precursor prodynorphin [86]. In Tourette's syndrome, CSF dynorphin was found to correlate with OCD (but not tic) symptom severity [87]. However, no correlation was found between dynorphin levels and symptom severity in children with OCD. Furthermore, challenges with opioid antagonists in OCD have produced inconsistent results [88,89].

In summary, preclinical evidence suggests that various neuropeptides may play a role in the pathogenesis of OCD. While the evidence for neuropeptides inducing OCD-like behaviors in animals is fairly robust, studies in humans have produced less convincing results. Differences between results in adult and pediatric populations suggest that developmental factors impact the functioning of the different neuropeptides. Further studies are warranted to fully elucidate the role of these peptides in OCD.

V. CONCLUSION

In the last two decades significant strides have been made in our understanding of the pathogenesis of OCD. We now know that it is a disorder mediated by specific neuroanatomic and neurochemical mechanisms. Furthermore, we have translated our improved understanding of the neurobiology of OCD into several effective therapeutic modalities. However, there are still gaps in our understanding of OCD. The challenge now is to bridge these gaps and to develop new therapeutic modalities so that we may even more effectively treat this fascinating and complex disorder.

I. INTRODUCTION

Panic disorder (PD) is a common and disabling illness, with a reported lifetime prevalence of 1.5–3.5% [1,2]. Women are affected about twice as often as men, and the disorder is most common in the ages 30–44 [3]. PD is frequently comorbid with mood disorders and the other anxiety disorders, and, in terms of severity, approximately one-third of patients report poor physical and emotional health, rates comparable with those for major depression [2]. At the same time, there is accumulating evidence that PD has a distinct neurobiology from the other anxiety disorders as well as the mood disorders. Panic may also differ from a normal fear reaction [4], defined by Walter Cannon as a biologically disposed alarm reaction to perceived threat that mobilizes the organism for action [5].

The occurrence of *unexpected* and *spontaneous* panic attacks is required for the diagnosis of panic disorder; however, individuals with PD may report *situationally bound* panic attacks as well. Besides recurrent unexpected panic attacks, sequelae of the attack are necessary for diagnosis, which might include anticipatory anxiety about having another attack, phobic avoidance of situations associated with the panic attack, and worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack, "going crazy"). Agoraphobia (a fear of circumstances in which escape or getting help is limited) occurs in ∼ 30% of patients with PD, and is generally associated with a worse prognosis [6].

This chapter begins with a synopsis of neurodevelopmental issues relevant to understanding the relationship between childhood anxiety disorders and adult PD. Characterizing the ontogeny of psychobiological alterations throughout development is potentially important for the early identification and treatment of at-risk children. Accordingly, this article attempts to build the case that there likely exist distinct genetically mediated trait markers for PD beginning in childhood that are chronic and persistent even after effective treatment and disease remission. The trait markers span the gamut of areas investigated biologically in PD, including respiratory, cardiovascular, neuroendocrine, genetic, and neuroanatomic systems.

A growing body of evidence implicates hypothalamic-pituitary-adrenal (HPA) axis overdrive as an influential factor in the pathophysiology of a significant portion of adult mood and anxiety disorders [7]. As an example of the developmental complexity in the search

433

for trait markers, we examine in children the interrelationships between HPA axis and another area extensively investigated, ventilatory regulation. Second, we continue with an analysis of this interrelationship in adults, as well as examining evidence for traitlike respiratory irregularities in adults with PD. Selected reviews of neurotransmitter systems that have been extensively investigated (norepinephrine, glutamate/GABA, serotonin) in PD, all of which have marked dynamic interactions with HPA axis, are then presented.

Candidates for neuronal modulation of the varied cortical, subcortical, and brainstem circuits implicated in PD are most likely found in multiple brain regions. In moving away from the single-locus hypothesis, dynamic interactions of multiple brain regions over time are likely important. In this light, pertinent recent findings in neuroimaging and genetics are then discussed. Finally, we present several areas of research requiring future investigation.

II. NEURODEVELOPMENTAL STUDIES AS A MEANS TO IDENTIFY TRAIT MARKERS OF PANIC DISORDER

Detailed childhood and adolescent histories in adult PD patients often reveal the presence of significant premorbid anxiety, manifesting as separation anxiety disorder, isolated panic attacks, or overanxious disorder [8–11]. Even in those adult patients with PD without overt childhood symptoms, biological trait markers for the illness can manifest before the presence of any overt symptoms. Only recently has work begun to probe the biological substrates of these childhood variants of PD [12–14].

A heightened response to carbon dioxide (CO_2) inhalation (a so-called CO_2 hypersensitivity) has been identified in adults with PD [15,16], in related conditions such as isolated panic attacks [16,17], and in non-ill first-degree relatives of patients with PD [18,19]. CO_2 hypersensitivity appears to be specific for PD and premenstrual dysphoric disorder, as compared with major depression, which appears to be insensitive to CO_2 inhalation [20].

Pine et al. [12] showed that CO_2 hypersensitivity was also found in children with separation anxiety disorder (and to a lesser degree in generalized anxiety disorder), while absent in social phobia. Using the same pediatric cohort, our group demonstrated a significant relation between HPA axis activation and susceptibility to ventilatory-based laboratory-induced panic using CO_2 inhalation [14]. In striking resemblance in adults

with PD [21], elevations of salivary cortisol concentrations taken immediately prior to a standard CO_2 inhalation procedure were associated with increased rates of CO_2-induced panic. Subjective anticipatory anxiety and HPA axis activation, but not anxiety disorder diagnosis, were the most significant predictors of CO_2-induced panic in this pediatric sample [14].

Also as seen with adults [22], the CO_2 challenge itself had little effect on salivary cortisol values, suggesting that certain mechanisms for "suppression" of the HPA axis [23] may already be in place in childhood [14]. These preliminary reports are suggestive of a pathophysiological link between ventilatory disturbances and HPA axis from childhood into adulthood.

One implication of these reports is that children undergoing CO_2 challenge who display anticipatory anxiety, HPA axis activation and CO_2 hypersensitivity should likely be observed for the development of PD. CO_2 hypersensitivity might thus represent one important biological trait marker of familial vulnerability to panic disorder.

III. BIOLOGICAL SYSTEMS OPERATIVE IN ADULT PANIC DISORDER

In early investigations, Klein and Fink noted the effectiveness of imipramine hydrochloride in aborting spontaneous panic, but not chronic anxiety or agoraphobic avoidance [24]. Spontaneous panic was further distinguished biologically from fear, which did not respond to antidepressant treatment and is not marked by dyspnea [see 4 for review]. Since these early suggestions of distinct biological findings in panic, numerous investigations have further attempted to discriminate the core neurobiological features of PD. In this section we will focus on three areas extensively studied—respiratory physiology, HPA axis functioning, and the noradrenergic (NE) system—to delineate specific abnormalities unique to PD.

A. Respiratory Physiology in Panic Disorder

The unique clinical finding of dyspnea in patients with PD, compared with other anxiety disorders as well as normal fearful reactions to danger, has prompted numerous investigations into the role of respiratory regulation in PD. A prominent theory of pathophysiology is Klein's false suffocation alarm hypothesis [4], which suggests a respiratory control center abnormality in patients with PD. The suffocation alarm system

posits an evolutionarily derived set point subject to various influences, which can be triggered by increasing levels of brain lactate and blood CO_2 [4].

Another prominent view is that respiratory stimulation such as with CO_2 challenge could act as a nonspecific stimulus that activates an overly sensitive neuroanatomical anxiety network in patients with PD [25]. The nonspecific stimulus notion is concordant with cognitive theories of panic and might explain in part the efficacy of cognitive-behavioral therapy for PD [26].

Several lines of evidence suggest that perhaps neither theory—suffocation alarm or cognitive catastrophe—is sufficient by itself to explain particular respiratory findings in PD. A recent study in fact found no difference in minute ventilation (MV) response to CO_2 inhalation–induced panic or in formal CO_2 sensitivity between patients with PD and other groups [27]. This study showed that once a panic attack is triggered, MV and respiratory rate increase regardless of diagnosis, and the physiological features of the panic attack itself appeared similar across groups [27]. A generalized fear response involving the amygdala and limbic regions, thought to be abnormally sensitive in PD, was proposed [27]. Based on the neural circuit that subserves conditioned fear in rodents, Gorman et al. have hypothesized that an overactive central nucleus of the amygdala, which has caudal projections to respiratory brain stem sites such as the parabrachial nucleus, might result in dysregulated breathing patterns in certain patients with PD [28]. Contrary to earlier reports, this study suggests that there might not be any fundamental abnormality in an adult panic patient's ventilatory physiology [27], but rather that the primary abnormalities likely involve central fear pathways.

Central pathways might be responsible for the increased baseline respiratory variability observed in PD. A recent report found that PD patients had greater tidal volume irregularity as well as elevated frequency compared to controls at baseline, which was primarily attributable to a sighing pattern of breathing [29]. The irregular breathing patterns were essentially stable over time and were, surprisingly, independent of doxapram (a respiratory stimulant)-induced panic or cognitive manipulation [29]. Similarly, our group recently confirmed that PD patients show increased baseline variability in tidal volume and minute ventilation compared to normal controls and major depressives [30]. The increased variability at baseline was predictive of subsequent vulnerability to CO_2-induced panic [30].

As noted above, respiratory variability manifesting as sighing appears to be a cardinal feature of panic, and has been an area of recent research interest as a potential trait marker for the illness. Sighing, defined as breaths with twice the size of a person's average resting tidal volume, abruptly lowers PCO_2 and is believed to relieve respiratory distress. Klein has argued that the sighing observed in PD patients may represent a compensatory mechanism to keep PCO_2 below a depressed suffocation alarm threshold [4].

Preliminary studies support the specificity of sighing in PD versus both social phobia [31] and generalized anxiety disorder [32]. Sighing occurs in PD patients even when not exposed to immediate anxiety provocation, suggestive of a traitlike characteristic [33]. PD patients seem to not only have more frequent sighs, but the magnitude of sighs are greater than controls. Presigh PCO_2 levels also return to baseline slower, suggesting either deficits in peripheral chemoreceptor compensation or an adaptive maintenance hyperventilation [33].

At the same time, there is evidence that some sighs are independent of peripheral chemoreceptor and PCO_2 effects [29], and could be centrally mediated. Central mediation of respiratory function is suggested by inputs from brain regions beyond brainstem respiratory control centers, such as the hippocampus [34], paraventricular hypothalamus [35], and the central nucleus of the amygdala (CeN) [36], structures integral to the anxiety neurocircuitry described in Gorman's hypothesis.

In summary, there are numerous unanswered questions regarding the role of respiration in panic, although the unique relationship is increasingly evident. While there is longitudinal evidence of respiratory variability and irregular breathing patterns that might be operative in the familial transmission of PD [12,16,30,37,38], there are contradictory conclusions when examining the CO_2 challenge literature. As noted by Roy-Byrne, the most important weakness in the CO_2 paradigm is its probable lack of neuroanatomic specificity, potentially limiting its usefulness as an endophenotypic trait marker [25]. More recent investigations suggest that the breath-by-breath variation in tidal volume manifested as sighing may provide a robust and fairly stable marker for PD [29,33].

Intimately related to the respiratory physiological abnormalities are the cardiovascular findings in panic disorder, which are briefly reviewed herein [see 39 for review]. Patients have shown faster heart rates in baseline laboratory measures, and tachycardia is a prominent feature of panic attacks [40]. More recent findings,

however, suggest that there is not consistent evidence for baseline elevations in heart rate and blood pressure in PD [41].

Findings from the Epidemiological Catchment Area (ECA) study demonstrated that PD patients were at greater risk of high blood pressure, myocardial infarction, and stroke than were to subjects with no psychiatric disorder [42]. This association has been explained by a decreased cardiac vagal tone or an increased cardiac sympathetic responsiveness, both of which are associated with increased cardiovascular mortality [43]. It is known that PD patients have reduced parasympathetic innervation to the heart compared with control adults [44,45], and display reduced heart period variability (HPV) in some studies [44,46], another risk factor for proarrhythmic cardiac events.

Yeragani [45] showed that PD patients have increased adrenergic and decreased cholinergic responsiveness by an analysis of power spectrum. Alterations in central cholinergic activity in PD was also recently suggested in a study in which biperden, a centrally active muscarinic antagonist, blocked the response to CO_2 challenge in 12 patients [47]. Thus, while brainstem cholinergic neurons appear to play a role in modulating CO_2-induced panic, the precise role of cholinergic systems in PD itself is unclear.

In conclusion, the findings in HPV, autonomic, and cardiovascular regulation in PD require further investigation until its full consideration as a biological trait marker. Where the heart might in fact have the most relevance for PD is in the production of atrial natriuretic peptide (ANP), which was found to inhibit CCK-4-induced increases in corticotropin and cortisol levels in a recent study [48]. Further, ANP inhibited sympathetic stimulation in PD patients and controls [48]. A greater understanding of the role of this peptide as a modulator among the heart, hypothalamus and brainstem sites in anxiety conditions is necessary.

B. HPA Axis

PD has generally been distinguished from two comorbid conditions, major depression and post-traumatic stress disorder (PTSD), by its relative lack of persistent elevation of hypothalamic corticotropin-releasing factor (CRF) and adrenal cortisol dysregulation [49], although there are inconsistencies in studies examining these systems. CRF has emerged as a neurotransmitter/neuropeptide that plays a critical role in stress and stress-related disorders [50]. Recent data of cortisol regulation suggest a reexamination of the role of the HPA axis in PD.

Early evidence for dysregulation of CRF systems focused on the blunted ACTH response to CRF stimulation in panic patients compared to controls [51,52], a finding contradicted in a later study with a small sample size [53]. In fact, the preponderance of early studies investigating the discrete panic attack itself showed a curious lack of activation of a corticoid response in both normal controls and PD patients, both in naturalistic and laboratory settings [see 4 for review]. In a more recent, 24-h study of ACTH and cortisol secretion in PD, patients had increased overnight plasma cortisol secretion and greater amplitude of ultraradian secretory episodes [54], although the findings could be attributed to anticipatory anxiety.

More recent work has focused on salivary cortisol and has contradicted earlier reports of suppressed HPA axis activity. Salivary cortisol might represent a better measure of HPA axis activity than plasma values in that it highly correlates with free plasma cortisol [55], the biologically active component. Salivary cortisol levels were found to be elevated following spontaneous panic attacks in a naturalistic setting [56]. Increased salivary cortisol could of course reflect increased stressful experiences during an attack, and might not suggest an underlying dysregulation of the HPA axis. However, Bandelow's group further noted that basal levels of total plasma, plasma-free cortisols, and salivary cortisols were all significantly elevated in PD patients compared to controls [57]. The major limitation of the salivary cortisol reports, however, is that the distinction between anticipatory anxiety and panic cannot be made from the study design.

In our analysis of 170 PD patients undergoing lactate infusions at our center, the strongest predictors of lactate-induced panic, prior to infusion, were fear and the combined or "interactive" effect of high cortisol and low pCO_2 [21]. We also examined blood cortisol responses to CO_2-induced panic. Cortisol levels did not increase and actually decreased significantly in 10 panicking subjects with PD, while in a separate study no reductions were noted after CO_2 inhalation in normals and nonpanicking PD patients [22].

We have hypothesized that the psychological, neuroendocrinological, and ventilatory interactions observed in the above studies could be explained by a CRF-mediated amygdaloid complex overactivation interacting with the following brain regions: (1) reciprocal cortical areas (cognitive misappraisal of fear); (2) the paraventricular nucleus (PVN) of the hypothalamus (cortisol response); and (3) the nucleus parabrachialis in the medulla (hyperventilation-induced low pCO_2) [58]. Thus, dysregulated HPA axis function

might represent another trait marker of vulnerability to panic disorder, although current laboratory assessments have notable methodological limitations in differentiating the endocrine response in panic versus anticipatory anxiety.

C. The Noradrenergic System in Panic Disorder

Exploring functional linkages between the noradrenergic (NE)/locus ceruleus (LC) systems and relevant systems such as HPA axis, and other neurotransmitter systems, might further illustrate underlying neurobiological mechanisms of PD, given the prominence of hyperadrenergic symptoms in panic attacks (e.g., tachycardia, increased diastolic blood pressure, diaphoresis). Anatomically, there are important connections between the LC and the amygdala mediated by CRF-secreting neurons. The LC contains the highest concentration of NE cell bodies in the brain and sends numerous efferent projections to regions important in fear responses [for review, see 59].

Several other neurotransmitter systems appear to play an important interactive effect on LC functioning, including glutamatergic systems. The medullary nucleus paragigantocellularis (NPGi) sends excitatory input via glutamatergic receptors to the LC, suggesting an important link between glutamate and noradrenergic systems [60]. Given the neuroanatomical efferents to the LC, we hypothesized that chronic attenuation of glutamatergic transmission with the novel metabotropic glutamate (mGlu2/3) agonist LY354740 would blunt both HPA axis and LC responsivity in nonhuman primates [61]. We found that chronic treatment (6 weeks) with a functional glutamate antagonist did indeed reduce baseline cortisol levels, but failed to attenuate yohimbine (an alpha-2 adrenergic antagonist) challenge-induced plasma 3-methoxy-4-hydroxyphenylglycol (MHPG) levels [61].

In a prior clinical study, we had demonstrated that clonidine (an alpha-2 adrenergic agonist) induced greater decreases in MHPG and serum cortisol in PD patients versus control subjects, an effect which persisted even with effective treatment with fluoxetine [62]. In contrast to controls, PD patients demonstrated an "uncoupling" of the NE system and the HPA axis, meaning a lack of the typical correlation between MHPG and cortisol. Treatment with the glutamate antagonist in the nonhuman primate study selectively "uncoupled" the two systems, protecting the HPA axis, while retaining LC responsivity. Thus,

LY354740's ability to modulate the HPA axis suggests a potential therapeutic action in stress-related conditions such as PD, and its effect on LC functioning as evidenced by the yohimbine-induced MHPG response is potentially important in understanding the role of glutamatergic neurotransmission on noradrenergic function.

Pharmacological probes employing clonidine and yohimbine have provided the most useful clinical data linking NE and the HPA axis. One of the most replicated findings in PD is the blunted growth hormone (GH) response to clonidine challenge, which results in less sedation, a greater hypotensive response, and a disproportionate reduction in plasma MHPG in patients compared to controls [63–65]. Limitations of this finding, however, are both its nonspecificity to PD and its ambiguous pathophysiological significance, in that the blunted GH response might represent an intrinsic alpha-2 receptor abnormality, or a dysregulation of other afferent neuronal systems (such as CRF) affecting this receptor. Regarding the latter possibility, we recently found that adversely reared nonhuman primates with relatively high CRF concentrations exhibited relatively diminished GH responses to clonidine [66]. These data raise the possibility that reductions of GH response to clonidine may relate, in part, to trait-like increases of CNS CRF activity [66].

Yohimbine challenge, which is accompanied by increased serum MHPG, cortisol, and cardiovascular responses, elicits high rates of panic attacks in PD patients ($\sim 54\%$) [67]. A series of studies have revealed that the group of PD patients who experienced panic attacks with yohimbine had significantly greater increases in plasma MHPG following yohimbine than healthy subjects or PD patients who did not experience panic attacks, although these findings have not been consistently replicated [reviewed in 67].

Although much has been written about noradrenergic mechanisms in PD, the centrality of the NE system in the pathogenesis of panic anxiety has come into question. First, there is inconsistent evidence for increases in measures of NE function during provocative challenge with "respiratory" panicogens such as lactate, CO_2, and doxapram [4,68,69]. Further, there is supportive evidence that the LC/NE system might actually be more important in modulating arousal and anticipatory anxiety (by LC activation of amygdalo-hippocampal structures) than in mediating panic attacks themselves [69,70]. See **Figure 1** for a review of noradrenergic pathways in PD.

In summary, the study of ventilatory physiology, HPA axis, and the NE system has been useful in lending direction for the identification of endophenotypic trait markers of the illness. Some of the inconsistencies in the literature might reflect differences in subject illness severity or clinical characteristics; for example, Abelson's finding of increased nocturnal cortisol [54] was most evident in patients recruited from clinical settings versus those responding to advertisement. Some inconsistencies might reflect failure to distinguish among normal fear reactions, panic disorder, anticipatory anxiety, and generalized anxiety.

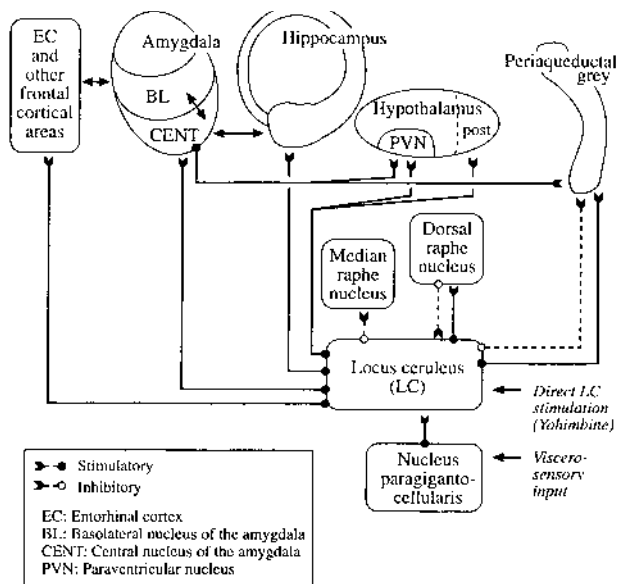
Despite the inconsistencies, tentative conclusions can be made. First, during anticipatory anxiety, such as is observed in PD subjects prior to lactate infusion, increased cortisol secretion coupled with hypocapnia is the profile most strongly predictive of subsequent panic. Second, during the panic attack itself, cortisol appears suppressed. The recent findings of elevated salivary cortisol levels require refinement in methodology to distinguish between anticipatory anxiety and panic. Finally, patients with PD appear to have increased within-subject noradrenergic volatility during clonidine challenge [71], which is in accordance with the increased variability in baseline ventilatory measures reported.


Figure 1 Noradrenergic pathways in panic disorder. (From Ref. 131.)

D. GABA/Glutamate Systems in Panic Disorder: Potential Markers for Assessment of Early Environmental Influences on Stress Response

The benzodiazepines remain very useful drugs for certain patients with PD, suggesting a role for the inhibitory neurotransmitter GABA in the pathophysiology of PD. There is evidence that the benzodiazepines, which potentiate synaptic actions of GABA, exert their anxiolytic effects at critical sites such as CRF neurons within the amygdala and the ascending noradrenergic systems [72]. A series of investigations strongly suggest that the CRF system is in fact a principal target for the anxiolytic effects of benzodiazepines [73,74]. Additionally, there is evidence of frontal cortex involvement as a target site for benzodiazepines. Antidepressants, which are recognized as clinically useful in treating PD, also interact with the GABA(A) receptor complex and enhance its function [75,76]. Of course, none of the preclinical investigations discussed above are specific for PD. Indeed, in certain subsets of patients, such as those with prominent dyspnea, benzodiazepines might fare poorly, as imipramine has been shown to be more effective than alprazolam in these patients [77].

Preclinically, a series of studies by Meaney's group have found that repeated periods of prolonged maternal separation resulted in decreased $GABA_A$ receptor binding, as well as diminished central benzodiazepine (BZ) receptor levels [72]. The potential relevance to PD stems from the observed epidemiological association between early maternal death and agoraphobia with panic attacks, as well as parental separation or divorce, findings specific for PD among the anxiety disorders [78].

Although the clinical studies of PD have yet to directly demonstrate decreased central BZ receptor levels as seen in Meaney's work in rodents, several human studies are highly suggestive of such. A positron emission tomography (PET) study in unmedicated patients with a history of PD revealed a significant decrease in brain BZ receptor levels using the flumazenil ligand [79], with a striking decrease in right orbitofrontal cortex and right insula. Another group more recently reported a decrease in left hippocampal and precuneus BZ receptor binding in a SPECT study, which was hypothesized to be due to changes in GABA-ergic transmission or to endogeneous BZ compounds [80]. Notably, PD patients who panicked at the time of the scan had a decrease in prefrontal cortex BZ receptor binding compared to patients who did not

panic [80], suggesting differences between state and trait-related panic anxiety.

Compared to the GABA/BZ system, much less attention has been given to the major excitatory amino acid, glutamate, in PD, although there is accumulating evidence that it plays a role in modulating stress responses. Rodent models indicate that prefrontal cortical efferents, either directly or via thalamic nuclei efferents, utilize the glutamatergic system as a primary source for neuronal stimulation of the "fear" neurocircuitry, which originates from the central nucleus of the amygdala and bed nucleus of the stria terminalis [81]. Stressful situations faced by a person with PD or other anxiety states might stimulate glutamate release in hippocampal [82] and other brain regions. In this light, agents that attenuate glutamatergic neurotransmission should reduce anxiety levels, as well as the concomitant biochemical alterations associated with stress [see 83 for review of glutamate-HPA axis interactions].

Thus, the balance between GABA and glutamate systems can be potentially disrupted with early environmental stressors, which may be associated with the development of PD in adulthood [84]. We have shown that subtle disruptions in the maternal-infant interaction results in CRF overexpression in bonnet macaques [85]; this in turn could result in alterations in other systems relevant to stress, anxiety and PD, such as the GABA/glutamate and LC/NE systems. Again, the specificity to PD is lacking in these models, an important limitation in their overall applicability.

IV. SSRI THERAPY AND PATHOPHYSIOLOGY

The use of antidepressants, particularly the SSRIs, has supplanted the long-term use of benzodiazepines in PD, and the former are now considered the first-line treatments. Questions remain as to why the SSRIs are beneficial in PD, what subtypes of patients are most likely to improve with the SSRIs, and what the role of serotonin in this disorder is. Effective treatments for PD, such as the SSRIs, might work by downregulation of overactive HPA/LC-NE systems. Indeed, our group demonstrated that after 12 weeks of treatment with fluoxetine, PD patients responding to treatment showed a decrease in plasma MHPG volatility during clonidine administration [71]. By having a noradrenergic-stabilizing effect, SSRIs would have a therapeutic role in decreasing symptoms associated with panic

attacks such as tachycardia and increased diastolic blood pressure.

Other serotonergic projections of potential therapeutic relevance in PD include the projection of the raphe neurons to the periacqueductal gray region of the midbrain, which is important in defense/escape behaviors [86]. SSRIs, by inhibiting the periacqueductal gray region, might allow a disinhibition of the avoidance behaviors seen with panickers. Another important target for the SSRIs attenuates the hypothalamic release of CRF [87], which, as discussed above, appears to play a role in the mediation of fear in preclinical models. Regarding serotonin receptors, recent serotonergic challenge data postulate an increased sensitivity of central 5HT2C receptors and decreased responsiveness of 5HT1A receptors in panic, although replication is needed [88].

Finally, SSRIs might be effective in aborting panic attacks by a direct modulatory effect on the central nucleus of the amygdala. Stutzmann and Ledoux [89] have shown that 5HT inhibits excitatory glutamatergic inputs from thalamus and cortex at the lateral nucleus of the amygdala. An increase in 5HT with chronic SSRI use might prevent amygdaloid activation, as the amygdala is known to receive dense serotonergic input from raphe nuclei. So in effect, SSRIs might ultimately work in PD by attenuating glutamatergic hyperactivity at the level of the amygdala, as well as in other areas of excessive release in stress, such as the hippocampus, thalamus, and anterior cingulate, although this hypothesis remains to be tested.

We conclude that serotonergic abnormalities are unlikely the primary cause of PD, although antidepressants with serotonin activity are effective. SSRIs remain effective treatments for PD probably by diminishing the activity of brainstem centers that receive input from the amygdala and control autonomic and neuroendocrine response during attacks.

V. NEUROIMAGING STUDIES

A comprehensive review of the neuroimaging literature in PD is beyond the scope of this chapter [see 90]; herein we identify several key findings in the clinical literature. In general, PD patients do not differ from controls in cerebral blood flow (CBF) measures at baseline, but show different blood flow patterns when given panicogenic stimuli. PET and SPECT studies have found regional abnormalities in metabolism and blood flow in limbic structures, including hippocampus, parahippocampus, and temporal lobe [91–

94]. The studies measuring cerebral blood flow in PD, however, have methological limitations [28], including the fact that PD patients hyperventilate when anxious, and the resultant hypocapnia-induced vasoconstriction might obsure results by counteracting expected increases in blood flow.

There is accumulating evidence that PD patients are more sensitive to the vasoconstrictive effects of hyperventilation-induced hypocapnia than comparison subjects [28]. When controlling for level of hypocapnia, as measured by the end tidal CO_2 level, PD patients who hyperventilated during [^{133}Xe]-SPECT scans showed significantly greater decreases in CBF than normal controls [28]. A transcranial Doppler ultrasonography study similarly showed that patients with PD had greater reduction in basilar artery flow rates after hyperventilation than normal controls [95]. The implication from these studies is that patients with PD display greater cerebral vessel vasoconstriction, independent of degree of hyperventilation and hypocapnia. These findings might account for the development of neurological symptoms during certain panic attacks, such as dizziness, lightheadedness, and aura-like symptoms.

Several factors might explain these findings. First, the noradrenergic system activation observed in panickers might be contributory. It is known that noradrenergic fibers innervate cerebral blood vessels and cause vasoconstriction [96]. During periods of hyperventilation, increased LC discharge stemming from a hyperadrenergic state might cause a NE-mediated vasoconstrictive pattern observed in CBF studies [97]. Another explanation for the vasoconstrictive pattern in PD is the role of the parabrachial nucleus, a medullary structure that has been shown to cause cerebral vasoconstriction when stimulated [98]. The anatomical route is via the rostral serotonergic raphe nuclei, which relay information from the brainstem parabrachial nucleus (adjacent to the pontine locus ceruleus) to the cerebral cortex. Hyperventilation in a PET or SPECT study might produce symptoms reminiscent of a panic attack and trigger an amygdala-centered fear network, leading to increased activity in parabrachial nucleus sites, which then in turn mediates the vasoconstrictive effects seen in PD [28]. Another relevant brainstem nucleus is the nucleus tractus solitarius. In rats, stimulation with microinjection of L-glutamate causes vasoconstriction and a decrease in CBF. The NTS has afferents from the lungs and may be stimulated by hyperventilation, which we have observed to be increased in PD patients. Thus, increased stimulation of these various brainstem nuclei involved in the

vasoconstrictive process might explain some of the CBF findings in PD. See **Figure 2** for a review of key neuroanatomical pathways in PD.

Besides CBF abnormalities, neuroimaging studies have explored anatomical morphometric volumes in PD. Unlike those observed in major depression and PTSD, patients with PD do not appear to have volumetric deficits in hippocampus [99]. In a quantitative MRI study, patients with PD displayed decreased overall temporal lobe volumes bilaterally compared with normal controls [99], a finding consistent with prior MRI studies. Previous MRI studies [100,101] showing asymmetric temporal lobe atrophy and larger dilatation of the temporal horn of the lateral ventricle were limited by the the use of qualitative MR measures. The pathophysiological significance of the reduction in the temporal lobe volume in the absence of hippocampal volume reduction is unclear, as are the CBF studies documenting alterations in hippocampal and adjacent cortex (parahippocampus) structures. Further prospective MRI studies are indicated to determine whether decreased temporal lobe volumes are a risk factor for panic disorder, a consequence of severity and duration of the illness or both.

VI. GENETIC CONSIDERATIONS AND ROLE OF COMORBIDITY

The struggle to identify biological trait markers for panic disorder likely reflects the complex genetic heterogeneity of the illness. This section briefly highlights important genetic considerations in PD [see 102 for a comprehensive review].

Family studies, while unable to differentiate between genetic and environmental influences, have shown that PD rates are substantially elevated over the base rate in the population if one has a first-degree relative with PD [103]. Twin studies that compare the rate of PD between monozygotic (MZ) and dizygotic (DZ) twins are useful for identifying genetic factors if the rate of monozygotic concordance is much higher than dizygotic rates. Although there is a higher concordance rate for PD in monozygotic than in dizygotic twins, the ranges observed (14–31%) are unimpressively low [104–106].

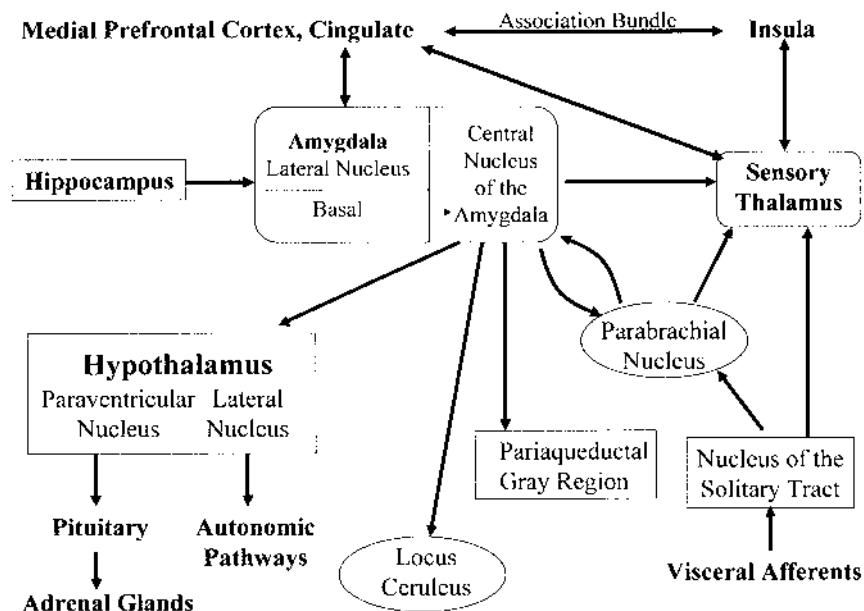
Genetic factors also likely play a limited role in the etiology of sporadic panic attacks, as suggested by Perna et al.'s twin study comparing the MZ/DZ ratio of PD with sporadic attacks [107]. They found no significant difference in concordance rates of sporadic


Figure 2 Viscerosensory information is conveyed to the amygdala by two major pathways: downstream, from the nucleus of the solitary tract via the parabrachial nucleus or the sensory thalamus; and upstream, from the primary viscerosensory cortices and via corticothalamic relays allowing for higher-level neurocognitive processing and modulation of sensory information. Contextual information is stored in memory in the hippocampus and conveyed directly to the amygdala. Major efferent pathways of the amygdala relevant to anxiety include the following: the locus ceruleus (increases norepinephrine release, which contributes to physiologic and behavioral arousal), the periaqueductal gray region (results in defensive behaviors and postural freezing), the hypothalamic paraventricular nucleus (activates the hypothalamic-pituitary-adrenal axis, releasing adrenocorticoids), the hypothalamic lateral nucleus (activates the sympathetic nervous system), and the parabrachial nucleus (influences respiratory rate and timing). (From Ref. 28.)

panic attacks between MZ and DZ twins, while there was a highly significant difference seen in PD (73% vs. 0%) [107]. Certainly classical Mendelian genetics does not provide an ideal model for PD.

Linkage studies investigating candidate genes thus far have yielded many negative results. These negative studies have included investigations of genes coding for the GABA(A) receptor, adrenergic receptor, pro-opiomelanocortin, serotonin transporter [108], and most recently, the CCK and CCK B receptor [109], and dopamine receptor and transporter [110]. Association studies exploring candidate genes have also yielded many negative results, notably the functional promoter polymorphism of the serotonin transporter [111], a finding consistent with the negative results in the linkage study.

A recent genomewide screen, however, yielded evidence for linkage with a marker on chromosome 20p [112]. Data from the same pedigrees, examining the parent of origin effect, suggest that the 2:1 increased female ratio observed in PD might be

hereditary [113]. As has been noted in schizophrenia [114], a single major locus model for PD is improbable, and a complex inheritance model is likely. The genetics of PD is likely further complicated by incomplete penetrance and pleiotropy (e.g., a single genotype with multiple expressed phenotypes), as is discussed below.

A. Comorbid Medical Conditions and Preliminary Evidence for a Genetic Panic "Syndrome"

While there are often no physical abnormalities found on examination, there is an overrepresentation of several medical conditions in patients with PD. Recent data have emerged suggesting a panic disorder "syndrome," linked to chromosome 13, involving clustering of several medical illnesses such as bladder/ kidney problems, mitral valve prolapse (MVP), serious headaches, and thyroid problems [115]. Our group's and others' clinical observations have suggested

further clustering of medical disorders such as fibromyalgia, irritable bowel syndrome, chronic fatigue syndrome, asthma, joint hypermobility, and sinusitis/rhinitis in panic disorder patients [116–118]. These associations might lend support to the notion of pleiotropy playing a role in PD. The assumption of this work is that a candidate gene for the panic syndrome should be expressed in the various organs affected: kidney, thyroid, gut, heart, cerebral blood vessels, and of course, brain.

In this theory, a putative genetic change could give rise to dysfunction at several additional autonomically regulated sites [115]. Notably, autonomic mechanisms appear to be prominent factors in headaches, disorders of bladder contractility, and MVP. Another common pathophysiologic mechanism underlying some panic spectrum illnesses appears to be abnormalities in psychoimmune function. Regarding the panic-fibromyalgia link, a report by Klein [119] indicated elevations of antibodies to serotonin and gangliosides in patients with primary fibromyalgia. Given the putative role of serotonin in panic disorder [120], we measured plasma levels of antiserotonin and serotonin anti-idiotypic antibodies in PD patients and healthy controls, and found only the anti-idiotypic antibodies to be significantly elevated [121]. This preliminary report suggests that interruption of 5HT neurotransmission through autoimmune mechanisms may be significant in certain patients with PD [121]. Coupled with reports of elevations of plasma interleukin-1β in panic disorder [122], these data raise the possibility of psychoimmune dysfunction in panic spectrum illnesses, notably sinusitis/rhinitis, fibromyalgia, chronic fatigue syndrome, and Hashimoto's thyroiditis.

In accordance with the extended panic "syndrome" concept, there is evidence that effective antipanic treatments might ameliorate symptoms in the related medical disorders as well. For example, a resolution of MVP per echocardiogram criterion was observed following effective antipanic treatment [123]. Tricyclic antidepressants (TCAs) have long been used as effective migraine prophylaxis, and the SSRIs and TCAs have been used clinically with utility for irritable bowel syndrome.

In conclusion, genetic factors undoubtedly play a major role in the etiology of PD, although the specific mechanisms are unknown. A major challenge in future investigations will be the development and identification of valid and reliable "endophenotypes" based on potential biological markers of the illness (**Table 1**).

Table 1 Candidates for Biological Markers in Panic Disorder

Carbon dioxide hypersensitivity/respiratory dysregulation on CO_2 challenge
Increased respiratory variability at baseline marked by prominent sighing responses
Reduced heart period variability
HPA axis activity dysregulation
Noradrenergic system volatility
Decreased temporal lobe volume
Treatment responsivity to antidepressants vs. benzodiazepines (pharmacogenomics)
Chromosome 13 cluster illnesses

VII. CONCLUSIONS AND FUTURE DIRECTIONS

The search for biological trait markers in PD has been fraught with difficulty. This article has attempted to outline some of the important investigations in that search over the past four decades. Several areas requiring future research are addressed.

First, in the realm of experimental therapeutics, there is clearly a need for more effective treatments, as well as clearer delineation of treatment response by panic subtype. Experimental agents showing promise in paniclike models in rodents include the group II metabotropic receptor agonist LY354740 [124] and drugs acting at the neuropeptide receptors, including neuropeptide-Y agonists and neurokinin substance P antagonists [125]. Other new classes of drugs being studied include the benzodiazepine partial agonists abecarnil and pagoclone, and agents modulating the HPA axis such as CRF antagonists. Regarding subtype and treatment response, further cluster analyses investigating dyspneic versus nondyspneic PD treatment response are warranted.

Second, imaging studies represent an area of enormous potential. The preliminary findings of reduced temporal volumes in PD need to be replicated as well as investigations in other relevant anxiety neurocircuitry structures, such as the amygdala. A neurodevelopmental perspective on PD would mandate longitudinal prospective MRI studies beginning in childhood to assess what is a risk factor for the illness and what is a consequence. DeBellis [126] showed that children and adolescents with GAD had significantly larger right and total amygdala volumes than matched controls. Given the potential role of amygdaloid projections in

the pathogenesis of panic disorder, this type of study, employing both functional and morphometric components, would be illuminating.

PET and SPECT imaging studies in PD have relatively neglected serotonin and norepinephrine receptors and transporters sites that might be important in the pathophysiology of the disorder. Since chronic SSRI administration is the treatment of choice for both depression and PD, and presumably desensitizes presynaptic somatodendritic 5HT1A autoreceptors [127], it would be intriguing to investigate 5HT1A receptor function in PD. Serotonin-1A receptor binding potential (BP) was found to be abnormally decreased in the depressed phase of familial mood disorders [128,129]; this finding merits investigation in PD.

A potential use of magnetic resonance spectroscopy (MRS) is to assess 5HT-glutamate interactions in vivo. This interaction has been explored in pediatric OCD, as effective treatment with paroxetine attenuated the ''Glx'' (consisting of glutamate-glutamine-GABA) signal in the caudate in effectively treated patients [130]. Future investigations of this kind in PD would lend credence to the notion of the SSRIs attenuating a hyperglutamatergic state.

Finally, although researchers have productively utilized preclinical models such as conditioned fear in rodents to provide explanatory hypotheses for PD, there is no current animal model for panic that has been capable of generating the signature spontaneous panic attack. As these models provide the basis for much of our thinking about clinical conditions, the development of more realistic models of the disorder continues to pose a major challenge.

Neurobiology of Posttraumatic Stress Disorder Across the Life Cycle

MICHAEL D. DE BELLIS

Duke University Medical Center, Durham, North Carolina, U.S.A.

I. POSTTRAUMATIC STRESS DISORDER

As described in the Diagnostic and Statistical Manual of Mental Disorders: Fourth Edition Text Revision (DSM-IV-TR), the essential feature (criterion A) of posttraumatic stress disorder (PTSD) is exposure to an extreme traumatic stressor in which the person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others; and responded with intense fear, helplessness, horror, or, in children, disorganized or agitated behaviors [1]. The DSM-IV-TR diagnosis of PTSD is made when criterion A is experienced and when three clusters of categorical symptoms are present for > 1 month after the traumatic event(s): (1) intrusive reexperiencing of the trauma(s) (criterion B); (2) persistent avoidance of stimuli associated with the trauma(s) (criterion C); and (3) persistent symptoms of increased physiological arousal (criterion D).

Cluster B reexperiencing and intrusive symptoms can best be conceptualized as a classically conditioned response. An external or internal conditioned stimulus (e.g., the traumatic reminder) activates unwanted and distressful recurrent and intrusive memories of the traumatic experience(s) (e.g., the unconditioned stimulus). Intrusive phenomena take the form of distressing intrusions such as nightmares or night terrors, dissociative flashback episodes, and psychological distress and physical reactivity on exposure to traumatic reminders. In young children, these intrusive thoughts may be part of repetitive play or trauma-specific reenactment(s) or compulsive rituals. Cluster C symptoms represent both avoidant and dissociative behaviors and can be thought of as ways to control painful and distressing reexperiencing of symptoms. These include efforts to avoid thoughts, feelings, conversations, activities, places, people, and memories associated with the trauma; amnesia for the trauma; diminished interest in others; feelings of detachment from others; a restricted range of affect; and a sense of a foreshortened future. Cluster D hyperarousal symptoms consist of persistent symptoms of increased physiological arousal. These include difficulty falling or staying asleep, irritable mood or angry outbursts, difficulty concentrating, hypervigilance, and exaggerated startle response. PTSD symptoms are thought to be mediated by dysregulation of the neurobiologic stress systems which mediate the fear or anxiety response.

II. EPIDEMIOLOGY OF PTSD

PTSD is a serious and debilitating chronic mental illness with enormous societal costs [2]. Traditionally,

PTSD was primarily identified in male soldiers and combat veterans. However, PTSD may arise from a variety of traumatic events in both males and females throughout the life cycle. The diagnostic picture of PTSD in children is similar to that in adults [3,4], with the exception of children < 4 years where more objective criteria based on observable behaviors are warranted [5]. Children are more vulnerable to develop PTSD as they are more likely to be diagnosed with PTSD, once traumatized, than their adult counterparts [6]. According to the National Co-Morbidity Survey, the estimated lifetime prevalence of PTSD in persons aged 15–54 years is 7.8% [7]. The National Co-Morbidity Survey reported a lifetime history of at least one other Axis I disorder (i.e., mood, other anxiety, and substance use disorders) in 88.3% of men and in 79% of women with PTSD. In contrast to adult PTSD research, there are no epidemiological studies and hence no published community lifetime prevalence rates for PTSD in children or adolescents to date [8]. However, PTSD lifetime prevalence rates for children and adolescents are thought to be similar to or even higher than those of adults. Hence, a recent community sample estimated a DSM-III-R PTSD prevalence rate by use of the NIMH Diagnostic Interview Schedule Version III-R (DIS-III-R) of 6.3% in adolescents [9]. PTSD in childhood is also associated with high rates of comorbid mood and other anxiety disorders [10,11]. High rates of comorbid mood, other anxiety disorders, and substance use disorders are seen in adolescents with PTSD [9,12,13]. Furthermore, even if childhood trauma does not result in childhood PTSD, it increases the risk for adult PTSD [14] and adult psychiatric illness [15].

III. IMPORTANT CLINICAL FACTORS ASSOCIATED WITH PTSD

The PTSD trauma may have interpersonal origins if the cause of the trauma is of human design. Examples of this include military combat, violent personal assault (i.e., child abuse, kidnapping, incarceration as a prisoner of war, mugging, rape, robbery, terrorist attack, or torture), and witnessing domestic or community violence. The trauma may be of noninterpersonal origin such as experiences of natural or human-caused disaster(s) (i.e., floods, earthquakes, hurricanes), diagnosis with a life-threatening illness, and/or an accident. War experiences, child abuse, and domestic and/or community violence may be the most common causes of interpersonal trauma-related PTSD. This type of PTSD is thought to cause more

severe and long-lasting symptoms. The DSM-IV-TR states that the following constellation of symptoms occurs more commonly in association with an interpersonal stressor: anxiety, a loss of previously sustained beliefs, depression, dissociation, feeling permanently damaged, hostility, hopelessness, self-destructive and impulsive behaviors, somatization, shame, and personality and relational disturbances, and an increased risk for substance abuse/dependence [1]. Another way of looking at this clinical picture is PTSD with comorbidity or the concept of Disorders of Extreme Stress (DESNOS) [16].

A review of the longitudinal course of PTSD suggested that PTSD symptoms are common within the first month of a trauma. These symptoms may be a normal response to severe stress as these symptoms usually fade within 3 months [17]. However, certain risk factors increase the probability that an individual will develop PTSD after a trauma. These factors are divided into three categories: factors prior to; factors relating to; and factors following the traumatic experience(s). Factors that increase the risks of having PTSD prior to the traumatic experience include a prior history of poor social support and adverse life events, parental poverty, prior history of childhood maltreatment, poor family functioning, familial/genetic family history of psychiatric disorders, introversion or extreme behavioral inhibition, being female, and poor health and prior mental illness [18]. Of these, genetics and the trauma experience may play a critical role. In a twin study, True et al. [19] found that genetic factors accounted for 13–30% of the variance in the reexperiencing cluster, 30–34% in the avoidance cluster, and 28–32% in the arousal cluster of PTSD symptoms in Vietnam veterans with combat-related PTSD. While symptoms in the reexperiencing cluster and one symptom in the avoidance and numbing cluster were strongly associated with trauma exposure, shared environment did not contribute to the development of the disorder. Risk factors for PTSD associated with the trauma are the degree of trauma exposure and an individual's subjective sense of danger, and other related traumatic events [20]. Chronicity of psychiatric impairment from PTSD also increases with the dose of traumatic exposure [20]. Risk factors associated with PTSD after the trauma include lack of social supports, continued negative life events, and lack of posttrauma interventions [20]. Thus, effective clinical intervention posttrauma may alleviate the disability and chronicity associated with PTSD.

Consequently, PTSD may be regarded as a complex environmentally-induced psychiatric disorder on both

descriptive and neurobiologic levels. We will review the neurobiology of PTSD, one of four diagnoses (acute stress disorder, reactive attachment disorder of infancy or early childhood, and adjustment disorder[s]) in the DSM-IV-TR in which an identified stressor precipitated the onset of a mental illness, and the one which has been the most extensively studied.

IV. NEUROBIOLOGY OF TRAUMA: AN OVERVIEW

The essential feature of a criterion A trauma is to cause overwhelming fear or anxiety. Cannon, in 1929, was the first to demonstrate the "fight or flight" reaction in response to life-threatening stress [21]. He showed that physical and emotional stress triggered the same response from an organism. This response involves activation of the peripheral sympathetic nervous system (SNS), a division of the autonomic nervous system. Hans Selye then studied the effects of chronic stress on the hypothalamic-pituitary-adrenal (HPA) axis and the immune system and postulated the idea of "homeostatic balance." Selye said that successful coping to traumatic stress is followed by a restoration of homeostatic balance and unsuccessful adaptation may result in significant deviations from this normative balance [22]. McEwen went further to call this latter balance "allostatis," an equilibrium that places severe strain on an organism and may be impossible to sustain indefinitely [23].

Contemporary theories of the neurobiology of stress and PTSD have been extensively reviewed [24]. PTSD symptoms are thought to be mediated by dysregulation of biological stress systems, e.g., the neural circuits and neurotransmitter and neuroendocrine stress systems, which mediate the fear or anxiety response. The main physiological mechanisms for coping with trauma are the neurotransmitter systems, the neuroendocrine systems, and the immune systems. These systems are interconnected at many levels to coordinate the individual's responses and adaptations to acute and chronic environmental stressors. In this chapter, we will focus on the neurobiology of trauma and its relationship to the neurobiology of PTSD. We will pay particular attention to the neurobiological stress systems that can help inform us about the symptom profile and the psychopharmacology of PTSD.

Trauma is perceived by afferent sensory inputs through our senses of sight, hearing, and/or touch. Traumatic reminders (i.e., the sight of a gun, a city street, or the face of a perpetrator) can lead to PTSD reexperiencing and intrusive symptoms through the learning mechanisms of classical conditioning. The initial fear response is thought to be associated to the original fear-producing stimuli or stressors (unconditioned stimuli), whereas anxiety is thought to be associated with the conditioned stimuli or traumatic reminders. These fear-associated sensory inputs are relayed through the dorsal thalamus and to primary sensory cortical brain regions (i.e., occipital [vision], temporal [auditory], postcentral gyrus [tactile]). Olfaction is relayed directly to the amygdala and entorhinal cortex. Primary sensory brain regions, in turn, project to the lateral and basolateral nuclei of the amygdala, a part of the brain's limbic or emotional system. Information from the lateral and basolateral nuclei of the amygdala project of the central nucleus of the amygdala. The central nucleus of the amygdala has direct projections to a variety of anatomical areas that are important in fear- or anxiety-related behaviors [25,26]. The most important of these neuroconnections include projections to the locus ceruleus and the preoptic area of the hypothalamus, the bed nucleus of the stria terminalis, and the paraventricular nucleus and lateral nucleus in the hypothalamus, which are involved in SNS and limbic-hypothalamic-pituitary-adrenal (LHPA) axis activation. These neuroconnections also include important projections to: the ventral tegmental area, which is responsible for increases in prefrontal cortical dopamine activity during stress; the parabrachial nucleus, which is responsible for increased respiration during an anxiety or stress reaction; the central gray, which is involved in conditioned fear, freezing, and stress-induced analgesia; the nucleus reticularis pontis caudalis, which is involved in the fear potentiation of the startle reflex; the dorsal motor nucleus of the vagus, nucleus of the solitary tract, and ventrolateral medulla, which are involved with stress-induced modulation of heart rate and blood pressure; and the trigeminal and facial nerve which are involved in the facial expressions of fear (Fig. 1).

V. AMYGDALA AND PTSD

In preclinical studies, electrical stimulation of the amygdaloid region of animals is associated with fearful behaviors, including increases in heart rate, blood pressure, freezing, activation of fear-related facial movements, and increases in plasma corticosteroid levels. Amygdala lesions reduce these fearful behaviors and emotional reactivity, and interfere with the acquisition
Figure 1 An overview of the neurobiology of the traumatic stress response. PTSD symptoms are thought to be mediated by dysregulation of the neural circuits and neuroendocrine stress systems which mediate fear or anxiety responses. Trauma is perceived by afferent sensory inputs through our senses of sight, hearing, and/or touch. The initial fear response is thought to be associated to the original fear producing stimuli or stressors (unconditioned stimuli), whereas PTSD symptoms are thought to be associated with the conditioned stimuli or traumatic reminders. These fear-associated sensory inputs are relayed through the dorsal thalamus and to primary sensory cortical brain regions. Primary sensory brain regions, in turn, project back to the thalamus and to the lateral and basolateral nuclei of the amygdala, a part of the brain's limbic or emotional system. Information from the lateral and basolateral nuclei of the amygdala project to the central nucleus of the amygdala (AMY) which is responsible for activating the fear response and involved in emotional memory. The central nucleus of the amygdala has direct projections to the locus ceruleus (LC) and the hypothalamus (H), which are involved in SNS ("fight or flight") activation and limbic-hypothalamic-pituitary (Pit)-adrenal (LHPA) axis (increased ACTH and cortisol) activation. The central nucleus of the amygdala also has important projections to the ventral tegmental (VT) area, which is responsible for increases in prefrontal cortical dopamine activity during stress. During stress, the prefrontal cortex and the central and basolateral nuclei of the amygdala receive serotonergic inputs from the dorsal and median raphe nuclei in the brainstem. The hippocampus has important connections with the prefrontal cortex and amygdala, and also plays an important role in short-term memory and in assigning significance to events within space and time. CC, corpus callosum; DR, dorsal raphe nucleus; Hippo, hippocampus; M, mammillary bodies; SC, spinal cord.

of conditioned fear and the rise in plasma corticosteroid levels [for review see 25].

In human studies, electrical stimulation of the amygdaloid region of patients undergoing surgery for temporal lobe epilepsy is associated with complex fear states involving palpitation, mydriasis, pallor, and fear-related thoughts [for review see 27]. Children and adults who have a history of temporal lobe epilepsy or status epilepticus, with amygdala involvement, have ictal fear [28]. Results from a recent positron emission tomography (PET) study showed that during a modified Stroop task, bilateral amygdala activation was significantly greater during color naming of threat words than during color naming of neutral words in healthy subjects [29]. Moreover, results from recent functional magnetic resonance imaging (MRI) investigations showed activation in the amygdala during viewing of masked fearful faces [30] and in the amygdala/periamygaloid cortex during both conditioned fear acquisition and extinction in healthy subjects [31].

PTSD may be the result of hyperresponsivity of the central amygdala, which may mediate stimulus-bound fears or traumatic reminders and cluster B reexperiencing and intrusive symptoms. PTSD may also be the result of hyperresponsivity of amygdala projections, which may mediate trauma-related autonomic SNS hyperactivity and cluster D hyperarousal symptoms. For example, another PET study has implicated activation of the right amygdala in traumatic autobiographical memories [32]. Bilateral amygdaloid complex damage in humans is associated with loss of enhanced recall of emotionally aversive memories [33]. Furthermore, results from a recent functional MRI investigation showed that PTSD patients demonstrated exaggerated amygdala responses during viewing of general nontraumatic negative stimuli (i.e., masked fearful faces) [34]. The amygdala serves to enhance declarative memory for emotionally arousing and fearful events [for review see 35] and for the identification and recognition of emotion in human faces [36]. This process may be exaggerated in PTSD. Failures of the inhibitory influences of the medial prefrontal cortex may also contribute to amygdala hyperreactivity.

VI. MEDIAL PREFRONTAL CORTEX AND PTSD

Stress activates noradrenergic, serotonergic, and dopaminergic neurons in the prefrontal cortex. The anterior cingulate cortex, a region of the medial prefrontal cortex, is involved in the extinction of conditioned fear responses and is implicated in the pathophysiology of PTSD [for review see 37]. The anterior cingulate region is part of an executive attention system, as it is activated during decision making and novel or dangerous situations [38]. Since intrusive thoughts of trauma (danger) and poor concentration are core symptoms of PTSD, anterior cingulate integrity may be affected in PTSD. LeDoux has shown that medial prefrontal cortex may inhibit activation of the amygdala and its related nuclei and circuitry [for review see 26].

Recent neuroimaging studies provide evidence for medial prefrontal and anterior cingulate dysfunction in adult PTSD. PET investigations comparing women who had been sexually abused as children and who had PTSD with women with similar history who did not have PTSD found a lower level of anterior cingulate blood flow during traumatic script-driven imagery [39] and during memories of sexual abuse [40]. A lower level of anterior cingulate blood flow has also been seen in Vietnam combat veterans with PTSD compared to those without PTSD during exposure to combat-related traumatic stimuli [41]. In these studies, subjects with PTSD activated the amygdala, while subjects without PTSD did not show the same degree of limbic activation.

PET investigations are not feasible in developing children. However, magnetic resonance spectroscopy can be used to further study the in vivo neurochemistry of trauma associated neurobiological alterations in the brains of living children. The N-acetyl signal in the proton (^{1}H) spectrum mainly comprises of N-acetylaspartate (NAA) and is considered to be a marker of neural integrity. Decreased NAA concentrations are associated with increased metabolism and loss of neurons [for review see 42]. A preliminary investigation suggested that maltreated children and adolescents with PTSD have lower NAA/creatine ratios than sociodemographically matched controls [43]. These findings were suggestive of neuronal loss in the anterior cingulate region of the medial prefrontal cortex and were not specific to gender. Neuronal loss in the anterior cingulate of pediatric PTSD patients agrees with the recent adult neuroimaging studies, which provide evidence for medial prefrontal and anterior cingulate dysfunction in adult PTSD.

Exposure to mild to moderate uncontrollable stress impairs prefrontal cortical function in studies of humans and animals [for review see 44]. This impairment may be norepinephrine and dopamine mediated [for review see 45]. Thus, PTSD symptoms may represent dysfunction in the inhibitory influences of the

medial prefrontal cortex on amygdala hyperreactivity. Thus, dysfunction of the anterior cingulate cortex, which is involved in the extinction of conditioned fear responses, may be implicated in the pathophysiology of both adult and pediatric PTSD.

VII. DOPAMINE SYSTEM AND PTSD

Dopaminergic innervations of the prefrontal cortex originate from neurons of the substantia nigra and the retrorubral field in the ventral midbrain [for review see 46]. These mesencephalon brain regions receive inputs from the prefrontal cortex, ventral pallidum, lateral hypothalamus, and dorsal raphe nucleus. The dopaminergic inputs to the medial prefrontal cortex appear to be particularly sensitive to stress. An increase in the firing rate of mesoprefrontal cortical dopamine neurons inhibit the activity of prefrontal pyramidal cells by exerting a modulatory role over excitatory afferents to the prefrontal cortex. Dopamine neurons also inhibit prefrontal pyramidal cell activity indirectly by enhancing the release of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) from interneurons. Mild stressors (i.e., novel environment) which do not activate the locus ceruleus, SNS or the LHPA axis (see below) appear to selectively activate the dopaminergic innervations of the mesencephalon, the amygdala, and the prefrontal cortex. Enhanced dopamine prefrontal cortical function in response to stress may reflect the heightened attention or cognitive processes needed to cope with the stressor [47].

However, dopaminergic innervations of the prefrontal cortex block the stress-induced excitatory glutamatergic inputs onto prefrontal pyramidal cells [46]. These excitatory glutamatergic inputs from the prefrontal cortex originate in the basolateral amygdala. Gutamatergic inputs feedback to and activate the mesoprefrontal cortical dopamine neurons located in the ventral tegmental areas. Thus, excitatory glutamatergic efferents from the prefrontal cortex to mesoprefrontal cortical dopamine neurons further inhibit prefrontal activity by stimulating dopaminergic innervations of the prefrontal cortex. This process may result in more prefrontal cortical dopamine than is functionally necessary and thus may impair prefrontal cortical function. Thus, it has been suggested that some functional defect in cortical dopamine systems occur in PTSD (i.e., less dopamine-induced inhibition of orbital and medial prefrontal excitatory glutamatergic inputs). This deficit may lead a traumatized person with an inability to cope with the trauma [46].

Higher concentrations of urinary dopamine and its metabolite homovanillic acid were found in patients with combat-related PTSD [48], in sexually abused girls [49], and in abused male and female prepubertal children with PTSD [50]. Urinary dopamine was positively associated with overall severity of PTSD symptoms, particularly symptoms of intrusive flashbacks, avoidance, and hyperarousal in adult PTSD [48] and avoidant and dissociative symptoms in abused children with PTSD [50]. Findings of higher urinary dopamine concentrations may reflect higher central dopamine activity resulting in hypervigilance and paranoia in PTSD patients. Although a functional defect in cortical dopamine regulation may occur in PTSD, to date, dopamine function has not been extensively studied in PTSD.

VIII. LOCUS CERULEUS AND PTSD

Stress, particularly unpredictable and uncontrollable stress, is known to increase responsiveness of the central amygdala and the locus ceruleus to excitatory stimulation [51]. The locus ceruleus is the major norepinephrine-containing nucleus in the brain. Increased responsiveness of these locus ceruleus neurons, in turn, increases norepinephrine turnover in specific brain regions (locus ceruleus, hypothalamus, hippocampus, amygdala, and prefrontal cortex). These brain regions are associated with regulation of stress reactions, memory, and emotion in experimental animals [52]. Traumatic stress also results in simultaneous activation of another very basic and ancient cell body, the paragigantocellularis. It and the nucleus tractus solitarius in the brainstem receive inputs from visceral organs. The paragigantocellularis is reciprocally connected to the locus ceruleus, but also controls and activates the SNS causing the biologic changes of the fight-or-flight reaction, or of life-saving responses to acute threats [53]. Direct and indirect effects of the flight-or-flight reaction include: increased heart rate; increased blood pressure; dilated pupils; sweating; inhibition of renal sodium excretion; redistribution of the blood to the heart, brain, and skeletal muscle and away from skin, gut, and kidneys; enhanced blood coagulation by increasing platelet aggregability; increased glycogenolysis; and increased metabolic rate and alertness. Activation of the locus ceruleus results in activation of the LHPA axis via indirect connections through the amygdala.

In adult PTSD, it is hypothesized that the locus ceruleus/SNS/catecholamine system and LHPA axis

responses to stress become maladaptive, causing long-term negative consequences [for review see 54]. Results from adult combat-related PTSD studies suggest that there is increased sensitivity of the locus ceruleus/SNS/catecholamine system that is most clearly evident under experimental conditions of stress or challenge. These findings include increased heart rate, systolic blood pressure, skin conductance, and other SNS responses to adrenergic or traumatic reminder challenge compared to healthy combat or noncombat controls. Although most baseline studies of single or multiple time point plasma catecholamines found no significant differences between adult PTSD and controls, elevated levels of catecholamines (i.e., norepinephrine, epinephrine, and dopamine) were found in 24-hr urinary excretions in three of five studies. Single time point measures of catecholamines and cortisol may not provide an accurate measure of baseline functioning because these neurotransmitters have circadian influences (i.e., a 24-hr diurnal rhythm), and the stress of a single-stick venipuncture may result in elevations of cortisol and catecholamine concentration alone, obscuring any baseline differences. Cortisol, which reflects LHPA axis activity, and essentially all catecholamines and their metabolites, which reflect SNS activity, are excreted into urine [55,56]. Rather than randomly timed urine measures, timed 24-hr measures of urinary free cortisol (UFC) and catecholamine concentrations are a better way to noninvasively evaluate for alterations in baseline activity of the LHPA axis and the locus ceruleus/SNS/catecholamine system. Thus, in adult PTSD, elevated 24-hr urinary excretion of catecholamines provides evidence of an increase in baseline functioning of the catecholamine system. Combat-related PTSD is consistently associated with hyperactivity of the locus ceruleus/SNS, and increases in circulating catecholamines. Combat-related PTSD is associated with increased heart rate, systolic blood pressure, skin conductance, and other sympathetic nervous system responses to adrenergic or traumatic reminder challenge [reviewed by 54,57,58], decreased sleep latency and efficiency [59], and elevated 24-hr urinary excretion of catecholamines [48,60].

However, the limited data published to date in traumatized children suggest that the locus ceruleus/SNS/catecholamine system is dysregulated in traumatized children who may suffer from depressive and PTSD symptoms but who may or may not have a diagnosis of PTSD. Findings of elevated baseline 24-hr urinary catecholamine concentrations were seen: (1) in male children who suffer from severe clinical depression and had a history of parental neglect [61]; (2) in a

pilot study of sexually abused girls, 58% of whom had histories of severely depressed mood with suicidal behavior (but only one of whom had PTSD) [49]; and (3) in male and female children with abuse-related PTSD [50]. Furthermore, decreased platelet alpha$_2$-adrenergic receptors and increased heart rate following orthostatic challenge were found in physically and sexually abused children with PTSD, suggesting an enhancement of SNS tone in childhood PTSD [62]. An increase in baseline functioning of the locus ceruleus/SNS/catecholamine system in childhood PTSD is also provided by two separate, open-label treatment trials of the medications clonidine (a central alpha$_2$-adrenergic partial agonist) and propranolol (a beta-adrenergic antagonist), both of which dampen catecholamine transmission. Clonidine treatment was associated with general clinical improvement and decreases in the arousal cluster of PTSD symptoms and basal heart rate [62]. Propranolol treatment was associated with decreases in aggressive behaviors and insomnia [63].

IX. LHPA AXIS AND PTSD

Direct projections of the central nucleus of the amygdala to the paraventricular nucleus of the hypothalamus cause increases in secretion of corticotropin-releasing hormone (CRH) and activation of the LHPA axis [64]. CRH has important neurotransmitter and neuroendocrine effects. When given centrally to experimental animals, CRH promotes hypercortisolism, stimulates the SNS, and causes behavioral activation and intense arousal which are independent of its neuroendocrine effects of adrenocorticotropin (ACTH) and glucocorticoid secretion [65,66]. Consequently, CRH cell bodies and receptors are located in the amygdala as well as throughout the brain. Activation of these receptors is responsible for this behavioral activation. Activation of the locus ceruleus/SNS/catecholamine system and CRH results in animal behaviors consistent with anxiety, hyperarousal, and hypervigilance, which are the core symptoms of PTSD.

The important neuroendocrine functions of CRH include activation of the LHPA axis by stimulating the pituitary to secrete ACTH. Plasma ACTH in turn stimulates adrenal secretion of glucocorticoids or cortisol, which causes increases in gluconeogenesis, inhibition of growth and reproductive systems, and containment of the inflammatory response [for review see 55]. These functions enhance survival during a life

threat. Functionally, CRH and the locus ceruleus/SNS/catecholamine system seem to participate in a positive, reverberatory feedback loop. Amygdala lesions will disrupt some of these stress effects.

Unlike the increased sensitivity to stress of the locus ceruleus/SNS/catecholamine system seen in adult PTSD, results from baseline and challenge studies of the LHPA axis appear to show that this system functions in a more complicated manner. In adult combat-related PTSD, elevated levels of central CRH were found [67,68]. Infusion studies of metyrapone, which blocks the conversion of 11-deoxycortisol to cortisol and allows for the direct measure of pituitary release of ACTH, suggest that there is downregulation of anterior pituitary CRH receptors presumably secondary to elevated central CRH and enhanced negative feedback inhibition of the pituitary for cortisol [69]. Further evidence for enhanced negative feedback inhibition includes findings of increased number of glucocorticoid receptors on lymphocytes presumably secondary to decreased circulating cortisol [70], suppression of cortisol with low-dose dexamethasone [71], and lower 24-hr UFC concentrations in three of four studies of adult combat-related PTSD compared with controls [48,72,73]. Low 24-hr UFC levels were also found in one study of male and female adults with PTSD who survived the Holocaust during childhood compared to survivors without PTSD [74]. In two other studies, 24-hour UFC concentrations were higher in male combat veterans with PTSD than in combat veterans without PTSD [75] and in women with PTSD secondary to childhood sexual abuse compared to women abused as children without PTSD and healthy nonabused controls [76].

Results from investigations of the LHPA axis and childhood trauma are similar to those of adult studies in that the data also suggest that the LHPA axis functions in a complex manner. These discrepant findings may be related to a mechanism called "priming" or sensitization in which responses to repeated stress increase in magnitude. A possible long-term consequence of the trauma experience may be to prime the LHPA axis so that ACTH and cortisol secretion are set at lower 24-hr levels [50]. Priming may occur as a reflection of chronic compensatory adaptation of the LHPA axis long after trauma exposure. LHPA axis regulation is affected by other hormones that are stress mediated such as arginine vasopressin and the catecholamines, both of which act synergistically with CRH [55]. A "primed system" will "hyper"-respond during an acute stress. Thus when a new emotional stressor is experienced, LHPA axis functioning will be enhanced

(i.e., higher ACTH and higher 24-hr UFC concentrations in response to stress). Since the adult PTSD studies focus on past trauma, the latter hypothesis may best explain the data in childhood PTSD studies. For example, results fall into a predictable pattern when addressed as a reflection of a chronic compensatory adaptation of the LHPA axis long after trauma exposure. This compensatory adaptation may involve the "priming" mechanism.

In studies of children undergoing current adversity, evidence of elevations of cortisol or ACTH and priming are seen. For example, augmented mean morning serial plasma cortisol levels were found in sexually abused girls recruited within 6 months of disclosure compared with nonabused, sociodemographically matched controls. This suggests morning hypersecretion of cortisol in sexually abused girls [77]. Medically healthy, clinically referred prepubertal medication-naive abused children with chronic PTSD studied within a year of disclosure PTSD excreted significantly greater concentrations of 24-hr UFC than nontraumatized healthy controls [50]. Maltreated young children with major depression failed to show the expected diurnal decrease in cortisol secretion from morning to afternoon, suggesting higher baseline cortisol activity in these young children [78,79]. Increased ACTH response to human CRH, but normal cortisol secretion in maltreated prepubertal depressed children undergoing current psychosocial adversity compared to depressed children with prior histories of maltreatment, depressed nonabused children, and healthy children, were reported [80]. This last finding may be related to priming.

In studies of children with past trauma, chronic compensatory adaptation of the LHPA axis is seen. Attenuated plasma ACTH responses to ovine CRH in sexually abused girls studied several years after abuse disclosure were reported [81]. The abused subjects had histories of severely depressed mood with suicidal behavior, but only one had a diagnosis of PTSD. The abused girls exhibited reduced evening basal, ovine CRH-stimulated, and time-integrated total plasma ACTH concentrations compared with controls. Plasma total and free cortisol responses to ovine CRH stimulation did not differ between the two groups. Thus, sexually abused girls manifest a dysregulatory disorder of the LHPA axis, associated with hyporesponsiveness of the pituitary to exogenous CRH and normal overall cortisol secretion to CRH challenge. CRH hypersecretion may have led to an adaptive downregulation of CRH receptors in the anterior pituitary, which is similar to the mechanism suggested in adult PTSD [67,68]. Furthermore, adults with combat-related PTSD also

showed a blunted plasma ACTH responses to ovine CRH [82]. Armenian adolescents who lived close to the epicenter of the 1988 earthquake and experienced a significant direct threat to life had greater PTSD and comorbid depressive symptoms, lower baseline mean salivary cortisol levels, and greater afternoon suppression of cortisol by dexamethasone 5 years after exposure, when compared to Armenian adolescents who lived 20 miles from the epicenter [83]. These results are similar to the LHPA axis findings in adult PTSD. These studies show that traumatic experiences throughout the life cycle are associated with profound changes in the dynamics of the LHPA axis. These changes may contribute to PTSD symptoms.

X. HIPPOCAMPUS AND PTSD

Elevated levels of glucocorticoids during traumatic stress may have neurotoxic effects and lead to learning and concentration impairments secondary to damage to the brain's hippocampi [84], a principal neural target tissue of glucocorticoids [85]. The hippocampus has important connections with the prefrontal cortex and also plays an important role in short-term memory and in assigning significance to events within space and time. The hippocampus also has important connections to the amygdala, which, as discussed above, is involved in emotional memory. Elevated levels of cortisol may have neurotoxic effects on the hippocampus through the N-methyl-D-aspartate (NMDA) excitotoxicity [86]. Hippocampal degeneration was noted in monkeys after sustained social stress [87]. Smaller hippocampal volumes were reported in adults with Cushing's syndrome [88], combat veterans with PTSD [89,90], adult PTSD secondary to child abuse [91], and female adult survivors of childhood sexual abuse [92]. However, pediatric PTSD was not associated with the predicted decrease in hippocampal volume [93]. Subcortical gray matter structures which include the limbic system (septal area, hippocampus, amygdala) actually show an increase in volume during adolescence [94]. This increase may "mask" any effects of traumatic stress in maltreated children with PTSD.

However, the results of a pilot longitudinal study of hippocampal volumes in pediatric maltreatment-related PTSD do not support a role for neurodevelopmental stunting by cortisol as a possible explanation for the differences in hippocampal findings between children and adults with PTSD [95]. High rates of comorbid lifetime alcohol dependence were seen in the adult PTSD MRI studies. Although these investigators

attempted to control for lifetime alcohol consumption, these studies may not have controlled for adolescent-onset alcohol abuse. Results from animal studies show that the hippocampus is susceptible to the effects of chronic alcohol administration [96]. The additional negative impact of excessive alcohol consumption on the regulation of NMDA receptors [97] in persons with trauma history may lead to more profound excitotoxic neuronal damage in alcoholic adults comorbid for PTSD. Psychiatric comorbidity for alcohol and substance abuse/dependence in adult PTSD subjects, especially during adolescence [98], may have contributed to smaller hippocampal findings in adult PTSD.

XI. SEROTONIN SYSTEM AND PTSD

The serotonin system is a stress response system that may activate both anxiogenic and anxiolytic pathways. Serotonin is regarded as a master control neurotransmitter of complex neuronal communication [99]. The prefrontal cortex and the central and basolateral nuclei of the amygdala receive serotonergic inputs from the dorsal and median raphe nuclei in the brainstem. In primate studies of chronic stress, serotonin levels decrease in the prefrontal cortex [100]. In animal studies of unpredictable and uncontrollable stress (e.g., inescapable shock, restraint stress), serotonin turnover increases and serotonin levels decrease in the amygdala, medial prefrontal cortex, nucleus accumbens, and lateral hypothalamus. This process depletes serotonin and results in "learned helplessness" [101]. Drugs that increase brain serotonin (serotonin agonists) prevent some of these behavioral changes. Compared with controls, paroxetine binding (a measure of serotonin uptake) was significantly decreased in the platelets [102] and in platelet-poor plasma [103] of male combat veterans with PTSD.

Serotonin plays important roles in compulsive behaviors and the regulation of emotions (mood) and behavior (aggression, impulsivity). Serotonin is also implicated in major depression, impulsivity, and suicidal behaviors. Low serotonin function is associated with suicidal and aggressive behaviors in adults, children, and adolescents [for review see 104,105]. PTSD cluster B reexperiencing and intrusive symptoms most closely resemble another psychiatric disorder, obsessive-compulsive disorder, which is characterized by intrusive and recurrent and persistent thoughts, impulses or images and is a disorder of serotonin regulation [for review see 106]. Because of serotonin's interdependence with the noradrenergic system [107], another stress

response system that is involved in the psychobiology of adult and child mood disorders, dysregulation of serotonin may not only play a major role in cluster B symptoms but also may also increase the risk for comorbid major depression in PTSD. Consequently, it was shown that the onset of major depression is markedly increased for trauma-exposed persons who suffer from PTSD, but not in trauma-exposed persons who did not suffer from PTSD [108]. Thus, PTSD may lead to major depression and be influenced by common genetic vulnerabilities to serotonin dysregulation and trauma related factors as discussed above.

Recently, clinical studies have demonstrated strong support for the efficacy of the serotonin reuptake inhibitor antidepressant and anti-obsessive-compulsive disorder medications sertraline [109] and fluoxetine [110] in adult PTSD. Practice parameters for the treatment of pediatric PTSD, published by the American Academy of Child and Adolescent Psychiatry, state that selective serotonin reuptake inhibitors are the first-line medication treatment for child and adolescent PTSD, particularly PTSD comorbid with major depression [111].

XII. BENZODIAZEPINE RECEPTOR SYSTEM AND PTSD

Benzodiazepine receptors are functionally linked to inhibitory neurotransmitter GABA and are found in cortical gray matter. These binding sites are part of the same macromolecular complex and regulate GABA type A receptors to prolong and potentiate synaptic actions of the GABA inhibitory neurotransmitter systems. This system downregulates the locus ceruleus and cortical dopamine activity [112]. Animals exposed to experimental stress develop decreases in benzodiazepine receptor binding in the frontal cortex [113]. Decreases in benzodiazepine receptor binding have been demonstrated in the genetically fearful strain of Maudsley rats [114]. One can speculate that decreases in benzodiazepine receptor binding may initially be adaptive in an acutely stressful situation. However, a chronic decrease in benzodiazepine receptor activity could contribute to the cluster D hyperarousal symptoms seen in PTSD patients.

XIII. ENDOGENOUS OPIATE SYSTEM AND PTSD

Exposure to stress causes an increase in endogenous opiates and contributes to the development of stress-induced analgesia to pain [115]. Opiates also decrease the firing rate of locus ceruleus neurons and dampen down the stress response. Vietnam veterans with PTSD have reduced pain sensitivity during exposure to traumatic reminders of war [115]. This analgesia is reversible with the opiate antagonist naloxone [116]. Beta endorphin levels have been found to be higher in CSF [117] and lower in the plasma [118] of PTSD patients. Thus lower levels of endogenous opiates may contribute to PTSD cluster C avoidance and numbing symptoms or lower levels may contribute to PTSD cluster D hyperarousal symptoms. Endogenous opiate systems have not been studied in traumatized children and but may be contributory to the constricted affect and high incidence of self injury reported in maltreated children and in adults who have experienced maltreatment as children [119].

XIV. TRAUMA, PTSD, AND PHYSICAL HEALTH

An extensive review of the literature [120] indicates that PTSD promotes poor health (i.e., hypertension, atherosclerotic heart disease, gastrointestinal disorders, increased susceptibility to infections) through a complex interaction among excessive SNS activity, LHPA axis dysregulation, and negative life style choices. For example, increased rates of cardiovascular and gastrointestinal disorders were observed in World War II prisoners of war [121]. Chronic activation of the locus ceruleus/SNS/catecholamine system can lead to increased vulnerability to hypertension, atherosclerotic heart disease, peptic ulcer disorders, and immune dysfunction. Self-medication of PTSD symptoms can lead to alcohol and other substance abuse/dependence, which have independent adverse effects on physical health. A variety of stressors, including psychological stress, have been shown to modify measures of the immune system in experimental animals and humans. As discussed below, chronic stress has been shown to impair immune function and may also impair hypothalamic-pituitary-thyroid (HPT) axis regulation.

XV. IMMUNE SYSTEM AND PTSD

The central nervous system signals to the immune system are mediated by the LHPA axis and the sympathetic division of the autonomic nervous system. As early as 1936, Selye showed that restraining rats produced involution of the thymus and stress-induced lymphopenia [122]. An extensive review of the litera-

ture on the effects of stress on cellular immune response in animals concluded that a variety of acute and chronic stressors, such as inescapable noise, social isolation, and uncontrollable shock, are associated with suppression of immune responses [123]. Stressed animals are at significantly greater risk for development of infections, tumors, and death after experimentally induced immune (antigenic) challenge. Emotional or physical stress causes elevation of plasma cortisol which generally exerts immunosuppressive and antiinflammatory effects on circulating blood lymphocytes [124]. Activation of the SNS and peripheral catecholamines mediates suppression of the cellular immune response of cells located in physiological compartments such as suppression of splenic natural killer (NK) cell activity. Norepinephrine, the major neurotransmitter of the sympathetic nervous system, has a complex role in the modulation of the immune response, facilitating certain immunologic responses while inhibiting others. Stressful life events have been shown to suppress immune responses in humans [123]. Bereavement, sleep deprivation, job loss, and medical school final examinations have been associated with decreased lymphocyte proliferation to mitogenic stimulation, decreased NK cell activity, decreased phagocytosis, decreased interferon production, decreased salivary IgA, increased antibody titers to herpes virus, and decreased helper and suppressor T-cell percentages and helper-to-suppressor ratios.

In the last decade, scientific interest in trauma, PTSD, and immune function has increased and with somewhat contradictory results. Vietnam veterans with PTSD showed decreased NK cell activity in response to in vitro methionine-enkephalin challenge compared with healthy volunteers [125]. Victims of Hurricane Andrew with PTSD showed lower NK cell cytotoxicity than did community volunteers without PTSD [126]. However, studies have also found elevated rates of NK activity in PTSD patients [127] and in women displaced by war [128]. Other studies have shown that PTSD patients with a history of childhood sexual abuse exhibit chronic immune activation [129]. Vietnam veterans with PTSD showed clinically elevated leukocyte, total T-cell counts, and highly sensitized T-cell lymphocytes [130]. These findings may lead to and have been associated with autoimmune diseases. In children, a significantly higher incidence of plasma antinuclear antibody titers was seen in sexually abused girls when compared with the frequency of positive antinuclear antibody titers in a sample of adult healthy women [131]. One may speculate that the severe stress of sexual abuse may lead to suppression of the mechanisms

(T-suppressor cells) that actively suppress the autoantibody-producing lymphocytes (B-lymphocytes) and may thus increase the incidence of positive antinuclear antibody titers in these sexually abused girls. Decreased NK cell activity can lead to increased rates of infection and initiation and progression of cancers. Enhanced NK activity may be associated with the high rates of substance abuse in PTSD patients, and is related to enhanced immune surveillance. Highly sensitized T-cell lymphocytes and suppression of T-suppressor cells may lead to an increased incidence of autoimmune diseases in traumatized persons. Thus, these studies show that traumatic experiences throughout the life cycle are associated with profound changes in the immune system. Immune dysregulation may lead to the increase in reported rates of poor health in victims of PTSD.

XVI. TRAUMA, THE HPT AXIS, AND PTSD

Preclinical investigations have shown that acute stress leads to activation of the locus ceruleus noradrenergic neurons and results in direct stimulation of hypothalamic thyrotropin-releasing hormone (TRH)-secreting neurons [132]. TRH stimulates secretion of thyroid-stimulating hormone (TSH), which in turn stimulates the thyroid gland to secrete thyroid hormone. Additionally, during acute stress, direct stimulation by norepinephrine through postganglionic sympathetic innervation of the thyroid gland and by plasma epinephrine also stimulates release and increased synthesis of thyroid hormone through cyclic adenosine monophosphate (cAMP) production [133]. Thyroid hormone is responsible for the regulation of metabolism. During an episode of acute stress, the increased metabolic rate provides "emergency" energy. Thyroid hormones are also necessary for the normal growth and differentiation of brain neurons and glial cells throughout fetal, child, and adolescent development [134]. Thyroid hormone inhibits TSH release. Chronic TRH secretion secondary to prolonged stress may not cause sustained TSH secretion because of downregulation of pituitary TRH receptors. Thus, chronic stress is associated with decreased production of TSH and inhibition of the conversion of thyroxine to the more biologically active tri-iodothyronine in peripheral tissues. This mechanism would serve to conserve energy during chronic stress, and is seen in chronic medical illnesses.

There are few human studies of the association of stress and/or adult PTSD and the HTP axis. Elevated

levels of total and free triiodothyronine (T_3)- and thyroxine (T_4)-binding globulin were demonstrated in male combat veterans with combat-related PTSD [135]. These findings were not those classic hyperthyroidism or liver disease, but correlated with overall PTSD symptoms, especially those of hyperarousal. There were no significant differences between the TSH responses of adults male combat veterans with PTSD and controls to TRH stimulation in another study [136]. However, this study was confounded by the fact that 6 of the 11 subjects were taking psychotropic medications, and there was a wide variation of individual responses [136]. In a pilot study of traumatized children, thyroid function tests did not differ between sexually abused and control girls [131]. However, chronic stress such as childhood maltreatment may lead to physiologically normal central suppression of the HPT axis. Because lower TSH can result in a reduced set point for metabolic rate, we speculate that lower TSH may contribute to the higher rates of obesity reported in women with a history of sexual abuse [137]. We also speculate that suppression of the HPT axis secondary to chronic stresses of childhood maltreatment may lead to profound changes in brain development and possibly decreased intelligence.

XVII. SUMMARY

In this chapter, evidence supporting that chronic hyperresponsivity of the amygdala, prefrontal cortical dysfunction, chronic activation of the locus ceruleus/SNS/catecholamine system, and dysregulation of the LHPA axis associated with trauma may be responsible for PTSD symptoms. The functional interconnections of these neurobiological stress systems may also influence other neurotransmitter and neuroendocrine systems. These changes may be adaptive [for review see 55]. However, in PTSD, the responses of these neurobiological stress systems become maladaptive. These maladaptive changes may also cause adverse cardiac changes and suppression of immune function in adults. In the adult brain, alterations of locus ceruleus/SNS/catecholamine system and the LHPA may result in sensitization of mature structures. However, in the developing brain, elevated levels of catecholamines and cortisol may lead to adverse brain development through the mechanisms of accelerated loss (or metabolism) of neurons, delays in myelination, abnormalities in developmentally appropriate pruning, and/or by inhibiting neurogenesis [for review see 138]. Evidence of adverse brain development (i.e., smaller

cerebral volumes and corpus callosum areas) were seen in maltreated children and adolescents with abused-related PTSD [93]. It is highly probable that many of the acute and chronic symptoms associated with traumatic child maltreatment arise in conjunction with disturbances and dysregulation of these systems. Consequently, evidence of chronic activation of these neurobiological stress systems is seen in victims of PTSD throughout the life cycle. As was reviewed throughout this chapter, preliminary research and clinical data show that dysregulated neurobiological stress systems can be treated with antianxiety and antidepressant medications and psychosocial interventions.
