More recently, labeling of B cells based on GC zonal location with a photo-activatable green fluorescence protein tag provided more conclusive evidence for these activities in vivo.[162] These elegant studies indicated that proliferation was largely restricted to the dark zone followed by a net movement to the light zone. Importantly, movement back into the dark zone and reinitiation of proliferation was controlled by antigen presentation to GC T_{FH} cells.[162] These studies provide experimental evidence for the reiterative cycles of BCR diversification and positive selection as central events during affinity maturation driving clonal evolution in the antigen-specific memory B cell compartment (Fig. 10.4).

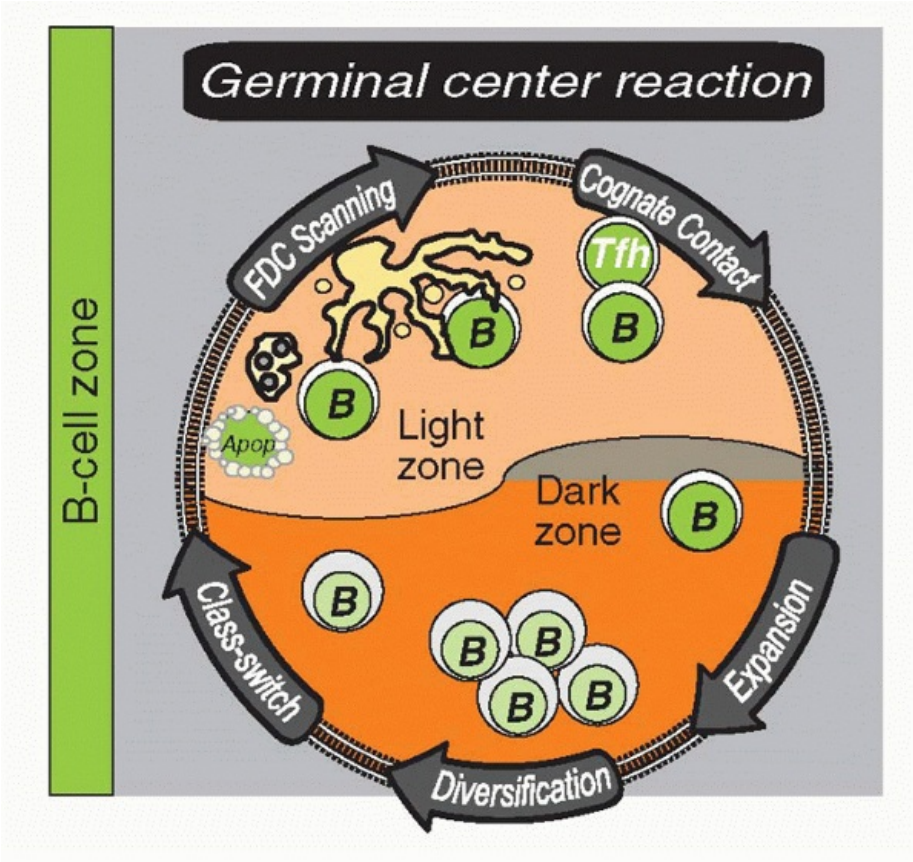

FIG. 10.4. The Germinal Center (GC) Cycle. The GC cycle is initiated through pre-GC contact with cognate follicular helper T (T_{FH}) cells that promotes extensive proliferation of antigen-primed B cells. The GC cycle is thought to begin when immunoglobulin D-secondary follicles polarize into micro-anatomically distinguishable dark zones (DZ)

(containing centroblasts) and light zones (LZ) (containing centrocytes, antigen-laden follicular dendritic cell [FDC] networks, and antigen-specific GC T_{FH} cells). Antigen-specific GC B cells' clonal expansion in the DZ is accompanied by B-cell receptor (BCR) diversification through SHM and antibody class switch. Both SHM and CSR are associated with transcriptionally active gene loci, are associated with deoxyribonucleic acid replicative and repair machinery, and occur during cell cycle. Hence, we associated these activities with the DZ phase of the GC cycle. Exit from cell cycle coincides with relocation of noncycling GC B cells to the LZ. Continual scanning of immune complex-coated FDC is observed in the LZ and has been associated with the potential for GC B cells to test variant BCR for antigen binding. Loss of antigen binding can lead to death by apoptosis and clearance of dead cells by tingible body macrophages in the LZ. Positive signals through the BCR during FDC scanning program GC B cells to compete for contact with cognate GC TFH cells. Productive contact with GC TFH cells can induce reentry into the GC cycle through movement back into the DZ and induction of cell cycle and BCR rediversification. Alternatively, affinitymatured GC B cells can exit the GC as either a nonsecreting memory B cell precursors for the memory response, or secreting long-lived “memory” plasma cells that contribute to serologic memory.

Memory B-Cell Evolution

The GC reaction requires T-cell help as it is absent in athymic nude mice, CD40- and CD40L-deficient mice, and is diminished using reagents that block or deplete T_H-cell function such as anti-CD4, anti-CD40, and anti-CD28.[163,164,165] Mice deficient in ICOS also display profound defects in all aspects of T-cell-dependent B-cell responses.[74,75,76] Conversely, mice deficient in Roquin, an inhibitor of ICOS expression, produce excessive numbers of T_{FH} cells and GCs and are prone to autoimmunity.[64] However, TI antigens can also promote GC

reactions, but they collapse within the first week after priming with no evidence of BCR diversification.[166] In contrast, marginal zone B cells can be recruited into T-cell-dependent responses and form GCs that diversify and affinity mature.[167] Interestingly, in these studies, the marginal zone B cells responding to antigen challenge expressed a preimmune BCR repertoire distinct from that of the follicular B cells responding in the same animals. Hence, there is some redundancy to the control of GC formation and flexibility to the origins of the B cells recruited into the GC reaction.

The transcriptional repressor Bcl6 is highly expressed in the GC and is necessary for GC formation.[168] However, IgM and IgG1 antigen-specific memory B cells can develop in the absence of Bcl6.[169] These studies were based on direct labeling with antigen and their capacity to respond to soluble low-dose antigen recall. However, there were no GC formed, and the memory B cells expressed no SHM or evidence for affinity maturation. Bcl6 has been shown to repress p53, the tumor suppressor gene that controls DNA-damage-induced apoptosis.[170] Regulation of p53 in this manner may protect GC B cells to allow for the DNA breaks that are necessary intermediates in SHM and CSR. Bcl6 also directly represses Blimp-1[171] and hence must be lost at some point during the GC reaction to allow

subsequent development of memory B cells and post-GC PCs in vivo.[137]

The GC cycle of activity regulates clonal evolution within antigen-primed B-cell responders. All pre-GC B cells express some measure of antigen specificity and appear preselected into the memory B-cell pathway based on germline BCR expression. Massive and rapid clonal expansion with doubling times of 6 to 8 hours underpins secondary follicle formation and drives clonal expansion in the GC reaction. It is now clear that GC B cells in the light zone also have the capacity to proliferate.[172] Intravital studies emphasize the more open nature of the GC itself demonstrating the capacity of naive B cells to traverse the follicular region occupied by the antigen-responsive GC.[173] Importantly, antigen-specific B cells could also be recruited into ongoing GCs if they expressed sufficiently high-affinity BCR. While these studies use high frequencies of BCR transgenic B cells pulsed into the ongoing response, it is intriguing to consider the ramifications of such an open network of affinity-based selection and its impact on the composition of the memory B-cell compartment.

Somatic Hypermutation

BCR diversification is dependent on DNA replication and largely restricted to GC B cells in the pathway to memory. Upon expansion in the GC reaction, antigen-specific B cells downregulate their germline BCR and diversify their variable region genes through SHM. Single base substitutions, rare insertions, and deletions are introduced into a region spanning 1.5 to 2.0 kb downstream of the transcription initiation site; however, activity peaks within the V(D)J region and decreases within the J-C intronic region of IgH and IgL variable genes.[174] The mutation rate approaches 10-3 per base pair per generation, which is approximately six orders of magnitude higher than spontaneous mutation frequencies. Thus, approximately one mutation is introduced with each cell division. Analysis of mutation in “passenger” Ig transgenes that are not under selection pressure indicate intrinsic sequence hot spots for the mutator mechanism.[175] Hence, BCR diversification accompanies extensive clonal expansion within the GC reaction generating progeny that express variant antigen-binding BCR (Fig. 10.5).

AID is the central component of the SHM mechanism. Originally discovered through complementary DNA subtraction focused on novel genes in GC B cells,[176] it was then found to be defective in an autosomal-recessive form of hyper-IgM syndrome.[108] Mice deficient in AID were able to form the GC reaction but were unable to undergo CSR or SHM.[107] AID deaminates cytosine to uracil in singlestranded DNA that can be processed by a mutagenic repair pathway.[105,177] The initial changes target sequence-dependent hotspots within rearranged variable region genes of antibodies. Uracil excision by uracil DNA glycosylase is then processed by error-prone DNA replication to introduce point mutations within the actively transcribed Ig locus. Errorprone processing using mismatch repair and base excision repair factors is selectively offset with high-fidelity processing to protect genome stability.[178] The targeting spectrum of AID associated with its active site can be altered to modify variable region gene SHM[179] and rate of antibody diversification.[180] AID stability within the cytoplasm of Ramos B-cell lines can be regulated by heat shock protein 90 with specific inhibition leading to destabilized AID[181] providing a means to modify the rate of antibody diversification. The details of this mutating complex, as well as its action and regulation within

the GC reaction, are active areas of research that have been reviewed in detail elsewhere.[182]

Cell Cycle Arrest and Apoptosis

The control of cell cycle in the GC environment is of fundamental importance to the evolution of high-affinity B-cell memory. Variant GC B cells exit the cell cycle and move toward the light zone to undergo selection. Dysregulated cell cycle arrest promotes enlarged GCs in situ. This phenotype is found in multiple genetic knockout models that also influence the composition of the memory B-cell compartment. Large GCs form in the absence of AID and are thought to indicate a negative feedback mechanism that follows SHM and/or CSR.[107] The absence of the CDK inhibitor $p18^{INK4c}$ more directly impacts GC size through blocking cell cycle arrest and also decreases the formation of long-lived PCs.[183] The large GCs in the absence of Blimp-1[137] may also be related to the lack of cell cycle control that may contribute to the post-GC PC defect in these mice. The absence of the main regulatory subunit of calcineurin, CnB1, results in the large GC phenotype, the loss of late stage antibody production, and the diminution of the memory B-cell response to antigen recall.[184] It will be important to assess whether these putative cell cycle defects directly impact high-affinity memory B-cell evolution or indirectly modify GC B-cell fate and the onset of apoptosis.

It is generally believed that the majority of GC B cells expressing variant BCR will die in situ. Extensive local apoptosis

is characteristic of the GC reaction. Furthermore, overexpression of antiapoptotic molecules such as Bcl-2 or Bcl-xL prolongs survival of GC B cells without improving selection efficiency.[185] In the absence of CD95 (Fas), there is also a dilution of high-affinity clonotypes in the memory B-cell compartment.[186] Cell death is a prevalent outcome of the GC cycle.[187] Fas receptor expression on B cells regulates negative selection in the GC.[188] Moreover, myeloid cell leukemia sequence 1 has emerged as a major antiapoptotic factor controlling GC B-cell formation and survival.[189] Positive selection of variant GC B cells must be a major driving force within the GC and is based on the increased capacity of the mutated BCR to bind antigen. Mutations in the comodifiers of BCR signal also impact GC B-cell dynamics. Unlike the CnB1 mutation, defects in CD45 and CD19 reduce proliferation and survival of GC B cells arguing for a more global impact of these molecules on BCR signal integration.[172,190,191] Initiation of the GC development program may also be altered to differing degrees in these animal models in ways that are difficult to dissect. Driving the expression of Cre recombinase at a stage in development when germline Cγ1 has been transcribed has helped to overcome these problems.[192] This model allows the conditional deletion of alleles at a late stage in antigen-driven B-cell development that occurs after the first T_H -B-cell checkpoint in development.

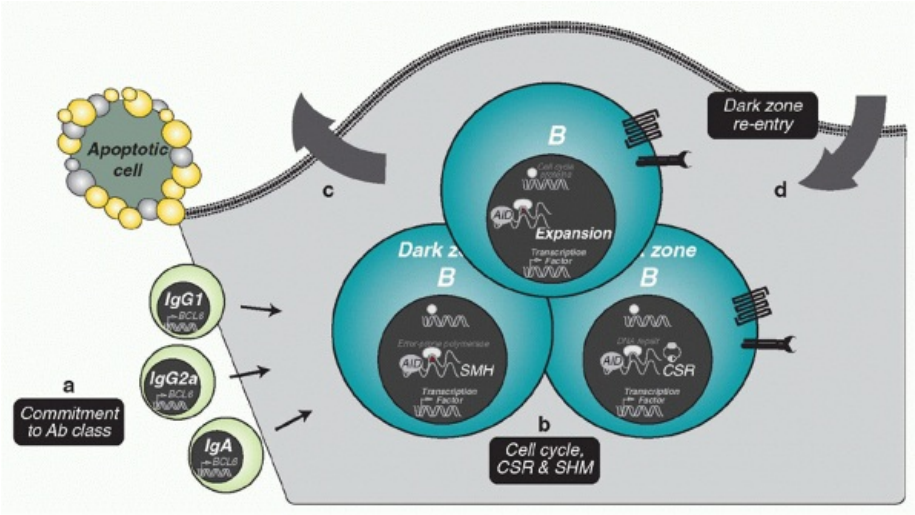

FIG. 10.5. The Germinal Center (GC) Dark Zone (DZ). A: Pre-GC cognate follicular helper T cues instruct antigen-primed B cells to initiate the GC reaction. It is likely that commitment to antibody class is preprogrammed at this initial juncture and all classes of B cells can seed the primary GC response. **B:** Molecular control of the cell cycle is an integral component of DZ B-cell dynamics and Bcl6 expression involved in ways that remain poorly resolved. Activation-induced cytidine deaminase (AID) expression, cytosine deaminase activity, and uracil deoxyribonucleic acid (DNA) glycosylase initiate the somatic hypermutation (SHM) machinery targeted to single-stranded DNA. Uracil excision is then processed by error-prone DNA replication to introduce point mutations into the rearranged antibody variable genes. Class switch recombination (CSR) can also occur during this DZ phase using AID to target DNA cleavage to antibody switch regions, generate double strand DNA breaks that trigger the DNA damage machinery to complete the CSR event. The interrelatedness of cell cycle control, SHM, and CSR is not clearly resolved in vivo. **C:** DZ GC B cells will reexpress diversified B-cell receptors and enter the light zone (LZ) of the GC reaction to undergo antigen-based selection. **D:** Following antigen-based selection and cognate contact with GC follicular helper T cells, LZ GC B cells can reenter the DZ regions and rediversify the BCR to initiate secondary rounds of affinity maturation.

Affinity Maturation

Affinity maturation requires the positive selection of GC B cells expressing high-affinity variant BCRs. The details of this process are still poorly understood. Receipt and integration of signals through the BCR are clearly involved in positive selection and must be based on the affinity for antigen. Ablation of BCR signals such as calcineurin-dependent signals, mutations in the CD19 signaling pathway, and loss of CD45 interferes with positive selection and memory B-cell development.[172,184,190,191] However, as discussed previously, it is difficult to dissect the GC BCR interactions with antigen from the initial BCR triggers that recruited naive B cells into the primary response. Most models suggest immune complex (IC) trapping on FDCs as the most likely means for variant BCRs to receive a rescuing signal from native antigen. Antigen appears rapidly in this location and can persist for extended periods of time focused to FDC in lymphoid tissue draining the site of antigen administration.[193] In support

of this notion, complement receptors CD21/CD35 on FDCs are needed to generate long-term serum antibody responses.[194] However, animals that

do not secrete antibody and therefore cannot form ICs can still support affinity maturation.[195] In the absence of inhibitor of NF-κB kinase 2-dependent activation of the NF-κB pathway, FDCs can still capture ICs but are not stimulated to upregulate vascular cellular adhesion molecule-1 and intercellular adhesion molecule-1.[196] In the absence of these adhesion molecules, GC B cells appear more susceptible to apoptosis with evidence for altered gene expression and decreased affinity maturation.

Evidence connecting BCR signal strength within the GC B-cell compartment and affinity maturation has been lacking. BCR signaling and antigen presentation are required to initiate the GC reaction and hence are difficult to manipulate specifically within the GC. In the absence of DOCK8, which causes compromised early immune synapse formation, early GCs still develop.[14] However, without DOCK8, these GCs do not persist and GC B cells do not undergo affinity maturation. Calcium influx as a consequence of BCR signaling also appears dispensable for affinity maturation under multiple T cell-dependent priming conditions in vivo. Although B cells deficient for stromal interaction molecule 1 and stromal interaction molecule 2 or for CNB1 exhibit profound defects in proliferation in vitro,[15,18] these signaling molecules are dispensable for the maturation of antibody responses in vivo. Downstream of BCR signals, the transcription factor myocyte enhancer factor 2c is necessary for early B-cell proliferation and GC formation,[16,17] but dissecting the pre-GC versus GC function remains unresolved. B cell-specific deletion of nuclear factor of activated T cells, cytoplasmic 1 also compromises B-cell responses in vivo[197] but the level of the defect remains unclear. Nevertheless, as BCR signal strength must drive affinity maturation at some level, it remains important to resolve the B-cell intrinsic mechanisms that also help to shape the affinity of the memory B-cell compartment.

Antigen Scanning on Follicular Dendritic Cell Networks

Polarity in the GC microenvironment is partly controlled by the differential expression of chemokines and their receptors.[198] Higher expression of CXCL12 in the dark zone assorts CXCR4-expressing centroblasts, while higher CXCL13 in the light zone attracts CXCR5-expressing centrocytes. This study used flow cytometry and cell cycle status to identify GC B-cell subsets and demonstrate the aberrant behavior of GC B cells from various genetically modified host animals. Recent two-photon analysis revealed the movement of GC B cells along FDC processes within the GC.[159] This study emphasized the lack of dwell time for GC B cells on FDC processes with little change in GC B-cell velocity upon FDC contact. Therefore, if antigen binding is associated with GC B cell-FDC contact, there appears to be no evidence for interclonal competition between different GC B cells. These studies describe when variant GC B cells are most likely to contact antigen with the opportunity to test the binding properties of their expressed mutated BCR (Fig. 10.6).

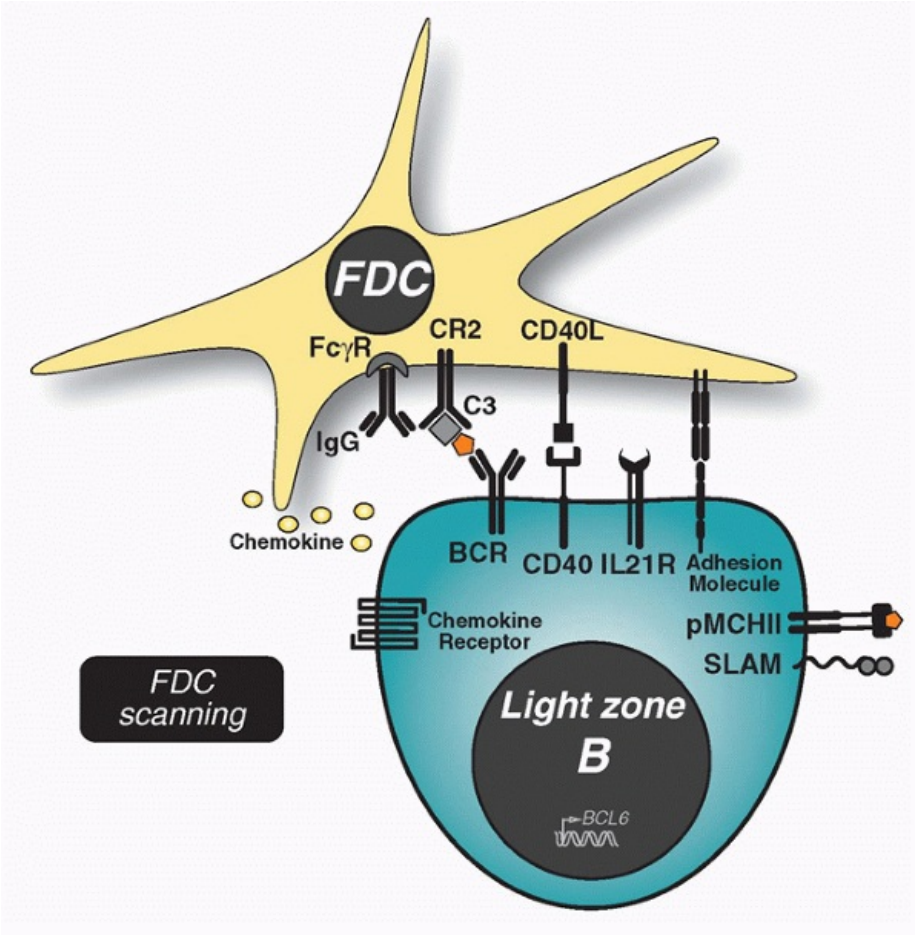

FIG. 10.6. Antigen Scanning on Follicular Dendritic Cell (FDC) Networks. FDC scanning appears as continuous movement of germinal center B cells along mature immune complex-laden FDC processes. These contacts are more similar to stromal cell-associated trafficking behavior than stable immune synapse-like interactions. Differential B-cell receptor (BCR) affinity for antigen may influence antigen-uptake and peptide major histocompatibility class II presentation at this juncture of development. Programs of gene expression for molecules able to modify cognate contact may also be differentially induced due to BCR signal strength through FDC scanning.

As with all in vivo studies, there are substantial influences associated with the choice of models, affinities of BCR, type of antigen, and method of immunization that will impact the observations presented in the studies. The issues of antigen receptor monoclonality are self-evident in BCR transgenic models in the context of repertoire studies, but are less clearly understood in association with the expression of diverse effector functions in vivo. More importantly, in the context of T-cell responses, it is now apparent that elevated precursor frequency deviates the dynamics of clonal expansion[199,200] and can alter the development of T-cell memory in vivo.[201] Changing the balance or affinity of regulator populations will impact cell fate of the target populations in ways that remain difficult to assess. Nevertheless, new insights offered by dynamic imaging continue to buttress our appreciation for the workings of the immune system and serve to challenge existing dogma in powerful and

productive ways.

Germinal Center Follicular Helper T Cells

In contrast to pre-GC effector T_{FH} cells discussed previously, CXCR5+ T_H in GC will be referred to as GC T_{FH} cells. Many CXCR5+ T_{FH} cells were found very early in the immune response (day 3), at the T-B borders and within follicular regions of LNs.[58] These early studies also provided evidence for a circulating compartment of CXCR5+ T_H cells. Hence, it is clear that CXCR5 expression is not a reliable marker of GC T_{FH} cells only. Further, the expected function of GC T_{FH} cells would be broadly different from those described for pre-GC effector T_{FH} cells. The presence of GC T_{FH} cells among the dense FDC networks of the GC light zone predict a role in the propagation of high-affinity variant GC B cells into the long-lived memory B-cell compartment[198] (Fig. 10.7). Subsequent to FDC scanning, some GC B cells were shown to make more stable, immune synapse-like contacts with GC T_{FH} cells, as determined by two-photon imaging.[159] These early images gave rise to the notion that competition for GC T_{FH} cells may be the limiting factor in GC B cell selection of variant high-affinity BCRs.[161] More recently, antigen presentation by GC B cells without engaging the BCR was shown to dominate the selection apparatus within GCs.[162] GC B cells capable of presenting more antigen rapidly exited the GC reaction and produced more post-GC plasma cells. These studies indicated similar mechanisms to the pre-GC selection event[102] and argued strongly that antigen presentation to GC T_{FH} cells was the rate-limiting event during affinity maturation in the GC cycle.

It remains technically difficult to manipulate cellular and molecular activities within the GC cycle without interfering with the developmental programs that initiate the GC reaction in the first place. Many of the molecules associated with pre-GC T_{FH} function may also function within the GC. BCL6 expression itself is reinforced within T_{FH} cells upon contact with pre-GC B cells.[98] ICOS-ICOSL interactions are important throughout this pathway at early DC contact,[202] pre-GC contact,[78] and likely during the GC reaction itself. IL-21 and its receptor appear of continued importance at the pre-GC stage and during the GC reaction.[86,87] Sphingosine-1 phosphate receptor 2 has an important role in confining GC B cells to the GC niche in vivo.[203] Elevated programmed cell death 1 expression also correlates with GC localization of the T_{FH} compartment[82] and the absence of programmed cell death ligand 2 on B cells impacts PC production and affinity maturation.[204] Most interestingly, cytokine production and class-specific GC B cells appear to be associated in the GC well beyond the original CSR event.[205] This surprising functional pairing between GC T_{FH} cells and switched GC B cells (eg, IL-4+ T_{FH} cells with IgG1+ GC B cells; IFNγT_{FH} cells with IgG2a+ GC B cells) hints at the extended level of heterogeneity that exits within the GC cycle of memory B-cell development. Hence, it is likely that each separable class-specific GC B-cell compartment requires cognate contact with separate class-specific GC T_{FH} cells. During antiprotein immune responses, the T_{FH} cells within the light zone of the GC express pMHCII-specific TCRs. There appears to be sequential movement of antigenspecific T_{FH} cells from

the T-cell zones into the GC microenvironment 40,[206] with evidence that suggests GC T_{FH} cells can also move between different GCs.[207] Interestingly, all antigen-specific T_{FH} cells responding to a protein antigen are not represented within the GC reaction, indicating pre-GC functional differentiation for responders T_{FH} cells.[208] Furthermore, non-GC T_H cells can reemerge in a memory response, indicating that the GC is not required for memory T_H-cell development.[40] Downregulation of CD90 (Thy-1) has been used as a marker of GC T_{FH} cells in the mouse, although when this occurs and how well it discriminates only GC T_{FH} cells is not clear.[207] Interfering with CD40L-CD40 interactions disrupts the GC reaction, while blocking B7-2 interaction impairs memory B-cell development.[209] Hence, the cognate control of GC B-cell fate appears to be modified by the cellular and molecular context of pMHCII presentation.

The work on human T_{FH} cells use expression of CD57, as well as CXCR5, to define T_{FH} cells that are contained within the GC of tonsils.[63,210] Microarray analysis highlights the distantly related functional programs of CD57+ GC T_{FH} cells as compared to naive T_H cells, central memory T_H cells, and effector memory T_H cells from the peripheral blood.[210] Differences in adhesion molecules, chemokine receptors, cytokines, and transcription factors appear as distant as different lineages. Interestingly, the CXCR5 ligand, CXCL13, is highly expressed in GC T_{FH} cells. In vitro-derived T_H1 and T_H2 effector T_H cells also appear distant in gene expression program to GC T_{FH} cells.[63] This analysis associates CD84, CD200, IL-21, and BCL6 with CD57+ GC T_{FH} cells. A separate analysis of T_{FH} cells by function and gene expression demonstrates that T_{FH} activity in human tonsil is independent of CD57 expression.[65] These studies highlight $ICOS^{hi}$ $CXCR5^{hi}$ T_{FH} as CXCL13 secretors and the most potent inducers of antibody production in vitro. Therefore, it is clear in situ that all GC T_{FH} cells express CXCR5 and many express CD57; however, these molecules are not exclusively expressed on GC T_{FH} cells nor expressed on all T_{FH} cells in the tonsil. Nevertheless, it remains important to clarify GC T_{FH} phenotype so that the details of their function can be pursued in vivo.

MEMORY B-CELL RESPONSE

It is now clear that centrocytes can undergo proliferation in the light zone,[191] and there is direct evidence for movement

of centrocytes back into the dark zone of GCs.[159,173] Thus, it appears that one outcome of GC B cell-GC T_{FH} interactions is reentry into the GC cycle permitting reiterative rounds of expansion, diversification, and selection. In this model, each subsequent round of clonal expansion and BCR diversification is applied to GC B-cell variants that have been positively selected based on increased BCR affinity. Hence, the introduction of a few mutations in each clonal progeny of selected variants is less likely to destroy BCR specificity and leaves room for further increases in an already high-affinity variant BCR.

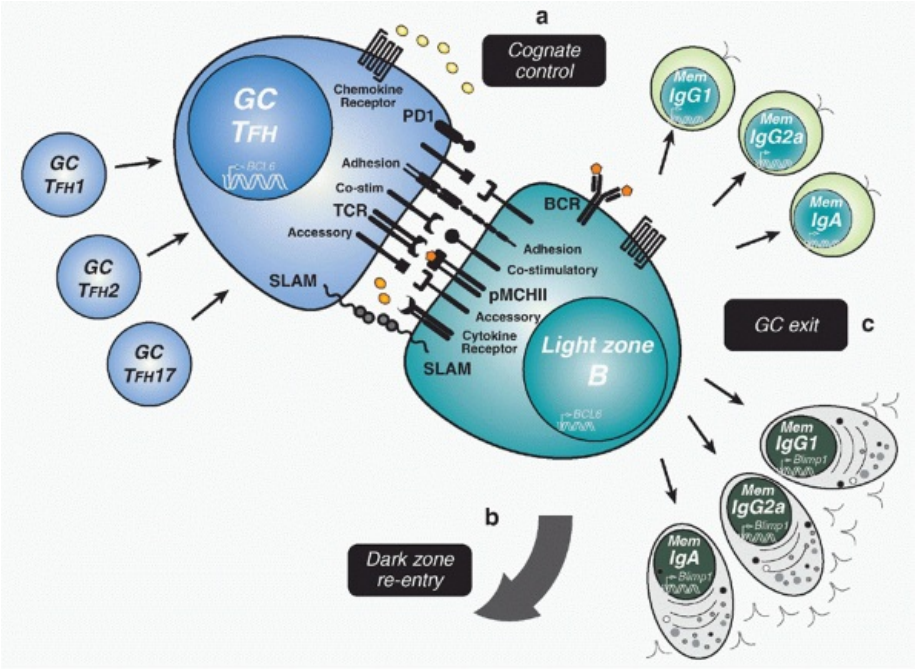

FIG. 10.7. Germinal Center (GC) Follicular Helper T (TFH)-B-Cell Contact. A: Longer duration cognate contact with GC TFH cells in the light zone can be visualized directly in vivo. Similar to earlier pre-GC events these contacts must focus around T-cell receptor-peptide major histocompatibility class II interactions and can be modified by a multitude of intercellular exchanges of molecular information. There is still little detailed analysis of these interactions in vivo. We depict the class of molecules that can be associated with this critical programming event but do not appreciate the organization of these interactions or their precise developmental imprint as yet. **B:** Antigen presentation by B cells can influence dark zone reentry and reinitiation of B-cell receptor diversification with cell proliferation, somatic hypermutation, and class switch recombination. **C:** GC cognate contact can also initiate GC exit into separable nonsecreting memory B cell and post-GC longlived memory plasma cell compartments.

The second major developmental outcome of cognate contact in the GC is exit from the GC cycle and entry into the memory B-cell compartment. The GC reaction produces at least two broad categories of affinity-matured memory B cells.[187] The most typical memory B cells are the precursors for a memory response to antigen recall. These memory B cells are easily distinguished functionally from the second cellular compartment of memory, the post-GC PCs.[211] The post-GC PCs are terminally differentiated cells that continually produce high-affinity antibody and will not be drawn into a secondary response. In both categories of memory B cells, the expression of antibody isotype distinguishes separable memory B-cell compartments. By definition, these subsets differ in the antibody they can produce and hence their developmental program and cellular function is distinct. However, these “class-specific” memory B-cell subsets may also differ in migration patterns, survival needs, and the requirements for reactivation at the time of antigen recall. These issues define a level of heterogeneity that has received

very little attention at the current time and remain important features in the organization of B-

cell memory in vivo (Fig. 10.8).

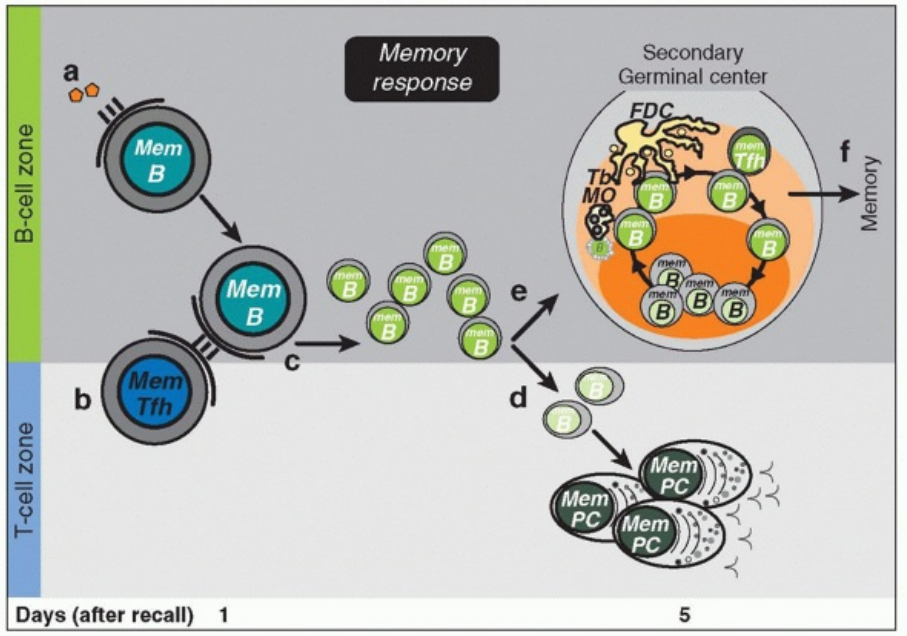

FIG. 10.8. Memory Response to Antigen Recall. A: Memory B-cell responses can emerge in the absence of innate inflammatory stimuli. In this case, the central antigen presenting cells are the affinity-matured memory B cells themselves. **B:** Memory B-cell response to T-cell-dependent antigens still require helper T (T_H)-cell regulation upon antigen recall. When priming and recall antigens are identical, memory T_H cells are the rapid responders and are thought to emerge preferentially over their low-frequency naïve counterparts. Regarding the regulation of memory B-cell responses, antigen-specific memory T_{FH} cells are the most likely candidate for rapid cognate regulation. **C:** Cognate contact at this developmental juncture occurs across sets of memory B cells and memory T_{FH} cells with an organization and kinetics that remain poorly resolved in vivo. There is rapid and vigorous local clonal expansion within the first 2 to 3 days in both memory B and memory T_{FH} compartments. **D:** Expansion of affinity-matured memory B response plasma cells occurs very quickly with evidence that most memory-response plasma cells already appear affinity-matured. **E:** There is evidence for memory B-cell subsets that express a germinal center (GC) phenotype and create GC-like structures upon antigen recall. Whether these structures are residual from the primary response GC or reemerge with GC activities upon recall has not been resolved. **F:** Increased numbers of memory B cells and memory-response plasma cells persist after antigen recall. It remains unclear whether these cells are the product of memory GC reactions or extrafollicular non-GC memory response outcomes.

Memory Response Precursors

There are reports of non-GC early memory B-cell development,[86,169] although how well these germline BCR-expressing memory B cells compete with post-GC memory B cells in the response to antigen recall remains to be evaluated. Affinity-matured IgM+ memory B cells can

emerge from the GC reaction and persist for long periods in vivo.[212] These nonswitched memory cells appear more active in secondary responses in the absence of circulating antibodies. Genetic labeling of AID-expressing cells with yellow fluorescent protein allowed memory B cells to be monitored over long periods.[213] Surprisingly, primary response GC reactions were persistent for extended periods of time (over 8 months after priming) depending on the form of antigen used to immunize. In these studies, class-switched memory B cells rapidly promoted plasma cell differentiation, whereas their IgM+ counterparts promoted secondary GC reactions. Depending on the form of antigen delivery and the combination of innate stimuli, B-cell responses can be skewed toward memory formation with extended GC reactions, which can last over 1.5 years.[214] Hence, it is possible that persistent GCs can continuously produce nonsecreting memory B cells well after the initial priming event. Memory response precursors are more typically affinity-matured post-GC B cells that have switched to non-IgM antibody isotypes and can respond, in a T_H -cell-dependent manner, to low-dose soluble antigen recall. The long-term persistence in vivo of antigen-binding B cells, after the decline of the primary response, provides the single best indicator for all memory response precursors. Beyond this particular attribute, antibody isotype and

stage of development within the memory B-cell compartment introduces a level of cellular heterogeneity that is only recently being appreciated.

As soluble antigen is the ligand for the BCR, most experimental approaches use variations of labeled antigen to identify antigen-specific B cells. While panning techniques used gel-associated antigen to detect antigen-specific B cells,[215,216] flow cytometry provided the most reliable access to antigenspecific B cells.[217,218] These earliest studies[217,218] coupled cell sorting technology and direct labeling to enrich antigen-specific B cells for adoptive transfer. These early studies helped to demonstrate that B cells with receptors for antigen were the precursors for antibody-forming cells. This approach has been adopted by many groups,[219,220,221,222] with the subsequent evaluation of specificity and purity demonstrated by the frequency for antibody forming cells or the enrichment for production of antigen-specific antibodies in vitro. Early studies indicated antigen-binding B-cell populations of long-lived cells with slow or no turnover in vivo.[223] These memory B cells can survive independent of their expressed BCR specificity and hence do not require persistent antigen depots in vivo.[224] Loss of surface IgM/IgD and expression of downstream isotype are also indicative of antigen experience but are not required for memory-cell development.[218,220,225] Further, the expression of mutated BCRs with evidence for affinity increasing changes is the most useful molecular marker for the memory B-cell compartment.[131,226,227,228] However, there are also abundant examples of germline-encoded BCRs expressed by memory response precursors. Location has also been a reliable means for isolating memory B cells from the blood very soon after intentional priming.[226] The combination of location, phenotype, genotype, and time after intentional priming has many elements of a comprehensive definition for memory B cells.

Post-Germinal Center Plasma Cells

High-affinity antibody-producing PCs that emerge from the GC reaction can also be considered an integral part of antigen-specific B-cell memory. High-affinity GC B cells preferentially assort into the PC compartment giving rise to highaffinity circulating antibodies.[229] In LNs, affinity-matured PCs dwell in paracortical areas to mature[230] then migrate toward the medullary regions prior to export.[231] CD93 is expressed at this early stage and is required for PC survival in the bone marrow.[232] Clearly, the circulating antibody that is produced by post-GC PCs contributes to ongoing serologic immune protection.[233] Post-GC PCs do not self-replenish through turnover, secrete isotype-switched antibody, and display evidence of SHM with affinity increasing mutation patterns.[211,234,235] This post-GC antigen-specific B-cell compartment appears during the second week after initial antigen exposure[131] and preferentially homes to the bone marrow for growth factor support of stromal cells.[236] Based on gene ablation studies, these cells use a variety of redistribution mechanisms such as upregulation of CXCR4, α4β1 integrin binding to its ligand vascular cellular adhesion molecule-1[135] to get to the bone marrow, where they can persist for the life of the animal.[133,237,238,239,240,241] In the bone marrow, long-lived PC need signals through the tumor necrosis factor receptor family member, BCMA, for survival.[242] It has also been proposed that a pre-PC precursor[243] or memory cells themselves[233] produce PCs in a non-antigen-dependent manner as a means of maintaining serum antibody levels for extended periods.

The extended longevity of the post-GC PC can be demonstrated using BrdU incorporation and adoptive transfer.[238,239,240,241] The extinguished gene programs associated with PC development[142,244,245] support a terminally differentiated end-stage cell that needs to arrest cell cycle progression[183] and will not be reactivated on antigen recall. Nevertheless, based on the evidence of a GC phase in development, the extended longevity of these PCs and the continued production of high-affinity antibody, it is reasonable to consider that these end-stage B cells belong to the memory B-cell compartment. We have recently demonstrated that post-GC antibody-secreting B cells not only express BCR, but also present antigen and can modulate cognate T_{FH}-cell responses.[132] These surprising studies further demonstrate that PCs negatively regulate BCL6 and IL-21 expression in antigen-specific T_{FH} cells.[132] Thus, PCs are not only the producers of antibody, but can also engage in antigen-specific immune regulation. Signals through the BCR or MHC class II on post-GC PCs may serve to regulate the ongoing production of high-affinity antibodies in the serum. The longterm antigen presenting or regulatory function of post-GC PCs has not yet been elucidated.

Based on variability in memory B-cell formation across different antigen models, it appears likely that different sets of initiating stimuli modify the balance of cells within the different memory B-cell compartments. The memory cell balance may be a quantitative “interpretation” of the quality of the initial immunizing signals. Ultimately, memory B-cell fate is likely to be controlled by interactions in the GC itself. The strength of BCR signal and costimulatory context serve to select variant BCR and initiate changes in memory B-cell development. Cognate interactions with GC T_{FH} cells may consolidate these functional outcomes. Understanding the role of the different memory B-cell subsets in long-term protection and the

rules that govern their development in vivo remain important unresolved areas in this field.

Memory Response to Antigen Recall

Persistent high-affinity serum antibody provides the first layer of protection against antigen recall. While binding to antigen is a clearance mechanism, it also serves to increase the efficiency of antigen presentation to memory B cells through rapid IC formation and binding to FcR or complement receptors on cells of the innate system. In this manner, antibody may amplify the sensitivity of the memory B-cell response to antigen recall. However, the boost with antigen rechallenge also seems necessary to establish adequate longterm protection following protein vaccination. The cognate cellular dynamics and molecular regulation of the memory response boost are important factors in the consolidation of B-cell memory that remain poorly understood and inadequately optimized in most vaccine regimes.

Primary response GCs persist for about 3 weeks after initial priming, but this timing may vary substantially depending on the immune stimuli.[151,152] There is evidence for continued selection in the memory B-cell compartment even after the demise of the GC reaction.[235] This selection process represents more typical interclonal competition without further BCR diversification.[246] Where this secondary selection occurs and how it relates to the selection mechanisms in the GC remains to be determined. Nevertheless, secondary selection events appear capable of reshaping the memory compartment toward higher-affinity clonotypes that can substantially influence the quality of the secondary response and consolidation of the memory compartment.[233] Recent evidence indicates that memory B cells can reinstitute a GC reaction upon antigen recall. The form of antigen appears to have a role in primary response GC persistence with particulate antigen more likely to promote GC longevity.[213] Moreover, innate system stimuli differentially impact persistent GC structures with combinations of toll-like receptor-4 and toll-like receptor-7 more effective than single stimuli.[214] Whether the secondary GC is a continuation and reexpansion of a primary GC activity remains unclear. More importantly, whether these secondary or persistent GC-like structures support the rediversification of affinity-matured BCR and the selection of even higher-affinity clonotypes remains to be determined. These issues are central to the future management of prime-boost vaccination protocols with substantial practical impact in this field.

Using priming doses of antigen and adjuvant, antigenspecific memory T_H-cell responses[40,41,247] and memory B-cell response[248] emerge more rapidly than their naive response counterparts. Memory T_H-cell responses reach peak levels more rapidly but to similar levels as the primary response. In contrast, memory B cells display accelerated kinetics and reach substantially higher maximal levels compared to the primary response. Even in the presence of priming doses of antigen and adjuvant, the memory responders dominate the recall response,[40,130] outcompeting naive lymphocytes that may express specific Ag-R.

Antigen recall promotes accelerated clonal expansion and rapid differentiation to high-affinity PCs. Initiation and microclustering of IgG1 BCRs is enhanced at the single cell level due to membrane proximal regions in the cytoplasmic tail of IgG1.[249] The cytoplasmic tails of class-

switched memory B cells can contribute substantially to the expanded clonal burst associated with retriggering by antigen.[250] There is evidence for distinct changes in BCR signaling pathways.[251,252,253,254] Increased affinity of the BCR on memory cells must also contribute to memory B-cell sensitivity to low-dose soluble antigen that does not induce a primary immune response. In addition to these intrinsic attributes, circulating highaffinity antibody contributes to differential management of antigen in vivo. Rapid presentation of immune complexes to the memory B cells maybe enhanced. Furthermore, memory B cells require antigen-specific T_H-cell regulation to initiate secondary immune responses.[255] These issues have not been well studied but remain central to the capacity of memory B cells to expand, self-replenish, and boost high-affinity PCs and circulating antibody levels that provide long-term immune protection.

Antigen-Specific Memory Follicular Helper T Cells

Memory B-cell response to protein antigens require antigen-specific T-cell help.[187] Under normal physiologic circumstances, this secondary T-cell help must be antigen-specific and is most likely delivered by memory T_H cells that are specific to the immunizing antigen. Under typical low-dose antigen rechallenge regime in the absence of immune adjuvant, antigen-specific B cells are likely to be the predominant APC for the memory response. Hence, the cognate interactions of pMHCII+ memory B cells and antigen-specific memory T_H cells define a major developmental checkpoint in the evolution of long-term immune protection. Alternately, circulating antibody and innate immune activation induce an accelerated memory response due to increased frequencies and heightened responsiveness of memory response precursors. In this scenario, the memory T_H cell-memory B-cell checkpoint may be preceded by an independent series of antigen presentation events prior to cognate memory T_{FH}-memory B-cell contact.

The major cellular outcome of the secondary boost is rapid and exaggerated memory B-cell expansion and the production of large numbers of high-affinity PCs. While high-affinity B cells can be drawn into GC reactions,[158] it is not clear that the GC pathway is operative at the time of the secondary boost. Regardless, there is clear evidence for secondary selection events upon antigen rechallenge that are more likely to be driven by cellular selection without somatic BCR diversification.[187] The nature of the selection mechanism for B cells at this stage of the response is also poorly understood. In contrast, the accelerated local reexpansion of antigen-specific memory T_H cells occurs with little change in the expressed TCR repertoire[256] or cytokinesecreting potential.[247] Hence, the antigen-specific memory T_H-cell compartment appears to conserve and reexpress many of the functions associated with the initial primary immune response.

There is evidence for a division of labor in the memory T-cell compartment that involves the migratory capacity of memory T_H-cell subsets.[257] Recirculating central memory T cells and tissue-homing effector memory T cells further divide on their readiness to reexpress effector function upon reexposure to antigen. It is reasonable to propose that each antigen-specific effector T_H-cell subset will produce a memory T_H-cell counterpart.[247] However, the range of T_H memory effector attributes required to control antigenspecific memory B-cell responses is

not well understood. Compartments of tissue-localized memory T_H cells provide rapid "reactive" immune protection that is antigen-specific.[257] For example, the focal placement of effector memory T-cell subsets at sites of original antigen entry preempts the behavior of the pathogen. In this manner, location provides an opportunity to accelerate the recall response enhancing the capacity of the immune system to block overt infection. As the precursors of the memory response to antigen recall,

high-affinity memory B cells belong to a similar "reactive" set of memory cells. However, in contrast to local hypersensitivity responses by T_H cells, antigen reexposure promotes rapid and exaggerated memory B-cell responses in the lymphoid tissue that drains the site of rechallenge. In this context, we can refer to the memory T_H-cell compartment that controls memory B cell responses as memory T_{FH} cells.

We have provided evidence for the local persistence of an antigen-specific memory T_{FH} cell compartment. CXCR5+ T_{FH} cells bind pMHCII tetramers, express lower levels of ICOS, and have lost the capacity to express messenger ribonucleic acid for a series of cytokines.[53] These putative memory T_{FH} cells rapidly upregulated cytokine signals following specific peptide restimulation in vivo. We propose that these locally confined memory T_{FH} cells are the cognate regulators of the memory B-cell response. Many of the antigen-specific memory T_{FH} cells retain expression of CD69, which suggests recent contact with pMHCII complexes and provides a plausible mechanism for local retention. It is likely that memory B cells with high-affinity BCR will rapidly capture minute levels of secondary antigen and present this antigen to the cognate memory T_{FH} cells. Hence, memory B cells may be the primary APC in the memory response, further accelerating the memory B-cell response to recall.

It is not clear whether memory T_{FH} cells would necessarily express CXCR5+ like their primary response T_{FH} compartment. Furthermore, it is not clear whether both effector T_{FH} and GC T_{FH} produce memory T_{FH} counterparts. Nevertheless, it will be important to unravel the programs of cognate control used by antigen-specific memory T_{FH} to regulate the memory B-cell response to antigen rechallenge. It is plausible that manipulating cellular and molecular interactions at this developmental juncture can alter the shape of antigen-specific B-cell memory.

Antigen Persistence In Vivo

Tonic signaling through the BCR and the downstream activation of phosphoinositide 3-kinase, together with B cell-activating factor signaling through the B cell-activating factor receptor are required for survival of naïve B cells in the periphery.[224,258] Similarly, inducible deletion of phospholipase Cγ2 after the formation of antigen-specific B-cell memory substantially depleted the memory B-cell compartment and suggested a BCR signaling requirement in memory.[259] Nevertheless, earlier genetic studies indicated that cognate BCR specificity was not required after formation of B-cell memory to provide the tonic survival signal.[224] Thus, persistent antigen appears not to be required for the survival of antigen-specific memory B cells, although memory B-cell function has not been addressed in this model. More recently, there has been evidence of persistent pMHCII complexes in the context

of antiviral responses in vivo,[260] leading to local activation of naïve T_H cells even after clearance of virus. We recently demonstrated a similar persistence of pMHCII complexes for longer than 100 days following protein antigen vaccination in a nondepot adjuvant.[261] The depots of pMHCII complexes were restricted to the LNs draining initial vaccination site and persistent antigen presentation induced naïve T_H-cell proliferation.[261] We proposed that pMHCII complexes on immunocompetent APCs had a role in confining the antigenspecific memory T_{FH}-cell compartment to LNs draining the site of initial priming.[262] Although it has been known for some time that FDC networks are capable of trapping whole antigen as immune complexes for extended periods of time,[161] the nature of the long-lived local APC remains unresolved. Unlike CD8 T cells, CD4 T_H cells appear to require continued presence of antigen to reach maximal clonal expansion in vivo. The conditional induction and abrogation of pMHCII molecules demonstrate that as soon as a lower threshold level of antigen is breached, T_H cells cease to divide.[263] Surprisingly, this model induces no form of inflammation and would otherwise be considered a model of tolerance induction. Recent intravital imaging studies also indicate that antigen-responsive T_H cells engage multiple DCs at successive early stages after priming.[264] These multiple DC-T_H-cell contacts also impact the development of effector T_H-cell function in vivo. Most surprisingly, there is evidence for persistent depots of pMHCII complexes up to 3 weeks after viral infection.[265] These pMHCII depots are present at times after viral clearance in vivo. The same persistent depots can be demonstrated for pMHCI with the capacity for local activation of viralspecific naive CD8 cells.[266] While persistent antigen is not required for the maintenance of antigen-specific T-cell memory,[267,268] there may be a role for persistent depots of pMHC complexes as local guidance cues for antigen-specific memory T cells.

CONCLUSION

Understanding the cellular and molecular control of antigen-specific memory B-cell development remains a high priority for basic research with important application to future vaccine design. The largest growing class of pharmaceutical agents today is the antigen-targeting antibodies with an endless spectrum of biologic impact. Producing potent antibodies with high affinity is an important facet of this growing new industry.

There has been substantial progress in our understanding of this complex developmental cascade in vivo with many of the cellular processes being more carefully defined in their most relevant in vivo context. The sophisticated manipulation of mouse genetics provides a powerful set of tools that begin to unravel the regulatory mechanisms operative across each developmental checkpoint controlling cell fate in vivo. Real-time intravital imaging provides a major advance to our appreciation of cell dynamics and intercellular communication as it proceeds in the crowded confines of secondary lymphoid tissue. Most importantly, a surge in research activity has revealed many of the mechanisms controlling T_{FH}-cell development and function in ways that have changed the conceptual landscape surrounding our appreciation of cognate regulation in B-cell memory.

Beyond antigen recognition, antibody class determines immune function and binding affinity

controls sensitivity within memory B cells. Antigen contact initiates presentation by B cells and a program of events, which is consolidated following B-cell contact with antigen-specific T_{FH} cells. We have outlined these events as a progressive developmental program across three related but distinct phases of antigen encounter. We remain cautious of manipulating critical adaptive immune functions but quietly optimistic. The molecular regulation of antigen-specific cellular events initiates a complex but finite set of regulatory programs that can be modified both indirectly, following vaccination with innate stimuli, and perhaps directly, during the acquisition of high-affinity B-cell memory. The vaccine boost is the most readily accessible phase of this strategy that can directly target antigen-specific adaptive responses. Unraveling the molecules and programs that control each phase of memory B-cell development provides a plethora of new targets for vaccine-based modification in vivo.

ACKNOWLEDGMENTS

I would like to acknowledge Louise McHeyzer-Williams in the collaborative unfolding of the ideas that structure this chapter and the images that illustrate the flow of ideas presented here. There has been immeasurable input from the members of our laboratory and collaborators over the years that help to shape and reshape the nature of our understanding of these fascinating processes in vivo.

Chapter 11

T-Cell Antigen Receptors

Mark M. Davis

Yueh-Hsiu Chien

T-lymphocytes expressing αβ or γδ T-cell antigen receptors (TCRs) are found together with B-lymphocytes in all but the most primitive vertebrate animals. These three cell types are the only ones that use random variable (V), diversity (D) in the case of TCR-β and -δ, joining (J), gene rearrangement to generate diverse antigen receptors. During the last two decades, there has been a great deal of progress in identifying the molecules and genes of TCRs, and there is considerable information on their biochemistry and structure. While TCRs share structural and genetic similarities with B-cell antigen receptors (immunoglobulins [Igs]), they also possess a number of unique features pertinent to their specific functions. The first major difference was suggested by the experiments of Zinkernagel and Doherty, who found that cytotoxic cells specific for a viral antigen could only lyse infected cells that expressed a particular major histocompatibility complex (MHC) molecule.[1,2] This phenomenon of "MHC-restricted recognition" is in marked contrast to the recognition of intact antigens by Igs.[3,4] Later work demonstrated that what was being recognized by these T cells, which were of the αβ TCR type, were fragments of antigens or peptides bound to a characteristic groove in MHC molecules.[5] These αβ TCRs are expressed on classical helper and cytotoxic T cells, which predominate in most lymphoid compartments (90% to 95%) of humans and mice.[6] They are also expressed on natural killer (NK)T cells,[7] regulatory T cells,[8] and T cells in the mucosal sites such as the intestinal epithelial compartment (IEL).[9] In most cases, the αβ TCR ligand is a peptide antigen bound to a class I or class II MHC molecule; but in the case of NKT cells, the antigen is a glycolipid bound to a nonclassical class I MHC molecule, cluster of differentiation (CD)Id.[7]

T cells bearing γδ TCRs are less numerous than the αβ type in most cellular compartments of humans and mice (<5%). However, they make up a substantial fraction of T-lymphocytes in cows, sheep, and chickens.[10] γδ T cells coexist with αβ T cells but seem to be better represented in the mucosal compartments.[10,11] Although αβ T cells perform most of the functions classically attributed to T cells, mice lacking γδ T cells are clearly have a compromised immune defense indicating that γδ and αβ T cells contribute to host immune defense differently.[11,12] γδ TCRs also recognize antigens directly, like antibodies, with no apparent need for antigen processing,[13] at least in the most thoroughly studies cases. During the past few years, there have been considerable advances in our understanding of antigen recognition by γδ T cells. This should lead to a better understanding of how γδ T cells contribute to immune competence.

T-CELL ANTIGEN RECEPTOR POLYPEPTIDES

The search for the molecules responsible for T-cell recognition first focused on deriving antisera or monoclonal antibodies specific for molecules on T-cell surfaces. Ultimately, a number of groups identified "clonotypic" sera[14] or monoclonal antibodies.[15,16,17,18,19] Several of these antibodies were able to block antigen-specific responses by the T cells they were raised against or, when coated on a surface, could activate the T cells they are specific for. They were also able to immunoprecipitate 85,000 to 90,000 molecular weight (MW) disulfide-bonded heterodimers from different T-cell clones or hybridomas consisting of two 40,000 to 50,000 MW glycosylated subunits referred to as α and β. Peptide mapping studies showed that there was a striking degree of polymorphism between heterodimers isolated from T cells of differing specificity, thus suggesting that these antigen recognition molecules

might be akin to Igs.[20,21]

Work in parallel to these serologic studies exploited the small differences (approximately 2%) observed between B- and T-cell gene expression,[22] and isolated both a mouse[23,24] and a human[25] T cell-specific gene that had antibodylike V, J, and C region sequences and could rearrange in T-lymphocytes.[24] This molecule was identified as TCR-β by partial sequence analysis of immunoprecipitated materials.[26]

Subsequent subtractive cloning work rapidly identified two other candidate TCR complementary deoxyribonucleic acids (DNAs) identified as TCR-α[27,28] and TCR-γ.[29] It was quickly established that all antigen-specific helper or cytotoxic T cells expressed TCR-αβ heterodimers. Where TCR-γ fit in remained a puzzle until work by Brenner et al.[30] showed that it was expressed on a small (5% to 10%) subset of peripheral T cells together with another polypeptide, TCR-δ. The nature of TCR-δ remained unknown until it was discovered within the TCR-α locus, between the Vα and Jα regions.[31] Formal proof that the TCR-α and -β subunits were sufficient to transfer antigen/MHC recognition from one T cell to another came from gene transfection experiments,[32,33] and equivalent experiments have also been done with γδ TCRs.[34]

As shown in Figure 11.1, all TCR polypeptides have a similar primary structure, with distinct V, D in the case of TCR-β and -δ, J, and constant (C) regions exactly analogous to their Ig counterparts. They also share many of the amino acid residues thought to be important for the characteristic variable and constant domains of Igs.[35] The Cβ region is particularly homologous, sharing 40% of its amino acid sequences with C_K and C_λ. The TCR polypeptides all contain a single C region domain (versus up to four for Igs) followed by a connecting peptide. These usually contain the cysteine for the disulfide linkage that joins the two chains of the heterodimer (some human TCR-γδ isoforms lack this cysteine and consequently are not disulfide-linked[36]). *N*-linked glycosylation sites vary from two to four for each polypeptide with no indications of O-linked sugar addition. C-terminal to the connecting peptide sequences are the hydrophobic transmembrane regions. These have no similarity to those of the *IgH* genes but instead have one (TCR-β and -γ) or two (TCR-α and -δ) positively charged residues. As discussed later, these charged residues are critical for the association of the ligand-binding TCR polypeptides with the CD3 signaling polypeptides. This is important because the TCR polypeptides have very short cytoplasmic regions with no known role in signaling.

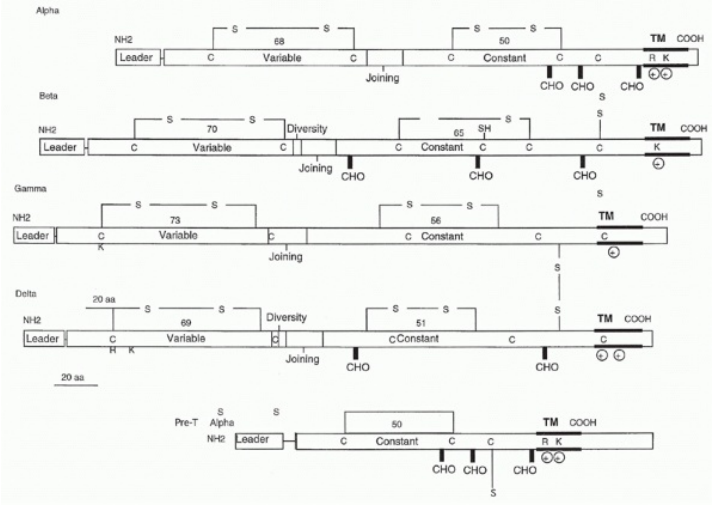

FIG. 11.1. Structural Features of T-Cell Receptors and Pre-T α Polypeptides. Leader (L), variable (V), diversity (D), joining (J), and constant region (C) gene segments are indicated. *Transmembrane* and *bold horizontal lines* delineate the putative transmembrane regions; *CHO* indicates potential carbohydrate addition sites; *C* and *S*

refer to cysteine residues that form interchain and intrachain disulfide bonds; *R* and *K* indicate the positively charged amino acids (arginine and lysine, respectively) that are found in the transmembrane regions.

A more recent member of the TCR polypeptide family is the pre-Tα chain, which serves as a chaperone for TCR-β in early thymocytes, similar to the role of λ5 in pre-B cells.[37] It was first identified and cloned by von Boehmer and colleagues.[38] It has an interesting structure that consists of a single Ig constant region-like domain followed by a cysteinecontaining connecting peptide, a transmembrane region

containing two charged residues: an arginine and a lysine spaced identically to the TCR-α transmembrane region. The cysteine in the connecting peptide is presumably what allows heterodimer formation with TCR-β and the similarity to TCR-α in the transmembrane region is most likely to accommodate the CD3 polypeptides. Recently, Rossjohn and colleagues have presented a structure of the pre-Tα chain that is comprised of a single Ig-like domain that is distinct from the C domain of the TCR-α chain; nevertheless, the mode of association between pre-Tα and TCR-β mirrored that mediated by the Cα-Cβ domains of the αβTCR.[39] The pre-TCR has a propensity to dimerize in solution, and the molecular envelope of the pre-TCR dimer correlated well with the observed head-to-tail pre-TCR dimer. This mode of pre-TCR dimerization enables the pre-Tα domain to interact with the Vβ domain through residues that are highly conserved across the Vβ and Jβ gene families, thus mimicking the interactions at the core of the αβ TCR's Vα-Vβ interface. Disruption of this pre-Tα-Vβ dimer interface abrogates pre-TCR dimerization in solution and impaired pre-TCR expression on the cell surface. Their work suggests a mechanism of pre-TCR self-association that allows the pre-Tα chain to simultaneously "sample" the correct folding of both the V and C domains of any TCR β-chain, regardless of its ultimate specificity,[39] which likely represents a critical checkpoint in T-cell development.

In both the mouse and humans, the cytoplasmic tail of pre-Tα is much longer than any of the TCR chains (37 and 120 amino acids, respectively), and the murine sequence contains two likely phosphorylation sites and sequences homologous to an SH3 domain binding region. These are not present in the human sequence, however, and so their functional significance is unclear.[38] Thus, at least in principal, the murine pre-Tα molecule could function as signaling intermediate independent of the CD3 polypeptides, and it has recently been shown that at least one CD3 component (δε, see the following) is not required for it to function normally in early thymocyte differentiation.[40]

CLUSTER OF DIFFERENTIATION 3 POLYPEPTIDES

Immunoprecipitation of the human TCR with anti-idiotypic antibodies after solubilization with the nonionic detergent, noniodet P-40 (NP-40), initially revealed only the α- and β-chain heterodimer. However, the use of other detergents, such as digitonin or Triton-X100, revealed four other proteins.[41,42,43,44] These are known as the CD3γ, δ, ε, and ζ. γ and δ form distinct heterodimers with ε within the TCR/CD3 complex (γε and δε), and ζ usually occurs as a disulfide-linked homodimer. In mouse T cells, NP-40 does not dissociate TCR heterodimers from CD3 molecules.[44,45] In some cases, the ζ-chain can be part of a heterodimer in at least two forms. In mouse T cells, the ζ-chain can disulfide bond with a minor variant called the η (eta) chain.[46,47] This latter chain is an alternate splicing variant of the ζ-chain gene.[48] This alternatively spliced species of the ζ-chain is not found in significant quantities in human T cells.[48] The second type of ζ-chain containing heterodimer contains the γ-chain associated with the $F_C\varepsilon RI$ ($F_C\varepsilon RI$ γ) and $F_C\gamma RIII$ (CD16) receptors.[49,50] These CD3 subunits, in their various forms, are an integral part of TCR-mediated T-cell recognition because only they possess the immunoreceptor tyrosine-based activation motifs (ITAMs) that are necessary for cellular activation when the TCR engages ligand.

Characterization and Structural Features of the Cluster of Differentiation 3 Polypeptides

Figure 11.2 illustrates the principal structural features of the CD3 γ, δ, ε, and ζ polypeptides

as derived from gene cloning and sequencing,[42,51] and more recently by protein crystal structures of the extracellular domains of γ, δ, and ε.[52,53,54,55] The extracellular domains of the γ, δ, and ε chains show a significant degree of similarity to one another. These domains retain the cysteines that have been shown to form intrachain disulfide bonds and each consists of a single Ig superfamily domain. The spacing of the cysteines in these domains produces a compact Ig-fold, similar to a constant region domain. The γ and δ subunits form distinct heterodimers with ε via highly conserved residues at the dimerizing interface.[52,53,54,55] The connecting peptides of the CD3 γ, δ, and ε chains all contain highly conserved, closely spaced cysteines just before the membrane-spanning regions. These residues are likely candidates for the formation of interchain disulfide bonds and appear to play a role in the assembly of the CD3 and TCR polypeptides.[52,56] The extracellular domain of the ζ chain consists of only nine amino acids and contains the only cysteine, which is responsible for the disulfide linkage of the ζζ homodimer or the ζ $F_C\varepsilon RI\gamma$ heterodimer. Each of the γ, δ, ε, and ζ polypeptides contain a conserved, negatively charged amino acids in their transmembrane region complementary to the positive charges seen in the TCR transmembrane regions.[57,58,59,60]

The cytoplasmic regions of the γ, δ, ε, and ζ chains are the intracellular signaling "domains" of the TCR heterodimer. Each of these molecules contains one or more amino acid sequence motifs that can mediate cellular activation.[61] The intracellular sequences responsible for this activation are contained within an 18 amino acid conserved ITAM[62] with the sequence $X_2YX_2L/IX_7YX_2L/I$. Both of the tyrosines in this motif are absolutely required to mediate signal transduction as mutation of either completely prevents the mobilization of free calcium or cytolytic activity.[63] This sequence occurs three times in the ζ chain and once in each of the CD3 γ, δ, ε, and $F_C\varepsilon RI$ γ chains. There are also pairs of tyrosines present in the cytoplasmic domains of the γ, δ, ε, and ζ chains. This sequence motif is also present in the mβ-1 and B29 chains associated with the Ig β-cell receptor and in the $F_C\varepsilon RI$ β-chain but there are many more[10] in TCR/CD3 than in any other receptors which use ITAMs. The tyrosines in these cytoplasmic sequences are substrates for the tyrosine phosphorylation that is one of earliest steps in T-cell signaling[61] and is thought to occur aberrantly in nonproductive T-cell responses (eg, antagonism; see following). Serine phosphorylation of the CD3γ also occurs upon

antigen or mitogenic stimulation of T cells[64] and may play a role in T-cell activation as well.

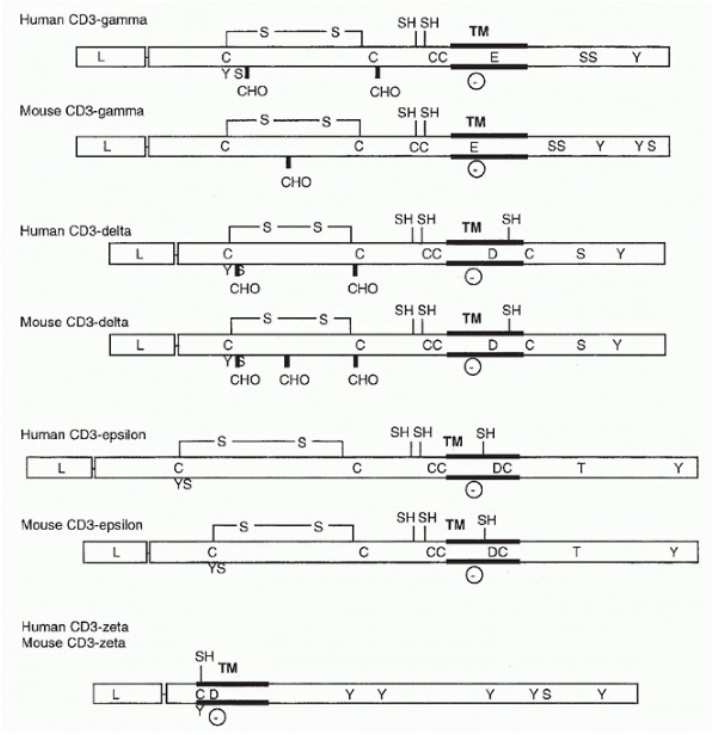

FIG. 11.2. Structural Features of the CD3 Molecules. As in Figure 11.1, transmembrane regions, carbohydrate addition sites, and cysteine residues are indicated. In addition, negatively charged transmembrane residues (*D* for aspartic acid and *E* for glutamic acid) and putative phosphorylation sites are shown.

Recently, live-cell imaging studies have shown a close interaction of the CD3epsilon cytoplasmic domain of the TCR with the plasma membrane, using fluorescence resonance energy transfer (FRET) between a C-terminal fluorescent protein and a membrane fluorophore.[65] Electrostatic interactions between basic CD3epsilon residues and acidic phospholipids enriched in the inner leaflet of the plasma membrane were required for binding. Nuclear magnetic resonance studies of the lipid-bound state of this cytoplasmic domain revealed a deep insertion of the two key tyrosines of the ITAM into the hydrophobic core of the lipid bilayer, likely preventing their phosphorylation.[65] Similar studies of CD3 zeta have confirmed that this is also the case for that component of the TCR/CD3 complex as well.[66] This then likely defines the “off” state of the TCR/CD3 complex and is a novel explanation for how it can prevent tyrosine phosphorylation by Ick. What is still mysterious is how ligand binding by the TCR disengages these signaling modules from the plasma membrane and triggers the kinase cascade needed to activate T cells.

Assembly and Organization of the T-Cell Receptor/Cluster of Differentiation 3 Complex

The assembly of newly formed TCR-α and -β chains with the CD3 γ, δ, ε, and ζ chains and their intracellular fate have been studied in detail.[39,40,41,61,63] Early studies have focused on mutant hybridoma lines, which fail to express TCR on their cell surface, and on transfection studies using complementary DNA for the different chains in the receptor; but recently, Wucherpfennig and colleagues have developed an elegant in vitro translation and assembly system that has clarified a number of important issues.[54,55]

Experiments in a nonlymphoid cell system[67] have shown that TCR-α can assemble with CD3 δ and ε but not CD3 γ

and ζ. In contrast, the TCR-β chain can assemble with any of the CD3 chains except the ζ chain. When the ζ chain was transfected with either α or β chain genes, or any of the three CD3 chains, no pairwise interaction occurred.

Only when all six complementary DNAs were cotransfected was it shown that the ζ chain could be coprecipitated with the other chains.[67] Based on these data, a model has been proposed that suggests that TCR-α pairs with CD3 δ and ε chains and that TCR-β pairs with the CD3 γ and ε chains in the completed molecule. The ζ chain is thought to join the TCR and other CD3 polypeptides in that last stage of assembly.

Pulse-chase experiments have shown that all six chains are assembled in the endoplasmic reticulum (ER), transported to the Golgi apparatus, and then transferred to the plasma membrane. It also appears that the amount of ζ chain is rate limiting, as it is synthesized at only 10% the level of the other chains. This results in the vast majority of newly synthesized α, β, or CD3 components being degraded within 4 hours of their synthesis. The remaining nondegraded chains are long lived due to the formation of complete TCR/CD3 complexes with the limiting ζ chain.[68] TCR/CD3 lacking CD3 ζ chains migrate through the ER and Golgi intact but then are transported to and degraded in the lysosomes. The immunologic significance of this pre-Golgi degradation pathway is most evident in CD4+CD8+thymocytes where, despite high levels of synthesis of both messenger ribonucleic acid and protein for all the TCR, CD3, and ζ chains, surface expression is relatively low. The TCR chains in immature thymocytes seem to be selectively degraded.[68] Thus posttranslation regulation appears to be an important means of controlling the cell surface expression of TCR heterodimers.

The TCR and CD3 γ, δ, and ε chains contain ER retention signals.[68,69] If the γ and δ signals are removed, then the chains are transported through the Golgi and rapidly degraded in the lysosomes. In contrast, removal of the CD3 ε ER retention signal allows this chain, and any associated chains, to be transported to the cell surface. Thus, association of the TCR and other CD3 chains with ε renders their ER retention signals inoperative. However, the ε ER retention signal remains functional. This prevents the surface expression of partial complex intermediaries until CD3 ζ is incorporated into the complex, which then masks the ε ER retention signal and allows the transport of mature complexes to the cell surface.

The overall stoichiometry of the αβ TCR/CD3 complex is controversial. The work of Call and colleagues[57] has shown the relationships between different CD3 dimers (γε, δε, and ζ ζ) and a single TCR αβ heterodimer (as shown in Fig. 11.3). Using mutagenesis, they found very specific interactions based on the positive charges in each TCR transmembrane domain with complementary negative charges in the transmembrane domains of the different CD3 components. The two positively charged residues of TCR-α mediate interactions with the negatively charged residues of the of CD3δε and CD3ζζ dimers, while the single positively charged residue of TCR-β mediates interactions with the negatively charged residues of CD3γε. In addition, their data suggest a highly ordered assembly process as they found that the TCR/CD3δε association facilitates the assembly of CD3γε into the complex and that the association of the TCR and CD3 heterodimers was a prerequisite for incorporation of CD3ζζ into the complex. Importantly, the data show that there is only one TCR heterodimer per nascent TCR/CD3 complex in their in vitro expression system.

In contrast, a number of groups have found evidence that there can be two TCR heterodimers in a given TCR/CD3 cluster on T-cell surfaces. In particular, Terhorst and colleagues[42] showed that in a T-T hybridoma, a monoclonal antibody against one TCR-αβ pair could comodulate a second αβ heterodimer. In addition, sucrose gradient centrifugation of TCR/CD3 showed a predicted molecular weight of 300 kDa, more than 100 kDa larger than expected from a minimal δ subunit complex (α, β, γ, δ, ε_2, ζ_2).[70] Another study suggesting that there are least two TCRs in a given CD3 complex is the Scatchard analysis indicating that the number of CD3ε molecules on a T-cell surface equals the number of αβ TCRs.[71,72,73] Finally, there is the work of Fernandez-Miguel et al.,[74] who showed that in T cells which have two transgenic TCR-β chains, antibodies to one Vβ can immunoprecipitate the other. It was also found that they are often close enough to allow fluorescence energy transfer, meaning that the two TCR-βs in a cluster are within 50 Angstroms of each other.[74] Interestingly, it appears that the TCR complexes with CD3 either have CD3 γ or CD3 δ, but not both, and these two

receptor types are expressed in different ratios in different cells. These data may not be

irreconcilable, because while the initial TCR/CD3 assembly may involve only one TCR, these may dimerize or multimerize later on the cell surface.[50,75]

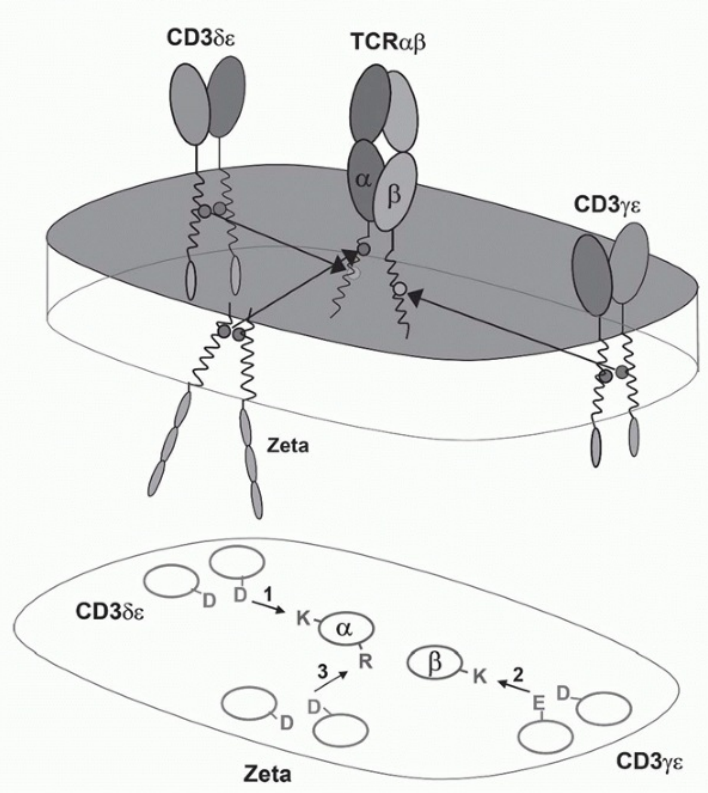

FIG. 11.3. A Model of the αβ T-Cell Receptor (TCR)-Cluster of Differentiation (CD)3 Complex. This shows the approximate positions of the αβ TCR chains and the CD3α, δ, ε, and ζ chains based on the membrane reconstitution and mutagenesis experiments of Call and Wucherpfennig.[55] More recent experiments suggest that the CD3 polypeptides may be somewhat more clustered on the side of the TCR heterodimer.[299]

The composition of TCR/CD3 complexes on γδ T cells is distinct from that of αβ T cells and changes with the activation state of the cell. Biochemical analysis showed that most murine γδ TCRs contain only CD3 γε dimers. Interestingly, a differentially glycosylated form of CD3 γ was found to associated with γδ TCRs dependent on the activation state of the cells.[76] In addition, while C3ζζ is incorporated into the complexes of naïve cells, activation results in the expression and incorporation of $F_c\varepsilon RI$ γ into the γδTCR complex.[76] Using quantitative immunofluorescence, Hayes and Love have derived data and proposed a model of murine γδTCR stoichiometry in which there are two CD3γε dimers, as well as one CD3ζ dimer in each TCR complex.[77] Taken together, these findings strongly suggest that signal transduction through the TCR will occur differently in γδ versus αβ T cells.

T-CELL RECEPTOR GENES

As shown in Figure 11.4, TCR gene segments are organized similarly to those of Igs and the same recombination machinery is responsible for joining separate V and D segments to a particular J and C. This was initially indicated by the fact that the characteristic seven and nine nucleotide conserved sequences adjacent to the V, D, and J regions with the 12 or 23 nucleotide spacing between them, first described for Ig genes, are also present in TCRs.[78] The most conclusive evidence of this common rearrangement mechanism is that both a naturally occurring recombination-deficient mouse strain (severe combined immune deficiency[79]) and mice engineered to lack recombinase activating genes 1[80] or 2[81] are unable to rearrange either *TCR* or Ig gene segments properly. Many of the other molecules

involved in Ig gene rearrangement serve the same function in TCRs as well.[82] As with Igs, if the V region and J region gene segments are in the same transcriptional orientation, the intervening DNA is deleted during recombination. DNA circles of such material can be observed in the thymus,[83,84] the principal site of TCR recombination (see the following). In the case of *TCR-β* and *TCR-δ*, there is a single V region 3' to the C in the opposite transcriptional orientation to J and C. Thus, rearrangement to these gene segments occurs via an inversion. Variable points of joining are seen along the *V, D*, and *J* gene segments as well as random nucleotide addition (N regions) in postnatal TCRs. The addition of several nucleotides in an inverted repeat pattern, referred to a P element insertion, at the V-J junction of the TCR-γ chains has also been observed.[85]

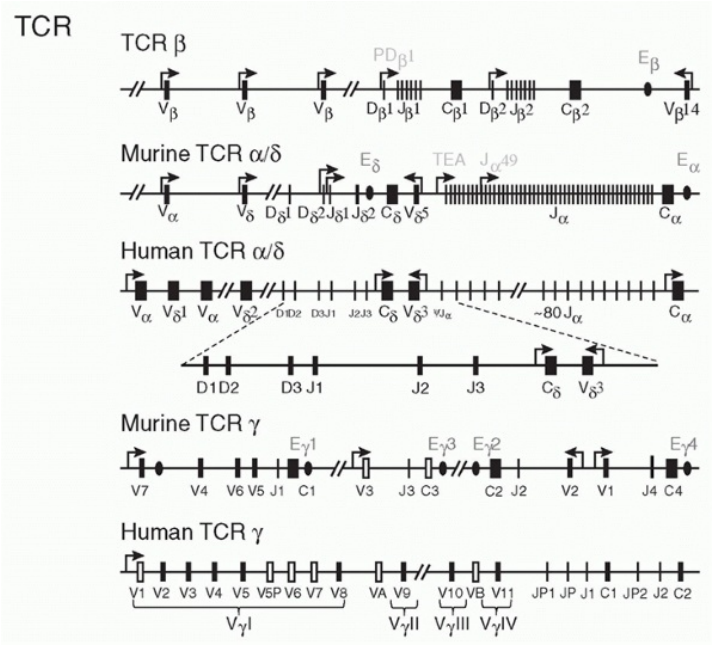

FIG. 11.4. T-Cell Receptor Gene Organization in Mice and Humans. Schematic of V, D, J, and C elements of the T-cell receptor genes. Transcriptional orientation is from *left to right*, except where noted. *E* designates enhancer elements, and *S* are silencer elements.

Organization of the T-Cell Receptor α/δ Locus

In humans and in mice, there is a single α-chain C-region gene that is composed of four exons encoding: 1) the constant region domain, 2) 16 amino acids including the cysteine that forms the interchain disulfide bond, 3) the transmembrane and intracytoplasmic domains, and 4) the 3' untranslated region (see Fig. 11.4). The entire α/δ locus spans about 1.1 MB in both mice and humans. There are 50 different J-region gene segments upstream of the C-region in the murine locus. At least eight of these J-regions are nonfunctional because of in-frame stop codons or rearrangement and splicing signals that are likely to be defective. A similar number of α-chain J-regions are present in the human locus. This very large number of J-regions compared to the Ig loci may indicate that

the functional diversity contributed by the J segment of the TCR (which constitutes a major portion of the complementarity-determining region [CDR]3 loop) makes an important contribution to antigen recognition (see the following).

In both the murine and human loci, the Cδ, Jδ, and two Dδ gene segments are located between the Vα and Jα gene segments. In the murine system, there are two Jδ and two Dδ gene segments on the 5' side of Cδ and the Cδ exons are approximately 75 kb upstream of the Cα gene and approximately 8 kb upstream of the most 5' known Jα gene segments. The human organization is similar, with three Dα gene segments and three Jδs. Surprisingly, in both species all of the D elements can be used in one rearranged gene rather than

alternating as is the case with TCR-β or IgH. That is, in mice one frequently finds Vδ D_1, D_2, and Jδ rearrangements,[86] and in humans Vδ, D_1, D_2, D_3, and Jδ.[87] This greatly increases the junctional or CDR3 diversity that is available, especially because of the potential for N-region addition in between each gene segment. This property makes TCR-δ the most diverse of any of the antigens receptors known, with approximately 10^{12} to 10^{13} different amino acid sequences in a relatively small (10 to 15 amino acid) region.[86] The implications for this and comparisons with other antigen receptor genes are discussed subsequently.

The location of Dδ, Jδ, and Cδ genes between Vα and Jα gene segments suggests that TCR-δ and -α could share the same pool of V gene segments. While there is some overlap in V gene usage, in the murine system, four of the commonly used Vδ genes (Vδ1, Vδ2, Vδ4, Vδ5) are very different than known Vα sequences and they have not been found to associate with Cα.[88] The other four Vδ gene families overlap with or are identical to Vα subfamilies (Vδ3, Vδ6, Vδ7, and Vδ8, with Vα6, Vα7, Vα4, and Vα11, respectively).

The mechanisms that account for the preferential usage of certain gene segments to produce δ versus α chain are not known. While some Vδ genes are located closer to the Dδ and Jδ fragments than Vα genes (such as Vδ1), other Vδs (such as Vδ6) are rarely deleted by Vα Jα rearrangements and thus seem likely to be located 5' of many Vα gene segments.

One of the Vδ gene segments, Vδ5, is located approximately 2.5 kb to the 3' of Cδ in the opposite transcriptional orientation and rearranges by inversion. Despite its close proximity to Dδ Jδ gene segments, Vδ5 is not often found in fetal γδ T cells. Instead, the Vδ5 → DJδ rearrangement predominates in adult γδ T cells.

An implicit characteristic of the α/δ gene locus is that a rearrangement of Vα to Jα deletes the entire D-J-C core of the δ-chain locus. In many αβ T cells, the α-chain locus is rearranged on both chromosomes and thus no TCR δ could be made. In most cases, this is due to Vα → Jα rearrangement, but evidence suggesting an intermediate step in the deletion of TCR-δ has been reported.[89] This involves rearrangements of an element termed T early alpha (TEA) to a pseudo-Jα 3' of Cδ. The rearrangement of TEA to this psuedo-Jα would eliminate the δ-chain locus in αβ T cells. Gene targeting of the TEA element resulted in normal levels of αβ and γδ T cells, but usage of the most Jαs was severely restricted,[90] suggesting that its function is to govern the accessibility of the most proximal 5' Jαs for recombination.

Organization of the T-Cell Receptor β Locus

The entire human 685 kb β chain gene locus was originally sequenced by Hood and coworkers[91] (Fig. 11.5). One interesting feature is the tandem nature of *Jβ-Cβ* in the *TCR-β* locus. This arrangement is preserved in all higher vertebrate species that have been characterized thus far (mouse, human, chicken, frog). The two *Cβ* coding sequences are identical in the mouse and nearly so in humans and other species. Thus it is unlikely that they represent two functionally distinct forms of *Cβ*. However, the *Jβ* clusters have relatively unique sequences, and thus this may be a mechanism for increasing the number of *Jβ* gene segments. Together with the large number of Jα gene segments, there is far more combinatorial diversity (Jα × Jβ = 50× 12=600) provided by J regions in αβ TCRs than in Igs.

Most of the V-regions are located upstream of the joining and constant regions and in the same transcriptional orientation as the D and J gene element, and rearrange to DβJβ gene via deletion. Similar to the case of Vδ5, a single Vβ gene, Vβ14 is located 3' to C-regions and in the opposite transcriptional orientation, thus rearrangements involving Vβ14 occur via inversion.

In the NZW strain of mouse, there is a deletion in the β chain locus that spans from Cβ1, up to and including the Jβ 2 cluster.[92] In SJL, C57BR and C57L mice, there is a large deletion[93] in the V-region locus from Vδ5-Vβ9. These mice

also express a V gene, Vβ17, that is not expressed in other strains of mice. Deletion of about half of the V genes (in SJL, C57BR and C57L mice) does not seem to have any particular effect on the ability of these mice to mount immune responses whereas mice that have deleted the *Jβ*2 cluster show impaired responses.[94]

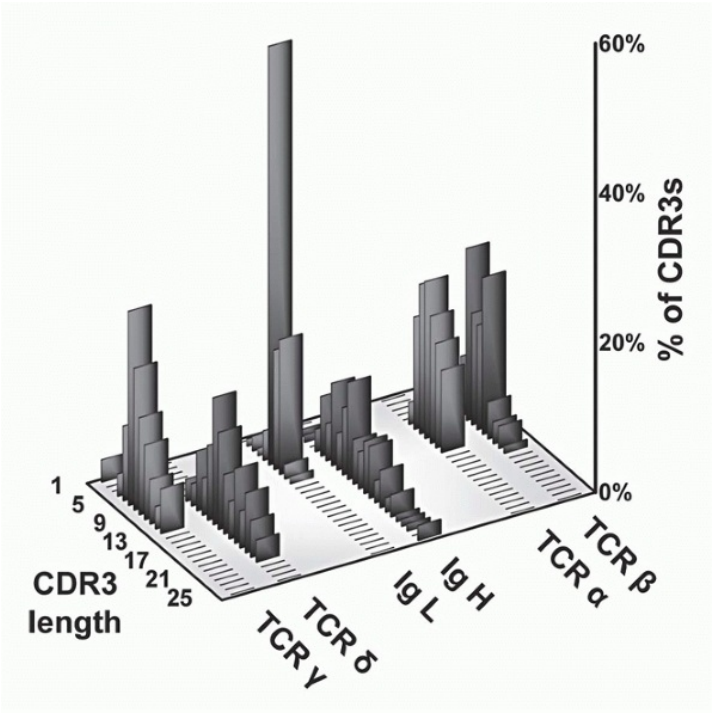

FIG. 11.5. Complementarity-Determining Region (CDR)3 Length Analysis of T-Cell Receptor (TCR) Polypeptides versus Immunoglobulin (Ig) Heavy and Light Chains. These data, modified from Rock et al.,[129] show that whereas TCR-α and -β CDR3 regions are relatively uniform with respect to each other, the other antigen receptor pairs show a marked asymmetry. Specifically, both Ig light chains (κ and λ) show very short CDR3s, as do TCR-γ chains. In contrast, both IgH and TCR *S* TCRs are quite heterogeneous and tend to be longer. These data suggests that γδ TCRs have a more antibody-like structure and binding properties. This has been borne out by subsequent analysis (see text).

Organization of the T-Cell Receptor γ Locus

The organization of the mouse and human γ-chain loci are shown in Figure 11.4. The human γ genes span about 150 kb[85] and are organized in a fashion similar to that of the β chain locus with two JγCγ regions. There is more than one nomenclature commonly used to describe the γ chain genes.[85,96,97,98] Here, we use that of Lefranc and Rabbitts[99] and Tonegawa and colleagues[85] for the human and mouse γ chains, respectively. The organization of the human γ chain genes consists an array of Vγs in which at least six of the V-regions are pseudogenes is located 5' to these JγCγ clusters, and each of the V genes are potentially capable of rearranging to any of the five J-regions. The sequences of the two human Cγ regions are very similar overall and only differ significantly in the second exon. In Cγ2, this exon is duplicated two or three times and the cysteine that forms in the interchain disulfide bond is absent. Thus, Cγ2-bearing human T cells have an extra large γ-chain (55,000 MW) that is not disulfide bonded to its δ-chain partner.

The organization of the murine γ chain genes is very different than that of the human genes in that there are three separate rearranging loci that span about 205 kb.[100,101] Of four murine Cγ genes, Cγ3 is apparently a pseudogene in BALB/c mice, and the Jγ3 Cγ3 region is deleted in several mouse strains including C57 Bl/10. Cγl and Cγ2 are very similar in coding sequences. The major differences between these two genes is in the five amino acid deletion in the Cγ2 gene that is located in the C ll exon at the amino acid terminal of the cysteine residue used for the disulfide formation with the δ chain. The Cγ4 gene differs significantly in sequences from the other Cγ genes (in 66% overall amino acid identity). In addition, the Cγ4 sequences contains a 17 amino acid insertion (compared to Cγ1) in the C ll exon located at

similar position to the five amino acid deletions in the Cγ2 gene.[101a] Each Cγ gene is associated with a single Jγ gene segment. The sequences of Jγ1 and Jγ2 are identical at the amino acid level, whereas Jγ4 differs from Jγ1 and Jγ2 at 9 out of 19 amino acid residues.

The murine Vγ genes usually rearrange to the Jγ Cγ gene that is most proximal and in the same transcriptional orientation. Thus Vγ1 rearranges to Jγ4; Vγ2 to Jγ2; and Vγ4, Vγ5, Vγ6, and Vγ7 to Jγ1. Interestingly, some Vγ genes are rearranged and expressed preferentially during γδ T-cell ontogeny and in different adult tissues as well.[101] In particular, Vγ5+ and Vγ6+ T cells are generated in the fetal thymus with very limited/no junctional diversity. Instead, the adult thymus produces γδ T cells expressing Vγ1, Vγ2, Vγ4, and Vγ7 gene segments with highly diverse junctional sequences. Moreover, γδ T cells that localize to the secondary lymphoid organs tend to express Vγ4, Vγ1, and Vγ2, whereas those that localize to the intestinal epithelium express Vγ7.[88,102,103,104,105,106] There are also reports suggesting that some intestinal epithelial γδ T cells develop extrathymically.[107] Regardless, it has been suggested that the Vγ gene rearrangement is a programmed process.[108,109]

Control of Transcription and Rearrangement

It has become increasingly apparent that transcriptional accessibility and rearrangement of TCR and Igloci are closely linked, following the early work of Alt and Yancopoulous.[110] Factors governing accessibility and rearrangement include histone methylation,[111,112,113,114] DNA methlyation, and the presence of enhancer and specific promoter elements.[115] Even specific variations in the recombination signal sequences have been shown to elicit specific biases in V(D)J joining.[86] With respect to enhancer elements in the TCR loci, these were first identified in the TCR-β locus, 3' of Cβ2,[116,117] and subsequently for the other TCR loci as well,[115] as indicated in Figure 11.4. These TCR enhancers all share sequence similarities with each other. Some of the transcriptional factors that bind to the TCR genes are also found to regulate Ig gene expressions. It has been shown that TCR-α enhancer (Eα) is not only important for normal rearrangement and expression for the α chain locus but also is required for the normal expression level of mature TCR-δ transcripts.[118] Also interesting is the work of Lauzurica and Krangel,[119,120] who have shown that a human TCR-δ enhancer-containing minilocus in transgenic mice is able to rearrange equally well in αβ T cells as in αδ T cells but that an Eα-containing construct was only active in αβ lineage T cells. Similar to Ig genes, promoter sequences are located 5' to the V gene segments. Although D → J_β rearrangement and transcription occur fairly often in B cells and in B-cell tumors,[121] V_β rearrangement and/or transcription appears highly specific to T cells. In addition to enhancers, there also appear to be "silencer" sequences 3' of C α[122,123] and in the Cγ1 locus.[124] It has been suggested that these "repressor sites" could turn off the expression of either of these genes, influencing T-cell differentiation toward either the αβ or the γδ T-cell lineage.

The murine TCR Cγ1 gene cluster comprises four closely linked Vγ gene segments, in the order Vγ7, 4, 6, and 5, which rearrange to a single common downstream J gene segment, Jγ1 (see Fig. 11.4). In early fetal thymocytes, rearrangements of Vγ5 and Vγ6 genes predominate, and the resulting Vγ3+ and Vg4+ cells migrate to the skin or reproductive tissue, respectively. Later in ontogeny, Vγ4 and Vγ7 rearrangements predominate, and cells expressing these V regions migrate from the adult thymus to the secondary lymphoid organs and the intestinal epithelium.[100,101] At least two *cis*-acting, enhancer/locus control region (LCR) elements are present in the Cγ1 cluster. One is a T cell-specific transcriptional enhancer, 3γEγ, located 3 kb downstream of the Cγ1 gene segment.[125] A second element, "has," was found between the Vγ7 and Vγ4 genes, based on DNAse I hypersensitivity.[126] Similar enhancers have also been found to be associated with the Cγ2 and Cγ3 genes.[95] Experiments suggest that simultaneous deletion of both enhancer elements in Cγ1 cluster severely diminishes TCR-γ transcription, but only modestly reduces TCR-γ gene rearrangement, while deletion of each element

separately has little effect.[127] In contrast to these results in thymocytes, deletion of "has"

alone reduces transcription of one Vγ gene specifically in peripheral γδ T cells. Thus, the two elements not only exhibit functional redundancy in thymocytes but also have unique functions in other settings.

Allelic Exclusion

In Igs, normally only one allele of the heavy chain locus and one of the light chain alleles is productively rearranged and expressed, a phenomenon termed "allelic exclusion." With respect to αβ TCR expression, while TCR-β exhibits allelic exclusion,[128] TCR-α seems much less constrained,[129,130] and many mature T cells express two functional TCR-α chains. As the chances of forming an in-frame joint with any antigen receptor is only one in three, the probability that a T cell would have two productively rearranged TCRαs is only 1/3 × 1/3 = 1/9, or 11%. However, even when this happens, the two TCR-α chains may not form heterodimers equally well with the single TCR-β that is expressed; thus, only one heterodimer may be expressed. But this simple calculation is complicated by the likelihood that only thymocytes that make at least one productive TCR rearrangement of each type will have a chance at maturation, which would eliminate almost half of the T cells (four-ninths, which is the product of a two-thirds chance of failure on one chromosome, followed by the same failure rate on the second). Secondly, it has been found that there is a mechanism called receptor editing, which means that a given rearrangement that is not productive, either because of an out-of-frame joint or for reasons of self reactivity, can induce a V region further 5' or "upstream" of the initial VJ joint to rearrange to one of the remaining Jas.[131] In any event, it has been reported that one-third of human T cells express two TCRs,[132] which is slightly higher than what is expected from the probabilities discussed previously (approximately 20%), perhaps reflecting the effect of receptor editing.

There also appears to be an important role for the pre-TCR heterodimer (eg, pre-Tα:TCR-β) in blocking further TCR-β rearrangement and thus ensuring allelic exclusion at that locus.[133,134] In particular, pre-Tα-deficient mice had a significant increase in the number of cells with two productive TCR=β rearrangements, compared with wildtype mice.[133]

T-Cell Receptor Diversity

Although the basic organization and V(D)J recombination machinery are shared between TCR loci and Igs, there are a number of striking differences. One of these is somatic hypermutation. In antibodies, this form of mutation typically raises the affinities of antigen specific Igs several order of magnitude, typically from the micromolar (10^{-6} M) to the nanomolar (10^{-9} M) range.[135,136] We now know that most cellsurface receptors that bind ligands on other cell surfaces, including TCRs, typically have affinities in the micromolar range (see later section) but that they compensate for this relatively low affinity by engaging multiple receptors simultaneously (eg, increasing the valency) and by functioning in a confined, largely two-dimensional volume (eg, between two cells). Cells employing such receptors require weak, but highly specific, interactions so that they can disengage quickly.[137,138] The rapid off-rates seen with TCRs (see later section) may even amplify the effects of small numbers of ligands.[139,140]

There has also been no enduring evidence for a naturally secreted form of either an αβ or γδ TCR. Here again, it can be argued that such a molecule would have no obvious use as the affinities are too low to be very useful in solution. Thus, for most TCRs, the concentration of protein would have to be extremely high in order to achieve an effect similar to soluble antibodies (in the milligram/milliliter range).

A third mechanism seen in antibodies but not TCRs is C_H switching, which allows different Ig isotypes to maintain a given V region specificity and associate it with different constant regions that have different properties in solution (such as complement fixation, basophil binding, etc.). As there is no secreted form of the TCR, this feature would also lack any obvious utility.

Where TCRs are equal—and in fact generally superior— to Igs is in the sheer number of possible receptors that can be generated through recombination alone. Table 11.1 summarizes the potential V region diversity that TCRs are capable of when the number of V region gene segments is multiplied by D, J, and N region diversity. It can be seen from this

table that while the V region number is generally lower in murine TCRs, particularly TCR-δ and TCR-γ, this is more than compensated for by the degree of junctional diversity (where V and J or V, D, and J come together) and chain combinations, such that overall TCRs have orders of magnitude greater potential diversity than Igs. This junctional region corresponds to CDR3 as originally defined by Kabat and Wu for Igs.[141] With respect to αβ TCRs, the concentration of diversity in this region (in both chains) can be explained by the key role that these sequences play in recognizing diverse peptides in MHC molecules (see later section), as supported by mutagenesis and structural studies. For γδ TCRs and Igs, however, the diversity is almost all in just one chain (TCRδ and IgH, respectively), and the implications of this are discussed subsequently. Recent work using high throughput sequencing techniques are in remarkable agreement with these crude early estimates of TCR-β diversity.[142]

The Complementarity-Determining Region 3 Length Distributions of γδ T-Cell Receptors are More Similar to Those of Immunoglobulin than to Those of αβ T-Cell Receptors

Because CDR regions are loops between different β strands of an Ig or TCR V region (see later section), the configurations they adopt are generally very sensitive to their length, such that a difference of even one amino acid may produce a significant change in the overall structure.[3,143] A comparison of CDR3 length distributions between the αβ TCRs, γδ TCRs, and Igs (see Fig. 11.5)[144,145] showed that those of TCR-α and -β have a very constrained distribution of lengths and that these are nearly identical in size. These length constraints may reflect a requirement for both the α

and β chains of TCRs to contact both the MHC molecules and bound peptides on the same plane, as borne out by structural studies (see later section). In contrast, the CDR3s of Ig heavy chains are long and variable, whereas those of Ig light chains are short and constrained. This may reflect the fact that Igs recognize both very small molecules (eg, haptens) as well as very large ones (eg, proteins). Surprisingly, γδ TCR CDR3 length distributions are similar to those of Igs in that the CDR3 lengths of TCR-δ chains are long and variable, whereas those of the TCR γ chains are short and constrained. Thus, on the basis of this measure of ligand recognition, one might expect γδ TCRs to be more similar to Igs than to αβ TCRs. This has been validated in subsequent biochemical and structural studies (see later sections).

TABLE 11.1 Sequence Diversity in T-Cell Receptor and Immunoglobin Genes

	Immunoglobulin		**TCR-α/β**		**TCR-γ/δ**	
	H	**κ**	**α**	**β**	**γ**	**δ**
Variable segments	250-1,000	250	100	25	7	10
Diversity segments	10	0	0	2	0	2
Ds read in all frames	Rarely	—	—	Often	—	Often
N-region addition	V-D, V-J	none	V-J	V-D, V-J	V-J	V-D1, D1-D2, D1-J
Joining segments	4	4	50	12	2	2
Variable region combinations	62,500-250,000		2,500		70	
Junctional						

combinations	~10^{11}	~10^{15}	~10^{18}

Calculated potential amino acid sequence diversity in TCR and immunoglobulin genes without allowance for somatic mutation. The approximate number of V gene segments are listed for the four TCR polypeptides and contrasted with immunoglobulin heavy and light chains. CDR1 and CDR2 are encoded within the V gene segments. The pairing of random V regions generates the combinatorial diversity listed as "variable region combinations." Because there are fewer TCR V gene segments than immunoglobulin V gene segments, the combinatorial diversity is lower in TCRs than in immunoglobulins. Estimates for the number of unique sequences possible within the junctional region are contrasted for TCRs and immunoglobulins. Amino acids within CDR3 are encoded almost entirely within the D and/or J region gene segments. (The last few amino acids encoded by a TCR V gene segment can contribute to diversity within the TCR CDR3-equivalent region, but the effects of these residues on junctional diversity are not included in these calculations.) The mechanisms for generation of diversity within the junctional region that are used for this calculation include usage of different D and J gene segments. N region addition up to six nucleotides at each junction, variability in the 3' joining position in V and J gene segments, and translation of D region in different reading frames. Numbers are corrected for out-of-frame joining codon redundancy and N-region mimicry of germ-line sequences. Modified from Elliott et al.[86]

CDR, complementarity-determining region; TCR, T-cell receptor.

Chromosomal Translocations and Disease

The chromosomal locations of the different TCR loci have been delineated in both mouse and humans, and the results are summarized in Table 11.2. One significant factor in cancers of hematopoietic cells are chromosomal translocations that result in the activation of genes normally turned off or the inactivation of genes that are normally turned on. Thus, B- or T-lymphocyte neoplasia is frequently associated with inter- or intrachromosomal rearrangements of Ig or TCR loci or in some cases both.[146,147]

These translocations seem to mediated by the V(D)J recombinase machinery, indicating the inherent danger and need for tight regulation of this pathway. Such rearrangements are particularly common in the α/δ locus, perhaps because this locus spans the longest developmental window in terms of gene expression, with *TCR-δ* being the first and *TCR-α* the last gene to rearrange during T-cell ontogeny (as discussed in more detail in the following). In addition, the α/δ locus is in excess of 1 mb in size, and this provides a larger target for rearrangement than either TCR-β or TCR-γ. Interestingly, in humans, *TCR-α/δ* is on the same chromosome as the *IgH* locus and $V_H \rightarrow J_\alpha$ rearrangements (by inversion) have been observed in some human tumor material.[148,149] The functional significance of this is not known.

Particularly frequent is the chromosome 8-14 translocation [t(8;14) (q24;q11)] that joins the α/δ locus to the c-myc gene, analogous to the c-myc → IgH translocation in many mouse myeloma tumors and in Burkitt lymphomas in humans. In one cell line, a rearrangement occurred between the Jα-region coding sequences, and a region 3' of c-myc.[150] In both B- and T-cell malignancies, the translocation of c-myc into IgH or TCR-α/β appears to increase the expression of c-myc and may be a major factor in the unregulated cell growth that characterizes cancerous cells. Other

putative proto-oncogenes that have been found translocated into the TCR-α/β locus are the LIM domain-containing transcription factors Ttg-1[151] and Ttg-2,[152,153] which are involved in neural development; the helix-loop-helix proteins Lyl-1[154] and Scl,[155] which are involved in early hematopoietic development; and the homeobox gene Hox 11,[156] which is normally active in the liver. How these particular translocations contribute to malignancy is unknown, but they presumably causes aberrations in gene expression that contribute to cell growth or escape from normal regulation. In patients with T-cell leukemia infected with the human T-cell

lymphotrophic-I virus, there are large numbers of similar translocations; it is thought that human T-cell lymphotrophic-I itself is not directly leukemogenic but acts by causing aberrant rearrangements in the T cell that it infects, some of which become malignant.

TABLE 11.2 Chromosomal Locations of T-Cell Receptor, Immunoglobulin, and Related Loci in Mouse and Human

	Mouse Chromosome	Human Chromosome
TCR-α	14	14(q11-q12)
TCR-δ	14	14(q11-q12)
IgH	12	14(qter)
TCR-β	6	7(q35)
CD4	6	12
CD8	6	2(p11)
Igκ	6	62(p12)
TCR-γ	13	7(p14)
CD3-γ	9	11(q23)
CD3-δ	9	11(q23)
CD3-ε	9	11(q23)
CD3-ζ	1	1
Thy-1	9	11(q23)
Ig-λ	16	22(q11.2)
MHC	17	6(p21)
Pre-Tα	17	6

CDR, complementarity-determining region; Ig, immunoglobulin; MHC, major histocompatibility complex; TCR, T-cell receptor.

Another disorder, which frequently associates with TCR and Ig locus translocation, is ataxia telangiectasia, an autosomal recessive disorder characterized by ataxia, vascular telangiectasis, immunodeficiency, increased incidence of neoplasia, and an increased sensitivity to ionizing radiation. Peripheral blood lymphocytes from patients with ataxia telangiectasia have an especially high frequency of translocations involving chromosomes 7 and 14.[157] These sites correspond to the TCR-γ, -β, and -α loci, and the Ig heavy chain locus. Thus, it appears as though one of the characteristics of patients with ataxia telangiectasia is a relatively error-prone rearrangement process that indiscriminately recombines genes that have the TCR and Ig rearrangement signals.[158]

The Structure of αβ and γ δ T-Cell Receptors

As discussed previously, the sequences of TCR polypeptides show many similarities to Igs, and thus it has long been suggested that both αβ and γδ heterodimers would be antibodylike in structure.[24,25,159] The similarities between TCRs and Igs include the number and spacing of specific cysteine residues within domains, which in antibodies form intrachain disulfide bonds. Also conserved are many of the inter- and intradomain contact residues and, in addition, secondary structure predictions are largely consistent with an Ig-like "β barrel" structure. This consists of three to four antiparallel β strands on one side of the "barrel" facing a similar number on the other side, with a disulfide bridge (usually) connecting the two β "sheets" (sets of β strands in the same plane). All Ig variable and constant region domains have this structure, with slight variations in the number of β strands in variable region domains (by convention including V, D, and J sequences) compared with constant domains.

α β T-Cell Receptor Structure

Efforts to derive x-ray crystal structures of TCR heterodimers and fragments of heterodimers presented many technical hurdles.[160] One difficulty is that structure determination required engineering the molecules into a soluble form. A second problem is that many of the TCRs are heavily glycosylated, and it was necessary to eliminate most or all of the carbohydrates on each chain to achieve highquality crystals. An alternative is to express soluble TCRs in insect cells, where they have compact N-linked sugars, or in *Escherichia coli*, where they are unglycosylated. The first successes in TCR crystallization come from the laboratory of Mariuzza and collaborators who solved the structure of first a Vβ Cβ polypeptide[161] and then a Vα fragment.[162] In the following year, the first complete αβ TCR structures were solved.[163,164] The structure of the 2C TCR, by Garcia and colleagues, is shown in Figure 11.6.[163] In general, as predicted from sequence homologies, these domains are all Iglike, with the classical β-barrel structure in evidence in all three domains. At each end of the barrel in each V-region domain there are four loops between the β sheets, three of which form the CDRs of Igs, which are numbered in Figure 11.6. The fourth loop, between the D and E strands, has been implicated in superantigen binding. The six CDR loops from the two variable domains form the antigenbinding surface in both Igs and TCRs. The major anomaly in terms of similarity of TCRs to Igs is the structure of the Cα.[165] Cα consists of one-half of the classical β-barrel, that is, one set (or "sheet") of β strands while the rest of the partially truncated domain exhibits random coils. This type of structure is unprecedented in the Ig gene family. The functional significance of such a variant structure in unknown, but it has been suggested that this incompletely formed Iglike domain may be responsible for the observed lability of TCR-α, and this may allow greater flexibility in the regulation of its expression. Another possible explanation is that this configuration is designed to accommodate one or more of the CD3 molecules.

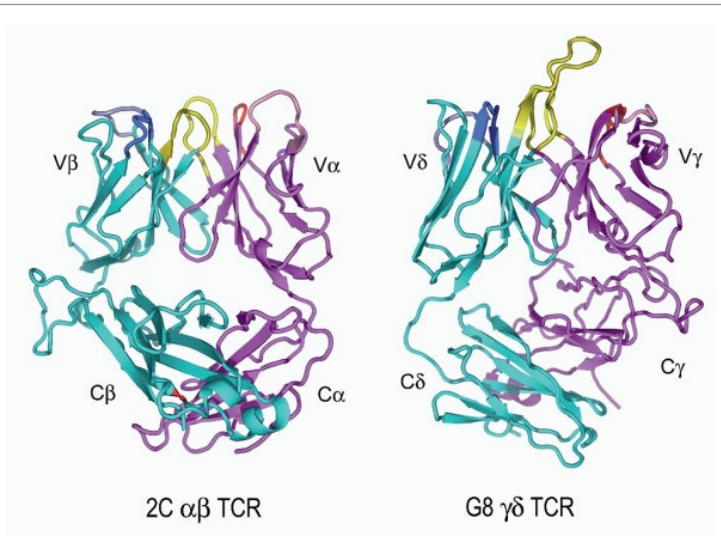

FIG. 11.6. Ribbon Diagrams of the T-Cell Receptor (TCR) Structures. This shows

the structures of the 2Cαβ TCR[150] versus the G8γδ TCR.[153] The TCR-β and the -γ chains are in *cyan*, and the TCR-α and -γ chains are in *vermillion*. The complementarity-determining regions (CDRs) of both are in *yellow*. The very long TCR-δ CDR3 in G8, which binds the T10/T22 ligands, is very apparent here but is shorter in most other γδ TCRs. Note the different C-region interactions with these TCRs and the deviations from the classic "β barrel" structure in both Cα and Cδ. The prominent Cβ loop to the left is also unusual and may mediate interactions with CD3 or other molecules on the T cell surface. (Figure courtesy of Dr. K.C. Garcia)

The now large number of solved αβ TCR structures can be compared to the three γδ heterodimers (discussed in more detail in the following), and while these also resemble the Fab fragment of an antibody, there are several features that are unique to the αβ molecules, which may be significant. These include the following:

1. In one structure,[165] four out of seven N-linked sugars diffracted to high resolution, indicating that they are not free to move very much and thus are likely to play a structural role, particularly in Cα:Cβ interactions. This correlates with mutagenesis data indicating that certain Cα sugars cannot be eliminated without abolishing protein expression[166] and the disordered state of a Cα domain in the structure of a TCR lacking glycosylation.[164]
2. There is significantly more contact between Vβ and Cβ and between Vα and Cα than in the equivalent regions of antibodies.
3. The geometry of the interaction of Vα and Vβ more closely resembles that of the C_H3 domains of antibodies than V_HV_L.
4. Between the CDR3 loops of Vα and Vβ, there is a pocket that can (and does in at least one case[165]) accommodate a large side chain from the peptide bound to an MHC.

γδ T-Cell Receptor Structure

There are now three γδ heterodimer structures: a γδ TCR from a human T-cell clone G115,[167] which can be activated by natural or synthetic pyrophosphomonoesters, a γδ TCR from the murine T cell clone G8 together with its ligand, the nonclassical MHC class I molecule T22,[168] and a human MHC class I chain-related-reactive γδ TCR (δ1A/B-3),[169a] which was determined as a single-chain Fv construct. The G8 structure is shown in Figure 11.6, alongside the 2C αβ TCR. The structure of a single human Vδ domain also has been determined.[169] The Vδ domain of the G115 structure is similar to the isolated Vδ domain and the quaternary structure of G8 is similar to that of G115.[168]

The most distinctive feature of both the G115 and the G8 TCR, when compared with αβ TCRs and Igs, is that the C domains "swing out" from under the V domains. This unusual shape is highlighted by both a small elbow angle of 110 degrees, defined as the angle between the pseudo twofold symmetry axes that relate V to V and C to C, and a small V-C interdomain angle. This contrasts with an average of 149 degrees for αβ TCR structures. The small angle between the Vγ and Cγ domains shifts both Cδ and Cγ to one side. Moreover, the molecular surfaces of the constant domains are different than those of αβ TCRs with no clear similarities either in the shape or the nature of the CαCβ and CγCδ surfaces; there are only a few solvent-exposed residues that are conserved in both Cβ and Cγ domains as well. Thus, it is unclear where or how the extracellular domains of the CD3 subunits interact with the extracellular portions of γδ TCRs compared with αβ TCRs. This may explain why the CD3 components of αβ TCRs are so different from those of γδ TCRs.

In terms of ligand binding surfaces, we note that the Vδ CDR3 of G8 protrudes significantly away from the other CDRs, as shown in Figure 11.6. This has significance in that this is the major region of contact with the T22 ligand (see later section). In the case of G115, both Vδ and Vγ CDR3 loops protrude from the rest of the putative binding surface and create a cleft between them. Portions of the CDR1γ and δ and CDR2γ combine with the clefts between the CDR3 loops to form a pocket, which is surrounded by positively charged amino acid residues contributed by CDR2γ and δ, and CDR3γ. The jagged surface of this TCR resembles the

surface of an antibody that binds a small-molecule antigen. Although this would be consistent with the supposition that this TCR binds the negatively charged phosphate compounds,[170] direct binding between the TCR and phosphoantigen including crystal-soaking and cocrystallization experiments have not been successful. Instead, a soluble G115 was found to bind a soluble form of adenotriphosphate (ATP) synthase F1 and apolipoprotein A-1.[171]

While the δ1A/B-3 TCR maintains an overall fold similar to the other γδ TCR structures, it was noted that unlike the G115 and G8 CDR3 regions, which are protruding out, the δ1A/B-3 CDR loops together generate a nearly flat surface on the combining site. This difference is anticipated, as the CDR3 length distribution of the TCRδ chains is quite variable as discussed previously, and like antibodies should have a broad range of binding site shapes.

αβ T-CELL RECEPTOR-LIGAND RECOGNITION

Binding Characteristics

Although it has long been established that this type of T cell generally recognizes a peptide bound to an MHC molecule, a formal biochemical demonstration that this was due to TCR binding to a peptide/MHC complex took many years to establish. Part of the difficulty in obtaining measurements of this type has been the intrinsically membrane-bound nature of MHC and TCR molecules. Another major problem is that the affinities are relatively low, in the micromolar range, which is too unstable to measure by conventional means.

To some extent, the problem of measuring the interactions of membrane-bound molecules can be circumvented by expressing soluble forms of TCR and MHC, which is also essential for structural studies (see previous discussion). For TCRs, many successful strategies have been described, including replacing the transmembrane regions with signal sequences for glycolipid linkage,[172] expressing chains without transmembrane regions in either insect or mammalian cells,[173] or a combination of cysteine mutagenesis and *E. coli* expression.[164] Unfortunately, no one method seems to work for all TCR heterodimers, although the combination of insect cell expression and leucine zippers at the c-terminus to stabilize heterodimer expression has been successful in many cases.[174] The production of soluble forms of MHC molecule has a much longer history, starting with the enzymatic cleavage of detergent solubilized native molecules[175] as well as some of the same methods employed for TCR such as glycophosphatidylinositol (GPI) linkage,[176] *E. coli* expression and refolding,[177,178] and insect cell expression of truncated

(or leucine zippered) molecules.[179] One interesting variant that seems necessary for the stable expression of some class II MHC molecules in insect cells has been the addition of a covalent peptide to the N-terminus of the β chain.[180]

The first measurements of TCR affinities binding to peptide/MHC complexes were performed by Matsui et al.[181] and Weber et al.[182] Matsui and colleagues used a high concentration of soluble peptide/MHC complexes to block the binding of a labeled anti-TCR Fab fragment to T cells specific for those complexes, obtaining an equilibrium binding affinity (K_d) value of approximately 50μM for several different T cells and two different cytochrome peptide/I-E^k complexes (as shown in Table 11.3). Weber and colleagues used a soluble TCR to inhibit the recognition of a flu peptide/I-E^d complex by a T cell and obtained a K_D value of approximately 10 μM. While these measurements were an important start in TCR biochemistry, they gave no direct information about the kinetics of TCR-ligand interactions. Fortunately, the development of surface plasmon resonance instruments, particularly the BIAcore™ (Pharmacia Biosensor, Uppsala, Sweden) with its remarkable sensitivity to weak macromolecular interactions,[183] has allowed rapid progress in this area. In this technique, one component is covalently crosslinked to a surface and then buffer containing the ligand is passed in solution over it. The binding of even approximately 5% of the surface-bound material is sufficient to cause a detectable change in the resonance state of gold electrons on the surface. This method allows the direct measurement of association and dissociation rates, that is, kinetic parameters, and also has the advantage of requiring neither cells nor radioactive labels. Recently, microcalorimetry has also been used to measure some TCR

ligand affinities; and these analyses have confirmed the surface plasmon resonance (SPR) values,[184] but do not allow kinetic measurements. These and other data[138,160] showed definitively that TCR and peptideloaded MHC molecules alone are able to interact and also that expression in a soluble form has not altered their ability to bind to each other. As shown in Table 11.3, SPR measurements show that while the on-rates of TCRs binding to peptide/MHC molecules vary from very slow (1,000 M sec) to moderately fast (200,000 M sec), their off-rates fall in a relatively narrow range (0.5 to 0.01 sec^{-1}) or a $t_{1/2}$ of 12 to 30 seconds at 25°C. This is in the general range of other membrane bound receptors that recognize membrane molecules on other cells,[137] but it has been noted that most TCRs have very slow on-rates,[138] which reflects a flexibility in the binding site that might help to foster cross-reactivity (see the following). In the case of a class I MHC-restricted TCR, 2C, this relatively fast off-rate may be stabilized (10-fold) if soluble CD8 is introduced,[165] but this result is controversial.[185] CD8 stabilization of TCR binding has been seen by Luescher et al. in cell-based TCR labeling assay[186]; however, no enhancement of TCR binding has been seen using soluble CD4[187] (see the following for more discussion of CD4 and CD8).

BIA1, TCR amine coupled; BIA2, TCR cysteine coupled; BIA3, MHC-peptide amine coupled in competition experiment; BIA4, TCR coupled by using H57 antibody and MHC coupled via amine chemistry; MHC, major histocompatibility complex; P, peptide; sol., soluble; TCR, T-cell receptor.

More recently, new methodologies have been utilized to measure TCR binding in its native state, that is, on a T-cell surface and interacting with peptide-MHC ligands on either an artificial bilayer[188] or on the surface of a red blood cell[189] "reporter." These types of measurements are important because studies of TCRs and peptide/MHCs binding in

solution only partially reflect what is happening between two membranes. This is because of the very severe constraints on binding that are present in this specialized environment. For one, it is likely that TCRs on T cells and peptide/MHCs on antigen-presenting cells are fixed into a fairly rigid alignment that maximizes their ability to bind to each other, as opposed to the same molecules in solution that are diffusing in all directions and for which only a fraction of collisions will result in a productive binding event. Secondly, binding is happening in a very small space/volume of liquid, making the effective concentration very high. While this environment is not strictly two-dimensional, Dustin and others have used this as a simplifying assumption with relative success. But a direct measurement of TCR affinity and kinetics has been made by Huppa and colleagues,[188] who used a fluorescent probe on an anti-TCR antibody to create a system in which this fluorophore could form a FRET pair with a complementary label on the c-terminus of the peptide that could emit photons of the appropriate wavelength only when the TCR bound its peptide-MHC ligand. This enabled precise measurements of the dissociation rate (koff) and affinity (KD) within an immunologic

synapse, and these measurements could also be used to estimate an average association rate (kon). Another advantage of these measurements is that they can be done at 37°C, whereas most of the SPR measurements cited previously were performed at 25°C due to instrument limitations. Dissociation rates at higher temperatures are significantly faster. As expected from the previous discussion, the association rate was greatly accelerated approximately 100× over the solution rate, presumably because of the ideal orientation of the TCR and peptide/MHC with respect to each other. Not expected was an accelerated dissociation rate of 4 to 10 times faster. This turns out to be a function of actin polymerization and depolymerization activity within the T cell, as shown dramatically in the actin dynamics studies of Vale and colleagues.[190] Once this was inhibited, the dissociation rates within the synapse were quite close to the solution values.[191] Still, it is worth noting that TCR binding to peptide/MHC is even more unstable within an active synapse than the solution measurements have suggested, with half lives of less than 1 second in many cases.

A second experimental system that has been applied to the question of TCR binding in the context of cell-cell contact has been that of Chung and colleagues,[189] in which red blood cells coated with peptide-MHC complexes are brought into repeated contact with a T cell of the appropriate specificity. By visualizing the response of the peptide/MHC-coated red blood cell to different frequencies and durations of T-cell contact, one can infer parameters of TCR affinity, at least in the two-dimensional aspect.[192] While this system has worked well in describing integrin binding, it is indirect and it some ways contradicts results obtained with the FRET system of Huppa et al.[188] and even some of the basic properties determined in solution measurements. Nonetheless, it may be telling us important properties of cell-cell contact that are more difficult to discern with more directly molecular methods.

To what extent are we now able to predict a T-cell response based on the binding characteristic of its TCR to a ligand? One of the most intriguing discoveries concerning T-cell reactivity has been the phenomenon of altered peptide ligands. These are single amino acid variants of antigenic peptides that either change the nature or degree of the T-cell response (partial agonists) or prevent a response to a normally stimulating ligand (antagonists).[193,194] Discussions concerning the mechanism of these “altered peptide” responses have centered on whether they are due to some conformational phenomenon involving TCRs and/or CD3 molecules or to affinity or kinetic characteristics. With the data now available, we can now say that most, but not all, T-cell responses correlate well with the binding characteristics of their TCRs. In particular, Sykulev et al.[195] first noted that higher-affinity peptide variants elicited more robust T-cell responses. Subsequently, Matsui et al.[196] found that in a series of three agonist peptides increasing dissociation rates correlated with decreasing agonist activity. Lyons et al.[197] found that this correlation extended to antagonist peptides in the same antigen system (moth cytochrome c/I-E^k). They also showed that while an antagonist peptide might differ only slightly in affinity compared with the weakest agonist, its dissociation rate differed by 10-fold or more. This data in a class II MHC-restricted system is largely supported by the studies of Alam et al. in a class I MHC system,[198] who also saw a drop-off in affinities and an increase in off-rates (with one exception as noted in Table 11.2) with antagonist versus agonist ligands. In the cell-based TCR labeling system of Luescher and colleagues, a survey of related peptide ligands of varying potency also found a general, but not absolute, correlation between receptor occupancy and stimulatory ability.[199] Thus, while there is a general trend toward weaker T-cell responses and faster off-rates and lower affinities, this does not seem to be an absolute rule, and thus other factors may be important in some cases. Alternatively, Holler[200] has suggested that some or all of the discrepancies may derive from differences in peptide stability (in the MHC) between the relatively short (minutes) time scale of BIAcore analysis at 25°C compared with the much longer (days) cellular assays at 37°C. But this explanation probably only applies to a fraction of the anomalous cases in which TCR ligands fail to adhere to the “$t_{1/2}$ rule.” In particular, Krogsgaard et al.[201] performed a very comprehensive survey of both known and newly derived cytochromic peptide antigens and found that almost half of the peptide-MHC ligands analyzed failed to exhibit a linear relationship between $t_{1/2}$ and T-cell stimulatory ability (Fig. 11.7). Extensive thermodynamic analyses of these ligands showed that one particular

parameter, the change in heat capacity (-ΔCp), which reflects changes in conformation or flexibility upon binding, seems to be synergistic with $t_{1/2}$ in enhancing a ligand's stimulatory capacity. In fact, as shown in Figure 11.7, when ΔCp values are combined with $t_{1/2}$, the x axis values for the range of ligands correlate much better with T-cell stimulation. This suggests that ΔCp may be the "missing" variable in correlating ligand binding to stimulation.

How could a negative change in heat capacity synergize with the stability of binding? One possibility is that large conformational changes at the binding surface of a TCR that can occur when it engages peptide/MHC ligands (as

shown by structural studies; see the following) can translocate the TCR deeper into the membrane—as suggested by the "piston"[52,202] and "twist cap"[184] models—and trigger conformational changes in the CD3 signaling domains. Chakraborty and colleagues recently suggested another possibility for how conformational changes at the binding surface might exert their effect.[203] They found that in the context of membrane-membrane interactions, conformational changes in the surfaces of relatively rigid proteins (such as all but the CDR3 regions of TCRs appear to be) would act to increase the effective half-life of TCR-peptide/MHC interactions. Thus $t_{1/2}$ and ΔCp may be equivalent in the unique environment between two cell surfaces.

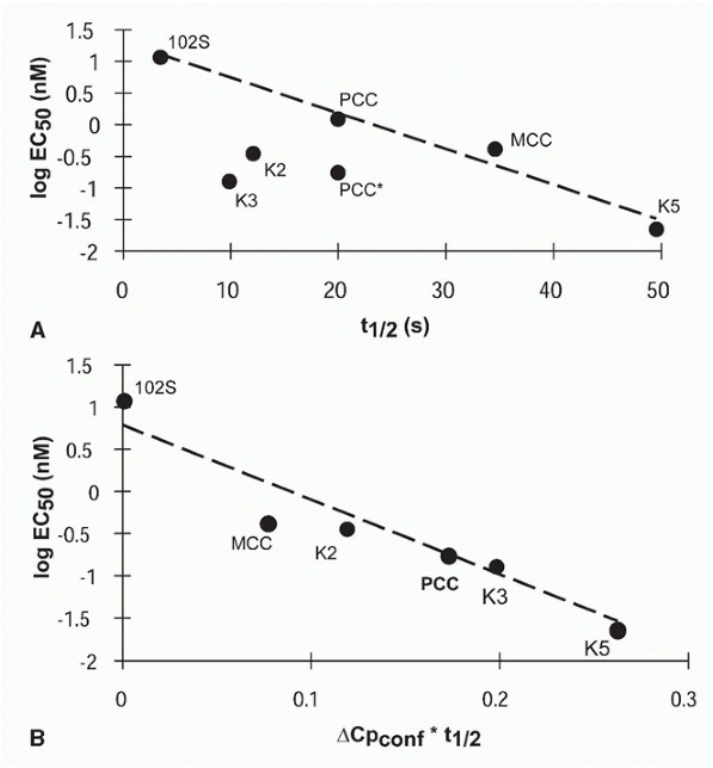

FIG. 11.7. Dissociation Rate and Heat Capacity with Peptide-Major Histocompatibility Complex (MHC) Ligands Both Influence T-Cell Activation. Data from Krogsgaard et al. show that where deviations from the general dependence of T-cell activation on dissociation rate occur, they may be compensated for by another factor, namely the heat capacity (ΔC_P) of the T-cell receptor (TCR)-peptide/MHC interaction. This is a measure of changes in mobility or conformation during the binding interaction and suggests that other binding parameters can influence TCR-mediated activation besides half-life.[184] **A:** The relationship between the half-maximal peptide concentration needed for T-cell activation (EC50) and the half-life ($t_{1/2}$) of the TCR binding to that particular ligand. In this series, three of the seven peptides tested (K2, K3, and PPC) do not seem as dependent on $t_{1/2}$ as the others (PCC* represents a correction for a lack of stability when bound to the MHC at 37°C). **B:** When ΔC_P is factored in, all of the peptides can be plotted on a line.

How might the relatively small differences in the binding characteristics of the ligands cause such different T-cell signaling outcomes as agonism or antagonism? As McKeithan[204] and Rabinowitz[205] have noted, a multistep system such as T-cell recognition has an inherent ability to amplify small differences in signals that are received on the cell surface to much larger differences at the end of the pathway, in this case gene transcription in the nucleus. Thus antagonism may occur at one threshold and an agonist response at another. Alternatively, an antagonist ligand may traverse the activation pathway just far enough to use up some critical substrate, as proposed by Lyons et al.[197] Yet another possibility that has also been suggested is that some antagonists may act even earlier by blocking TCR clustering at the cell surface.[206] Lastly, Germain and colleagues have found evidence that a feedback loop involving the phosphatase SHP-1 may act as an alternative pathway to inactivate TCR signaling of insufficient strength.[207,208]

Another controversy that relates to TCR binding characteristics is the "serial engagement" model of Valittutti and Lanzavecchia and colleagues,[139,209] which proposed that one way in which a small number of peptide/MHC complexes can initiate T-cell activation is by transiently binding many TCRs in a sequential fashion. While the dissociation rates reviewed here show that TCR binding is likely to be very transient, they do not in fact support the statement that more interactions are better. This is because, in most cases, improvements in TCR-peptide/MHC stability within any one system result in a more robust T-cell response. This has been shown by the work of Kranz and colleagues,[210] who selected a nanomolar affinity TCR from a mutagenized library expressed in yeast. With an approximately 100-fold slower off-rate than the original, this TCR should have been only poorly stimulatory based on the serial engagement model. Instead, T cells bearing it are considerably more sensitive to antigen, which casts considerable doubt on this aspect of the model. Similar work of Allen and colleagues on another TCR-ligand interaction produced similar results.[211] Furthermore, recently Xie et al. cross-linked peptide-MHCs to a cognate TCR and found that when aggregated they can still signal efficiently.[212] But the concept that the rapid dissociation rates of TCRs for peptide-MHC ligands could serve to amplify signaling under limiting conditions is still very likely and has been cited in the context of the "pseudodimer" model,[140,213] as discussed in the following.

Topology and Cross-Reactivity

As discussed previously, TCR sequence diversity resides largely in the region between the V and J region gene segments, which corresponds to the CDR3 regions of antibodies.[214] This has led to models in which the CDR3 loops of Vα and Vβ make the principal contacts with the antigenic peptide bound to the MHC.[214] Support for this model has come from many studies in which it has been shown that the CDR3 sequences of TCRs are important predictors of specificity,[214] as well as elegant mutagenesis studies which showed that a single CDR3 point mutation could alter the specificity of a TCR[215] and also a CDR3 "transplant" could confer the specificity of the donor TCR onto the recipient.[216] In addition, a novel approach to TCR-ligand interactions was developed by Jorgensen et al.,[217] who made single amino acid changes in an antigenic peptide at positions that affect T-cell recognition but not MHC binding. These variant peptides are then used to immunize mice that express either α or β chain of a TCR that recognizes the original

peptide and the responding T cells are analyzed. Using these "hemitransgenic" mice allows the resulting T cells to keep one-half of the receptor constant, while allowing considerable variation in the chain that pairs with it. The results from this study and work in another system by Sant'Angelo et al.[218] are very similar in that every mutation at a TCR-sensitive residue triggered a change in the CDR3 sequence of Vα, Vβ, or both, and in some cases, changed the Vα or Vβ gene segment as well (as summarized in Fig. 11.8). One of the more striking examples of a CDR3-peptide interaction occurred in the cytochrome c system where a Lys → Glu change in the central TCR determinant on the peptide triggered a Glu → Lys charge reversal in the Vα CDR3 loop, suggesting a direct Lys → Glu contact between the two

molecules.[217] This prediction has recently been confirmed in the structural work of Newell et al.[219] and extended to a closely related TCR, 2B4, which contacts the central lysine on the peptide with an oppositely charged residue in CDR3β.

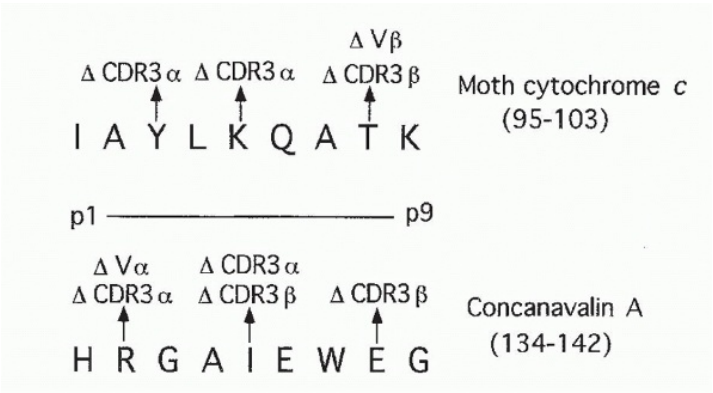

FIG. 11.8. Sensitivity of T-Cell Receptor (TCR) Complementarity-Determining Region 3 (CDR3) Sequences and Vα/Vβ Usage to Changes in the Antigen Peptide. This figure summarizes the data of Jorgensen et al.[196,198] and Sant'Angelo et al.,[197] who immunized single-chain transgenic mice (TCR-α or TCR-β) with antigenic peptides (MCC or CVA) altered at residues that influence T-cell recognition but not major histocompatibility complex binding. These data show that such changes invariably affect the CDR3 sequences of Vα or Vβ or both, and that there appears to be a definite topology in which Vα governs the N-terminal region and Vβ seems more responsible for the C-terminal portion of the peptide.

Another interesting finding was the order of Vα → Vβ preference going from the N-terminal to the C-terminal residues of the peptides. This led Jorgensen to a proposed "linear" topology of TCR-peptide/MHC interaction in which the CDR3 loops of Vα and Vβ line up directly over the peptide.[217,220] Sant'Angelo et al.[218] proposed an orientation of the TCR in which the CDR3 loops are perpendicular to the peptide. This was partially based on intriguing data they found suggesting an interaction between the CDR1 of Vα and an N-terminal residue of the peptide.

This controversy regarding orientation has been largely resolved by the numerous crystal structures of TCR-peptide/MHC complexes.[160,221] These studies show that TCRs bind in roughly diagonal to 90-degree configurations, ranging over 30 degrees. In these structures, one of which is shown in Figure 11.9,[165] the CDR3 loops are centrally located over the peptide, but the Vα CDR1 and the Vβ CDR1 are also in a position to contact the N-terminal and C-terminal peptide residues, respectively. The confined nature of TCR recognition constitutes a major departure from antibodyantigen interactions and may reflect a need to accommodate other molecules into a particular configuration that is optimal for signaling, such as CD4, CD8, and/or CD3 components. Particularly relevant to this possibility are the recent observations by Garcia and colleagues[222] suggesting that TCR signaling can be limited by the docking geometry of the TCR to the peptide/MHC complex. They used a yeast library in which millions of different peptides bound to a class I MHC can be interrogated by a single TCR. Structural analysis showed that three of the peptides isolated bound to the TCR with the typical orientation and induced TCR signaling. But a fourth peptide bound the TCR not in the typical diagonal mode but in a parallel fashion, and failed to induce signaling.[222] This suggests that the typical TCRMHC docking mode is selected for in the thymus and may be critical for signaling.

As αβ TCR heterodimers are first selected in the thymus for reactivity to self-peptides bound to MHC molecules, all foreign-peptide reactive TCRs could be considered to be inherently cross-reactive. Indeed, a number of T cells have reactivity to very different peptide sequences, as shown by Nanda and Sercarz.[223] It has also been argued by Mason[224] that

the universe of peptides is so large that each T cell must on average be cross-reactive to approximately 10^6 different peptides (although many of the differences in peptide sequence in this calculation would not be accessible to the TCR, being buried in the MHC binding groove). Several large-scale screens of a random 9-mer peptide library with different T cells did turn up a great many stimulatory

peptides, but very few have changes in the two to four key TCR-sensitive residues.[225] This led Garcia and colleagues to conclude that cross-reactivity to different agonist peptides may not be a general feature of T-cell specificity.[226] Instead, the major requirement for cross-reactivity may be in thymic selection[227] and/or in the use of endogenous peptide-MHCs to augment T-cell sensitivity to agonist ligands.[207,213,228] Direct evidence of TCR plasticity was first obtained by Garcia et al.,[229] who in comparing the x-ray crystal structures of the same TCR bound to two different peptide-MHC ligands found a large conformational change in the CDR3 loop and a smaller one in the CDR1α loop. An even larger conformational change (15 Å) has been found in the CDR3β residue of another TCR as it binds to a peptide/MHC complex,[230] as shown in Figure 11.10. That each TCR may have many different conformations of its CDR3 loops is suggested by the two-dimensional nuclear magnetic resonance studies of Reinherz and colleagues, who found that the CDR3 regions of a TCR in solution were significantly more mobile than the rest of the structure.[231] That this may be a general feature of most TCRs is supported by thermodynamic analyses of various TCRs binding to their peptide/MHC ligands, both class I and class II. Here, the binding is often accompanied by a substantial loss of entropy (Table 11.4) and, in most cases, an "induced fit" mechanism.[184,192,232] This seems to be a situation where an inherently flexible binding site achieves greater order upon binding. This is a mechanism which is also employed by DNA recognition proteins, and Boniface et al.[192] have suggested that it might represent a common mechanism of "scanning" an array of very similar molecular structures (MHCs or DNA) rapidly for those few that "fit" properly. We have seen previously that the association rates are often remarkably slow, with K_as ranging from 1,000 to 10,000 $M^{-1}s^{-1}$ (see Table 11.3). This indicates that either a multistep process is occurring before stable binding can be achieved or that only a fraction of the TCRs in

solution have the correct conformation. Just how such a scanning mechanism might work for TCRs is seen in the analysis of Wu et al.,[233] who found that a cytochrome c/MHC II-specific TCR derived most of its stability of binding from antigenic peptide residues, but very little of its initial activation energy from these residues. In contrast, MHC residues contributed by far the most of the initial binding, but had relatively modest effects on stability. This indicates that "scanning" may be a process (as shown in Figure 11.11) that first involves contact with (and orientation by) the α-helices of the MHC and then a "fitting" process with and stabilization by peptide residues that involves a substantial loss of entropy. This model of TCR binding might help to explain the striking efficiency and sensitivity of T-cell recognition with the MHC helices guiding the TCR into the correct orientation. It might also be the structural basis for cross-reactivity in which structurally very different peptides bind to the same TCR, as the CDR3 regions of TCR could "fold" into the peptide in many possible configurations. While attractive, there remain caveats about this "two-step binding" model; one is the existence of some important human class I MHC antigens that "bulge" out of the binding groove, creating a barrier to "scanning" as a mechanism of binding to those antigens.[234] A second issue is that one would expect a reproducible "footprint" for MHC binding of particular TCR V regions, which until recently has been elusive. But Garcia and colleagues,[235] as well as Kappler and colleagues,[236] have documented such specific footprints that correlate to particular Vβ usage, although it does seem that there are multiple ways way in which a particular V region can contact a particular MHC.

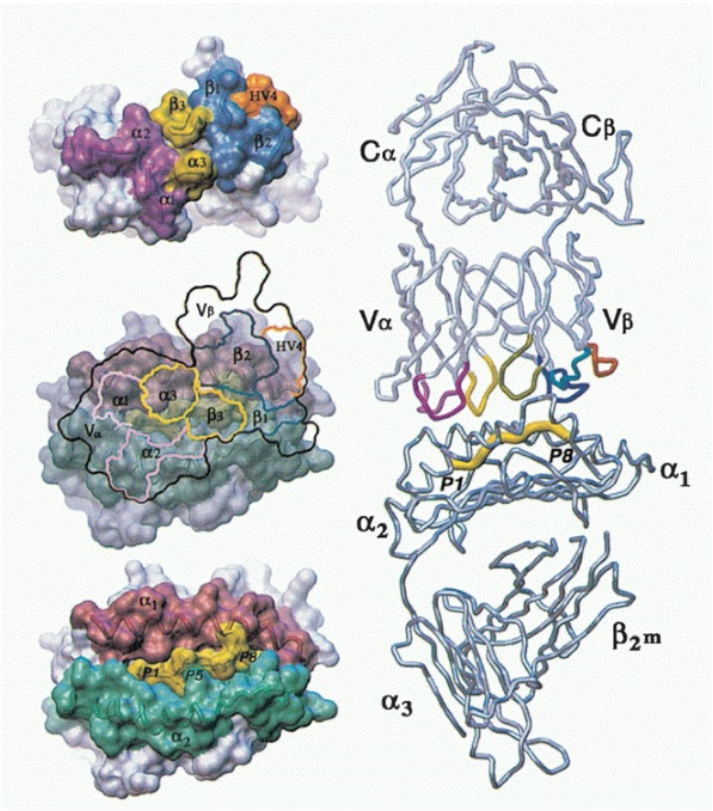

FIG. 11.9. T-Cell Receptor-Peptide/Major Histocompatibility Complex Crystal Structure of a T-Cell Receptor-Peptide/Major Histocompatibility Complex Complex. Peptide and complementarydetermining regions are portrayed in different colors.[150]

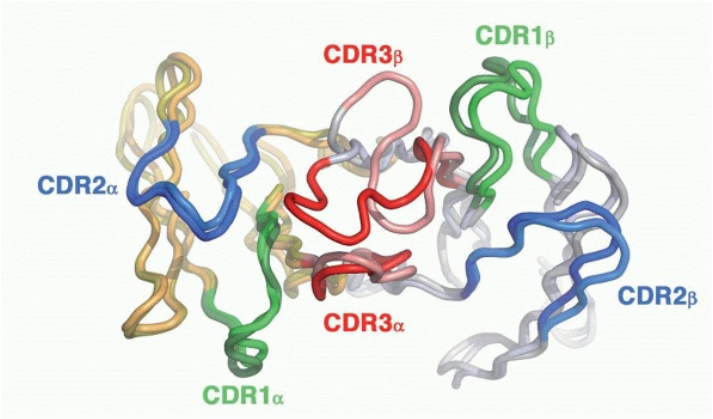

FIG. 11.10. Complementarity-Determining Region (CDR)3 Movement in αβ T-Cell Receptor (TCR) Binding. In most cases where there is a structure for an αβ TCR as well as for one (or more) for that TCR in complex with a peptide-major histocompatibility complex, there is a marked movement of one or the other of the Vα or Vβ CDR3s. This example from Mallissen et al.[209] shows a particularly large (14 A) movement of CDR3β with binding. This meshes well with thermodynamic data showing an “induced fit” binding mechanism for most TCRs.[173,211]

The ΔG values were derived from the equation $\Delta G=RT \ln(K_A)$ where R=0.001987 kcal/mol/K. CDR, complementarity-determining region; ND, not determined; p/MHC, peptide/major histocompatibility complex; TCR, T-cell receptor.

[a] No major conformational change observed after ligand recognition.

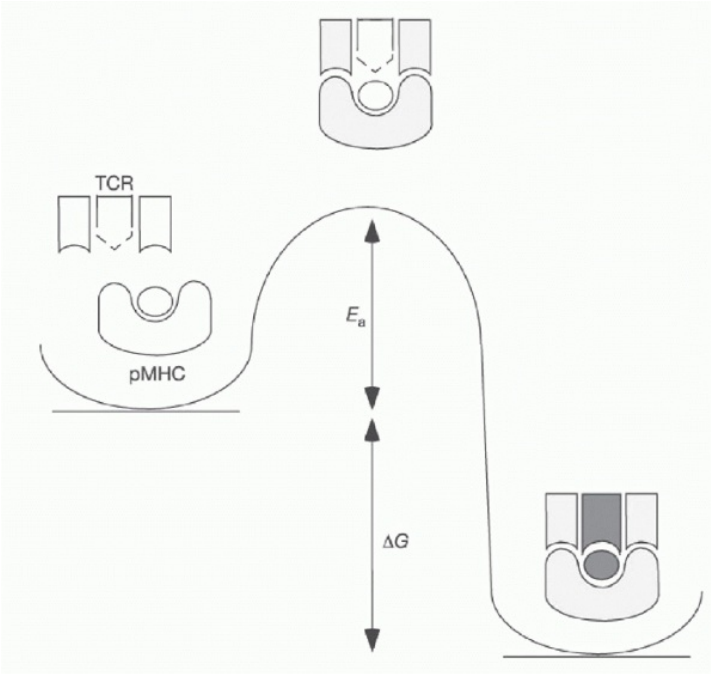

FIG. 11.11. As Shown by Wu etal.,[212] Mutational Analysis of T-Cell Receptor (TCR)-Peptide/Major Histocompatibility Complex (MHC) Binding Indicates that the TCR First Contacts MHC Residues (in the Transition State), and the Peptide has Very Little Influence. Subsequently, however, the peptide residues contribute greatly to the stability of the complex. Thus, we have proposed that the transition state largely involves TCR-MHC contact followed by stabilization of mobile complementarity-determining region 3 residues into a stable state, usually involving significant conformational change and loss of entropy.

The rules for the conserved reaction of αβ TCRs with MHC proteins plus peptides are addressed by evaluating the contact residues between TCR and MHC in cocrystal structures

of TCR/peptide/MHC complexes. Thus it has been suggested that each TCR variable-region gene product engages each type of MHC through a “menu” of structurally coded recognition motifs that have arisen through coevolution.[235,236]

Role of Cluster of Differentiation 4 and Cluster of Differentiation 8

What is the role of CD4 and CD8 with respect to the T-cell response to agonist and antagonist peptides? Clearly, their expression greatly augments activation, and in some cases, determines whether there is a response at all.[237] In addition, the results of Irvine et al.[238] and Purbhoo et al.,[239] using a single-peptide labeling technique, found an appreciable T-cell response to even one agonist peptide in all four T cells analyzed, resulting in a “stop” signal for the T cell and a small, but detectable rise in intracellular calcium. In CD4+ T cells, these effects are attenuated by antibody blockade of CD4, such that many more (25 to 30) peptides

are required in order to elicit a stop signal and a calcium flux.[238] Much of this effect likely comes from the recruitment of lck to the TCR/CD3 complexes via the cytoplasmic tails of either molecule. But in addition, there is also a significant positive effect even with CD4 molecules that are unable to bind lck and thus there appears to be an effect on TCR-ligand interaction as well. Nonetheless, while a weak binding of CD4 to class II MHC has been observed,[187] most recently in a complete crystal structure of CD4-TCRpeptide/MHC,[240] there was no apparent stabilizing effect on TCR binding to peptide-MHC in measurements of binding within a synapse by Huppa et al.[188] This is in contrast to the earlier data of Luescher and colleagues,[241] who found that CD8 had a measureable stabilizing effect on TCR binding to ligand on T cells expressing that molecule. This later result is consistent with measurements of CD8 affinity for class I MHCs that are very similar, or even superior, to that of many TCRs for peptide/MHC.[242] So, are CD4 and CD8 playing very different roles with respect to TCR binding to peptide/MHC? Chakraborty and colleagues suggest not in a model they have developed that indicates that the differences in CD4 and CD8 affinity for MHCs contribute at best marginally to activation and that delivering lck to productive TCR-peptide/MHC complexes is their most important property.[243] In this view, the specificity of these molecules for their respective MHC molecules is more of a targeting mechanism than the stabilization function implicit in the ubiquitous illustrations originally proposed by Janeway[116] and featured in many subsequent models.

How could CD4 be facilitating the recognition of small numbers of peptides? Irvine et al. [238] proposed a “psuedodimer” model, which suggests that a CD4 molecule associated with a TCR binding to an agonist peptide-MHC could bind laterally to an endogenous peptide-MHC complex that is also being bound by an adjacent TCR. This takes advantage of the apparent abundance of endogenous peptide/MHCs that can be bound by a given TCR[244] and uses two weak interactions (CD4 → MHC II and TCR → endogenous peptide-MHC) to help create a dimeric “trigger” for activation. This is supported by the work of Krogsgaard et al.,[213] who also showed that disabling CD4 binding to the endogenous peptide/MHC in a heterodimer had a much a greater effect on activation than the same mutation on the agonist peptide/MHC.

What about the timing of CD4 or CD8 binding with respect to TCR-peptide/MHC? The first hints of this came from the work of Hampl et al.,[245] who found that antagonist peptide/MHCs showed no apparent influence of CD4 versus agonists, and because these interactions are much briefer, suggested that CD4 binding was subsequent to TCR engagement with a ligand. That this is likely to be a general effect was shown recently by Jiang et al.,[246] who found that whereas very brief T-cell contacts with peptide/MHC loaded red blood cells involved TCR but not CD8, longer contact periods involved both molecules. Thus it seems that the TCR must first bind to a high quality (eg, agonist) ligand and then CD4 or CD8 comes in to deliver lck and dissociates (based on the lack of stabilization, at least in the case of CD4). But more direct measurements are needed, as well as further definition of the role of endogenous ligands.

Superantigens

One of the most interesting and unexpected areas to emerge from the study of αβ T-cell reactivities is the discovery of "superantigens." Whereas a particular antigenic peptide might only be recognized by 1 in 100,000 or fewer T cells in a naive organism, a given superantigen might stimulate 1% to 20% of the T cells.[247,248] As will be discussed in more detailed in the following, the physical basis for this is that the superantigen binds to a Vβ domain of the TCR on T cells while simultaneously binding to an MHC class II molecule on an antigen-presenting cell (although not in the peptide-binding groove). This allows a single superantigen, such as staphylococcal enterotoxin A (SEA) in Table 11.5, to stimulate virtually every murine T cell bearing Vβ 1, 3, 10, 11, 12, or 17 (about 15% of all αβ T cells), in most cases regardless of what Vα it is paired with or what CDR3 sequence is expressed. Clearly, this is a unique class of T-cell stimulatory molecules.

The first indication of a superantigen effect was the discovery of minor lymphocyte stimulating determinants by Festenstein in the early 1970s.[249] Many years later, Kappler and colleagues characterized a mouse strain-specific deletion of T cells expressing a specific TCR Vβs that were attributable to these loci.[250] It emerged that these effects were due to endogenous retroviruses of the mouse mammary tumor virus family.[251,252,253,254,255] Different family members bind different TCR Vβ domains (as shown in Table 11.5) and stimulate T cells expressing them. Meanwhile, Janeway and colleagues[256] had shown earlier that staphylococcus enterotoxins could polyclonally active naive T cells in a Vβ-specific manner without a requirement for antigen processing. Many of these enterotoxins have been characterized extensively.[247,248,257,258] Unlike the MMTV proteins, which are type II membrane proteins, the enterotoxins are secreted. Subsequently, proteins having similar properties have been isolated from other bacteria (*Yersinia pseudotuberculosis*,[259,260] streptococcus,[261] and from mycoplasma[262,263]). There is also evidence of superantigen-like activities in other mammalian viruses such as rabies,[264] cytomegalovirus,[265] herpes virus,[266] Epstein-Barr virus,[267] and also in *Toxoplasma gondii*.[268] As so many pathogenic or parasitic organisms possess these molecules, apparently by convergent evolution, there must be some selective advantage, but in most cases there is no conclusive evidence as to what this might be. The one exception is the case of the MMTV superantigens, where it has been shown that polyclonal T-cell stimulation allows the virus to more efficiently infect the B-lymphocytes that are activated by the T cells.[269,270] This may be a special case, however, and most authors have suggested that superantigens primarily serve to confuse and occupy the immune system while the pathogen escapes specific targeting and elimination. Large doses of superantigens have also been implicated in various "shock" syndromes, such as food poisoning or "toxic shock,"[247] but this is probably not their everyday purpose, as it would violate the general rule that the host and parasite should coexist.

It has also been suggested by Stauffer et al.[271] that superantigens might be involved in triggering autoimmune diseases. Here the hypothesis is that a large number of some Vβ-bearing T cells are activated by a pathogenic superantigen

and that subsequently self-reactive T cells within those activated cells are more easily stimulated by a particular tissue antigen. That this may occur in some cases is supported by their work on a human endogenous retrovirus which specifically stimulates Vβ7 T cells and is implicated in the initiation of type I diabetes.[271] Another report implicates a superantigen in Crohn disease, another autoimmune disorder.[272]

[a] The nomenclature in use before the discovery that the phenotype resulted from endogenous retroviruses.

While the biochemistry of superantigen binding to TCR and MHC is similar to that of TCR peptide/MHC interactions,[273] mutagenesis, and particularly x-ray structural data, has shown that the topology is both quite different and variable.[248] In particular, it has been found that Mls-la presentation to T cells is most affected by mutations on the "outside" surface of the Vβ domain, which do not affect peptide/MHC recognition.[162] In contrast, CDR1 and CDR2 of regions of Vβs are involved in bacterial superantigen reactivity.[274]

An example of the structural data is shown in Figure 11.12, which shows how a model TCR-SAg-MHC complex (derived from separate structures) would displace the TCR somewhat (but not entirely) away from the MHC binding groove,[275] thus making the interaction largely insensitive to the TCR/peptide specificity. Other TCR-SAg-MHC complexes have very different geometries.[276,277]

Why do all the many independently derived superantigens interact only with the TCR β-chain? One possibility is that the β-chain offers the only accessible "face" of the TCR, perhaps because the CD4 molecules hinders access to the Vα side, as suggested by the antibody blocking studies of Janeway and colleagues.[278,279]

ANTIGEN RECOGNITION BY γδ T CELLS

γδ T cells together with αβ T cells are present together in all but the most primitive vertebrates. This finding argues that γδ T cells functions are different from those of αβ T cells. Yet, most γδ T cells produce cytokines that are similar to

those produced by αβ T cells. γδ T cells also can mount cytotoxic responses upon activation

like CD8+ αβ T cells. These results, together with the fact that αβ T cells are almost always found alongside and usually in excess of γδ T cells, suggest that the difference in how γδ T cells and αβ T cells contribute to host immune competence is less likely because of differences in effector functions or in tissue distribution but rather because of differences in how these two types of cells are triggered. Thus, to understand how γδ T cells function, it is essential to know the antigens and the target cells recognized by γδ T cells.

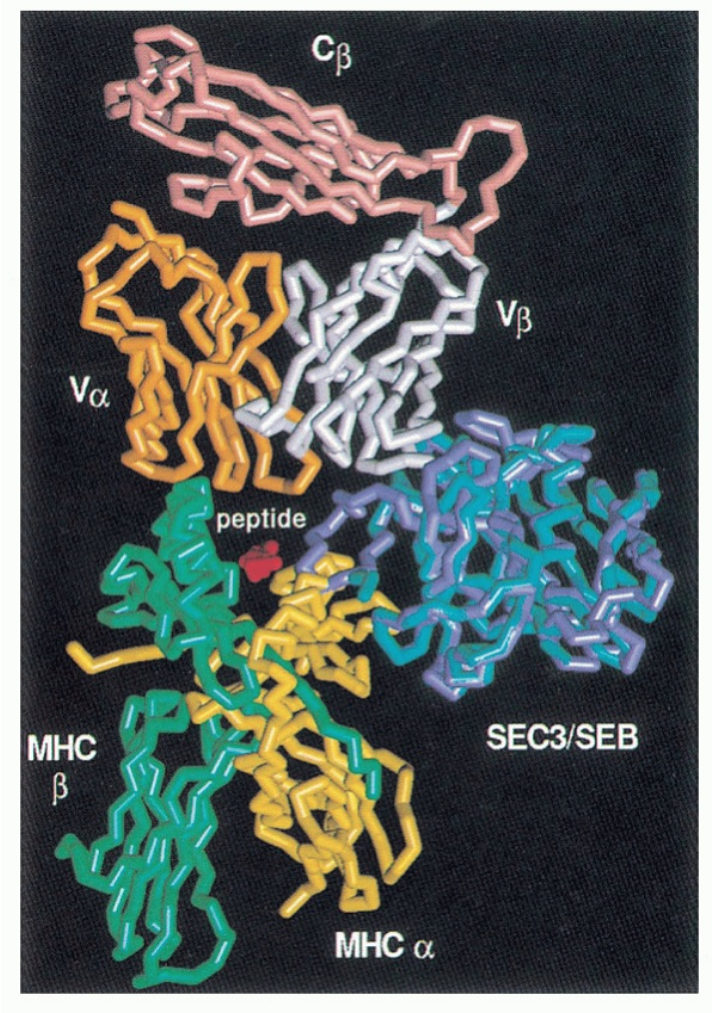

FIG. 11.12. Crystal Structure of a T-Cell Receptor (TCR) β/Superantigen (SAg) Complex. Fields et al.[253] crystallized TCR-SAg complexes and from the structure of the same superantigens with a class II major histocompatibility complex (MHC) molecule and were able to deduce the relative spatial arrangement of the three molecules. This model suggests that TCR does not contact the MHC very strongly, which is consistent with the relative peptide insensitivity of SAg activation.

Antigen Recognition Requirements and γδ T-Cell Ligands

Because the study of γδ T cells is relatively recent and does not stem from any knowledge of their biologic function, experiments designed to characterize their specificity and function had drawn heavily on our knowledge of αβ T cells. Because αβ T-cell recognition requires antigen presentation by MHC and related molecules, it was assumed that γδ T-cell recognition would also follow the same rules. Even in cases where classical MHCs are clearly not involved, it has been suggested that nonclassical MHC molecules or some as yet to be identified surface molecules might play a similar role. These possibilities are difficult to test experimentally. Thus, analysis of γδ T cells specific for MHC molecules were carried out to determine the antigen recognition requirement of γδ TCRs. This approach asks the following questions: When γδ T cells recognize MHC molecules, what kind of antigen processing is required, is

any of the specificity conferred by bound peptide, and which part of the MHC molecule is recognized? This approach took advantage of the detailed knowledge of the molecular structure of MHC class I[280,281] and MHC class II molecules,[282] thus making T-cell epitope mapping feasible and interpretable. In addition, and more importantly, the biosynthetic pathways and antigen-processing requirements for both MHC class I and MHC class II molecules had been extensively studied. Mutant cell lines defective in either pathway were readily available and could be transfected with various MHC class I and class II genes. Therefore, potential antigen processing and presentation requirements for alloreactive γδ T cells could be studied with precision and compared with those of αβ T cells.

The γδ T cell LBK5[283,284] recognizes I-$E^{b,k,s}$ but not I-E^{d}. An analysis of the fine specificities of LBK5 showed that the peptide bound to the I-E molecules does not confer specificity and that no known antigen-processing pathways were required in the recognition of I-E by LBK5. All variations in the ability of different stimulator cells to activate LBK5 can be attributed solely to their level of surface I-E expression and are independent of their species origin (mouse, hamster, human) and cell type (B cells, T cells, fibroblasts). Modifications of the repertoire of peptides loaded onto MHC molecules also showed no effect because native I-E^{k}, GPI-linked I-E^{k}, I-E^{k} expressed with or without invariant chains, and the presence or absence of functional MHC class I or class II antigen-processing pathways all stimulated LBK5 similarly.[285] Thus, LBK5 recognizes native I-E^{k} molecules with a variety of different bound peptides or in the case of GPI-linked I-E^{k}, which most likely does not complex with a peptide. In addition, LBK5 recognizes *E. coli*-produced I-E^{k} α and β chains folded with a single peptide.[285]

The functional epitope on I-E for LBK5 recognition maps to the β67 and β70 residues.[285] This explains why LBK5 recognizes I-$E^{b,k,s}$ but not I-E^{d} and why peptide bound to I-E^{k} does not confer the specificity. Surprisingly, I-E^{k} mutants with an altered carbohydrate structure on the α84 position are not recognized by LBK5.[286] Although the binding interface of the LBK5 γδ TCR and I-E has yet to be determined, it is reasonable to assume that it will not deviate much from those reported for antibodies, αβ TCRs and the G8 γδ TCR. From the coordinates of a published crystal structure of I-E^{k},[287] the distance between β67-70 (the LBK5 epitope) and the carbohydrate attachment site at position α82 was estimated to be around 28-33Å. Hence, it is likely that the carbohydrate structure is peripheral to the core of the LBK5/I-E interaction. This type of interaction may be similar to that described for human growth hormone and the extracellular

domain of its receptor[288] where a central hydrophobic region at the contact site, which is dominated by two tryptophan residues, accounts for more than three-quarters of the binding free energy and where peripheral electrostatic contacts contribute substantially to the specificity of binding but not to the net binding energy. This type of protein-protein interaction has been postulated to ensure the specificity of an interaction without requiring a high affinity.[289]

Two independently derived γδ T-cell clones, KN6[290] and G8,[291] are found to recognize T10 and T22, two closely related, nonclassical MHC class I molecules that have 94% amino acid identity. T22 appears to be expressed constitutively on a variety different cell types, whereas the expression of T10 is inducible on cells of the immune system. Among strains of mice tested so far, all express T22. However, mice of the H-2^{d} or H-2^{k} MHC haplotypes (eg, BALB/c and C3H, respectively) lack functional T10 molecules.[291,291a] T10 and T22 have also been identified as natural ligands for murine γδ T cells. Approximately 0.2% to 1% of the γδ T cells in normal, unimmunized mice are T10/T22-specific (Fig. 11.13).[292]

The primary sequences of T10 and T22 suggest that the necessary structural features that enable classical MHC class I molecules to bind peptides are absent. Indeed, x-ray crystallography has shown that T10 and T22 adopt a severely modified MHC-like fold that lacks a classical peptide- binding groove and exposes part of the β sheet “floor” of the α1/α2 platform.[293,294] Consistent with the structural data, no endogenous peptides can be eluted

from chimeric T10/L^d molecules that are expressed by transfected cells.[295,295a] This indicates that these molecules can reach the cell surface devoid of peptide. Importantly, the *E. coli*-produced, in vitro-folded T10/β_2m and T22/β_2m molecules can stimulate the G8 γδ T cell,[295,296] which provides unequivocal evidence that these peptide-free molecules retain their immunologic function.

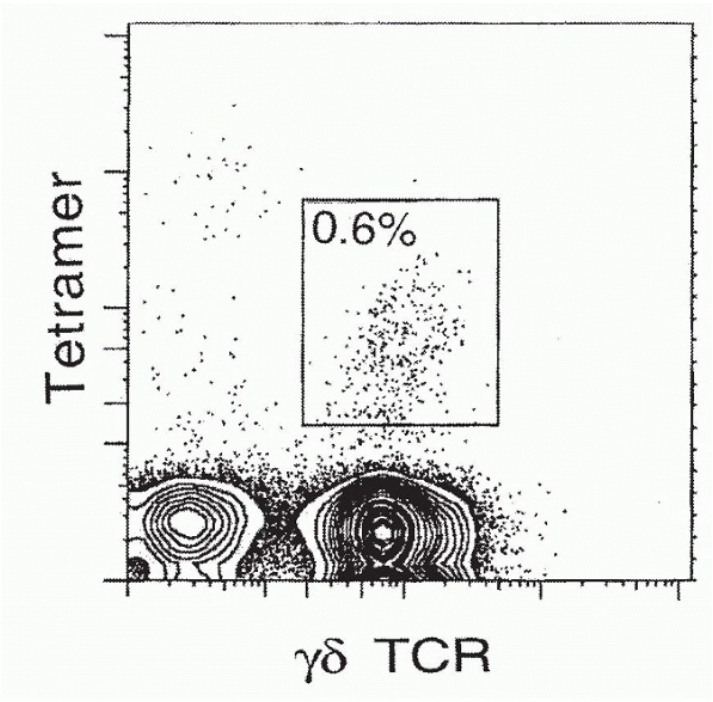

FIG. 11.13. T10/T22-Specific γδ T Cells can be Detected in Normal Mice Through Use of a Tetrameric T22 Staining Reagent. As shown by Crowley et al.,[274] a T22 reagent that was generated by similar methods as tetrameric peptide/major histocompatibility complex reagents stained approximately 0.6% of splenic γδ T cells in normal animals. More than 90% of these cells are cluster of differentiation (CD)4-CD8-; the rest are either CD4 or CD8 single positive (about 3% to 4% each). A similar frequency of tetramer-positive γδ T cells was also found in the intestinal intraepithelial lymphocyte population (data not shown).

Direct binding between soluble G8 γδ TCRs and T10/β_2m and T22/β_2m complexes has been measured.[297] Surface plasmon resonance showed that the dissociation rates for the interaction between G8 and $T10^b$ and $T22^b$ were similar ($k_d = 8.1 \pm 2.3 \times 10^3 s^{-1}$) and slower than those that had been observed for most interactions between αβ TCRs and peptide/MHC complexes. The association rates ($k_a = 6.53 \pm 1.73 \times 10^4\ M^{-1}s^{-1}$) are among the fastest that had been reported for αβ TCRs and their ligands. Therefore, compared to αβ TCRs, the affinity between G8 γδ TCRs and their ligand is rather high ($K_D = 0.13 \pm 0.05$ μM). A Scatchard analysis of equilibrium binding generated a similar affinity of 0.11 ± 0.07 μM for this interaction.[297]

There are only two other pairs of ligand-TCR interaction have been reported. The binding between the soluble form of G115 and its ligand F1-ATPase and the apolipoprotein A-I complex showed a K_D of 1.5 μM and 0.8 μM, respectively.[171] These affinities are within the range of soluble αβ TCRs and their peptide/MHC ligands. Surprisingly, a K_D of 110 to 900 μM was reported for δ1A/B-3:MICA interactions.[299] This affinity is one to two orders of magnitude weaker than the NKG2D:MICA interaction, more on a par with MHC class I:CD8 interactions (from 11 to ≥ 1,000 μM).

It should be noted that the same human γδ T-cell clones that recognize AS/ApoA-I complexes

are activated by a set of nonpeptidic pyrophosphomonoesters that are collectively referred to as phosphoantigens (phosphoAgs).[170] It has been observed for well over a decade that some human peripheral blood Vγ9Vδ2 cells can be stimulated by phosphoAgs such as isopentenyl pyrophosphate and dimethylallyl pyrophosphate. These cells show in vitro responses to tumors, phosphoAgs produced by eukaryotes and prokaryotes, natural and synthetic alkylamines, and aminobisphosphonates. However, repeated attempts to show interactions between phosphoAgs and Vγ9Vδ2 TCRs have failed. The identification of AS/ApoA-I complexes as antigens of some of these T cells further challenges this notion.

As indicated in Table 11.6,[145] other than toward phosphoAgs, the reactivities of Vγ9Vδ2-expressing T cells to other challenges such as tumors and AS/ApoA-I are far from homogeneous. Further, these cells mount a much more robust response to phosphoAgs than to CD3 cross-linking. Thus, it is possible that isopentenyl pyrophosphate and other isoprenoid intermediates enhance antigen-specific responses of Vγ9Vδ2 cells without being TCR antigens themselves. Isopentenyl pyrophosphate and dimethylallyl pyrophosphate are metabolites of the mevalonate pathway that regulates the biosynthesis of cholesterol as well as of isoprenoids that mediate the membrane association of certain GTPases. The addition of isoprenoid intermediates has been shown to augment antigen-specific αβ T-cell responses and to alter their cytokine profiles.[300]

These experimental observations together with the CDR3 length distribution analysis described previously make it clear that the molecular nature of γδ T-cell antigen recognition is fundamentally different than that of αβ T cells. While MHC and MHC-related molecules are recognized by

γδ T cells, γδ T-cell antigens need not be MHC or MHCrelated molecules. Moreover, in all cases, the antigens are recognized directly. This suggests that pathogens and damaged tissues can be recognized directly and cellular immune responses can be initiated by γδ T cells without a requirement for antigen degradation and specialized antigen-presenting cells, such as B cells, macrophages, and dendritic cells. This would allow for greater flexibility than is present in classical αβ T-cell responses. T10/T22, I-E, as well as MICA and MICB expression can be induced under certain physiologic/pathologic conditions.[301] ATP synthase F1 is normally localized in the membranes of mitochondria, but it has also been found on the surfaces of tumors, hepatocytes, and endothelial cells.[302,303] Thus, γδ T-cell activation may be regulated through the level of protein expression. In addition, the recognition of I-E by LBK5 is acutely sensitive to changes in the glycosylation of the I-E molecule. This suggests a novel way by which antigen recognition by γδ T cells can be regulated. Changes in the posttranslational modifications of surface glycoproteins often indicate that tissues have become infected, have undergone neoplastic transformations, or have experienced other types of cellular stress. For example, it has been shown that the infection of mice with *Listeria monocytogenes* impairs the addition of sialic acid to host cell glycoproteins that include MHC molecules.[304] Additionally, whereas the surface glycoprotein mucin is heavily glycosylated in normal cells, it is underglycosylated in breast, ovarian, and pancreatic carcinomas such that the peptide backbone is unmasked.[305] Thus, both the quantity and the quality of the ligand could contribute significantly to the specificity of γδ TCR recognition.

TABLE 11.6 Partial List of γδ T-Cell Reactivities[a]

Name (referred to as)	Source	Reported Reactivities	Comments	Reference
Murine				
DGT3	Lymph node cells from DBA2	Qa-1/($Glu^{50}Tyr^{50}$)		317

	mouse primed with poly ($Glu^{50}Tyr^{50}$)			
KN6	Double-negative thymocytes from C57Bl/6	$T10/T22^{b,k}$ not d		318
Tgl4.4	Lymph node of HSV-infected C3H mouse and restimulated with L cells transfected with HSV-gl	HSV-gl	Can be stimulated by gl protein alone	319,320
G8	BALB/c nu/nu immunized with B10. BR APCs	$T10/T22^{b,k}$ not d	Direct binding and cocrystal structure have been shown	153,274,323
LBK5	C57Bl/10 nu/nu immunized with B10. BR splenocytes	$I\text{-}E^{b,k,s}$ not d	Can be stimulated by I-E proteins alone; reactivity is not peptide-specific	322,323
LKD1	B10.BR immunized with B10.D2 splenocytes	$I\text{-}A^{d}$		322
69BAS-122	C57Bl/10, adult splenocyte	HSP-60 peptide, cardiolipin, β2-glycoprotein 1	Transferring TCR transfers reactivity	324,325
BNT-19.8.12	C57Bl/10, newborn thymocyte	Mycobacterium PPD, cardiolipin, β2-glycoprotein 1	Transferring TCR transfers reactivity	325,326
7-17 and other dendritic epidermal T cells	γδ T cells from murine epidermis	Keratinocytes	Transferring TCR transfers reactivity	33
Human				
Panels of T cell clones expressing Vγ 9Vδ 2	PBMC stimulated with irradiated PBMCs and PHA	Tumor cells (eg, Molt-4), MT, metabolites in the mevalonate pathway	20% of Vγ9Vδ2 clones do not react to MT; only slightly	327,328

			more than 50% of MT- or Molt-4-specific clones recognize the other specificities	
Panels of T-cell clones expressing Vγ9Vδ2 including G42 and G115	γδ T cells from PBM cultured with irradiated PBLs and lymphoblastoid cells	phosphoAg, tumor cells (eg, Daudi), AS/ApoA-I (G115TCR)	Close correlation between Daudi and mycobacterial reactivity; direct binding between AS/ApoA-I; heterogenous reactivity to ApoA-I	156,329,330
DG.SF13 (Vγ9Vδ2)	γδT cells isolated from RA synovial fluid stimulated with sonicate of *Mycobacterium tuberculosis*	Daudi cells, *Mycobacterium tuberculosis*, MEP	Transferring TCR transfers reactivity	331
Panels of T-cell clones expressing Vγ 9Vδ 2 including CP1.15 and DG.SF68	PBMC γδ T cells stimulated with *Mycobacterium tuberculosis* extract	phosphoAg, alkylamines, aminobisphosphonates	Reactivities require cell-cell contact	332,333
Clones 1,2,3,4, 5 (Vδ1)	Lymphocytes extracted from human intestinal epithelial tumors cultured with irradiated ClRMICA and ClR-MICB cells	MICA, MICB	Transferring TCR transfers reactivity; Vδ1-Jδ1 with diverse CDR3 are used; not all Vδ1-Jδ1 cells are MIC-specific	334,335
JR.2 and XV.1 (Vδ1)	PBL stimulated with autologous $CD1^+$ DC and M. tuberculosis extract	CD1c expressing cells	Transferring TCR transfers reactivity; many Vδ1 positive γδ T cells are not	335

			CD1c-reactive	
Vγ1.3Vδ2 expressing BW5147	γδ TCR chains from muscleinfiltrating T cells of a polymyositis patient and transfected into TCR-deficient BW5147	Muscle cell extract and *Escherichia coli* extract		336,337
4-29 and 5-3 (Vδ2 negative)	PBMC from CMV-infected transplant recipients stimulated with irradiated PBMC and PHA	CMV-infected fibroblasts, Hela, HT-29, Caco-2		338

[a]The names of the T cells, the way they are generated, and their reported reactivities.

CMV, cytomegalovirus; HSA, herpes simplex virus; MEP, monoethylphosphate; PBMC, peripheral blood mononuclear cell; PHA, phytohaemagglutinin; PPD, microbacterium purified protein derivative; RA, rheumatoid arthritis.

Thymic Ligand Recognition and γδ T-Cell Repertoire and Function Development

γδ T cells, like αβ T cells, develop in the thymus before entering the periphery. In the case of αβ T cells, thymic development entails endogenous ligand-driven positive and negative selection, which determine what αβ T cells can recognize and whether these T cells will develop into CD4+ helper or CD8+ cytolytic T cells. However, the role of ligandmediated selection in γδ T-cell development and function has been less clear. Recently, this issue has been reexamined and the emerging picture is fundamentally different from what we know about αβ T-cell development and differentiation. These work suggest that thymic development does little to constrain γδ T cell antigen specificities, but determines γδ T cell effector fate.[306] In particular, γδ thymocyte development and exit into the periphery is not contingent on encountering cognate antigen in the thymus and TCR dimerization may be sufficient to induce signaling for γδ T cells to develop in the thymus.[306a] Thus, once the antigen specificity repertoire is generated by V(D)J rearrangement, it is only marginally modified by thymic selection. In fact, a large fraction of peripheral γδ T cells have not encountered ligand either in the thymus or in the periphery, and this antigen-naïve population is actively maintained by rapidly turning over, and cells that have encountered self-ligands do not accumulate.[306a]

While ligand expression does little to constrain antigen specificities of the γδ T cell repertoire, it does play a role in endowing γδ T cells with different functional programs, in that TCR signaling strength experienced by γδ thymocytes seem to determines the functional specification of γδ T cells: γδ thymocytes that have not encountered cognate ligands make IL-17, γδ thymocytes that have encountered thymic ligands make IFN-γ,[306a] and those that are strongly self-reactive make IL-4. Importantly, regardless of ligand experience, some γδ T cells in normal mice are able to make cytokines immediately upon TCR engagement. IL-17 is a cytokine, which regulates the expansion and recruitment of neutrophils and monocytes to initiate the inflammatory response.[306b] In acute inflammation, a swift IL-17 response must be elicited without prior antigen exposure. Therefore, γδ T cells may be uniquely suited to produce IL-17 at the onset of the inflammatory response to initiate an acute inflammatory

response to pathogens and to host antigens revealed by injury. In addition, by acting early in the inflammatory response, γδ T cells may modulate and shape the subsequent αβ T cell and B cell responses that develop during the inflammatory process and thus may play a much larger role in the adaptive immune response than previously recognized.

Antigen Recognition Determinants of γδ T-Cell Receptors: V Genes Versus Complementarity-Determining Region 3 Regions in γδ T-Cell Receptor Ligand Recognition

In part because γδ T cells from different anatomic sites show preferential V gene expression, γδ T cells are commonly been divided into subsets based on V gene usage.[309,310] Numerous studies have also reported that γδ T-cell functions segregate with Vγ or VγVδ usage.[311,312,313,314] These observations have led to suggestions that the bias in V gene usage enables γδ T cells to respond to antigens that are specific to their resident tissues.[11,312,315] If this were the case, then γδ TCRs would function like innate immune receptors even though VDJ recombination of the TCR δ chain leads to orders of magnitude higher potential junctional (CDR3 region) diversity than is found in Ig and αβ TCRs (as discussed previously).

To resolve this issue, it is essential to understand the basis of γδ TCR antigen recognition. Based on the analysis of T22-specific γδ T cells isolated from normal mice, the majority of T22-specific γδ TCRs use Vγ1 and Vγ4 in the spleen and a sizeable number use Vγ7 in the IEL compartment.[316] Thus, at least for T22 specificity, Vγ usage reflects tissue origin and not antigen specificity. Consistent with this, it has been demonstrated that the preferential usage of Vγ7 by γδ T cells that can migrate into the IEL compartment primarily results from interleukin-15-driven control of Vγ7 accessibility during thymic VJ rearrangement.[317]

While different Vγs and Vδs were associated with T22-specific TCR sequences, there is one defining feature that is common among them.[316] This is a prominent CDR3δ motif shown in Figure 11.14 that consists of a Vδ or Dδ1-encoded Trp (W); a Dδ2-encoded sequence of Ser, Glu, Gly, Tyr, and Glu (SEGYE); and a P-nucleotide-encoded Leu (L). Gene transfer experiments established that TCRs with the W-(S)

EGYEL motif bound T22 while those lacking the motif did not[316] (see Table 11.6).

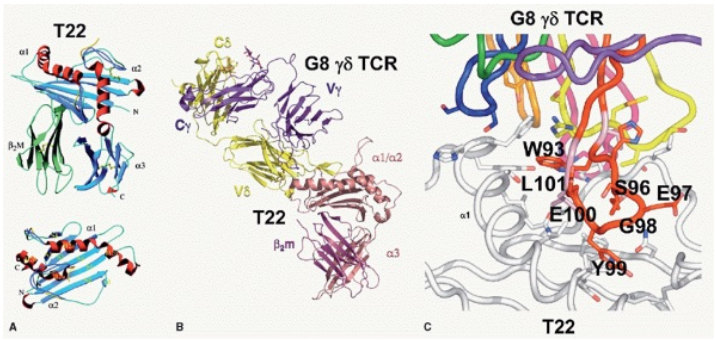

FIG. 11.14. The T22 Structure and the Interaction with the G8 γδ T-Cell Receptor (TCR). A: The structure of a T22 molecule, a nonclassical class I MHC that is missing half of an alpha helix and does not bind peptides.[270] **B,C:** The intersection with the G8 TCR, where the long TCR δ CDR3 accounts for almost all of the contact residues.[153]

Proof that the W- (S)EGYEL motif is the antigen contact site came from the crystal structure of the G8 γδ TCR bound to T22.[168] As discussed in the previous section, T22 has an MHC class I-like fold, but one side of what would normally be a peptide-binding groove is severely truncated and exposes the β-sheet "floor."[296] G8 binds T22 at a tilted angle that contrasts with the essentially parallel alignments of the long axes of the αβ TCR and the peptide/MHC when in complex (Fig. 11.15). The majority of the contact residues are contributed by the β-

sheet floor and the α1 helix of T22, and the fully extended CDR3d loop with Trp anchoring at the N-terminal end and residues Gly, Tyr, Glu, and Leu together with a Thr residue encoded in the J region anchoring the loop at its C-terminal end. This is similar to Ig, where antigen specificity in nonsomatically mutated antibodies resides predominantly in the CDR3 of the heavy chain.[318] This mode of antigen recognition

also fits well with analyses of CDR3 length distributions of all immune receptor chains that first suggested that γδ TCRs bind antigens more similarly to Igs than to αβ TCRs.[144]

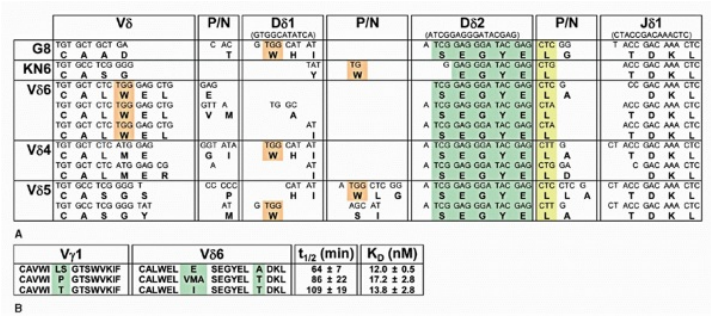

FIG. 11.15. Conserved T-Cell Receptor (TCR) δ Complementarity-Determining Region (CDR)3 Sequences Correlate with T10/T22 Specificity in γδ T Cells.

Sequence data from Shin et al.[290] showing that both established cell lines (G8 and KNG) and γδ T cells from clonal cultures that are specific for the T10/T22 share highly conserved TCRδCDR3 sequences. These are largely derived from the Dδ2 gene segment and from the structural data.Adams et al., color plate 4, [153] These conserved sequences constitute the main interaction between these γδ TCRs and their ligands.

There are two G8/T22 complexes in the asymmetric unit.[168] While the contact residues are similar at the interface of the CDR3/T22 β sheet, the two complexes differ by a relative rotation between the G8 TCRs. This shift alters the contacts formed between the CDR1, CDR2, HV4, and CDR3 loops and T22 in each TCR, suggesting that the CDR3 loop acts as a pivot point for G8 binding, with some flexibility in the interaction between the other CDR loops and T22. The hinge-like flexibility around this pivot point stands in stark contrast to interactions seen in antibody/antigen and αβ TCR-peptide/MHC complexes. In those cases, the relatively straight-on docking mode results in multipoint (ie, multi-CDR) attachment of the receptor to the ligand, essentially rigidifying the intermolecular orientations between the two binding partners. In most cases, the αβ TCR CDR1 and CDR2 loops provide a perimeter of contacts with the MHC helices surrounding the CDR3 loops, and so far, no variation has been seen in the docking angle of TCR to MHC in cases where multiple complexes exist in the asymmetric unit. Thus, the CDR3 motif of G8 and other γδ TCRs may be thought of as a somewhat autonomous binding entity that is presented by a variety of germline-encoded variable domain scaffolds without strong preference for particular CDR1 and 2 sequences. It would be interesting to see other examples of γδ TCR/ligand binding. CDR3 regions were found to be important for γδ T-cell recognition of MICA/MICB. In this case, the reactivity correlates only with a junction between Vδ1 and Jδ1. Aside from the W-(S)EGYEL motif, the T22-specific CDR3γδ sequences were diverse and were encoded by various Vδs, N- and P-nucleotides, and Dδ1s of different lengths and reading frames. Importantly, it was shown that sequence variations in the CDR3 regions around this motif modulated the affinity and the kinetics of T22 binding.[313] In fact, the T22-specific repertoire in normal mice covers a range of affinities, as is evident by the large range of T22 tetramer staining intensities.[300,316] This allows for the selection of T cells with the “most optimal” antigen-binding capabilities during an immune response, which is a hallmark of the adaptive immune response.

Nonetheless, such a repertoire that is created mainly by V, D, and J region-derived germline-encoded nucleotides, despite requiring VDJ recombination, would be “innate” in character, because the antigen specificities would be predetermined and the repertoire would be much

less variable among individuals of the same species.

Analysis of the formation of T10/T22-reactive repertoire indicates that biases linked to the recombination machinery influence the generation of a γδT-cell repertoire toward certain specificities. A repertoire that is generated by recombination but conferred by a limited set of germline or germline-like residues at the CDR3 region will be created at a much higher frequency than one whose specificity is conferred primarily by N-nucleotide additions, as is the case with that of αβ TCRs. Indeed, the 1 in 100 frequency of T22-specific γδ T cells in normal mice is much higher than the estimated 1 in 10^5 to 10^6 frequency of naïve peptide/MHC-specific αβ T cells.[315,316,317] This could provide a solution to the apparent paucity of γδ T cells and could allow for a significant response without an initial need for clonal expansion as is required for most αβ T-cell responses. It was shown that rearrangements at the TCR δ locus are biased towards full-length Dδ2 sequences rather than extensive D region nucleotide deletion, as is the case for the TCR-β locus.[313] Thus, different reading frames of Dδ2 may contribute to the recognition of other ligands by γδ TCRs in a manner similar to that of T22-specific γδ TCRs and would lead to a repertoire that is biased toward a relatively small number of ligands, more on the order of hundreds to thousands versus millions as estimated for αβ T cells, but with highly variable antigen-binding affinities. A repertoire of this type would allow more flexible and efficient responses to changes in ligand expression. These are testable hypotheses, especially once more γδ TCR ligands have been identified.

GENERAL FEATURES OF T-CELL RECEPTOR AND IMMUNOGLOBULIN DIVERSITY

A Dominant Role for Diverse Complementarity-Determining Region 3 Regions in Antigen Specificity

One interesting observation that emerges from a detailed analysis of the gene rearrangements that create both TCR and Igs is how the diversity of the CDR3 loop region in one or both of the chains in a given TCR is so much greater than that available to the other CDRs. A schematic of this skewing of diversity is shown in Figure 11.16 for human Igs and for αβ and γδ TCR heterodimers. In the case of αβ TCRs, this concentration of diversity occurs in both Vα and Vβ CDR3 loops, and numerous TCR-peptide/MHC structures[160] have confirmed that these loops sit largely over the center of the antigenic peptide (see previous section). While this concentration of diversity in αβ TCRs in the regions of principal contact with the many possible antigenic peptides seems reasonable, it is much harder to explain for Ig or γδ TCRs. Clearly, there must be some chemical or structural "logic" behind this phenomenon. A clue as to what this might be comes from the elegant work of Shin et al.[313] in the demonstration that for at least one γδ T-cell specificity, the antigen recognition determinants are encoded by germline V or D region residues, with remaining sequence diversity modulating the affinity. While this may be a feature of some or many γδ TCRs, it could not explain the much broader repertoire of Igs. Instead, one possible explanation comes from the studies of Wells and colleagues,[288] who systematically mutated all of the amino acids (to alanine) at the interface of human growth hormone and its receptor as determined by x-ray crystallography. Interestingly, only a quarter of the 30 or so mutations on either side had any effect on the binding affinity, even in cases where the x-ray structural analysis showed that the amino acid side chains of most of the residues were "buried" in the other. This study illustrates an important caveat to the interpretation of protein crystal structures, which is that while they are invaluable for identifying which amino acids could be important in a given interaction, they do not indicate which ones are the most important. This is presumably because the "fit" at that many positions is not "exact" enough to add significant binding energy to the interaction.

In this context, we have proposed a new model[319,320] in which the principle antigen specificity of an Ig or TCR is derived from its most diverse CDR3 loops. In the case of antibodies, we imagine that most of the specific contacts (and hence the free energy) with antigen are made by the V_H CDR3 and that the other CDRs provide "opportunistic" contacts that make generally only minor contributions to the energy of binding and specificity. Once

antigen has been encountered and clonal selection activates a particular cell, somatic mutation would then "improve" the binding of the CDR1s and 2s to convert the typically low-affinity antibodies to the higheraffinity models as observed by Berek and Milstein,[135] and also by Patten et al.[136] As a test of this model, Xu et al.[315] analyzed mice that have a severely limited Ig V region repertoire, consisting of one V_H and effectively two V_Ls (Vλ1 and Vλ2). These mice are able to respond to a wide variety of protein and haptenic antigens, even with this very limited complement of V regions. In several cases, hybridomas specific for very different antigens (ovalbumin versus 2,4-dinitrophenol [DNP], for example) differ only in the V_H CDR3. A limited V region repertoire also seemed no barrier to deriving high-affinity antibodies with somatic mutation, as repeated immunizations produced IgG monoclonals with very high affinities (10^9 to 10^{-10} M). The major immune deficit in these mice was in their inability to produce antibodies to carbohydrates, which may require a special type of binding site or specific V region. Thus, while these experiments only involved one V^H, the results are highly suggestive about the inherent malleability of V^HV^L in general, at least with respect to protein and haptenic epitopes. With respect to αβ TCRs, we expect that most of the energy of the interaction with a typical ligand will reside in the CDR3-peptide contacts and here again the CDR1 and 2 regions will make less energetically important contacts. For γδ TCRs, it is not yet clear whether the T10/T22 specificity[313] is an isolated case or the general rule. From the hypothesis discussed here, if there are γδ TCRs that use the very large inherent diversity in the Vδ CDR3 directly for antigen recognition, it may be that the lack of somatic mutation forces it to provide more diversity in the initial repertoire (versus Igs).

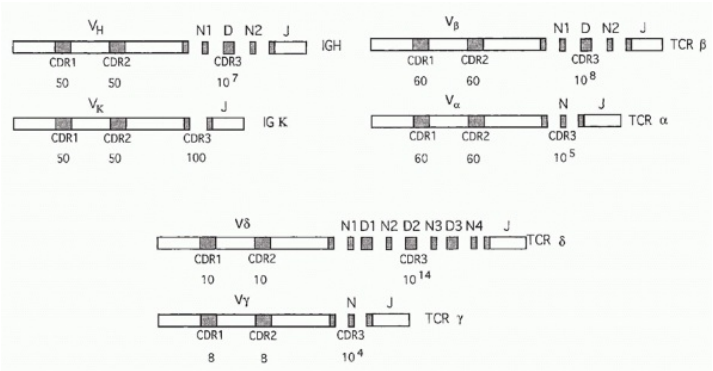

FIG. 11.16. Diversity "Map" of Immunoglobulins and T-Cell Receptors, Calculated Potential for Sequence Diversity in Human Antigen Receptor Molecules.[Adams et al.,153] The N region addition is assumed to contribute zero to six nucleotides to the junction of each gene segment, except for immunoglobulin K chains, in which this form of diversity is seldom used.

CONCLUSION

Because TCR genes were first identified in the early 1980s, information about their genetics, biochemistry, structure, and function has accumulated to become almost a field unto itself. Despite this very real progress, many issues still remain unsolved such as: What do γδ T cells normally "see," and what function do they serve? What do superantigens actually do during the course of a normal response and how is this of benefit to the pathogen/parasite? What is the structural/chemical basis of TCR specificity? What sort of rearrangements or conformational charges occur in the TCR/CD3 molecular ensemble upon ligand engagement? These and other questions will require many more years of effort.

ACKNOWLEDGMENTS

We are grateful to M. Call, K. Wucherpfennig, M. Krangel, M. Krogsgaard, and K.C. Garcia for providing some of the figures and tables used here. We also thank C. Tato, M. Kuhns, M. Krogsgaard, Qi-jing Li, and K.C. Garcia for invaluable help with the manuscript, and R. Cuevas for expert assistance. This work was supported by grants from the National Institutes

of Health (to M.M.D. and Y.C.) and from the Howard Hughes Medical Institute (to M.M.D.).

Chapter 12

Mechanisms of T-Lymphocyte Signaling and Activation

Takashi Saito

INTRODUCTION

The immune system protects us against attack by pathogens through two separate but interacting systems: innate immunity and acquired (or adaptive) immunity. Whereas innate immunity exhibits rapid and transient responses by recognition of conserved molecular patterns of pathogens, adaptive immunity distinguishes any small difference/heterogeneity of a huge number of pathogens and antigens and mediates a rather slow but long-lasting response. For this purpose, as is discussed elsewhere (see Chapter 6) in this volume, our body prepares a vast variety of receptors on T cells and B cells (immunoglobulins [Igs]) to be able to recognize virtually all potential antigens. Because each lymphocyte possesses single antigen specificity, antigen-specific responses begin with the recognition by and activation of a single cell and consequently the cells proliferate, a process called clonal expansion and selection many years ago by Macfarlane Burnet.[1] To understand the mechanism of antigen-specific activation of lymphocytes, it is necessary to study how a single cell of relevant specificity recognizes the antigen and induces its activation to mediate various functions and protection against pathogens. Recognition of antigen only on the cell surface by the T-cell receptor (TCR) of a T cell is unique and totally different from that of Ig on a B cell. Such differences in T-cell antigen recognition force the establishment of extensive cell-cell interactions/communications in the body to achieve protective immunity and to maintain immune homeostasis. In this chapter, we describe the unique feature of antigen recognition of T cells through their unique antigen receptor complex and the mechanisms that trigger T-cell activation.

T-CELL RECEPTOR COMPLEX

Antigen specific recognition is mediated by the TCR, which is composed of a heterodimer of either αβ or γδ polypeptides. This chapter will focus on signaling mediated through the αβ TCR. As described in Chapter 11, both TCRα and β chains contain variable regions, which together are responsible for binding to the complex of antigen peptide-major histocompatibility complex (MHC). After a decades-long search for the biochemical nature of TCR, the TCR genes were finally cloned and found to be quite similar to those encoding Ig genes.[2,3,4,5,6] TCRα and β chains both possess very short cytoplasmic domains without any particular protein-binding motif, and thus cannot transduce antigen-recognition signals into the cell. It is necessary, therefore, for the TCR to assemble with signaltransducing components, the cluster of differentiation (CD)3 complex, to transduce antigen-recognition

signals. The initial finding that CD3 chains are responsible for transducing activation signals into T cells came from the observation that treatment of T cells with a crosslinking anti-CD3ε antibody (OKT3) induces strong T-cell polyclonal activation[7] similar to that induced upon stimulation with mitogens such as concanavalin A. It was also shown that there is a physical but noncovalent association between TCR dimers and the CD3 complex. It is now known that the association of the TCR dimer and the CD3 complex is required first for cell surface expression and then to transduce antigen-recognition signals into T cells.[8,9] The CD3 complex is composed of four different chains. Three of them, γ, δ, and e, are closely related in their protein structure, gene structure, biosynthesis, and chromosome localization. While the γ, δ, and ε are genes are located within a neighboring region of the chromosome (chromosome 11 in human and 9 in mouse), ζ is located on chromosome 1 in both species (Fig. 12.1). The CD3 complex is composed of three distinct dimers, γε, δε, and ζζ, which associate with the TCRαβ dimer. Whereas γε and δε are noncovalently assembled, ζ-ζ is a covalently linked dimmer with a disulfide bond. The ζ chain has an isoform termed η, which is derived from alternative splicing of the ζ transcript and is found only in rodents but not in humans. The cell surface expression of the TCRαβ dimer requires its assembly with the CD3 complex due to a stringent quality control checkpoints in the endoplasmic reticulum (ER) that prevent the release of incompletely assembled TCR-CD3 complexes. Studies of the biosynthesis of these components of the this complex showed that CD3γ, δ, and ε as well as TCRα and β chains are synthesized in great excess and readily degraded in the ER in the absence of assembly with the other chains. The assembly with the partner chain protects the complex from ER degradation. CD3ζ is synthesized at limiting levels, and even the TCRαβ-CD3γδε complex cannot be transferred to the cell surface without assembly with CD3ζζ and is degraded in lysosome.[10] Therefore, the assembly with ζ-ζ defines the fully functional TCR-CD3 complex, and the entire TCRαβ-CD3γδεζζ complex is now allowed to transport to the plasma membrane where it is expressed as the complete and functional TCR-CD3 complex.

THE IMMUNORECEPTOR TYROSINE-BASED ACTIVATION MOTIF AND INITIAL SIGNALING

The cytoplasmic tails of all CD3 chains contain a common signaling motif, immunoreceptor tyrosine-based activation motif (ITAM), which has the consensus sequence YxxL/I x6-8 YxxL; composed of two repeats of YxxL/I motif (Y; tyrosine, L/I; leucine/isoleucine) with a spacer of six to eight

amino acids. CD3δ, γ, and ε have a single and CD3ζ has three tandem ITAMs within the intracellular region. The ITAM was first identified as a signature sequence present in several cell surface receptors on immune cells.[11] ITAM-containing molecules have since been found to be widely distributed among various important immune receptors, not only TCR (CD3s) but also in B-cell antigen receptors (Igα and Igβ), various types of Fc receptors (FcRγ), adaptor proteins associated with MHC-recognizing receptors, or paired receptors on natural killer (NK) cells (DAP12 and DAP10) (Fig. 12.2) and further in various pattern-recognizing receptors of innate cells such as macrophages and dendritic cells (DCs).[12] The ITAM turns out to be specific motif capable of transducing receptor-mediated recognition signals into cellular activation.[13] The function of the ITAM in transducing T-cell activation signals has been shown first by analyzing the capacity of a chimeric protein composed of the extracellular

domain of CD8 and the intracellular domain of CD3ζ to

induce T-cell activation.[14] Antibody crosslinking of the CD8 domain showed that the cytoplasmic tail of CD3ζ can induce almost all the events observed during normal T-cell activation, including tyrosine phosphorylation of various proteins, induction of intracellular calcium mobilization and inositol phosphate metabolism, induction of activation markers, cytokine production, and cell proliferation. Mutational analyses of the ITAM sequences within the CD3ζ cytoplasmic region revealed that both tyrosine and leucine (isoleucine) residues are critical for transducing a T-cell activation signal.[15,16]

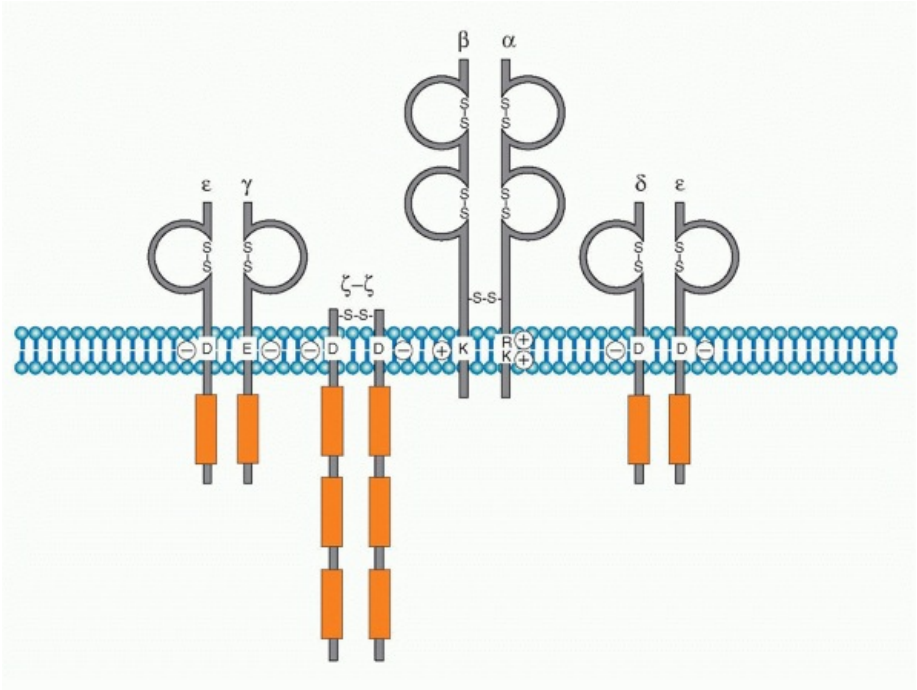

FIG. 12.1. Structure of the T-Cell Receptor (TCR)-Cluster of Differentiation (CD)3 Complex. The TCRαβ dimer is associated with three dimers of CD3 chains: CD3εγ, CD3εδ, and CD3ζζ. Whereas TCRα and β possess positively charged amino acids within the transmembrane region, all CD3 chains contain negatively charged amino acids, which are necessary to be assembled as the complex. CD3 chains possess immunoreceptortyrosinebased activation motif (ITAM) within their cytoplasmic tails as shown in *red boxes* (γ, δ, and ε have one; ζ has three).

FIG. 12.2. Structure and Signaling Function of Immunoreceptor Tyrosine-based Activation Motif (ITAM). Cluster of differentiation 3s (T cells), Ig-α/β (B cells), FcR (myeloid cells; macrophages, dendritic cells, neutrophils, etc.), NK cells, as well as some viruses possess ITAM within the cytoplasmic domain. There are increasing numbers of ITAM-bearing or ITAM+ adaptor-associated receptors in innate systems. The consensus sequence of the ITAM is composed of YxxL/I- (seven or eight spacers)- YxxL/I where x is any amino acid. The tyrosine residues within ITAM are phosphorylated by src family kinase Lck upon TCR engagement, followed by the binding of the tandem two SH2 domains of ZAP-70 to both phosphorylated tyrosines in T cells.

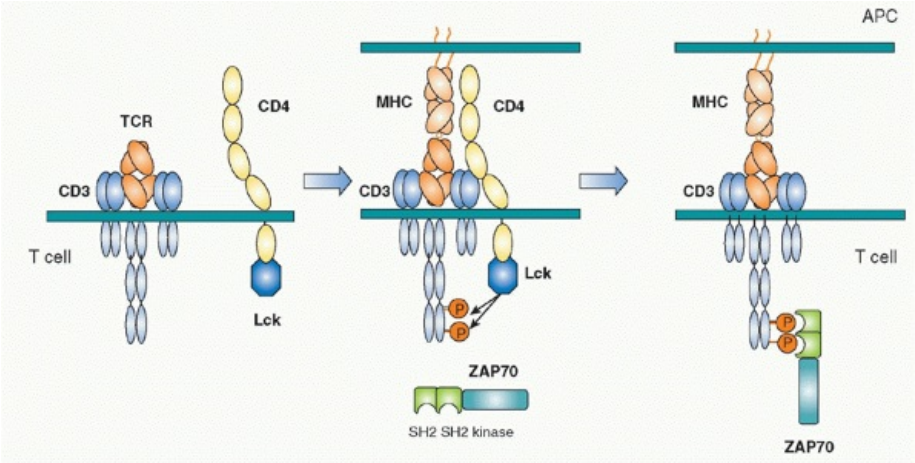

FIG. 12.3. Initial Activation of T Cells by Sequential Two Tyrosine Kinases. Left: The T-cell receptor (TCR)-cluster of differentiation (CD)3 complex and the complex of CD4 and the Src kinase Lck are located separately in resting T cells. **Middle:** Upon antigen peptide-major histocompatibility complex (MHC) recognition by TCR, the TCR complex and the CD4-Lck complex get near through the CD4-MHC binding, which induces Lck close to the CD3 chains. The immunoreceptortyrosine-based activation motif (ITAMs) of CD3 chains are tyrosine-phosphorylated by Lck. **Right:** The phosphorylated ITAM of the CD3 chains became the binding sites for the tandem two Src-homology 2 domains of the second tyrosine kinase ZAP-70. ZAP-70 is phosphorylated by Lck and by itself and activated, and then transduces activation signals by phosphorylating downstream signaling molecules.

Biochemical analyses to define the downstream signaling molecules recruited upon TCR stimulation resulted in the discovery of several important proteins that are involved in tyrosine phosphorylation and activation of several adaptor molecules including a Src family tyrosine kinase, Lck, and a Syk family kinase, Zeta-associated protein-70 (ZAP-70).[17] The ITAM is phosphorylated by Src kinase Lck upon TCR engagement by antigen. Once tyrosines are phosphorylated, they become susceptible to binding in general by proteins possessing Src-homology 2 (SH2) domains. The phosphorylated ITAMs recruit the second tyrosine kinase ZAP-70, one of Syk family kinases. ZAP-70 is contains two tandem SH2 domains in its N terminus and a tyrosine kinase region in the C-terminus.[18,19] The tandem SH2 domains with exactly the right spacing can bind the two phosphorylated tyrosines within an ITAM[20] (Fig. 12.3). Because TCR and CD3 chains do not have any intrinsic effector function, unlike tyrosine kinase-containing receptors such as the epidermal growth factor receptor or the insulin receptor, the binding of ZAP-70 to the phosphorylated CD3ζ ITAM changes the TCR-CD3 complex, making it competent for signal transduction. ZAP-70 assembled with the CD3 phospho-ITAMs must then be enzymatically activated by phosphorylation of otherwise inhibitory tyrosines in its juxtamembrane region by Lck as well as by itself. The binding and activation of ZAP-70 may be associated with the structural changes of CD3 chains induced by phosphorylation, a topic that will be described under the section Triggering Mechanism. Activated ZAP-70 induces phosphorylation of tyrosine residues of various downstream target molecules.[21] These include adaptor molecules LAT and SLP-76. These phosphorylation events lead to further activation of several adaptor and effector molecules and subcellular assembly as multimolecular signaling complex.

REGULATION OF PROXIMAL SIGNALING

Regulation of Tyrosine Kinases

Src family tyrosine kinases (Lck, Fyn in T cells) are composed of an N-terminus unique region, SH2, SH3, and a kinase domain at the C-terminus.[22] The N-terminus unique region contains palmitoylation sites by which Lck is localized in lipid rafts on the inner leaflet of the plasma membrane. Because Lck specifically associates with the cytoplasmic regions of CD4 and CD8 coreceptors, Lck accumulates at the site of TCR engagement because CD4 or CD8 are also present within the engaged site through binding to MHC.[23,24] As a result, Lck is recruited to the vicinity of the CD3 chains where it is able to phosphorylate them.

The activity of Lck is regulated allosterically by phosphorylation of a tyrosine in the carboxyl terminus by the

C-terminal kinase (Csk).[25] This phosphotyrosine interacts with the SH2 domain of Lck, and this induces a conformational change to maintain Lck in a catalytically inactive status. Csk normally and continuously acts to reduce Lck activity and thereby attenuate TCR signaling. Indeed, in the absence of Csk, peripheral T cells become autonomously activated. Dephosphorylation of the Cterminus tyrosine releases Lck from its inactive status. In addition, in order to fully activate Lck, the tyrosine phosphorylation in the catalytic domain is also required. Because the tyrosine phosphatase CD45 induces the dephosphorylation of both of these regulatory tyrosines, CD45 functions as both a positive and negative regulator of T-cell activation[26] through the C-terminal and kinase-domain tyrosines, respectively. The balance between Csk and CD45 regulates the status of T-cell activation[27] (Fig. 12.4). A considerable fraction of Lck in naïve T cells is catalytically active because of this dynamic balance. Such active Lck may be responsible for constitutive activation signals including phosphorylation of CD3ζ and help in initiating T-cell activation.[28] A related src-family kinase Fyn is also expressed in T cells and is weakly associated with the TCR complex. Fyn appears to have some signaling role because T cells deficient in both Lck and Fyn have a more complete block in T-cell development than Lck-deficient mice.

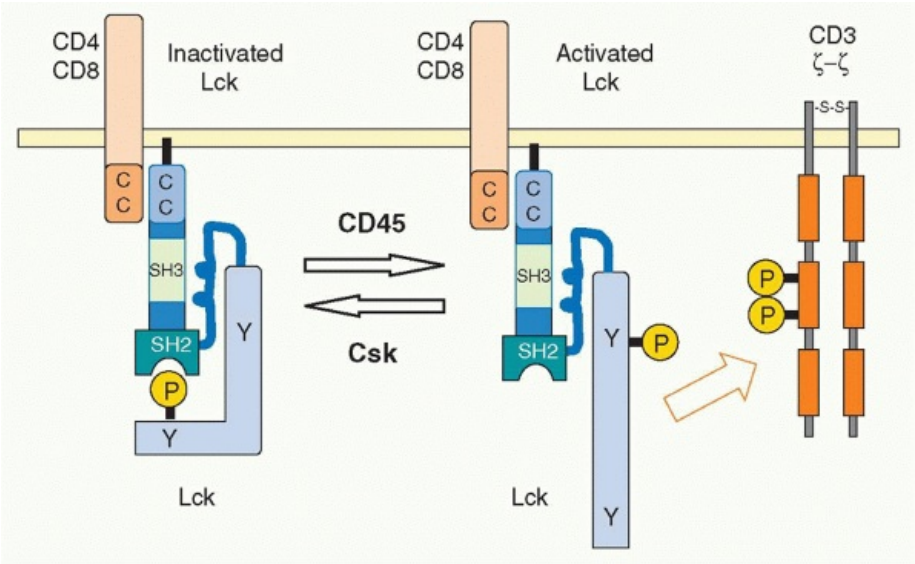

FIG. 12.4. Regulation of the Src Kinase Lck Activation by the Tyrosine Kinase Csk and the Phosphatase Cluster of Differentiation (CD)45. In resting T cells, Lck has a closed configuration through the intra-association between the phosphorylated tyrosine at the C terminus and the Src-homology 2 domain. C-terminus src kinase (Csk) phosphorylates this regulatory tyrosine residue. The association between CD4 and Lck is mediated by the interaction of the cysteine-containing regions of both molecules. CD45 dephosphorylates the C-terminus tyrosine, which alters the configuration from the closed structure as the “inactivated Lck” to an open shape as the “activated Lck” with active kinase function.

Adaptor-Mediated Signaling

Among the targets of ZAP-70-mediated phosphorylation, a transmembrane adaptor protein, linker for the activation of T cells (LAT),[29] and an intracellular adaptor protein, SH2 domain-containing leukocyte phophoprotein of 76 kDa (SLP-76),[30] are the most important substrates (Fig. 12.5). The discovery of these two adaptor proteins revealed the connection between the ZAP-70 tyrosine kinase and PLCγ activation. These adaptor proteins create an important signal assembly to induce downstream activation signals. The critical roles of these two adaptors are evidenced by the observation that T cells deficient in either LAT or SLP-76 exhibit complete defects in TCR activation signaling.

LAT is a transmembrane protein with a short extracellular region and resides in lipid rafts, membrane microdomains enriched in cholesterol and sphingolipids, via two palmitoylation sites within the juxtamembrane region. Mutation of these palmitoylation sites results in the failure of LAT to be expressed on the plasma membrane or to transduce T-cell activation, indicating that the association within lipid rafts regulates trafficking to the membrane. Upon TCR stimulation, LAT becomes tyrosine-phosphorylated on multiple tyrosine residues (five tyrosines among nine conserved residues), and these serve as the docking sites for several SH2-containing molecules. Important effector molecules containing SH2 domains that bind to phosphorylated LAT include PLCγ, growth factor receptor binding protein 2 family members, Grb2 and Gads, and a Tec family kinase, inducible T-cell kinase Itk.[31] Because Grb2 constitutively binds to son of sevenless (Sos), which is a guanine exchange factor (GEF) that mediates guanine triphosphate (GTP) binding of Ras, this LAT-Grb2-Sos complex induces Ras activation; however, RasGRP plays a more critical role for Ras activation than the Grb2-Sos pathway in T cells. Gads binds to phosphor-LAT upon T-cell activation, and Gads associates with SLP-76. Although all tyrosine mutations of LAT lost the function for T-cell activation, the LAT136 mutant mouse exhibits a lymphoproliferative disorder and induction of strong Th2-type cytokine production, suggesting the possibility of a LAT-independent pathway to activate T cells.[32,33]

SLP-76 is a cytosolic adaptor with three domains: an amino terminal region containing three major tyrosines that are phosphorylated upon TCR ligation and become binding sites for various SH2-containing proteins, a central proline-rich domain that binds to SH3-containing proteins, and a carboxy-terminal SH2 domain by which SLP-76 can bind to phosphorylated tyrosines of other proteins.[34] SLP-76 constitutively associates with Gads through its SH3 region, and the SLP-76/Gads complex is recruited to the phosphorylated LAT upon TCR engagement (Fig. 12.6). Both LAT and SLP-76/Gads bind to PLCγ1 independently, and formation of this tetramolecular assembly stabilizes the complex. Because LAT also binds to the Itk Tec family kinase,

which is responsible for phosphorylating PLCγ1, the stable complex of Itk-LAT-SLP-76-PLCγ1 induces PLCγ1 activation. Besides PLCγ1 activation, SLP-76 induces other functions through its association with several other important molecules. At its N-terminus, SLP-76 binds to Vav, a GEF, and Nck, an adaptor protein, both of which are critical for TCR-mediated cytoskeletal changes, and at its C-terminus it binds adhesion- and degranulation-promoting adapter

protein (ADAP),[35,36] an adapter protein coordinating TCR signals with integrin activation (see Fig. 12.12).

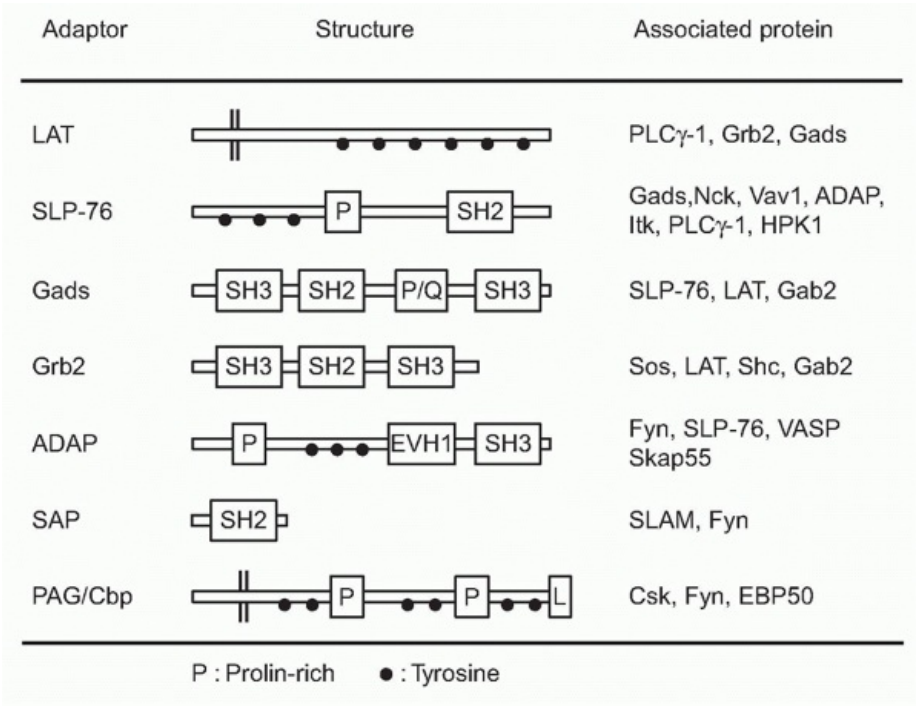

FIG. 12.5. Adapter Molecules Functioning Downstream of T-Cell Receptor Signals. The structure of several adapters described in the text are depicted. These adapter molecules are composed of several modules critical for signal transduction such as Src-homology 2(SH2) and Src-homology 3 (SH3). Whereas tyrosine residues (*black dot*) functions as the docking sites for SH2 upon phosphorylation, the prolin-rich regions (*P*) interact with SH3. Some of these adaptors with the transmembrane regions are localized on the plasma membrane as "membrane adaptors" such as LAT and PAG/Cbp, whereas others within the cytosol as "intracellular adaptors." ADAP, adhesion- and degranulation-promoting adapter protein; Gads, Grb2-related adapter downstream of Shc; LAT, linker for activated T cells; PAG/Cbp, phosphoprotein associated with glycosphingolipid-enriched domains/csk-binding protein; SAP, signal lymphocyte activation molecule-associated protein; SLP-76, SH2 domain-containing leukocyte-specific phosphoprotein of 76 kDa.

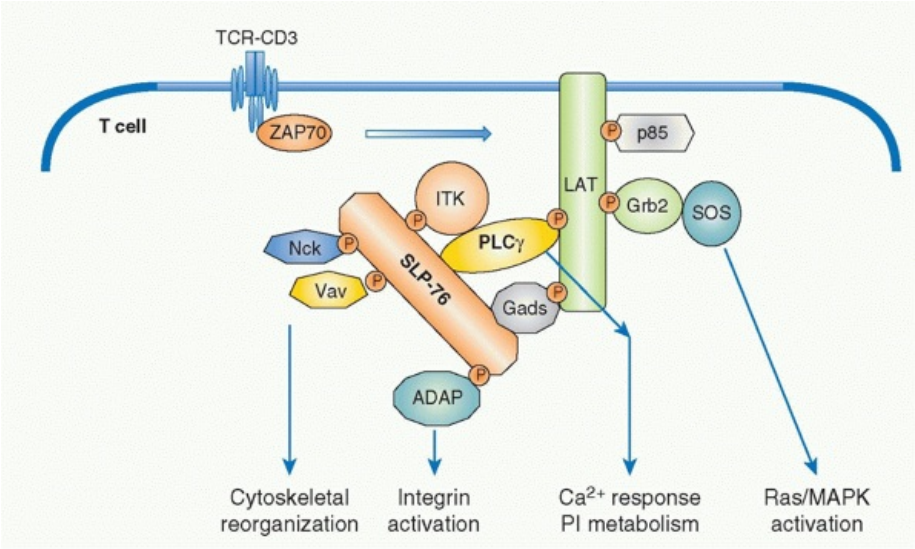

FIG. 12.6. Formation of Multimolecular Signaling Complex Critical for Initial T-Cell Receptor (TCR) Activation Signaling Pathways. Sequential activation of two tyrosine kinases Lck and ZAP-70 upon antigen recognition by TCR induces phosphorylation of two critical adapter proteins LAT and SLP76. Gads constitutively associates with SLP76 and is phosphorylated by TCR activation and recruited to LAT as the Gads-SLP76 complex. Thereafter, several adapter proteins form a physical complex centralized by LAT and SLP-76. Further recruitment of various adapters and effector molecules to the complex leads to the activation of differential signaling pathways. Phospholipase γ1 (PLC-γ1) and Gads link between LAT and SLP76 and a Tec-kinase family ITK, which binds to SLP76, is responsible to phosphorylate/activate PLC γ1. Association of these molecules generates a stable complex of LAT-Gads-SLP76-PLCγ1-ITK critical for further calcium and phosphatidylinositol (PI) responses (as in Fig. 12.7). SLP76 also binds Nck, Vav1, and ADAP, which links to cytoskeletal reorganization (as in Fig. 12.11). LAT binds Grb2/Sos, which induces Ras/MAPK activation (as in Fig. 12.8).

DOWNSTREAM SIGNALING PATHWAYS

The next step of the T-cell activation pathway after ZAP-70-induced phosphorylation of the adaptor LAT and SLP-76 upon TCR ligation is the activation of the key signaling enzyme PLCγ1. PLCγ1 is recruited to the plasma membrane through the binding of its PH domain to PIP3, which is generated within the membrane by the phosphorylation of PIP2 by PI3-kinase. PLCγ1 is activated upon phosphorylation by Itk,[37,38] which is composed of PH, SH2, SH3, and kinase domains, and is also recruited to the plasma membrane through its PH domain by interacting with PIP3. Phosphorylated and activated PLCγ1 then cleaves the membrane bound PIP2 to generate two critical products: the membranebound lipid diacylglycerol (DAG) and the diffusible inositol 1,4,5-triphosphate (IP3), both of which function as second messengers for further inducing downstream signaling.

Calcium-Nuclear Factor of Activated T Cells

Upon TCR stimulation, the levels of intracellular free calcium are regulated in two phases: there is an initial and transient induction of calcium release from storage in the ER, and this is

followed by the induction of a strong influx of high levels of calcium from outside of the cells by opening a calcium channel called the calcium release-activated calcium channel (CRAC) in the plasma membrane. IP3 generated by PLCγ1 catalysis diffuses into the cytoplasm and binds to IP3 receptors on the ER membrane. IP3 receptors are calcium channels and, after IP3 binding, they open and allow the release of the calcium stored within ER into the cytosol. The released low level of calcium induces cluster formation by the calcium-binding transmembrane protein, stromal interaction molecule-1 (STIM1), within the ER.[39] STIM1 is an ERresidential protein that contains an N-terminal sterile motif and paired EF hands that function as a calcium-binding motif and a coiled-coil motif at the C terminus. A critical CRAC called Orai1 has been identified from the analysis of a patient with severe combined immunodeficiency who had a major defect in lymphocyte activation.[40] Clustered STIM1 on the ER membrane is colocalized and assembled with Orai1 on the nearby plasma membrane to open the channel and introduce extracellular calcium into the cytosol (Fig. 12.7). Recent analysis has shown that oligomerization of STIM1 is sufficient to induce CRAC activation independent of ER calcium store depletion, but the mechanism by which STIM1 induces Orai1 oligomerization remains unknown.

Surprisingly, STIM1, STIM2 (another family member), and Orai1 are dispensable for T-cell development as deficiency of these molecules does not affect this process. Because calcium flux is also induced and is important in thymocytes, it is assumed that there must be other functionally redundant and critical calcium channels in thymocytes.[41]

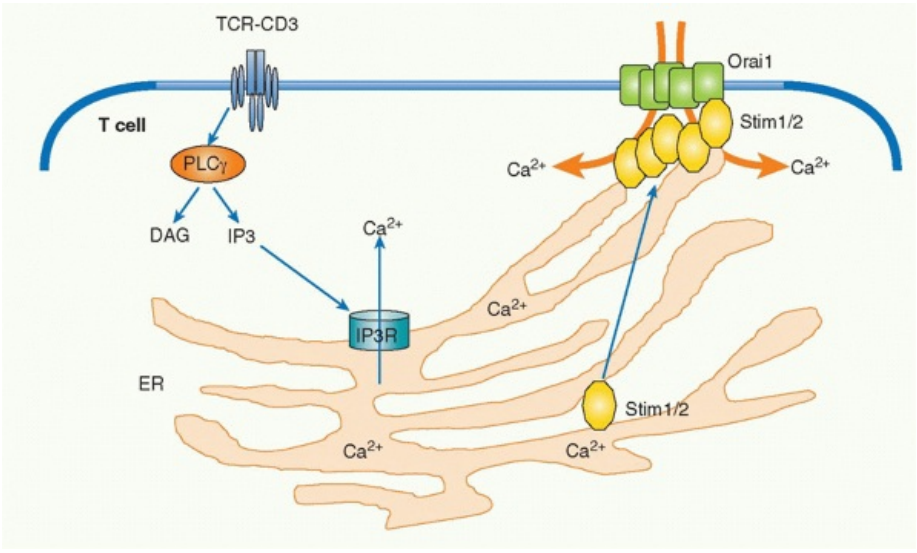

FIG. 12.7. The Mechanism of Calcium Response in T-Cell Activation. T-cell receptor engagement induces activation of PLCγ1 and generates inositol trisphosphate (IP_3), which binds to the IP_3 receptors (IP3R) present on the endoplasmic reticulum (ER) and stimulates the calcium release from intracellular calcium pool within the ER. Increase of intracellular calcium level activates a calcium-binding paired EF hands-bearing protein Stim1/2, which then translocates to the vicinity of the plasma membrane. Stim1 localizes with and induces dimerization of ORAI calcium release-activated calcium modulator 1 (Orai1), resulting in opening functional calcium release-activated calcium channel. The assembly between Orai1 and Stim1/2 induces the activation pathway dependent on

intracellular calcium concentration.

Upon T-cell engagement, intracellular calcium binds to a protein, calmodulin, and induces a conformational change that allows the protein to bind to various target proteins. An increase of cytosolic calcium induces activation of signaling molecules including calcium calmodulin-dependent kinase and a phosphatase calcineurin. Activated calcineurin acts on a critical transcription factor, nuclear factor of activated T cells (NFAT), to dephosphorylate the protein, which induces its translocation into the nucleus.[42] There are five NFAT family members (NFATc1, c2, c3, c4, and NFAT5), and they are expressed in many different tissues.[43] NFAT is present in the cytoplasm in the resting state in T cells. Cytosolic serine/threonine kinases such as glycogen synthase kinase 3 and casein kinase 2 phosphorylate the nuclear localization signal on NFAT to prevent its translocation into nucleus. Upon antigen stimulation, activated calcineurin dephosphorylates this critical phosphorylation site, which allows NFAT to enter into the nucleus, where it triggers various gene expression programs including various cytokine genes by cooperating with other transcription factors. The most well-characterized gene among NFAT targets is the interleukin (IL)-2 gene. NFAT binds to the IL-2 promoter by forming a cooperative complex with activator protein (AP)-1, which is a heterodimer composed of members of the Jun and Fos family, to induce IL-2 transcription. NFAT and AP-1 represent two signaling pathways of calcium and Ras/MAPK, respectively. It has been shown that T-cell activation in the absence of the induction of AP-1 results in anergic or unresponsive T cells.[44]

Ras-Mitogen-Activated Protein Kinase

In parallel with IP3, DAG is generated by PLCγ and remains localized within the plasma membrane where it recruits various signaling molecules that contain a specific DAG-binding motif (called the C1 domain), including members of the protein kinase C (PKC) family[45] and RasGRP,[46] a guaninenucleotide exchange factor for Ras. DAG binding activates PKC and promotes RasGRP to activate Ras by exchange from the guanosine diphosphate (GDP) to GTP-binding form.[47] Ras is active in the GTP-bound form, and this activation step is mediated by GEFs and suppressed by GTPaseactivating proteins (GAPs). RasGRP and Sos are two major GEFs in the TCR activation pathway (Fig. 12.8). In T cells, RasGRP functions dominantly for early activation of Ras. RasGRP is inducibly associated with the plasma membrane through binding of its C1 domain to DAG and is phosphorylated by PKCθ. On the other hand, Sos constitutively associates with an adaptor protein Grb2 and the Grb2 SH2 domain binds to phosphorylated LAT upon T-cell activation; Sos-Grb2 binds to LAT-SLP76, which results in its recruitment to

the vicinity of the TCR. The relationship between RasGRP and Sos appears to be cooperative rather than competitive as RasGRP-mediated Ras activation enhances Sos activity as a positive feedback to induce strong Ras activation.[48]

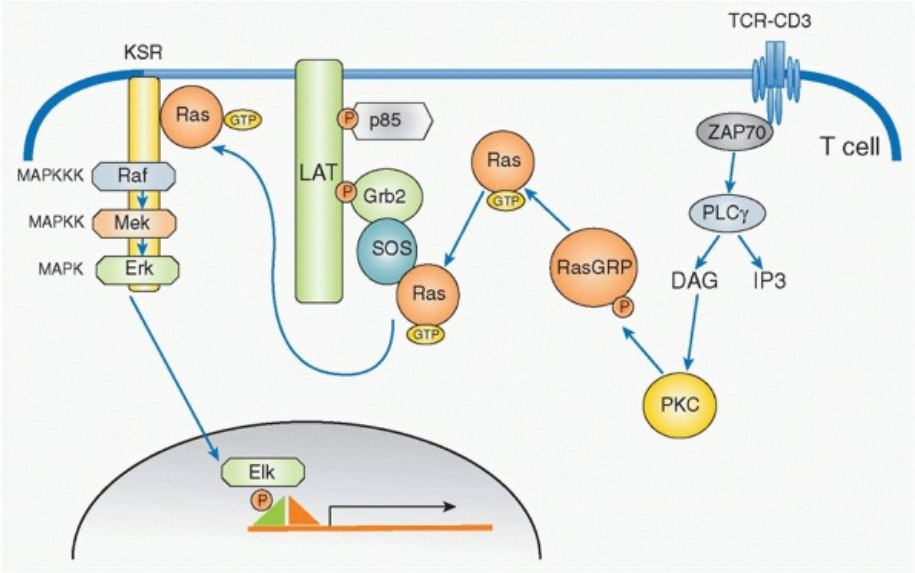

FIG. 12.8. Ras Activation Pathways by T-Cell Receptor (TCR) Stimulation. Activation of Ras in T cells following antigen engagement involves activation of two different guanine triphosphate (GTP) exchanging factors: one is Ras-GRP, and the other is son of sevenless (Sos). TCR activation induces diacylglycerol generation by PLCγ1, which recruits Ras-GRP to the membrane where Ras-GRP is activated by PKCθ. Activated Ras-GRP induces Ras activation by exchanging guanosine diphosphate (GDP) to GTP, which then binds to Sos, because Sos constitutively assembles with Grb2 and the Grb2-SOS complex is recruited to LAT upon TCR activation. Activated Ras then induces the activation cascade of mitogen-activated protein kinase which sequentially contains MAPK kinase kinase (Raf), MAPK kinase (Mek), and MAPK (Erk).

Ras activation triggers a cascade of kinase activation, which finishes by activating a serine/threonine kinase known as a mitogen-activated protein kinase (MAPK). The MAPK cascade is composed of three kinases: MAPK kinase kinase (MAP3K), MAPK kinase (MAP2K), and the MAPK itself. In the case of the TCR signaling pathway, the first MAP3K is Raf, which is a serine/threonine kinase that phosphorylates the next MAP2K, which in T cells is MEK1. MEK1 is called a dual-specificity kinase because it can phosphorylate both a tyrosine and a threonine of the last member of the cascade, the MAPK extracellular signal-regulated kinase 1 (Erk1) and Erk2 in T cells and B cells, respectively. Erk1/2 induces the activation of Elk1, which in turn activates the AP-1 transcription factor complex composed of Fos and Jun.

PKC-CARMA1/Bcl-10/Malt1-Nuclear Factor of KappaB

Historically, it has long been known that phorbol ester (phorbol 12-myristate 13-acetate) plus a calcium ionophore, a molecule that allows calcium ions to cross cell membranes, induce strong activation signals similar to TCR-induced signals.[49] Phorbol ester is known to activate PKC; thus, PKC is a critical component in T-cell activation. T cells predominantly express the PKCθ isoform of protein kinase C. PKCθ has a DAG-binding domain, is recruited to the plasma membrane through binding to DAG, and is activated upon generation of DAG by PLCγ1. One of the main pathways activated by PKCθ is NF-κB. PKCθ plays a critical role in

initiating several cascades of the classical pathway of NF-κB activation downstream of the TCR. NF-κB is a family of transcription factors composed of homo- and heterodimers of five members of the Rel family including NF-κB1 (p50), NF-κB2 (p52), RelA (p65), RelB, and c-Rel (Rel).[50] In resting T cells, NF-κB is found in the cytosol associated with one of a family of inhibitors of NF-κB (IκB) that prevents NF-κB from translocating into the nucleus. Upon T-cell activation, IκB is phosphorylated by the IκB kinase (IKK) complex, ubiquitinylated and degraded, which allows NF-κB to translocate into nucleus, where it activates various genes involved in survival, homeostasis, and activation of T cells and inflammatory responses.

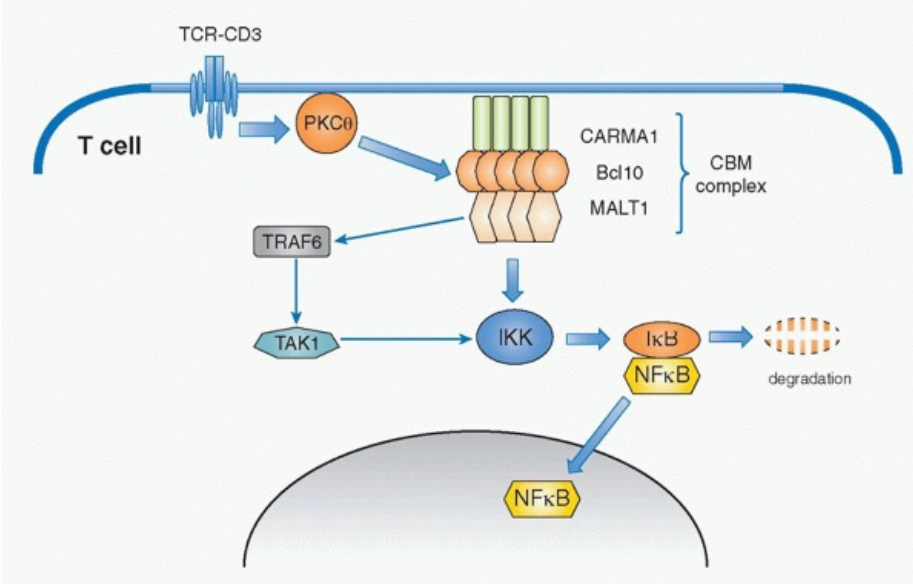

FIG. 12.9. Signaling Pathway for T-Cell Receptor (TCR)-Mediated NF-κB Activation. Upon TCR stimulation, PKCθ is activated and induces phosphorylation and aggregation of caspase-recruitment domaincontaining membrane-associated guanylate kinase protein-1 (CARMA1). Aggregated CARMA1 forms a complex (as the CBM [CARMA1-Bcl-10-Malt1] complex) with two other proteins: B cell lymphoma 10 (Bcl-10) and mucosal-associated lymphoid-tissue lymphoma-translocation gene 1 (Malt1). Malt1 induces the degradation of the regulatory component of IκB kinase (IKK) complex (IKKγ) by ubiquitination via activation of tumor necrosis factor receptor-associated factor-6. IKKγ degradation induces phosphorylation and subsequently degradation of the inhibitor of NF-κB (IκB), which results in activation and nuclear translocation of NF-κB.

Whereas this signaling pathway to activate NF-κB is common among many cell types and has been known for quite some time, the specific pathway by which PKCθ induces NF-κB activation has only been elucidated in the past decade. The critical molecule responsible for mediating the activation signal that connects PKCθ and NF-κB is now known as the CBM complex (Fig. 12.9). It consists of three proteins; a scaffold protein, CARMA1 (caspase recruitment domain [CARD] and membrane-associated guanylate kinase -containing scaffold protein), a CARD-containing

adaptor protein, B-cell lymphoma 10 (Bcl10), and mucosaassociated lymphoid tissue

lymphoma translocation gene 1 (Malt1).[51,52,53] Upon TCR stimulation, this trimolecular complex is induced by PKCθ-mediated phosphorylation of CARMA1, which is required for CARMA1 oligomerization and association with Bcl10. Malt1 binds to Bcl10 and mediates the degradation of the IKKγ subunit (also called NEMO) by inducing polyubiquitination through activation of an E3 ubiquitin-ligase, tumor necrosis factor receptor-associated factor 6 (TRAF6).[55,56] TAK1 recruited by TRAF6 phosphorylates IKK, which in turn induces IκB phosphorylation. This event, together with degradation of NEMO, induces consequently IκB degradation and release and translocation of NF-κB to the nucleus, and thereby induces gene activation.

Overexpression of the CBM complex induces spontaneous NF-κB activation without T-cell (or B-cell) activation. Recently, it has been shown that a high proportion of diffuse large B-cell lymphomas are induced by specific oncogenic mutations of CARMA1, which induce its spontaneous oligomerization of CARMA1, formation of the CBM complex, and subsequent continuous chronic activation of NF-κB, ultimately resulting in tumor induction.[57] This illustrates the importance of maintaining appropriate control of the CBM complex-mediated NF-κB activation for appropriate immune responses without inducing excess inflammation and diseases.

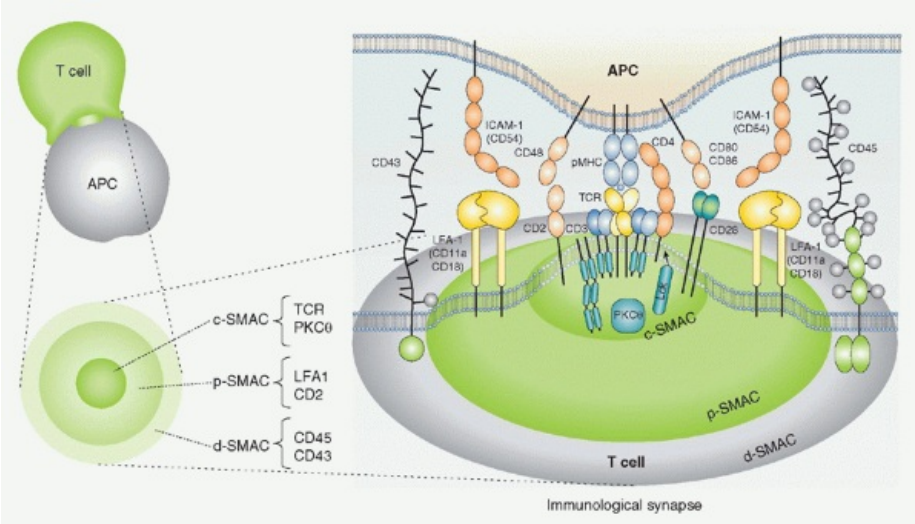

FIG. 12.10. Schematic Structure of the Immunologic Synapse. Antigen recognition and activation of T cells starts by the specific interaction between T cells and antigen-presenting cells (APCs) (**left**). In the interface of two cells, special structure with segregated arrangement of receptors and signaling molecules is induced where T-cell receptros (TCRs) and major histocompatibility complexes (MHCs) are accumulated in the central region termed as the central supramolecular activation cluster (SMAC), the adhesion molecule leukocyte function-associated antigen (LFA)-1-intercellular adhesion molecule 1 is localized at the surrounding area around the TCR-MHC (as the peripheral SMAC), and further large molecules such as cluster of differentiation (CD)45 are located outside peripheral region SMAC as distal SMAC (**right**). This “bulls eye-like” structure is dynamically induced after T cell-APC contact; LFA-1 moves outside and the TCR-CD3 moves into the center within 10 minutes. Activation signals are induced not at the synapse but at TCR microclusters, which are generated at the interface between T cell

and APCs prior to central SMAC formation, which is composed of TCR, kinases, and adaptors.

THE IMMUNOLOGIC SYNAPSE

T-cell activation is induced upon recognition of antigen peptide/MHC on antigen-presenting cells (APCs) such as DCs or B cells by the TCR on T cells upon the antigen-specific interaction between these two cell types. The interaction induces a specific structure with molecular segregation at the interface between the two cells, which is called the immunologic synapse (IS) or supramolecular activation cluster (SMAC).[58,59] In the IS, several surface receptors and intracellular signaling molecules are accumulated and segregated to form the concentric "bulls-eye"-like structure composed of three discrete regions (Fig. 12.10); there is enriched accumulation of molecules such as TCR, CD28, CD2, and PKCθ in the central region (cSMAC), adhesion molecules such as integrin LFA1 in the peripheral region (pSMAC), and large molecules such as CD43 and CD44 in the distal region (d-SMAC). The IS, particularly the cSMAC, was initially thought to be the structure responsible for transducing signals that lead to

T-cell activation. However, the formation of IS takes as long as 10 minutes after cellular conjugate formation, whereas the initial activation events such as intracellular calcium mobilization and protein phosphorylation occur within 1 minute, indicating that the activation signal is initiated much earlier than the IS is formed.[60] Recent studies revealed that the real signal transducing structure, called the TCR microcluster, is generated immediately after the T cell-APC contact and prior to IS formation.[61,62,63] TCR microclusters contain the TCR, kinases such as Lck and ZAP70, adaptor proteins such as LAT and SLP76, and several effector molecules such as PLCγ and PI3K. TCR microclusters function as the signalsome to induce T-cell activation because all TCR microclusters induce tyrosine phosphorylation of various proteins including CD3ζ, ZAP-70, and PLCγ, and their generation occurs in parallel to the initiation of the intracellular calcium flux. Therefore, the TCR microcluster is thought to be the minimal functional unit for TCR signaling. TCR microclusters are generated initially in the periphery of the interface between T cells and APCs, and are then translocated into the central region of the interface to make the cSMAC.[64]

Contrary to the initial idea that the cSMAC is the site for signal transduction, it is now thought that the cSMAC is the place where the accumulated TCR complex is internalized and degraded. In contrast to the negative function of the cSMAC for TCR degradation, costimulation receptors such as CD28 and cytotoxic T-lymphocyte antigen (CTLA)-4 accumulate in the cSMAC, suggesting that the cSMAC also serves a signaling function for costimulation.[65] In addition, T-cell activation results in the polarization of the T cells and movement of the microtubule organizing center toward the TCR-MHC/peptide contact sites. The microtubule organizing center movement appears to be driven by localized accumulation of DAG[66] and also involves ADAP, both of which recruit the microtubule motor protein dynein. cSMAC formation is closely regulated by cytoskeletal arrangement and leads to the polarization of T cells for polarized secretion of secretory vesicles including cytokines, chemokines, and lytic factors such as granzyme B. Various cytokine-containing vesicles are

accumulated at the TCR engaged site and are released directionally and locally. During the T cell-APC interaction, whereas some of cytokines such as interferon γ, IL-2, and IL-4 are secreted directionally toward the interface, some as tumor necrosis factor (TNF)α are randomly secreted.[67]

TRIGGERING MECHANISM

Signaling mechanisms for T-cell activation have been extensively analyzed and are now well understood, as described previously. It has been known for a long time that the antigen recognition event by the TCRαβ dimer is transmitted to the ITAM phosphorylation of the CD3 chains, which induce signal transduction for T-cell activation. However, the actual mechanism by which antigen recognition by the TCR initiates the initial activation event of the signal transduction cascade is still widely debated and controversial. There are several different models to explain the first events of T-cell triggering, and the proposed models can be divided into two main conceptual categories. One is through the receptor clustering by ligand binding, and the other is through the induction of conformational changes within the TCR-CD3 complex. None of these models or their variations (see the following discussion) can satisfactorily account for the diverse experimental observations regarding TCR triggering.

1. Kinetic proofreading model. This is an early quantitative model that attempted to explain a T-cell response by the half-life of the TCR-MHC/peptide interaction.[68] The length of time between the initial ligand binding and receptor signaling was proposed to induce qualitatively differential signaling. Longer and shorter half-life would induce a stronger and weaker response by either strong or weak agonist, respectively.[69]
2. Serial triggering model. T-cell activation requires a sustained signal that lasts for several hours. However, TCR affinity for MHC/peptide is very low, and activation of TCR induces only a brief spike of intracellular signals. This model attempts to resolve this paradoxical requirement for T-cell activation. The model states that sustained signaling is accomplished by the concerted action of multiple TCRs that are sequentially engaged with and triggered by the MHC/peptide complex.[70] A single complex could serially engage and trigger up to approximately 200 TCRs.
3. Kinetic segregation model. Signal initiation takes place by excluding inhibitory molecules such as the phosphatase CD45 from the tight contact area (cSMAC of the IS) between T cell and the APC, thereby shifting the enzymatic steady state toward an activating status. Such segregation is induced by sizes of the ectodomains of the excluded proteins.[71] This model is supported by the structure and kinetics of IS, as shown by the segregated regions.
4. Permissive geometry model. Binding between TCR dimers and MHC/peptide dimers induces rotational scissor-like conformational changes in the CD3 chains that reveal previously hidden intracellular activation motifs. This model integrates receptor clustering and conformational change models, together with the existence of preformed oligomeric receptors, providing a mechanism to explain TCR signal.[72]
5. Multimerization model. This model proposes that the minimum unit of T-cell activation is a dimer and is based on antibody-induced dimerization of B-cell receptors and MHC structure studies. A single MHC/peptide could induce initial and transient calcium signaling,

but monomeric MHC/peptide in solution did not induce stimulation of T cells. Obviously, more multioligomeric ligands induce more intense T-cell activation.[73]

6. Conformational change model. Extensive analyses of the crystal structures of TCR-MHC/peptide have not revealed any significant structural changes upon MHC/peptide binding by the ectodomains of TCRαβ dimers. However, biochemical analyses demonstrated structural changes of TCR complex, particularly in CD3ε. A

proline-rich region of CD3ε is a hidden determinant in the resting state but is exposed and recruits Nck upon stimulation to induce downstream activation signals.[74]

7. Safety model. This model is based on recent findings that the cytoplasmic domains of CD3ε and CD3ζ have affinity for the acidic lipids present on the plasma membrane, which may result in prevention of ITAM phosphorylation. Conversely, these chains in free aqueous solution may be readily phosphorylated by Lck. These results have led to the following model: whereas CD3εζ tails are tightly associated with the lipid-rich inner membrane of plasma membrane in resting T cells, they are released from this membranebound configuration and can be phosphorylated upon TCR ligation.[75]
8. Pseudodimer model. Only a few MHCs carry foreign cognate peptides for the specific TCRs, whereas a great majority of MHCs carry endogenous self-peptides. This model proposes that endogenous MHC/peptide amplify signals produced by agonist MHC/peptide by promoting TCR aggregation. Agonist MHC/peptide-TCR recruits a second TCR in a CD4-dependent manner, which binds endogenous MHC/peptide, stably forming a pseudodimer that triggers T-cell activation.[76]

The clustering models have been claimed to be incompatible with the presence of preformed oligomeric receptors on the surface of resting cells. However, the recent finding that TCR microclusters are the functional unit to transduce activation signals shows that aggregation of preformed TCR “nanoclusters” may form microclusters to induce signals.[77,78,79] On the other hand, models based on CD3 conformational changes that induced as a direct effect of ligand binding are not consistent with the requirement for multivalent ligand to initiate TCR signaling. Structural analyses of the complete molecular complex, including transmembrane regions and cytoplasmic tails, will provide a definite answer to this still confusing issue.

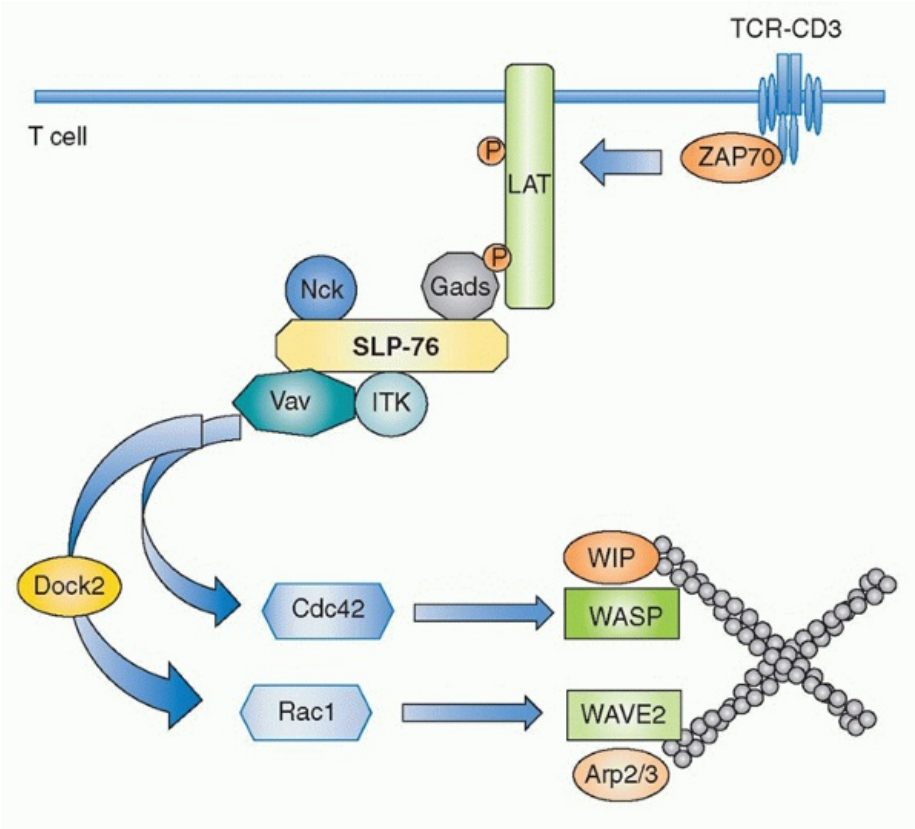

FIG. 12.11. Cytoskeletal Regulation by T-Cell Receptor (TCR) Signaling. TCR stimulation induces actin reorganization, which is required for the alteration of cell shapes, cell movement, and receptor clustering. Actin-related proteins such as Arp2/3, WASp, and WAVE2 regulate accumulation of F-actin. The LAT-SLP-76 signaling cluster induced upon TCR engagement recruits Nck, Vav1, and Itk. Whereas WASp binds to the adapter protein Nck and is activated by the Rhofamily GTPase Cdc42, WAVE2 binds to Vav1 and is activated by another Rho-family GTPase Rac1 through Dock2.

CYTOSKELETAL REGULATION

T-cell stimulation also induces a program for alteration of the cytoskeleton: actin polymerization, a microtubule rearrangement, which induces polarization and activation of T cells, and consequently changes the shape and regulates adhesion and movement of T cells. T cell-APC interaction results in morphologic changes: the cell becomes round and accumulates actin filaments at the stimulatory interface. These changes reflect the increase of fluidity of plasma membrane and a decrease of cellular motility. Accumulation of filamentous actin at the T cell-APC interface is the results of TCR-induced localized activation of multiple actin regulatory and polymerizing pathways. T-cell activation induces SLP76 phosphorylation, which recruits actin cytoskeleton regulatory proteins, Itk, Vav-1, Nck, and Cdc42 as the regulatory proteins. Localized activation of Cdc42 stimulates the actin-related protein 2/3 (Arp2/3)-regulating protein WASp, Wiskott-Aldrich syndrome protein, which interacts with Arp2/3 and activates actin polymerization.[80] WASp is recruited to the TCR activation complex by association with Nck and is activated by assembly with Vav-1, a GEF for the Rho family of GTP binding proteins and Vav-1, a central regulator of cytoskeleton,

migration, and adhesion (Fig. 12.11). WASp functions as a regulator of the Arp2/3 complex that is critical for actin polymerization. Itk recruits Vav-1 to the immune synapse. Cdc42 regulated by the Itk-Vav-1 complex directly stimulates WASp actively, and the Nck-WASP complex regulates actin dynamics. Vav-1-mediated activation of a second Rho family, GTPase Rac1, results in the activation of WAVE2.

CELL ADHESION REGULATION—INSIDE-OUT SIGNALING

Antigen stimulation of T cells induces their strong adhesion to APCs. This adhesion is mediated mainly by activation of integrin on T cells such as leukocyte function-associated antigen (LFA)-1, increasing its affinity and avidity for the ligand on APCs. Integrin activation is induced by a signaling cascade initiated by the TCR engagement and is a process termed inside-out signaling (Fig. 12.12). The inside-out signaling by TCR engagement results in integrin clustering and an increase in affinity and avidity for the ligands, which then induces high-affinity ligand binding.[81] It has been shown that the integrin LFA-1 goes through three conformational changes to achieve high affinity ligand: resting state, transitional state, and active conformation.[82] The integrins predominantly expressed on T cells are LFA-1 and very late antigen-4, which bind to their ligands, intercellular adhesion molecule (ICAM)-1 and 2, and vascular cell adhesion molecule and fibronectin, respectively. The process of inside-out signaling from TCR to integrin activation has been shown to include downstream signaling and actin-cytoskeletal rearrangement. Several critical adaptor molecules, particularly Rap1, ADAP, SKAP55, and RIAM, are necessary to translate TCR engagement to integrin activation.

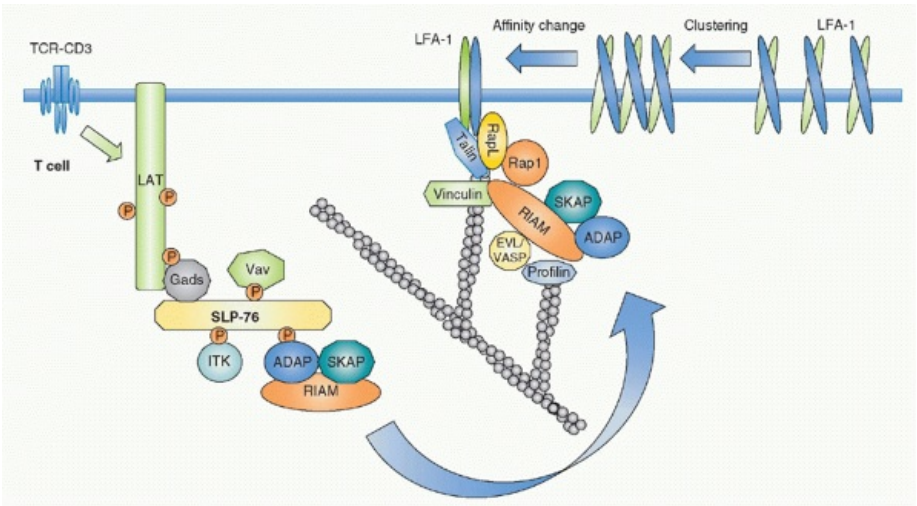

FIG. 12.12. Inside-out Signaling for T-Cell Receptor (TCR)-Mediated Integrin Activation as the Mechanism of TCR-Induced Cell Adhesion. TCR engagement induces signaling complex of linker for the activation of T cells and SLP-76. SLP-76 recruits Vav1 and Itk important for actin reorganization, as in Figure 12.11, and also adhesion- and degranulation-promoting adapter protein (ADAP), which constitutively associates with Src kinase-associated phosphoprotein of 55 kDa (SKAP55) and Rap1-GTP-interacting adapter molecule (RIAM). The complex of ADAPSKAP55-RIAM associates with and activates Rap1 upon TCR activation and then translocates Rap1 to

the membrane. The Rap1-RIAM/SKAP/ADAP complex induces the association of talin with the tail of integrin β. The local accumulation of talin is required for high-affinity binding by integrin. Integrin changes the status by clustering and then affinity maturation through structural changes. Integrin clustering involves Rap1 and Rap1-binding molecule RAPL that also associates with RIAM. RIAM associates with F-actin through the association with EVL/VASP proteins and the actin-binding protein profilin. PKD binds to the β1 integrin tails and recruits and activates Rap1 by Rap1-GEF C3G.

Ras proximity 1 (Rap1), which belongs to the Ras superfamily of GTPases, plays a critical role in the inside-out signaling for integrin activation. Active Rap1 induces increased cell adhesion through integrin activation without changing their expression levels on T cells.[83] TCR stimulation and chemokines induce Rap1 activation, which then induces clustering of high-affinity LFA-1 on the leading edge of the membrane.

Following TCR ligation, SLP-76 inducibly interacts with ADAP, which then forms a complex with SKAP55. The SLP-76-ADAP-SKAP55 pathway leads to regulation of T-cell adhesion.[84] Both ADAP- and SKAP55-deficient T cells showed defective LFA-1 clustering and adhesion. ADAP-induced T-cell adhesion involves Rap1-GTP-interacting adaptor molecule (RIAM), which is required for Rap1 localization at the membrane.[85] Because RIAM associates with integrin, the complex with ADAP-SKAP55-RIAM makes a complex with LFA-1, resulting in adhesion to ICAM-1 upon TCR ligation. RIAM also binds to a cytoskeletal binding protein, Talin, and the Talin-RIAM-Rap1 complex may induce Talin to bind LFA-1 with high affinity. RIAM is also the ligand of Ena/VASP and profiling, which bind to actin cytoskeleton. In addition, similar to Talin, other cytoskeletal proteins such as Vinculin, WAVE2, and the Arp2/3 complex are also involved in the TCR-induced integrin activation.

As to the effector mechanism of Rap1 signaling, Rap-1 binds to RAPL, the effector regulator of cell adhesion and polarization enriched in lymphoid tissues.[86] The interaction induces the membrane localization of RAPL and the binding to the αL subunit of LFA-1, which is critical for LFA-1 clustering and increasing its affinity. RAPL associates with a kinase Mst-1 as an effector molecule. Inside-out signaling induced by TCR engagement results in integrin clustering and increased affinity and avidity for the ligand, which then induces high-affinity binding to the ligand. Further analysis of the precise signaling cascade for inside-out signaling downstream of TCR is required.

COSTIMULATION

Cluster of Differentiation 28-Mediated Costimulation

T-cell activation is influenced by signals through several surface receptors including costimulation receptors (see following discussion), cytokine receptors, and adhesion molecules. T cells cannot be fully activated to proliferate and mediate cytokine secretion in the absence of costimulation signals through these costimulation receptors. TCR engagement induces various early activation signals such as an increase in the levels of intracellular calcium, tyrosine phosphorylation, and inositol metabolism, but these are not sufficient to induce full activation including cytokine production, cell proliferation, and effector

functions. Instead, in the absence of costimulation, T cells fall into a state of unresponsiveness or anergy where they do not respond to antigen stimulation. Therefore, two signals are required for efficient T-cell activation: “signal 1” is defined as the antigen-specific TCR signal by the binding of peptide/MHC complex, and “signal 2” refers to the additional costimulation signal through a costimulation receptor. This “two signal model” for T-cell activation, which was proposed in the early study of T cells,[87,88] has been proved by various observations, particularly of the peripheral tolerance induction in the absence of “signal 2.”[89,90] Although there are a number of receptors that can induce a costimulatory signal, the most physiologic, critical and well characterized is CD28[91] (Fig. 12.13A).

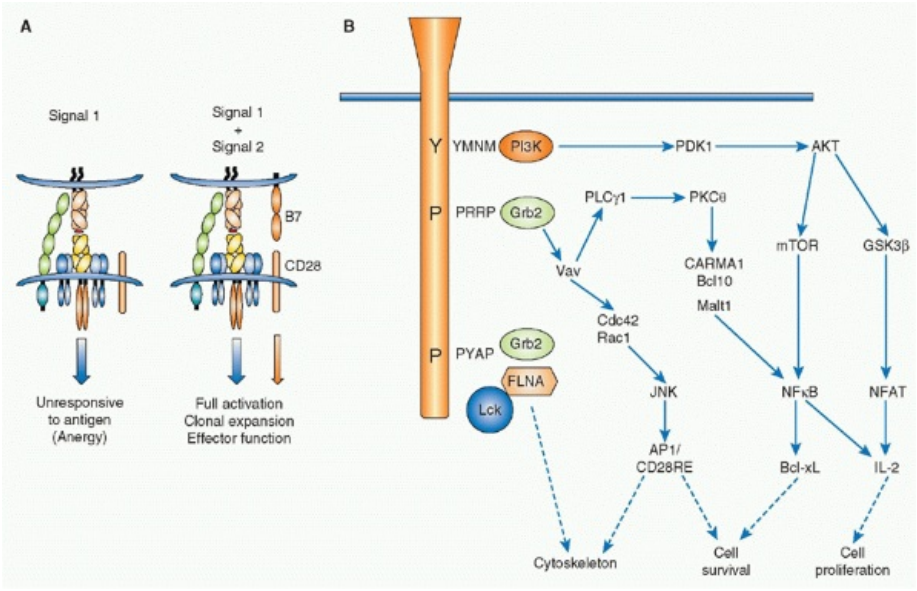

FIG. 12.13. Costimulation and Cluster of Differentiation (CD)28-Mediated Signals in T Cells. A: Full T-cell activation such as cell proliferation and cytokine secretion requires two signals: one (signal 1) through the T-cell receptor-CD3 complex as antigen-recognition signal, and the other (signal 2) through costimulation receptors such as CD28 as costimulatory signals. In the absence of costimulation signal, T cells become unresponsive to antigen stimulation (called anergy). **B:** Detailed signal pathway of CD28-mediated costimulation. The cytoplasmic tail of CD28 has major three motifs: N-terminus tyrosine motif YMNM associates with PI3K leading to the activation of Akt, which induces cell survival through mammalian target of rapamycin-mediated NFκB activation and cell proliferation, the upper Prolin-rich motif binds to Grb2 leading to Vav1 activation, which mediates cytoskeletal regulation and NFκB activation, and the last proline region associates with Lck and Filamin and Lck, which leads to actin-cytoskeletal organization.

CD28 is constitutively expressed on the surface of all T cells as a homodimer. The ligands for CD28 are the B7 family molecules, CD80 (or B7-1) and CD86 (B7-2), which are expressed on APCs. While CD80 is constitutively expressed, CD86 is expressed at low level on APCs in the resting state but is highly induced upon activation by innate signals, such as those

derived from pathogens, in parallel with the induction of high level expression of MHC class II.[92] The induction of MHC class II and B7 molecules on activated APCs such as mature DCs are critical for T-cell stimulation because they can deliver a strong signal 1 and signal 2, respectively.

CD28 induces a profound increase in IL-2 production by both transcriptional and posttranscriptional regulatory mechanisms, as well as increased proliferation and cell survival, which is partly due to the induction of the antiapoptotic gene Bcl-xL (Fig. 12.13B). Whether CD28 induces costimulation totally independently of TCR engagement has been a controversial question for a long time. CD28-specific signals responsible for the costimulation signal have been extensively analyzed. CD28 has a short cytoplasmic tail (41 amino acids in human, 38 amino acids in mouse) and no intrinsic enzymatic function. It contains several tyrosines including an YxxM motif and two PxxP motifs. The YxxM motif, which is conserved in CD28, CTLA-4, and inducible costimulator (ICOS), is a consensus motif for the binding of the p85 subunit of the lipid kinase phosphatidyl-inositol 3-kinase (PI3K). Functional relevance of the YxxM motif is suggested by the fact that PI3K activation is enhanced by CD28 signaling.[93,94] PI3K activation generates PIP2, which recruits various molecules containing pleckstrin homology domains such as Tec family kinases, a serine/threonine kinase Akt, phospoinositide-dependent kinase 1, Vav, and WASP to the plasma membrane. Akt can be phosphorylated by phospoinositide-dependent kinase 1 and plays an important role in cell survival, which is one of the benefits of CD28-mediated costimulation.[95] The PxxP motif, which ICOS and CTLA-4 do not have, also has binding specificity for Grb2/Gads. Grb2 recruits Sos and Vav, which in turn phosphorylates and activates Rac1 and Cdc42, which then activates the MEKK1 cascade to ultimately activate the Jun kinase JNK.[96] Whereas the TCR signal predominantly activates ERK as an MAPK family member, CD28 engagement induces activation of the other member of the MAPK family, JNK, and the balance between the activity of ERK and JNK as a consequence of CD28-mediated costimulation may regulate cell survival.

Early studies showed that the distal PxxP (PYAP) motif in CD28 may recruit Lck, and it was recently shown that filamin A also binds to this motif to connect to the cytoskeleton. Although in vitro analysis and an overexpression system indicated a critical function for these motifs in costimulation, in vivo analysis with specific knock-in mutations revealed that mice with mutated YMNM motifs that failed to bind PI3K and activate Akt had no overt phenotype. By contrast, mice with the mutant distal motif had evidence of impaired CD28-mediated costimulation, such as reduced proliferation and IL-2 production.[97,98]

Enhancement of IL-2 production by CD28 engagement is regulated at both transcriptional and posttranscriptional levels.[99] A specific region responsible for CD28-mediated transcriptional activation (termed a CD28-response element, CD28RE) was found in the IL-2 promoter.[100] The binding of transcription factors to CD28RE is dependent on CD28 signal.

In addition to enhancement of the transcription of the IL-2 gene, CD28-mediated costimulation augments IL-2 production by increasing the stability of IL-2 mRNA.[101] Many cytokine transcripts including IL-2 contain adenylate-uridylate (AU)-rich elements within the 3' untranslated region that stabilizes the message. Upon TCR stimulation, an AU-binding protein, TTP, binds to the AU-rich elements within the 3' untranslated region and induces

degradation of the mRNA. By contrast, CD28 costimulation induces other proteins, such as NF90, a transcription factor associated with NFAT, which may compete with TTP for binding at the AU-rich elements and enhance IL-2 mRNA stability.

CD28 signaling activates I-κB and consequently NF-κB. CD28 regulates the IKK activation step, and IKK activation results in I-κB activation/degradation and induces NF-κB activation. Extensive analysis to define the connection between CD28 signaling and IKK activation resulted in the discovery of CARMA1 as caspase recruitment domain-containing membrane-associated guanylate kinase protein-1, followed by identification of its associated proteins, Bcl-10 and Malt-1, which together form the CBM complex.[102,103] CARMA1 is phosphorylated by PKCθ and binds to Bcl10 through a CARD-CARD domain interaction.[104] The CBM complex is responsible for activation of NF-κB, thus T cells defective in any of the CBM components show impaired NF-κB activation and impaired T-cell proliferation. CD28-mediated activation of the CBM complex and NF-κB dramatically enhances IL-2 production.

Given its powerful activity as a second signal for T-cell activation, CD28 agonists and antagonists have been seriously considered for clinical application in humans. CD28 superagonist monoclonal antibodies were shown to polyclonally activate T cells in vivo, but such treatment ultimately led to the expansion of regulatory T cells, and several studies showed therapeutic benefit in autoimmune and inflammatory disease models in mice and rats. After preclinical safety testing in nonhuman primates, six healthy human volunteers were injected with the TGN1412 CD28 superagonist monoclonal antibodies, and the results were disastrous.[105] All six individuals suffered an immediate and life-threatening release of systemic proinflammatory cytokines, a “cytokine storm” that is now termed cytokine release syndrome. Recent studies suggest that the source of these cytokines was the effector memory population of T cells and have clarified why no such adverse effects were seen in rodents and nonhuman primates. Rodents do not accumulate a large population of effector memory population of T cells because the generation of these cells requires repeated exposure to infections; these experimental animals are kept in extremely clean conditions. The CD4 T

cells in macaques, the nonhuman primate used in the preclinical studies, unlike human T cells, lose CD28 expression when they differentiate into effector memory population of T cells.

COSTIMULATION THROUGH RECEPTORS OTHER THAN CLUSTER OF DIFFERENTIATION 28

CD28 is most prominent costimulation receptor and thus CD28-deficient mice have a general impairment in immune responses. However, not all immune response are dampened by CD28 deficiency, which indicates that other costimulation molecules can compensate for some of the remaining functions. These costimulation receptors include CD2, CD5, CD30, the Ig gene superfamily member ICOS, the TNF receptor family members CD137 (4-1BB) and CD134 (OX40), and LFA-1. These receptors are expressed on the T-cell surface to induce costimulation signals upon crosslinking with their ligands (Fig. 12.14).

In contrast to CD28, which is constitutively expressed on T cells, ICOS is expressed at a very low level on resting T cells and is inducibly expressed on activated T cells upon TCR

stimulation, which is the major difference in its function from CD28 on resting T cells.[106] As ICOS-deficient mice have impaired immune responses similar to that seen with CD28 deficiency, ICOS must play an important role in immune regulation.[107] ICOS binds to a novel B7 family member, ICOS ligand, which is expressed rather broadly as compared to CD80/86 including nonhematopoietic tissues upon stimulation with inflammatory cytokines. ICOS is expressed on the cell surface as a dimer similar to CD28 and shares some structural features with CD28, including the YMXM motif in the cytoplasmic tail that binds p85 of PI3K. ICOS-mediated PI3K activation is stronger than that mediated by CD28, whereas other signals through CD28 that are not triggered through ICOS include Grb2 binding.[108] Such differences in signaling between ICOS and CD28 lead to differential function. Most notably, unlike CD28, ICOS does not induce IL-2 gene transcription. Instead, ICOS-mediated costimulation is critical for B-cell help for Ig production and germinal center formation. ICOS deficiency causes one of the multiple forms of common variable immunodeficiency, and these patients suffered from impaired B-cell function and germinal center formation and from hypogammaglobulinemia including IgA deficiency.[109]

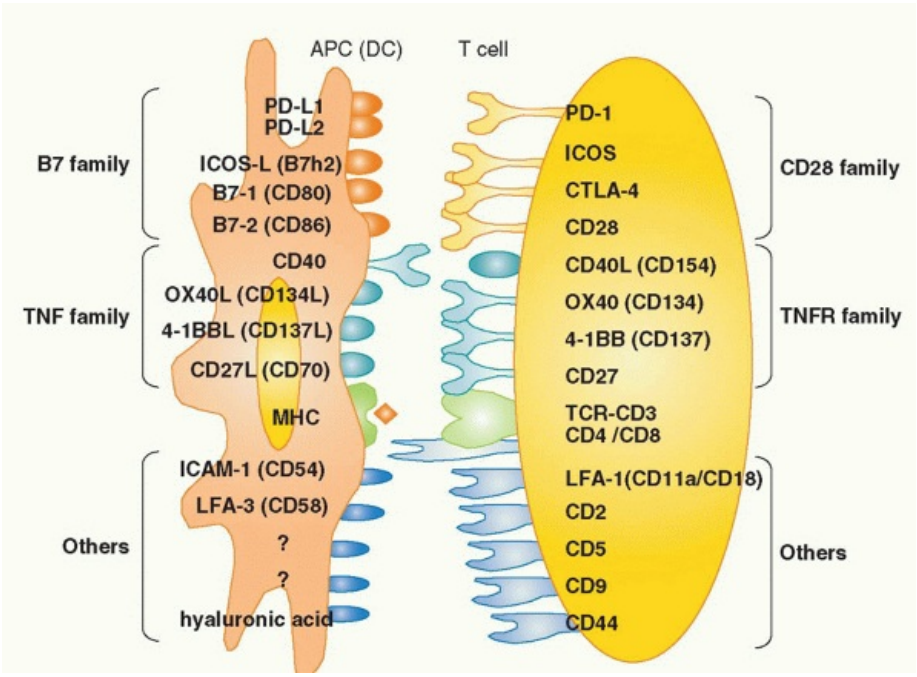

FIG. 12.14. Various Costimulation Receptors and Their Ligands. Various adhesion molecules between T cells and antigenpresenting cells (APCs) function to mediate costimulation signals for T-cell activation. These molecules are divided into three groups: cluster of differentiation (CD)28 family, tumor necrosis factor receptor family, and others including integrin leukocyte function-associated antigen-1. CD28 family molecules consist of two positive (CD28, inducible costimulator) and two negative (cytotoxic T-lymphocyte antigen [CTLA]-4, programmed death-1) receptors and the individually corresponding ligands. Whereas some receptors are constitutively expressed such as CD28, others are expressed upon T-cell stimulation such as CTLA-4 and OX-40. Whereas some of the ligands are expressed exclusively on APCs, others are widely expressed on variety cell types.

Among TNF receptor family molecules, the molecules with costimulatory function represent CD27, OX40 (CD134) and 4-1BB (CD137), CD30, herpes virus entry mediator A (HVEM), and glucocorticoid-induced TNF-receptor (GITR). Among them, OX40 and 4-1BB mediate the most prominent functions. These molecules augment T-cell activation upon engagement of their ligands, OX40L and 4-1BBL, respectively. Engagement of OX40 and 4-1BB with their ligand induces activation of signaling pathways similar to CD28: PI3K and Akt, and NF-κB and MAPKs (JNK and p38), but this is through activation of the TNF receptor-associated factor (TRAF) family of adaptor molecules, which is different from CD28.[110]

One of the most important functional differences between CD28 and others such as ICOS, OX40, or 4-1BB is that CD28 is constitutively expressed on naïve T cells and plays a critical role to stimulate naïve T cells for proliferation, effector function, and functional differentiation, whereas all the others are inducibly expressed upon T-cell activation and therefore play roles to induce costimulation on activated

effector T cells and memory T cells. Thus, there is a big difference in the timing of their function during immune responses. In addition, the distribution of the ligands for these two groups is different: stimulation through CD28 has to be induced by professional APCs such as DCs and macrophages, whereas costimulation through ICOS, OX40, and 4-1BB can even be induced by ICOS-L, OX40L, and 4-1BB-L expressed on nonhematopoietic cells in the periphery. The latter is critical for regulation of autoimmunity and infectious diseases.

Signal Lymphocyte Activation Molecule Family for T-Cell Activation

Signal lymphocyte activation molecule (SLAM; CD150) is a receptor of a family expressed on various cell types including T cells, B cells, NK cells, macrophages, and other cells, which mediate homotypic cell adhesion. This homotypic interaction induces costimulation in T cells. However, the signaling mechanism for SLAM-mediated costimulation has been unclear. Studies of the human immunodeficiency disease X-linked lymphoproliferative syndrome were quite informative when mutations in the SLAM-associated protein (SAP; SH2D1A) gene were identified as the cause of X-linked lymphoproliferative syndrome.[111] SAP was found to associate with SLAM through homotypic interaction upon activation. SAP is a small intracellular adaptor protein consisting of only single SH2 domain. SAP was found to associate with the src kinase Fyn and appears to function as a bridge between SLAM and Fyn (Fig. 12.15). This binding mode is quite unique in that the phosphotyrosine of SLAM binds SAP through its SH2 domain, whereas the SH3 domain of Fyn binds through an atypical proline-rich domain in the SH2 domain of SAP.[112] This unusual binding configuration has been confirmed by crystal structure analysis of the complex. The SAP-Fyn interaction is critical for optimal activation of PKCθ and NF-κB upon T-cell activation. In addition, SAP-induced signaling is important to communicate with B cells for delivering T-cell help for Ig production. Follicular T cells express ICOS and SLAM family members and may provide help for B-cell function in germinal center and humoral responses.[113,114]

The SLAM family is composed of six different members, SLAM (CD150), 2B4 (CD244), NTBA (Ly108), Ly9 (CD229), CD84, and CRACC (CD319), all of which associate with SAP. Mice deficient in each of these molecules exhibit a weak phenotype, probably indicating that the family members have overlapping and redundant functions.

NEGATIVE REGULATION OF ACTIVATION

T-cell activation is induced to trigger appropriate immune responses and must be regulated to have the right timing, to be at the right location, and to have the proper strength. To appropriately regulate these responses, it is necessary to impose negative regulation in order to promote a balanced response, to prevent an excessive response, and to terminate the response properly. As described previously, TCR stimulation induces several activation pathways, but simultaneously also induces negative regulatory pathways.

Inhibitory Effector Enzymes

T-cell activation is initiated by phosphorylation by the src family kinase Lck, and this most proximal signaling event is actively regulated by the balance between the kinase Csk and the phosphatase CD45, as described previously (Fig. 12.4). Positive and negative regulation is actively and in parallel induced downstream of TCR signaling. Therefore, Csk is the dominant negative regulator of TCR proximal signal by phosphorylating the inhibitory tyrosine on Lck, thus main-

taining it in the inactive state. CD45 has an opposing function by dephosphorylating this negative regulatory tyrosine and activating Lck.

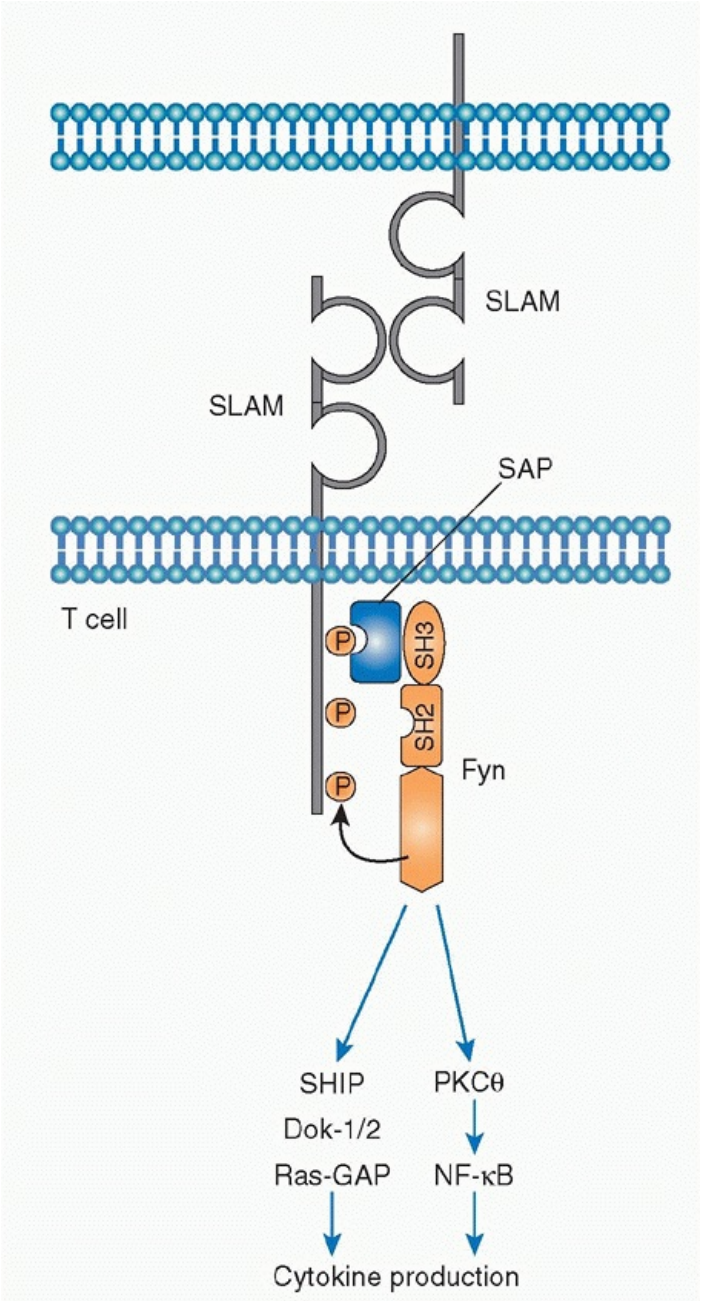

FIG. 12.15. Signal Transduction by Signal Lymphocyte Activation Molecule (SLAM) Family Members Through the Association with the Adaptor Protein SLAM-Associated Protein (SAP). The arginine 78 of SAP binds the SH3 domain of Fyn, which recruits Fyn to the SLAM/SAP complex. Fyn subsequently phosphorylates tyrosine residues in the cytoplasmic domain of SLAM, which serve as the docking sites for SH2 domain-containing inositol phosphatase, which then phosphorylates the adaptor proteins Dok1/2 and Ras-GAP. SAP also binds to PKCθ and activates NF-κB through CARMA1/Bcl-10/Malt1 complex, which cooperates with T-cell receptor signals.

Another set of inhibitory effector enzymes is a family of E3 ubiquitin ligases, which are responsible for ubiquitination of proteins with certain specificity to lead to degradation. These are represented by Cbl and Cbl-b,[115] and also include others such as GRAIL, Itch, and Nedd4. Cbl proteins mediate ubiquitination and targets for degradation of early signaling

proteins include ZAP-70, effectively inducing downregulation of T-cell activation. Evidence of the important negative regulatory role of these proteins in vivo comes from the analysis of Cbl- and Cbl-b-deficient mice, which display hypercellularity and spontaneous T-cell activation.[116,117] It has been shown that the anergic/unresponsive status of T cells is induced by these E3 ligases, particularly Cbl and Itch, by degradation of various signaling molecules.

Immunoreceptor Tyrosine-Based Inhibitory Motif-Mediated Negative Regulation by Phosphatases

Whereas the ITAM recruits the SH2-bearing tyrosine kinase ZAP-70/Syk to induce activation signals in T cells, the immunoreceptor tyrosine-based inhibitory motif (ITIM) recruits SH2-bearing phosphatases to induce negative signals.[118] The ITIM consensus amino acid sequence is very similar to the ITAM: S/I/V/Lx Y xx I/V/L. Receptors containing ITIM include killer inhibitory receptors, which mainly function in NK cells to inhibit activation upon recognition of MHC and also inhibit killing by cytotoxic T cells, the inhibitory receptors of various paired receptors expressed on NK cells, DCs and macrophages such as PIR-B and PILR, and the inhibitory IgG Fc receptor FcγRIIB on B cells, macrophages, and mast cells. The tyrosine residue of an ITIM in T cells is phosphorylated by the src family kinase Lck, similar to an ITAM, which then recruit phosphatases such as the SH2 domain-containing phosphatase (SHP)-1 and SHP-2 and the SH2 domain-containing inositol phosphatase (SHIP).

SHP-1/2 is cytosolic protein phosphatase containing twotandem SH2 domains at the N terminus and a phosphatase domain at the C terminus. The phosphatase is in an inactive closed configuration in the resting stage and becomes active upon tyrosine phosphorylation of the ITIM. These enzymes are recruited to the vicinity of the TCR complex by association with Lck and then dephosphorylate kinases themselves (Lck and ZAP-70), and upstream signaling molecules close to the TCR complex including Vav, PLCγ1, and SLP-76. The functional importance of SHP-1 is evident by the phenotype of SHP-1-deficient mice, which have severe autoimmunity.[119]

Positive versus negative regulation of Lck kinase activity appears to correlate with the capacity of T cells to discriminate between strong and weak stimuli.[120] It has been shown that weak antigens or antagonists induce rapid phosphorylation of SHP-1 by Lck prior to activation of a positive signaling cascade. SHP-1 then dephosphorylates the active site of Lck, resulting in inhibition of T-cell activation. On the other hand, strong agonistic stimuli induce Erk, which is rapidly activated and phosphorylates Lck. This prevents the phosphorylation and recruitment of SHP-1, resulting in T-cell activation. Whether such a dynamic regulation of the kinase-phosphatase regulatory loop is actually operating in vivo remains to be determined. Despite the similar structure and phosphatase activity, SHP-2 appears to have different specificity for SH2 binding receptors than SHP-1, such as programmed death (PD)-1 (see following discussion).

Another phosphatase critical for negative regulation of T cells is the lymphoid tyrosine phosphatase (Lyp), encoded by the PTPN22 gene. Lyp is a cytosolic protein phosphatase belonging to the prolin-, glutamic acid-, serine- and threonine domain (PEST)-rich family of protein tyrosine phosphatase, and its mouse homolog is the PEST domain-rich phosphatase

(Pep).[121] Lyp dephosphorylates various TCR upstream signaling molecules including CD3, Lck, ZAP-70, and Vav. The negative regulation of Lyp/Pep is mediated by its association with Csk. The Lyp-Csk complex is formed upon T-cell activation and exhibits synergistic negative regulation. Deletion of Pep in mice caused expansion of the memory T cells and increased TCR signaling in effector T cells as well as increased positive selection in the thymus, indicating that Lyp/Pep is a key negative regulator of TCR signaling.[122] Another critical finding is that a single-nucleotide polymorphism in the PTPN22 gene correlates strongly with the incidence of type 1 diabetes, rheumatoid arthritis, juvenile rheumatoid arthritis, systemic lupus erythematosus, Graves disease, generalized vitiligo, and various other autoimmune disease.[123] How such single-nucleotide polymorphism results in increased susceptibility to various autoimmune diseases remains to be determined.

Inhibitory Adaptors

There are several adaptor molecules that function to mediate negative regulation of T-cell activation by recruiting phosphatases.[124] These include SLAP, TSAd, Dok, and Gab2. Dok1,2 and Gab2 recruit rasGAP and SHP-2, respectively. Although the Gab and Dok family are known to be positive regulators of cytokine or growth factor signaling in nonhematopoietic cells, they show opposite inhibitory function in antigen receptor signaling. Gab2- and Dok-1/2-deficiency results in enhanced phosphorylation of upstream signaling molecules and increased T-cell activation including cytokine secretion and proliferation. Dok-1/2 expressed in T cells associates with the phosphorylated ITAM of the CD3ζ chain and therefore inhibits CD3ζ binding with ZAP-70. Dok-1/2 then functions to bridge the TCR complex and rasGAP to inhibit T-cell activation.[125] Gab2 is an adaptor protein and also negatively regulates TCR signaling by recruiting the phosphatase SHP-2. Gab2 associates with LAT through binding with Gads upon T-cell activation. Because Gads constitutively associate with SLP-76 and the Gads-SLP-76 complex binds to phosphorylated LAT, Gab2 is competing with the Gads binding with SLP-76. Upon TCR stimulation, ZAP-70 phosphorylates Gab2, which serves as a bridge between LAT and SHP-2 to mediate inhibitory signals, or

phosphorylates SLP-76, which serves to induce downstream activation signals.[126] It is important to note that expression of these inhibitory adaptor proteins is induced upon T-cell activation, indicating that these inhibitors function in feedback regulation of T-cell activation.

Whereas Dok targets the ITAM of CD3ζ and Gab2-SHP-2 targets LAT, the serine/threonine kinase HPK1 inhibits SLP-76 function by inducible association with its SH2 domain and recruitment of 14-3-3.[127] Deficiency of HPK1 in T cells results in enhanced phosphorylation of early TCR signaling molecules, indicating that HPK1 serves an inhibitory function for T-cell activation in vivo.

Inhibitory Costimulation

In contrast to the positive costimulation receptors leading to activation signals, there also exist sets of costimulation receptors that mediate negative signals for T-cell activation. These include CTLA-4 and PD-1. Neither of these inhibitory costimulatory receptors is expressed in resting T cells, but both are inducibly expressed on activated and specialized T cells, indicating that these inhibitory molecules are involved in the feedback regulation of T-cell

activation to prevent excess activation during immune responses. The physiologic importance of both receptors for inhibition of T-cell activation is evident by the strong phenotype of the respective gene targeted mice. CTLA-4-deficient mice have an excess of activated peripheral T cells, splenomegaly, and infiltration of lymphocytes in nonlymphoid tissues, and exhibit a lymphoproliferative disease in all immune tissues and early death.[128,129] On the other hand, deletion of PD-1 results in less dramatic and slow-onset autoimmune diseases, including the development of a lupus-like disease and cardiomyopathy in old mice.[130]

CTLA-4 and CD28 have common ligands, CD80 and CD86, on APCs (Fig. 12.14). However, as CTLA-4 has much higher affinity for these ligands than CD28, even low expression of CTLA-4 on the T-cell surface upon stimulation can effectively compete for ligand binding with CD28. This is the main mechanism by which CTLA-4 inhibits T-cell activation.[131] Except for regulatory T cells, naïve resting T cells do not express CTLA-4. CTLA-4 is transcribed upon T-cell activation and usually accumulates in the lysosome and is not expressed on the cell surface, probably because such strong inhibitory molecules should be transiently expressed only when needed upon T-cell activation. Upon TCR stimulation, the CTLA-4-containing lysosomes are translocated and fuse with the plasma membrane, and CTLA-4 is then expressed on the cell surface.[132] Once on the cell surface, CTLA-4 can compete for ligand binding with CD28 and thereby push CD28 and the associated PKCθ away from the central region of the interface between T cells and APCs, where the CD28-mediated costimulation signal is mediated.[133] The competition for ligand binding with CD28 by the ectodomain of CTLA-4 is a widely accepted phenomenon, but it has been controversial whether CTLA-4 can also exhibit inhibitory function by recruiting a phosphatase to its cytoplasmic tail in a manner independent of ligand binding. Although it has been shown that CTLA-4 is phosphorylated upon stimulation and several phosphatases including SHP-1/2 and PP2A have been suggested to be involved in CTLA-4-mediated inhibitory function,[131] further analysis is required to clarify this point.

PD-1 is also inducibly expressed on T cells upon TCR stimulation; its ligands are PD-L1 and PD-L2 (Fig. 12.14). Whereas PD-L1 is mainly expressed by professional APCs such as DCs and macrophages, PD-L2 is expressed by a relatively wide range of cells including in nonlymphoid tissues. PD-1 possesses two tyrosine motifs within its cytoplasmic domain: ITIM and immunoreceptor tyrosine-based switch motif, and the immunoreceptor tyrosine-based switch motif (ITSM) is the site for recruitment of the phosphatase SHP-2 upon PD-1 ligand engagement. PD-L1/2 ligation induces SHP-2 phosphorylation and dephosphorylation of various TCR upstream signaling molecules including CD3ζ, ZAP-70, Vav, and Erk, which results in inhibition of T-cell activation.[134,135] There is an interesting contrast between the mechanisms of PD-1 and CTLA-4 inhibition of T-cell activation. Whereas PD-1 inhibits the very proximal signaling just downstream of TCR complex, CTLA-4 mainly suppresses CD28-mediated costimulation signals targeting NF-κB activation. Recent studies indicate that T cells from chronic viral infection and immune senescence are in a nonfunctional or unresponsive/suppressive state that is mediated by PD-1.[136] Because the suppressive state can be reversed by interruption of the interaction between PD-1 and PD-ligand by anti-PD-1 or PD-L1 antibody, PD-1 appears to induce an ongoing active suppression of T-cell activation during the course of chronic infection.

CONCLUSION

We describe here the current knowledge of the mechanisms of T-cell recognition and activation as the central regulator of immune responses. The unique features of the antigen recognition by TCR are twofold. One is gene rearrangement to generate enormous diversity together with the unique T-cell selection processes as positive and negative selection during thymic development. The second is the result of MHC restriction, whereby T-cell recognition of antigen can only occur on the cell surface of APCs in the complex with MHC. That is why T cells communicate with many cell types of APCs.

The TCR genes and the TCR-CD3 complex were cloned and characterized nearly three decades ago, and the peptide-MHC binding structure and TCR recognition of a single MHC/peptide complex were clarified two decades ago. During the ensuing two decades, new insight regarding T-cell recognition and activation was obtained by the discovery of the IS, and more recently TCR microclusters, as the machinery for T-cell activation. The discovery of various T-cell subsets such as Th17 and regulatory T cells during the following decade brings closer to reality the possibility of regulating T-cell function by analyzing the detailed mechanism of their differentiation and function. Further analysis on T-cell recognition, differentiation, and activation can be addressed by using the combination of current technologies of conditional knockout mice with tissue or temporal

specificity, of imaging analysis of the dynamic features of various molecules within a cell at single molecule level, and of in vivo dynamics of lymphocytes, and also system biologic approaches including quantitative analysis of the expression of genes and proteins by proteome analysis, together with the pathway analyses of signaling molecules and modeling of regulatory networks.

Further elucidation of the mechanism of T-cell activation and function will provide benefits for overcoming immunologic diseases. The immunologically important questions, such as repertoire selection, induction, and maintenance of self-tolerance and long-term memory, are still elusive and all are related to the regulation of autoimmune diseases. Therefore, the future development of research in this area should be focused on overcoming these immunologic disorders by clarifying the principles of this regulation. In this regard, analysis should move more toward human diseases. Analysis of patients with immune disorders have revealed the identity of critical genes and regulatory mechanisms such as the calcium channel Orai1 and its activation and regulation, Foxp3 and its regulatory function in regulatory T cells, and SAP and SLAM family receptors. All of these insights came from the analysis of primary immunodeficiency patients. For the cure of such diseases, the development of suitable drugs is also critical in the near future. During the past decade, several immunologic reagents including monoclonal antibodies and inhibitors have been successfully developed and applied, such as FK506 as a potent inhibitor of T-cell activation and critical for organ transplantation, monoclonal antibodies against TNF, IL-6 receptors for various autoimmune diseases, and against JAK3 for therapy of tumors and immune disorders. These therapeutic reagents should be further developed on the basis of our understanding of the fundamental mechanisms of immune regulation. Such new developments should be targeted not only for simple inhibitors of kinases and phosphatases, but also to target the dynamic movement of lymphocytes, transcriptional and epigenetic regulation of gene expression, and the development of antibodies against functional surface molecules of several critical T-cell subsets.

Chapter 14

Peripheral T Lymphocyte Responses and Function

Marc K. Jenkins

INTRODUCTION

This chapter focuses on the processes by which conventional thymus-derived (T)-lymphocytes that express αβ T-cell antigen receptors (TCRs) become activated by their cognate peptide (p): major histocompatibility complex (MHC) ligand. It will cover how TCR ligation by foreign antigen-derived p:MHC ligands causes rare naïve T cells from the preimmune repertoire to proliferate in the secondary lymphoid organs (sometimes referred to by immunologists as the periphery) to become effector cells capable of producing microbicidal cytokines and eliminating foreign antigens from nonlymphoid tissues. It will also describe how the innate immune response and signals from costimulatory and cytokine receptors shape the functional and migratory properties of effector T cells, and ends with a discussion of how effector cells give rise to diverse memory cell subsets. An emphasis is placed on the dynamics and anatomy of naïve to effector to memory-cell conversion.

The chapter will focus on conventional T cells that express αβ TCRs. The reader is directed to other chapters in the book for details concerning natural killer T cells, γδ T cells, and regulatory T cells.

NAÏVE T CELLS

To understand effector T-cell generation, it is important to consider the naïve T cells from which they are derived. The capacity of the host to make effector and memory cells in response to new foreign proteins depends on the existence of naïve T cells that express αβ TCRs specific for MHC-bound peptides derived from that protein.[1] Naïve T cells with this particular p:MHC specificity are rare members of a vast repertoire also containing naïve T cells specific for other p:MHC ligands. Each naïve T cell expresses a randomly generated TCR, which is produced regardless of whether the relevant foreign antigen is in the host's body. Thus, naïve T cells are defined as T cells that have not yet been stimulated by a p:MHC ligand for which their TCR has a high affinity.

Generation

A naïve T cell is the end result of a complex developmental process that occurs in the thymus.[2] To complete development, each thymocyte must produce an αβ TCR by randomly recombining one of multiple variable (V), diversity (D), and joining (J) deoxyribonucleic acid segments at the *Tcrb* locus and one of multiple V and J segments at the *Tcra* locus.[3] Once an in-frame rearrangement at a locus has occurred on one chromosome, further rearrangement

on the other chromosome is suppressed, although not completely. These processes lead to the situation where most developing thymocytes express a single unique type of αβ TCR.

Thymocytes that successfully express a TCR must then pass positive and negative selection based on the p:MHC specificity of that TCR.[4] Positive selection occurs just after completion of TCR gene rearrangement at the time when thymocytes first express TCRs and coexpress both cluster of differentiation (CD)4 and CD8 coreceptors. To pass positive selection, a thymocyte must receive a TCR signal transduced by low affinity binding to a self p:MHC ligand on radio-resistant thymic epithelial cells in the cortex. It was thought that this process was inefficient due to the improbability of VDJ segment rearrangement by chance producing TCRs with any affinity for a self p:MHC ligand.[5] However, recent work from Marrack and colleagues has shown that all TCRs have germ-line encoded complementarity determining region (CDR) 1 and CDR2 domains within their V segments that bind MHC molecules.[6] This binding has been postulated to cause most thymocytes to undergo negative selection,[7] which is a desirable outcome for the host because these cells could cause autoimmunity if allowed to mature. In this model, the only thymocytes that receive the weak positive selection signal are those that produce a CDR3 through VDJ recombination that partially impairs CDR1 and 2 binding to MHC and allows weak binding to a self-p:MHC complex. Cells that undergo positive selection by recognition of a selfp: MHCI ligand lose CD4 and retain CD8, whereas cells that undergo positive selection by recognition of a self-p:MHCII ligand lose CD8 and retain CD4, in a process controlled by ThPOK and Runx3 transcription factors.[8] In contrast, thymocytes that undergo negative selection either die by apoptosis or differentiate into Foxp3+ regulatory T cells.[9]

Recirculation

CD4+ and CD8+ T cells that complete positive selection exit the thymus and enter the secondary lymphoid organs (lymph nodes, spleen, and mucosal lymphoid organs). Just before leaving the thymus, these cells turn on the KLF2 transcription factor, which promotes expression of several gene products that control thymus exit, such as S1P1, and subsequent circulation through secondary lymphoid organs, such as CD62L and CC chemokine receptor (CCR) 7.[10] T cells also express low levels of CD44 and CD45RO and high levels of CD45RB and CD45RA as they leave the thymus. Over the first 2 weeks after leaving the thymus in adults,

T cells increase the levels of expression of CD28 and the interleukin (IL)-7 receptor α chain, and become better able to proliferate and differentiate if confronted with the relevant foreign p:MHC ligand.[11,12] After completing this maturation process, T cells express a $CD44^{low}$ CD45RO- $CD45RB^{high}$ CD45RA+ CCR7+ CD62L+ $CD28^{high}$ IL-$7R\alpha^{high}$ phenotype, which is used to identify naïve T cells.

Naïve T cells spend their lives (T½ of 2 to 5 years in humans,[13] and 50 to 100 days in mice[14]) recirculating through secondary lymphoid organs. Expression of trafficking molecules that bind ligands that are only expressed on the specialized blood vessels and sinuses of these organs explain this behavior. For example, the extravasation of naïve T cells through the high endothelial venules (HEVs) of lymph nodes and mucosal lymphoid organs depends

on CD62L and CCR7, the ligands for which are only expressed on HEVs.[15] After passing through the HEVs, naïve T cells enter the T-cell-rich paracortical areas of the lymph nodes and mucosal lymphoid organs and are constrained in these regions by sensing CCL19 and CCL21 with CCR7.[16] Similarly, naïve T cells migrate from the marginal zone sinuses of the spleen into the T-cell-rich periarteriolar lymphoid sheathes (PALSs) via an unknown G-protein-coupled receptor-dependent mechanism. Naïve T cells again migrate within the PALSs through CCR7 sensing of CCL19 and CCL21. In all secondary lymphoid organs, naïve T cells are excluded from the B-cell-rich follicles due to lack of expression of CXC chemokine receptor (CXCR) 5, which binds to CXCL13 produced in follicles and guides cells to this location.

Survival

The T-cell areas within lymph nodes contain a network of thin collagen tubes called conduits, which carry lymphborne antigens and chemokines from the subcapsular sinus, where lymph enters the lymph nodes through afferent lymphatic vessels, to sinuses surrounding HEVs.[17] The conduits are wrapped with fibroblastic reticular cells, which produce IL-7. Naïve T cells migrate along the conduits, placing themselves in a good position to receive IL-7, on which they depend for survival.[18]

To survive for a normal lifespan, naïve T cells must also receive TCR signals through weak recognition of self p:MHC ligands, perhaps the ones that caused the T cells to undergo positive selection in the thymus.[1] Dendritic cells are probably the important antigen-presenting cell (APC) for this process because they are constantly in contact with T cells in the secondary lymphoid organs, and expression of MHCII molecules under the control of the dendritic cell-specific CD11c (*Itgax*) promoter is sufficient to maintain the survival of naïve CD4+ T cells. On the other hand, mice lacking dendritic cells by *Itgax* promoter-directed expression of diphtheria toxin have normal numbers of naïve T cells.[19] This result does not rule out a role for dendritic cells in naïve T-cell maintenance, however, because it is possible that the naïve T cells die at a higher than normal rate without dendritic cells but are also produced at a higher rate. Studies on the turnover rate of naïve T cells in dendritic cell-deficient mice will be needed to address this question.

Self p:MHC ligand presentation by dendritic cells has different consequences for naïve T cells than foreign p:MHC ligand presentation. For example, self p:MHC ligand presentation results in only a subset of the signals that emanate from the TCR when bound by a high affinity foreign p:MHC ligand, including partial phosphorylation of the TCR-associated CD3-zeta chain.[20] In addition, although signals through the TCR and IL-7 receptor are required for the survival of naïve T cells,[21] these signals do not cause the T cells to proliferate in hosts containing normal numbers of T cells due to competition for IL-7. The Tsc1[22,23] and Foxp1[24] transcription factors, the second of which regulates IL-7Rα levels, enforce the quiescent survival of naïve T cells in this situation. In contrast, naïve T cells proliferate when the number of T cells is very low and IL-7 becomes more available, for example, early in life or after radiation or chemotherapy. This “homeostatic” proliferation also depends on IL-7 and low-affinity TCR recognition of self p:MHC complexes,[21] but differs from proliferation in response to foreign p:MHC ligands by being independent of the CD28 costimulatory

receptor.[25] Thus, the same signaling events that cause naïve T cells to survive in interphase in T-cell-sufficient hosts cause these cells to proliferate in T-cell-deficient hosts, but using a program different from that engaged during the T-cell response to high affinity TCR ligands.

Survival and proliferation could both contribute to control of the number of naïve T cells in normal hosts. In adults, new naïve T cells are exported from the thymus into the secondary lymphoid organs that are already full of other T cells. Naïve T cells survive in interphase under these conditions. However, in neonates[26] and perhaps the very aged, new naïve T cells enter relatively lymphopenic secondary lymphoid organs and undergo homeostatic proliferation to fill the space. Notably, this proliferation causes the T cells to lose many of the markers that define the naïve phenotype and express surface molecules that are characteristic of memory cells.[21] Thus, although cells with the naïve phenotype dominate the preimmune repertoire, it can contain some cells with a memory cell phenotype.

Abundance

An adult mouse has about 10^8 αβ TCR+ T cells in the secondary lymphoid organs and another 5×10^6 in the blood.[1] The naïve T-cell population is split about 60:40 in favor of CD4+ T cells over CD8+ T cells. About 70% of the cells in both subsets are naïve phenotype cells, at least in young mice housed under specific pathogen-free conditions. Thus, an adult mouse has about 7×10^7 naïve phenotype T cells in its body, which extrapolates to about 3×10^{11} naïve phenotype T cells in an adult human. Because the number of potential TCR amino acid sequences that could be produced by VDJ recombination ($> 10^{15}$)[27] is greater than the number of naïve cells in the body, it is possible that each naïve T cell has a different TCR. Thus, it is possible that each of the 7×10^7 naïve T cells in a mouse has a TCR capable of binding to one of 7×10^7 different foreign p:MHC ligands. This would mean that the frequency of naïve cells expressing TCRs specific for a single p:MHC ligand could be as low as $1/7 \times 10^7$ naïve T cells.

The actual number of naïve T cells specific for single foreign p:MHC-specific ligands has been measured by flow cytometry following labeling with fluorochrome-labeled pMHC tetramers and enrichment with anti-fluorochrome antibody-coated magnetic beads. C57BL/6 mice contain about 200 naïve CD4+ T cells specific for an immunogenic peptide called 2W bound to I-A^b but only about 20 cells specific for peptide 427-441 from the FliC protein of *Salmonella typhimurium* bound to I-A^b.[28] Thus, the frequencies of cells capable of binding to these foreign p:MHCII ligands ranges from about 1:200,000 to 1:2,000,000 of the naïve phenotype CD4+ T cells in mice that were never exposed to these peptides. Similar analyses have been done for foreign p:MHCIspecific CD8+ murine T-cell populations.[29,30,31] The number of naïve CD8+ T cells in C57BL/6 mice ranged from 15 lymphocytic choriomeningitis virus (LCMV) $L_{338-346}$:D^b-specific cells to 1,100 vaccinia virus B8R:K^b- specific cells per mouse.[31]

An important conclusion from these studies is that naïve populations specific for different foreign p:MHC ligands vary in size in a predictable fashion. There is evidence that size

differences between foreign pMHC-specific populations in the preimmune repertoire are caused by negative selection.[32] In other words, naïve foreign pMHC-specific populations can be small because their TCRs by chance bind with high affinity to self p:MHC complexes. Another possibility is that peptides that are recognized by larger naïve populations have structural features that are conducive to recognition by a more diverse set of TCRs (eg, amino acids with prominent side chains).[32,33]

Another important conclusion from these experiments is that the size of naïve p:MHC-specific populations can predict the magnitude of the effector cell response after certain forms of antigen administration. For example, the presence of about 200 2W:I-A^b- and 20 FliC:I-A^b-specific naïve CD4+ T cells correlates with the 100,000 2W:I-A^b- and 15,000 FliC:I-A^b-specific effector T cells induced by injection of the relevant peptides.[28] Similarly, the size of naïve LCMV p:MHCI-specific T-cell populations plays a role the magnitude of the primary CD8+ T-cell response to the virus. LCMV infection of B6 mice activates CD8+ T cells specific for at least 28 different p:MHCI.[31] However, about one-third of the total response is directed against three p:MHCI complexes. The feature of these dominant p:MHCI ligands that correlates best with their potent immunogenicity is the large size of their naïve populations.[31] Therefore, although antigen abundance, efficiency of peptide generation by antigen processing, and MHC binding affinity are important factors in immunodominance,[34] so is naïve T-cell population size.

GENERAL ASPECTS OF EFFECTOR T-CELL FORMATION

Unlike the presentation of low-affinity self p:MHC ligands that maintains the survival of naïve T cells in interphase under nonlymphopenic conditions, the presentation of highaffinity foreign p:MHC ligands induces the specific naïve T cells to produce lymphokines, proliferate, and differentiate into effector T cells that aid in elimination of the antigen from the body. These more dramatic biological effects occur because the responding T cells receive much stronger or more durable signals through the TCR upon recognition of high-affinity foreign p:MHC ligands than they do when recognizing low-affinity self p:MHC ligands.[35] In addition, foreign antigens naturally enter the body during infection or tissue damage, which triggers dendritic cells and other innate immune cells to stabilize foreign p:MHC ligands and induce costimulatory receptors and cytokines.[36,37] The nature of the signals from the TCR, costimulatory receptors, and cytokine receptors then influences the type of effector cells that naïve T cells differentiate into. These three signals and how they vary depending on the nature of the antigen will be described.

Dendritic Cells as Initiating Antigen-Presenting Cells

Arguably, the most important of the three signals is transduced by the TCR pursuant to bind to a foreign p:MHC ligand on an APC. It is clear from ablation experiments that dendritic cells are the only APCs capable of initiating the TCR signal in CD8+ and CD4+ T cells in the spleen.[38] Dendritic cells are also important for initiating APCs for CD4+ T cells in lymph nodes, although other MHCII+ cells can do this job.[38] It has also become clear that many dendritic cell subsets exist.[38,39] A brief synopsis is presented here to give the reader a sense of which dendritic cell types function as APCs for different antigens. Refer to Chapter

16 on dendritic cells for more detailed information on their biology. Dendritic cells are defined in the mouse as cells that express the CD11c integrin, have large amounts of MHCI and MHCII molecules, and reside in or have the capacity to migrate to the T-cell zones of secondary lymphoid organs.[40] The spleen and lymph nodes contain two types of dendritic cells that develop from monocyte-dendritic cell precursors in these organs. One type expresses the myeloid marker CD11b and is often referred to as the myeloid dendritic cell. These dendritic cells are found mainly in the red pulp or marginal zones of the spleen and outer T-cell-rich regions of the lymph nodes. A second type depends on the Batf3 transcription factor, expresses CD8α, and is referred to as the CD8α+ dendritic cell.[41] These dendritic cells are located primarily in the PALSs of the spleen and the T-cell-rich regions of the lymph nodes, and are the major IL-12-producing cells in these locations. Myeloid and CD8α+ dendritic cells turnover rapidly with the latter population having only a 3-day half-life.

Another type of dendritic cell is called the plasmacytoid dendritic cell because of its morphology.[42] These cells develop in the bone marrow and then seed the spleen and lymph nodes from the blood. Plasmacytoid dendritic cells in mice express low amounts of CD11c and the B220 and Gr-1 molecules normally expressed by B cells and granulocytes, and are the most potent producers of type 1 interferons (IFNs)[43] when stimulated through pattern recognition receptors (PRRs).[44] These cells therefore play a key role in inducing an antiviral state in many cell types. The lymph nodes contain several additional migratory CD11c+ dendritic populations that move to this location

from tissues through afferent lymphatic vessels.[39] All lymph nodes contain CD11b+ dendritic cells that also express F4/80 and SIRPα, distinguishing them from myeloid dendritic cells and other CD103+ dendritic cells that often express an intracellular protein called langerin. In the case of the skin, these two types of dendritic cells migrate to lymph nodes from the dermis and are called dermal dendritic cells and dermal langerin-positive dendritic cells. The skin-draining lymph nodes also contain epidermal Langerhans cells, which express langerin and high levels of CD11b and EpCAM. Epidermal Langerhans cells are generated from a local radio-resistant precursor in the skin and are more long-lived than myeloid and CD8α+ dendritic cells.

The dendritic cell type that is most important for the presentation of p:MHC ligands depends on the nature of the antigen. Resident CD8α+ dendritic cells and CD103+ dendritic cell migrants are critical for p:MHCI ligand production from exogenous antigens because these are the only cells in the body that are capable of a process called cross presentation.[41,45] These dendritic cells express receptors such as CD36 that mediate uptake of apoptotic cells. After taking up apoptotic or other extracellular material, these dendritic cells have the unique capacity to move proteins from the phagosome directly into the cytoplasm. Once in the cytosol, the translocated proteins can be cleaved by the proteosome into peptides, which are then pumped by the transporter associated with antigen processing into the endoplasmic reticulum where binding to MHCI occurs. Other cells of the body cannot translocate ingested proteins into the cytosol and thus are only capable of producing p:MHCI complexes from proteins that are translated in their cytosols (eg, their own proteins or proteins from cytosolic microbes that infect them). Thus, the cross presentation pathway is important for initiating the CD8+ T-cell response to viruses that do not infect dendritic cells but kill their host cells. In

contrast, any dendritic cell including plasmacytoid dendritic cells can likely serve as an initiating APC for CD8+ T cells specific for MHCI-binding peptides derived from proteins from viruses that directly infect it.

Early activation of CD4+ T cells specific for p:MHCII ligands derived from soluble antigens can occur in two waves in lymph nodes.[46] Soluble antigens (eg, toxins secreted by bacteria in a subcutaneous infection site) rapidly flow through lymphatic vessels to the draining lymph nodes and into the conduit network. Resident dendritic cells associate with the conduits, then take up the antigen, perhaps from small gaps between the fibroblastic reticular cells that encircle these tubes.[47] These dendritic cells process the antigen, produce p:MHCII complexes, and display them for recognition by naïve CD4+ T cells. This process occurs within several hours of antigen deposition in the skin and results in CD69 induction and proliferation in the T cells.

The initial wave of p:MHCII presentation is followed by a second wave mediated by dermal dendritic cells that take up the antigen at the site of deposition and then migrate to the draining lymph node.[46] These dendritic cells arrive in the T-cell areas 12 to 24 hours after antigen enters the tissue. p:MHCII presentation by these dendritic cells prolongs induction of the IL-2 receptor and is required for T-cell acquisition of the capacity to cause a later delayed-type hypersensitivity reaction.

Other types of antigens are accessed and processed by different dendritic cells. Given their location in the spleen, myeloid dendritic cells probably play a key role as initiating APCs for CD4+ T cells in the case of antigens that are present in the blood.[48] Dendritic cells that migrate from the relevant tissue (eg, submucosal dendritic cells during vaginal infection are likely the only cells capable of producing p:MHCII ligands from microbes that are too large to enter the conduits.[43] For unknown reasons, dermal Langerin-positive dendritic cells are the most important APCs for induction of contact hypersensitivity-causing CD8+ T cells by protein-modifying chemicals applied to the skin surface.[49] Surprisingly, epidermal Langerhans cells are not required for contact hypersensitivity, although the sensitizing chemicals are applied to the skin surface. Rather, p:MHCII presentation by Langerhans cells inhibits the induction of delayed-type hypersensitivity by suppressing the priming of CD4+ Th1 cells and promoting the priming of Th17 cells.[50]

T-Cell Antigen Receptor Signaling

Once dendritic cells displaying foreign p:MHC ligands appear in the T-cell area of a secondary lymphoid organ, they can be recognized by naïve T cells expressing complementary TCRs. In vitro experiments have shown that highaffinity TCR ligation by p:MHC ligands causes the TCR to concentrate in a stable central supramolecular activating cluster (cSMAC) structure at the point of contact between the T cell and the APC.[51] cSMAC formation is often preceded by the formation of TCR microclusters at the periphery of the T cell-APC contact zone, which are capable of the transducing signals.[52] TCR clustering then activates protein tyrosine kinases such as lck, which stimulate signaling cascades that trigger protein kinase c theta, elevate intracellular calcium, convert ras into its active form, and activate the extracellular signal-regulated kinases (ERK1 and ERK2) and stress-activated protein kinases (jun kinase and p38 mitogen-activated protein kinase).[53] These pathways

culminate in the nuclear translocation and binding of transcription factors such as NFAT and NF-κB to deoxyribonucleic acid sequences that regulate lymphokine gene expression.[54]

Very little is known about early TCR signaling events in naïve T cells in vivo because the assays used to measure most of these events rely on cell lines and in vitro culture methods. Interestingly, in vivo imaging of naïve T cells showed rapid, p:MHC-dependent TCR internalization that was not contingent on prolonged contacts between T cells and APCs or cSMACs.[55] These transient interactions must be sufficient for TCR signaling, however, because intracellular staining with antibodies that recognize the active forms of the c-jun transcription factor and the p38 mitogen-activated protein kinase showed that both of these molecules are phosphorylated in p:MHC-specific naïve T cells in the spleen within minutes of intravenous injection of the relevant peptide.[56]

This rapid response is likely explained by the fact that the majority of naïve T cells are constantly contacting dendritic cells in the T-cell areas.[56]

Proliferation and Costimulation

Initial TCR binding to p:MHC ligands on dendritic cells causes naïve T cells to begin proliferating in vivo about 2 days later.[57] In vitro experiments indicate that this cell division is driven by production of IL-2[58] and induction of the IL-2 receptor alpha chain (CD25).[59] Surprisingly, however, p:MHC-driven proliferation of naïve T cells is minimally dependent on IL-2 in vivo.[60,61] Therefore, other signals or growth factors must be capable of driving T-cell proliferation in vivo, although IL-2 may contribute. The role of IL-2 as a T-cell growth factor may be difficult to reveal because IL-2 is also required to maintain regulatory T cells[62] and can promote death of activated T cells.[60] Thus, a reduction in IL-2-dependent effector T-cell proliferation could be masked by a removal of regulatory T-cell-mediated suppression and activation-induced cell death. In addition, although IL-2 is not essential for initial p:MHCI ligand-driven T-cell proliferation, it does appear to be essential for memory cell differentiation.[63]

The initial proliferation of naïve T cells is followed by an exponential increase in the number of p:MHC-specific T cells over the next several days.[64,65] Depending on the stimulus, the number of p:MHC-specific T cells reaches its highest level in the relevant secondary lymphoid organs, 5 to 7 days after antigen enters the body. As mentioned previously, naïve mice contain about 200 CD8+ T cells specific for a given p:MHC I complex. Because p:MHCI-specific CD8+ T cells can increase to 10^7 cells at the peak of the primary response,[64,65] it follows that CD8+ T cells can expand 500,000-fold in vivo. Although naïve CD4+ T cells are also capable of dramatic clonal expansion when stimulated appropriately, their burst size appears to be less than CD8-positive T cells.[64] For both CD4+ and CD8+ T cells, the amount of cell division is inversely proportional to the number of naïve precursors,[14,66,67] indicating that in vivo proliferation is limited by competition between p:MHC-specific T cells.

In vivo T-cell proliferation is regulated by signals from the costimulatory CD28 molecule, which is triggered by binding to CD80 and CD86 on APCs.[68] The proliferation of antigen-stimulated CD4+ or CD8+ T cells is greatly reduced in mice in which CD28 cannot interact

with its ligands. CD40 ligand (CD154) deficiency also affects T-cell expansion,[69] which may be related to the fact that CD40 signaling in APC induces CD80 and CD86.[70] Although costimulatory signals enhance TCR-driven IL-2 production, the in vivo significance of this effect for T-cell proliferation is unclear, as described above. Although it has been proposed that CD28 acts by promoting TCR aggregation in the cSMAC,[71] enhancing lymphokine messenger ribonucleic acid production[72] and stability,[73] and/or promoting T-cell survival by augmenting Bcl-X_L production,[74] the bulk of recent evidence indicates that it acts by NF-κB signaling.[75] Members of the TNF receptor family, such as OX40, CD27, and 4-1BB are induced in T cells by CD28 signaling several days into the primary response.[76,77] These molecules bind ligands of the TNF family on the surface of APC and transduce signals that sustain the proliferation or survival of p:MHC-stimulated T cells.

Enhancement of costimulatory signals may underlie the observation that in vivo T-cell proliferation is also influenced by inflammation at the time of initial p:MHC presentation. This effect is observed in the case of soluble antigens, where the magnitude of T-cell proliferation is several-fold greater if antigen is administered with a microbial substance[78,79] containing a pathogen-associated molecular pattern[43] such as lipopolysaccharide, which is recognized by a PRR such as toll-like receptor 4.[80] PRR signaling stimulates tissue macrophages to produce tumor necrosis factor-α,[81] which in turn stimulates dendritic cells to migrate from nonlymphoid tissues into the T-cell areas and express higher levels of CD80 and CD86.[82] In addition, these signals result in a maturation process that changes the antigen processing and presentation potential of all dendritic cell types.[83] When inflammation is not present, dendritic cells efficiently engulf extracellular fluid and produce p:MHC complexes from the ingested proteins. However, these p:MHC molecules turn over rapidly on the dendritic cell surface and are presented in the context of low amounts of CD80 and CD86. These factors are thought to be part of the explanation for why p:MHCII presentation by dendritic cells in uninflamed secondary lymphoid organs leads to poor T-cell priming and can result in tolerance.[84] In contrast, inflammatory signals cause dendritic cells to reduce antigen uptake and processing, stabilize p:MHCII molecules, and induce expression of CD80 and CD86. Therefore, inflammatory signals enhance proliferation by driving more dendritic cells into the T-cell areas to present p:MHC ligands and by increasing the costimulatory capacity of these dendritic cells.

PRR signaling in dendritic cells or macrophages can also trigger the production of proinflammatory cytokines, which enhance effector cell proliferation. For example, IL-1 from several sources enhances the proliferation of CD4+ T cells through an early indirect effect on APCs,[85] and a later more potent direct effect on the T cells themselves.[86] PRR signaling causes CD8α+ dendritic cells to produce IL-12[41] and plasmacytoid dendritic cells to produce type 1 IFNs,[42] both of which enhance the proliferation of CD8+ effector T cells.[87]

EFFECTOR T-CELL DIFFERENTIATION

The proliferation of p:MHC-specific effector T cells during the primary response is linked with the acquisition of functions that affect the elimination of antigen such as microbicidal cytokine

production and cytolysis. The functional properties that effector cells acquire are influenced by the presence of inflammatory cytokines and costimulatory ligands on APCs present at the time of initial p:MHC presentation in secondary lymphoid organs.

CD4+ T Cells

Many variations on this theme exist in the case of CD4+ T cells. Effector cells that are generated in the presence of IL-12, IL-4, IL-6 and TGF-β, or IL-6 and IL-21 become

IFN-γ-producing Th1 cells, IL-4-producing Th2 cells, IL-17-producing Th17 cells, or IL-21-producing follicular helper cells (Tfh), respectively. These effector T cells play specialized roles in the elimination of intracellular microbes, worms, and extracellular microbes. Polarization of Th cells is covered in detail elsewhere in this volume.

Signaling through the IL-2 receptor plays an essential and early role in the formation of Th1, Th2, and Th17 effector cells. IL-2 receptor alpha chain (CD25) expression is induced in naïve T cells by TCR signaling, which then pairs with IL-2/IL-15 receptor β (CD122) and IL-2 receptor γ(CD132) chains, to produce the high-affinity IL-2 receptor.[88] Under Th1 priming conditions, the IL-2-bound receptor recruits Jak1 and Jak3 that phosphorylate the STAT5 transcription factor, which enters the nucleus and enhances expression of the IL-12 receptor β2 chain and the T-bet and Blimp-1 transcription factors.[89] IL-12 receptor signaling through STAT4 then enhances T-bet expression and enforces the Th1 fate,[90] while Blimp-1 suppresses another transcription factor Bcl6 that is needed for other fates.[91] Under Th2 priming conditions, IL-2 receptor signaling through STAT5 regulates the Th2 cytokine gene cluster and expression of the IL-4 receptor α-chain.[89] In contrast, IL-2 receptor signaling inhibits Th17 differentiation by suppressing components of the IL-6 receptor.[89]

A variation on this theme was recently described for CD4+ T cells during acute systemic *Listeria monocytogenes* or LCMV infections.[92,93,94] In this case, CD25 is induced by TCR signaling in microbe p:MHCII-specific CD4+ T cells 1 day into the infection. However, by day 3, about half of the responding T cells lose CD25 expression and begin to express CXCR5, while half retain CD25 and do not express CXCR5.[92,94] The mechanism underlying this bifurcation is unknown, although asymmetric division of CD25+ mother cells into CD25+ and CD25- daughter cells is a possibility.[95] Another possibility is that very strong TCR signaling favors CD25 expression.[96] In any case, the CD25+ cells go on to form T-bet^{high} Th1 effector cells in the T cell areas, red pulp, and probably nonlymphoid organs where they could produce IFN-γ in response to p:MHCII presentation by macrophages. It is likely that early CD25+ effector cells become Th2 cells during infections that promote IL-4 production by innate immune cells.[97]

The CD25- CXCR5+ cells formed early during acute infection yield two T-bet^{low} effector cell populations,[92,93] both expressing the B-cell-follicle guiding CXCR5 receptor but only one expressing the Tfh marker PD-1.[98] Both of these CXCR5+ effector cell populations depend on the Bcl6 transcription factor for their formation.[92] The CXCR5+ PD-1- and CXCR5+ PD-1+ effector cell populations probably differentiate depending on quantitative differences in

signals from the TCR and the inducible costimulator (ICOS) receptor.[68,94,99,100] Following stimulation by p:MHCII ligands on dendritic cells, the naïve T cells that quickly lose CD25 and express Bcl6 migrate toward the follicles under the guidance of CXCR5 to interact with, and provide helper signals to, antigen-specific B cells that display the relevant p:MHCII complexes and ICOS ligand.[101,102,103] In return, the T cells receive signals from the TCR and ICOS. If these signals are relatively weak, then Bcl6 expression may not be maintained and the cells acquire a CCR7+ $CXCR5^{intermediate}$ P-selectin ligand (PSGL-1)+ PD-1- phenotype and live in the outer T-cell area. As discussed in more detail below, some of these effector cells yield multipotent central memory cells.

In contrast, if early CD25- CXCR5+ effector cells receive strong TCR and ICOS signals when interacting with B cells, perhaps because of expression of TCRs with very high affinity for the inducing p:MHCII ligand,[91,104] then they become $CCR7^{low}$ $CXCR5^{high}$ PSGL-1- PD-1+ Tfh cells. The cytokines IL-6 and IL-21 are also required for this process,[105,106] with IL-21 probably coming from the developing Tfh cells themselves. The $CCR7^{low}$ $CXCR5^{high}$ phenotype causes Tfh cells to localize in germinal centers, which are rich sources of CXCR5 but not CCR7 ligands.[16] Here, Tfh cells produce IL-21 and CD40 ligand that promote germinal center B-cell differentiation, antibody isotype switching, and plasma cell formation.[98]

CD8+ T Cells

As in the case of CD4+ T cells, IL-2 receptor signaling is not essential for the initial proliferation of p:MHCI-stimulated naïve CD8+ T cells.[63] However, IL-2 receptor signaling plays a key role in effector cell differentiation and memory cell formation. Naïve CD8+ T cells that are stimulated by p:MHCI ligands on dendritic cells in secondary lymphoid organs during acute LCMV infection rapidly express CD25 to produce highaffinity IL-2 receptors.[96] However, as in the case of CD4+ T cells, a subset of the CD8+ T cells sustains CD25 expression longer than the other cells in the population. The $CD25^{low}$ cells preferentially upregulate the IL-7 receptor and the central memory T-cell marker CD62L and produce long-lived memory cells. In contrast, the $CD25^{high}$ cells proliferate more rapidly and become apoptosis-prone terminally differentiated effector cells, although it is likely that some of these cells produce effector memory cells. Thus, for both CD4+ and CD8+ T cells, a lack of IL-2 receptor signaling early in the primary response produces effector cell precursors of central memory cells, whereas IL-2 receptor signaling promotes highly differentiated effector cells and like effector memory cells.

Again like CD4+ T cells, costimulatory signals and cytokines produced by innate immune cells are needed for optimal differentiation of CD8+ effector cells. Naïve CD8+ T cells that are stimulated by p:MHCI ligands also require CD28 signals and either IL-12 or type I IFN (IFNα/β) for maximal proliferation and development of cytolytic activity.[87] The effects of IL-12 and type 1 IFN are mediated directly on the CD8+ T cells. When either IL-12 or type 1 IFN are delivered with antigen, the responding CD8+ T cells form a memory cell population, while immunization with antigen alone induces some clonal expansion, but very few cells survive long-term and those that do are anergic. Thus, IL-12 and type 1 IFN provide a “third signal”

that is necessary, along with TCR and CD28 signals, for development of optimal effector functions and formation of a responsive memory population. Dendritic cells activated by PRRs, or CD40 signals pursuant to interaction with CD40 ligand (CD154)+ CD4+ T cells, produce IL-12 and type I IFNs, and are thus equipped to provide all three signals needed by a naïve CD8+ T cell to become a cytotoxic effector cell.

IL-12 and type I IFN are largely redundant in their capacity to support a productive CD8+ effector T-cell response, and which cytokine is critical depends on the infection. Studies using CD8+ T cells lacking receptors for one or both of the cytokines have shown that type I IFN is essential for response to LCMV,[107] while IL-12 signaling plays the major role in responses to vaccinia virus and *Listeria monocytogenes*.[108] In a minor histocompatibility antigen transplant model, rapid graft rejection depends on CD4+ T cells stimulating dendritic cells in a CD40-dependent manner to produce IL-12 needed for generation of cytotoxic CD8+ effector T cells.[109] Thus, it appears that one way in which CD4+ T cells can provide help for CD8+ T-cell responses is by stimulating dendritic cells to produce third signal cytokines.

CD8+ effector T cells differ from their naïve precursors regarding surface markers, function, and trafficking properties. CD8+ effector T cells that are generated in secondary lymphoid organs during microbial infections express slightly lower levels of CD8 and more surface O-glycans than naïve cells,[110] and in the human some CD8+ effector T cells lose CD27 and CD28 but retain CD45RA.[111] Unlike naïve cells, these cells express perforin and granzymes,[110] which are required for efficient cytolytic function. Expression of perforin and granzymes contributes to the defining feature of cytotoxic T cells,[110] that is, the ability to directly kill target cells that display the appropriate p:MHC I complexes. Interestingly, although large numbers of antigen-specific CD8+ T cells accumulate in mice injected with heat-killed *Listeria monocytogenes* bacteria, these T cells do not acquire cytolytic function.[112] This situation may come about because heat-killed *Listeria monocytogenes* bacteria are poor inducers of IL-12 by innate immune cells compared to live organisms.

EFFECTOR T-CELL FUNCTION IN NONLYMPHOID ORGANS

Some CD4+ effector T cells migrate into nonlymphoid tissues at the peak of the primary response.[113] Separate homing pathways to the intestines and skin have been characterized in detail,[114] although other pathways probably exist. Injection of antigen and cholera toxin into the skin induces two populations of CD4+ effector T cells in the draining lymph nodes that do or do not express the fucosylated form of P-selectin glycoprotein-1 (fPSGL-1), which binds to CD62P on inflamed blood vessels.[115] The fPSGL-1- cells are potent helpers of antibody production by B cells and are likely one of the CXCR5+ effector cell populations described above. In contrast, the fPSGL-1+ cells are poor helpers of antibody production by B cells but are capable of IFN-γ production and are likely similar to the T-bet^{high} Th1 effector cells induced during acute infections. After transfer into naïve recipients, these cells migrate to the skin as evidenced by a capacity to cause delayed-type hypersensitivity reactions. Injection of antigen into the skin with complete Freund's adjuvant also induces Th1 effector cells in draining lymph nodes, which migrate to the skin injection site in a CD62E- and

CD62P-dependent fashion.[116] Interestingly, in this case and another involving lung migration,[117] the CD4+ T cells in the lymph nodes that migrate to nonlymphoid tissues are those that undergo the most cell divisions in the secondary lymphoid organs. Thus, only the most-divided subset of Th1 effector cells in lymph nodes acquire the appropriate trafficking receptors and have the capacity to migrate to nonlymphoid organs.

The induction of skin-homing capacity is controlled by several factors produced by dendritic cells that migrate from the skin and present p:MHCII ligands to naïve T cells in the draining lymph nodes. One of these factors is IL-12, which induces the expression of enzymes that fucosylate PSGL-1 and convert it into the CD62P-binding form.[118] Dendritic cells from the skin also produce 1,25 dihydroxy-vitamin D3, which induces the putative skin-homing chemokine receptor CCR10 on T cells.[119] It should be noted, however, that regulation of CCR4, which is probably the most important skin-homing chemokine receptor on T cells,[120] is not understood in this context.

The generation of gut-homing CD4+ effector T cells is also controlled by factors produced by dendritic cells at the time of T-cell priming. Presentation of p:MHCII ligands to CD4+ T cells in mucosal lymphoid organs induces effector cells that express large amounts of α4β7 integrin, which facilitates T-cell migration into tissues containing mucosal addressin cell adhesion molecule-1+ blood vessels such as the intestines.[15] CD103+ dendritic cells in the mucosal lymphoid organs produce all-trans retinoic acid, which enhances the expression of α4β7 integrin and CCR9 on CD4+ T cells.[121]

Mycobacterium tuberculosis (TB) infection by inhalation provides another example of CD4+ effector T-cell migration to nonlymphoid tissue.[122] Inhaled TB organisms are taken up in the lungs by CD11b+ dendritic cells, which carry the bacteria to the mediastinal lymph nodes and present TB p:MHCII ligands to naïve CD4+ T cells expressing relevant TCRs. This presentation occurs in an IL-12-rich context, and Th1 effector cells are produced, many of which traffic back to the lungs. The molecules that control this migration are unknown although CCL27, MIP-1α, IP-10, CCR4, CCR5, and CXCR3 may be involved. Once in the lungs, effector T cells produce IFN-γ in response to TB p:MHCII presentation by infected dendritic cells and macrophages, which triggers the microbicidal functions of these cells. During this process, the lung effector T cells start out as PD-1^{high} $CD69^{high}$ cells that convert to $KLRG1^{high}$ $CD69^{low}$ short-lived, terminally differentiated cells as they become activated by local TB p:MHCII presentation. Because TB organisms are not completely eliminated by this process, it goes on for protracted periods of time as new effector cells migrate to the lungs from the draining lymph nodes, eventually damaging the lung tissue. Thus, TB p:MHCII-specific effector T cells and their effects on infected phagocytes knock the TB organisms down but not out, and in the process protect the host in the relative short-term and damage it in the long-term.

CD8+ effector T cells also migrate out of the T-cell areas and into many nonlymphoid tissues, particularly inflamed sites of antigen deposition (eg, the lungs during influenza infection[123,124] and the gut during vesicular stomatitis virus infection[125]). Strong or prolonged IL-2 receptor signaling is an important factor in the generation of highly differentiated nonlymphoid tissue-homing effector CD8+ T cells.[96] The migratory capacities

of effector CD8-positive T cells correlate with loss of receptors involved in lymph node

migration (CCR7 and CD62L) and acquisition of receptors such as α4β7 integrin,[126] following instructions from dendritic cells as described above for CD4-positive T cells. The migration of CD8+ effector T cells with cytotoxic potential into nonlymphoid organs is an effective way of eliminating cells that display p:MHC I complexes from all parts of the body.

Several CD8+ effector T-cell-specific homing phenomenon are worth mentioning. One is that CD8+ T-cell recruitment to nonlymphoid tissue depends on prior entry of CD4+ T cells in certain situations. Recognition of p:MHCI complexes on dendritic cells in the secondary lymphoid organs induces the expression of CXCR3 on effector CD8+ T cells, which facilitates entry into nonlymphoid tissues through blood vessels displaying CXCL9 and CXCL10.[127] During certain viral infections, CD4+ effector T cells first enter the relevant nonlymphoid tissue and are stimulated by their p:MHCII ligands to produce IFN-γ, causing local epithelial cells to secrete CXCL9 and CXCL10, which then recruit the CD8+ effector T cells.[128]

Another special homing property of some CD8+ effector T cells relates to the capacity to enter a nonlymphoid tissue and never leave.[129] Viral infections in the skin, brain, and intestinal mucosa result in expansion of viral p:MHCI-specific CD8+ effector T cells in the draining lymph nodes and then migration of some effector cells to the site of infection. Some of these cells can be found at this site long after the infection is cleared. Parabiosis experiments indicate that these T cells are not constantly leaving and entering the site from the blood as expected, but rather remain in the original site without leaving. These resident CD8+ T cells express CD103, which may tether them in the site by binding to E-cadherin on local epithelial cells. Tissue-resident CD8+ effector T cells also express CD69, a marker of acute activation, even under conditions where local relevant p:MHCI complexes cannot be detected. Thus, CD69 expression may be driven in these cells by cytokine receptor rather than TCR signaling. It should be noted that not all CD8+ effector T cells in nonlymphoid tissues are noncirculating residents as evidenced by the presence of p:MHCI-experienced CD8+ T cells in efferent lymphatic vessels, which carry cells from tissues to the blood.[130] The factors that determine whether naïve CD8+ T cells will become nonrecirculating CD103+ tissue-resident effector cells or effectors cells that recirculate through nonlymphoid tissues are not known.

GENERATION OF MEMORY T CELLS FROM EFFECTOR CELLS

Another key function of effector T cells is the production of memory cells.[131] The number of antigen-derived p:MHC-specific effector T cells in the body peaks about a week into the primary response, and then falls rapidly over a 2-week contraction period to about 10% of the peak value.[132] This decline must be due to cell death because the total number of cells in all parts of the body declines shortly after the peak.[113] The T cells that survive the contraction phase can persist stably for the life of the host even when the antigen is cleared from the body due to the expression and function of IL-7 and IL-15 receptors.[133] These long-lived cells are known as memory cells, which are capable of rapid secondary responses that can produce protective immunity to a later challenge from a microbe.[134] Memory cells can be distinguished from effector cells in that most memory cells are not blasts, are not in the cell

cycle, and many are not directly cytolytic or producing lymphokines.[135]

Memory cells are heterogenous, however, and exist in at least two subsets: effector memory (Tem) cells and central memory (Tcm) cells.[136] Tem cells express homing receptors that facilitate migration to nonlymphoid sites of inflammation[113] and produce microbicidal cytokines such as IFN-γ within several hours of TCR stimulation. In many ways, these cells resemble effector cells (eg, Th1 or Th2 cells), with the exceptions that they are no longer blasts and express IL-7 receptors. Tcm cells do not produce any of the prototypic effector cell lineage cytokines immediately after stimulation through the TCR, although they secrete IL-2 and proliferate extensively and acquire effector lymphokine production later. These cells express CD62L and CCR7, which are involved in migration through lymph nodes and mucosal lymphoid organs and positioning in the T-cell areas of these organs,[16] and IL-7 receptors, which are critical for their survival.[133]

The Tem and Tcm model fits well for CD8+ memory T cells. A subset of human CD8+ memory cells lacks the naïve cell marker CD45RA but expresses CCR7.[111,137] These memory cells also express CD62L and lack perforin and thus would not be expected to be directly cytotoxic. Mice contain a comparable $CD44^{high}$ memory cell population after clearance of acute viral infection.[125] These similar populations in mice and humans fit the description of Tcm cells. In mice, the CD62L+ Tcm cells undergo slow IL-15-dependent, MHCI-independent homeostatic proliferation, which is thought to account for their numerical stability.[138]

Mice and humans also contain CD45RA- CCR7- CD62L- CD8+ memory T cells. These cells express high levels of β1 and β7 integrins, fPSGL-1, and CCR5, which are predicted to facilitate migration into nonlymphoid tissues,[139] and produce IFN-γ rapidly after TCR stimulation.[125,137] These cells therefore fit the description of Tem cells. In mice, CD8+ Tem cells undergo much less IL-15-dependent, MHCI-independent homeostatic proliferation than Tcm cells,[140] and convert into Tcm cells over long periods of time in some[141] but not all[142] situations. Murine CD8+ Tem cells can recirculate through nonlymphoid organs or reside permanently in nonlymphoid organs, as described above.

Humans also contain a CD45RA+ CCR7- CD8+ T-cell subset that contains especially high levels of perforin and direct ex vivo cytotoxic activity.[111,137] These cells are likely effector cells that were recently stimulated by p:MHCI ligands.

Memory CD4+ T-cell populations also contain Tcm and Tem subsets. The microbial p:MHCII-specific CD4+ T cells that survive in secondary lymphoid organs long after clearance of *Listeria monocytogenes* or LCMV infections consist of two subsets.[92,93] One subset has the characteristics of Tem cells including a $T\text{-}bet^{high}$ CCR7- phenotype, expression of nonlymphoid tissue homing receptors, and immediate IFN-γ production after stimulation with the relevant p:MHCII ligand. These cells correspond to human CD45RA- CCR7- CD4+ Tem cells, which express low or

variable levels of CD62L and high levels of fPSGL-1, and/or β1 and β7 integrins and produce IFN-γ or IL-4 rapidly when stimulated with anti-CD3 antibody in vitro.[137] In the mouse, CD4+

Tem cells are also found in liver, lungs, and gut long after intravenous injection of antigen plus adjuvant.[113] Because CD4+ memory T cells are constantly coming out of tissues and into afferent lymphatic vessels,[130,143] it is likely that CD4+ Tem cells are not fixed in nonlymphoid organs but recirculate through these sites.

The other microbial p:MHCII-specific CD4+ T-cell population that survives after clearance of acute infections in mice has the characteristics of Tcm cells. This population has a T-bet^{low} CCR7+ CXCR5+ Ly6C^{-} PD-1- Tfh-like phenotype and produces IL-2 but not IFN-γ immediately after stimulation with the relevant p:MHCII ligand.[92,93] These cells have been found to be potent helpers of antibody production by B cells.[143,144,145] In humans, this population can give rise to Tfh cells when stimulated in vitro.[146] In mice, these cells also generate Th1 cells and themselves during secondary immune responses and thus have the capacity of Tcm cells to generate diverse effector cells.[92]

Evidence suggests that Tem and Tcm memory cells derive from like effector cells. IFN-γ-producing CD62L- CD4+ Tem cells that survive after clearance of acute LCMV infection are derived from similar IFN-γ-producing CD62L- effector cells present at the peak of infection.[147,148] Similarly, the T-bet^{low} CXCR5+ CCR7+ Tfh-like Tcm cells that survive after clearance of *Listeria monocytogenes* infection are derived from similar T-bet^{low} CXCR5+ CCR7+ effector cells present at the peak of infection.[92]

Even though the various types of memory cells are derived from effector cells, they must be subsets of their effector cell precursor populations because they are 10 times smaller than those populations. In other words, even though Th1 effector memory cells are derived from similar Th1 effector cells, the former cells are 10 times less abundant than the latter cells. Thus, to understand how memory cells emerge at the end of the primary response, it is useful to consider the factors that cause 90% of the effector cells to die. Effector cells produce reactive oxygen species, which can cause cell death by damaging mitochondrial membranes. Bcl-2 family proteins regulate this type of death. Naïve and memory T cells express anti-apoptotic Bcl-2 molecules in their mitochondria, which inhibit the formation of apoptosis-inducing complexes consisting of Bim and Bak. In mice overexpressing Bcl-2 or lacking Bim, a greater fraction of the effector cell population survive contraction and differentiate into memory cells.[149] Thus, it is conceivable that under normal circumstances, the effector cells that are destined to become memory cells produce less reactive oxygen species or protect themselves better than other effector cells in the population.

Another possibility relates to expression of the IL-7 receptor. The survival of naïve T cells depends on IL-7 receptor signaling, which maintains Bcl-2 expression and limits Bim expression.[149] TCR-driven activation causes effector cells to lose the IL-7 receptor, leading to the fatal situation where Bcl-2 is reduced and Bim is increased. It has been reported that a subset of CD8+ effector cells retains IL-7 receptor expression and survives the contraction phase to become memory cells,[150] although some evidence against this idea has accumulated.[151,152] Thus, it is possible that 10% of the effector cells present at the peak of the T-cell response retain the IL-7 receptor or some other survival factor, which allows these cells to become memory cells.

Another possibility is that metabolic rate determines whether an effector cell will survive to become a memory cell. Quiescent naïve and memory T cells produce adenosine-5′-triphosphate by mitochondrial oxidative phosphorylation.[153] In contrast, activation causes effector cells to shift to glycolytic adenosine-5′-triphosphate production by a pathway that depends on mammalian target of rapamycin. Inhibition of mammalian target of rapamycin with rapamycin early during the primary response promotes the formation of CD8+ memory T cells by inhibiting T-bet expression in favor of another transcription factor, eomesodermin.[154,155,156] This result fits with a model in which most effector cells are killed by products of their own high rate of glycolysis through a T-bet-dependent program, which when blocked allows a return to oxidative phosphorylation and memory cell formation. In this model, memory cells arise from effector cells with the lowest glycolytic rates in the population. Again, increased glycolytic rate and the favoring of effector cell death over memory cell formation could involve IL-2 receptor signaling.

Tumor necrosis factor receptor family proteins also promote CD4+ T memory cell survival by inducing antiapoptotic factors by TRAF-dependent triggering of NFκB.[77] For example, effector T cells that do not express CD27 survive poorly in vivo.[157,158] Other work indicates that OX40 is dispensable for effector cell generation but required for memory cell formation.[159]

Recent work indicates that Id transcription factors also regulate effector-memory cell conversion. Id2 is required for the maximal generation of CD8+ effector T cells and perhaps the formation of Tem cells.[160,161,162] Conversely, Id3 appears to be critical for CD8+ Tcm cell formation.[162]

CONCLUSION AND MODELS

What follows is an attempt to unify the information presented in this chapter into a theoretical sequence of events that occur after naïve CD4+ or CD8+ T cells encounter the relevant p:MHC ligands during skin or mucosal infections, respectively. Because these processes are not completely understood, certain aspects of what follows are speculative.

Naïve T-cell populations that are specific for single p:MHC epitopes exist at a frequency of about 1:200,000 in the preimmune repertoire.[1] These T cells, like other naïve T cells, spend their life spans (˜2 months in mice, ˜2 years in humans) in a series of 1-day stops in the T-cell areas of different secondary lymphoid organs with intervening trips through the blood. While in the T-cell area, these naïve T cells receive survival signals through the IL-7 receptor as it binds to IL-7 made by stromal cells and through the TCR as it binds to the relevant selecting self p:MHC ligand on the surface of an APC, probably a dendritic cell.

Consider first the case of the CD4+ T-cell response to a bacterial infection in the dermis of the skin (Fig. 14.1). In this case, local dermal dendritic cells take up the microbe,

produce microbe p:MHCII complexes,[45] upregulate CD28 ligands,[163] begin producing IL-12[164] and vitamin D3,[119] and migrate through an afferent lymphatic vessel to the draining

lymph node. Naïve T cells interact with these dendritic cells[165] and those CD4+ T cells that express bacterial p:MHCII-specific TCRs receive TCR and CD28 signals[56] and induce the translocation of NFAT and NF-κB to the nucleus,[54] which in turn drive expression of CD25, IL-2, Bcl6, and the IL-12 receptor β2 chain, and loss of the IL-7 receptor.[61,89,166] The T cells then divide in response to IL-2 and unknown growth factors,[57] perhaps asymmetrically,[95] to produce CD25+ and CD25- effector cell progeny.[92,94] The CD25+ cells activate STAT5 through IL-2 receptor signaling, [167] which further increases expression of the IL-12 receptor β2 chain,[89] which combines with the IL-12 receptor β1 chain, binds IL-12, and activates STAT4[168] to amplify T-bet expression.[169] IL-2 receptor signaling and STAT5 activation also stimulates Blimp-1 expression,[170] which represses Bcl6,[171] thereby enforcing the Th1 fate and preventing Bcl6-dependent cell fates. The Th1 effector cells also express CCR10, CCR4, and fucosylated PSGL-1 due to activation in the presence of IL-12 and vitamin D3.[114,118] Some of these effector cells then leave the lymph nodes through efferent lymphatic vessels, enter the bloodstream, and migrate into the infection site through skin blood vessels displaying CD62P, CCL17, and CCL27.[116,119,172] After entering this site, the Th1 effector cells interact with infected macrophages displaying bacterial p:MHCII ligands.[173] TCR signaling then causes the T cells to secrete IFN-γ, which triggers production of inducible nitric oxide synthase and nitric oxide as well as killing of intracellular bacteria.[173] Some of the Th1 effector cells in the lymph nodes survive the contraction phase, re-express the IL-7 receptor, and become Th1 effector memory cells,[147] which recirculate through the skin.

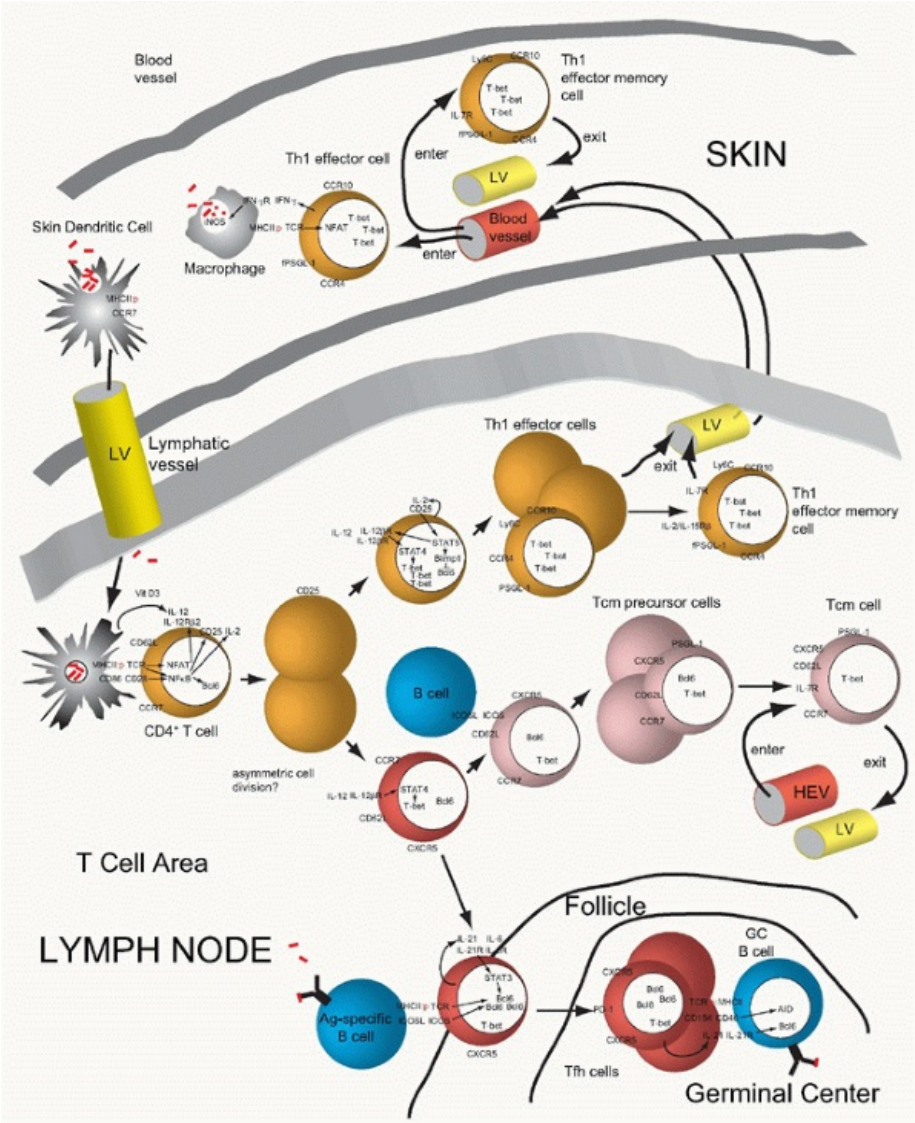

FIG. 14.1. CD4+ T-Cell Response to Bacterial Infection of the Skin. See the text for description. Bacterial antigen is indicated with red rectangles. Surface receptors are shown attached to the cell surface. Transcription factors are shown in the nucleus. Signals are shown with the *smallest arrows*. Sequential cell fates are shown with the *next largest arrows*. Migration routes are shown with the *largest arrows*. LV, lymphatic vessel; R, receptor.

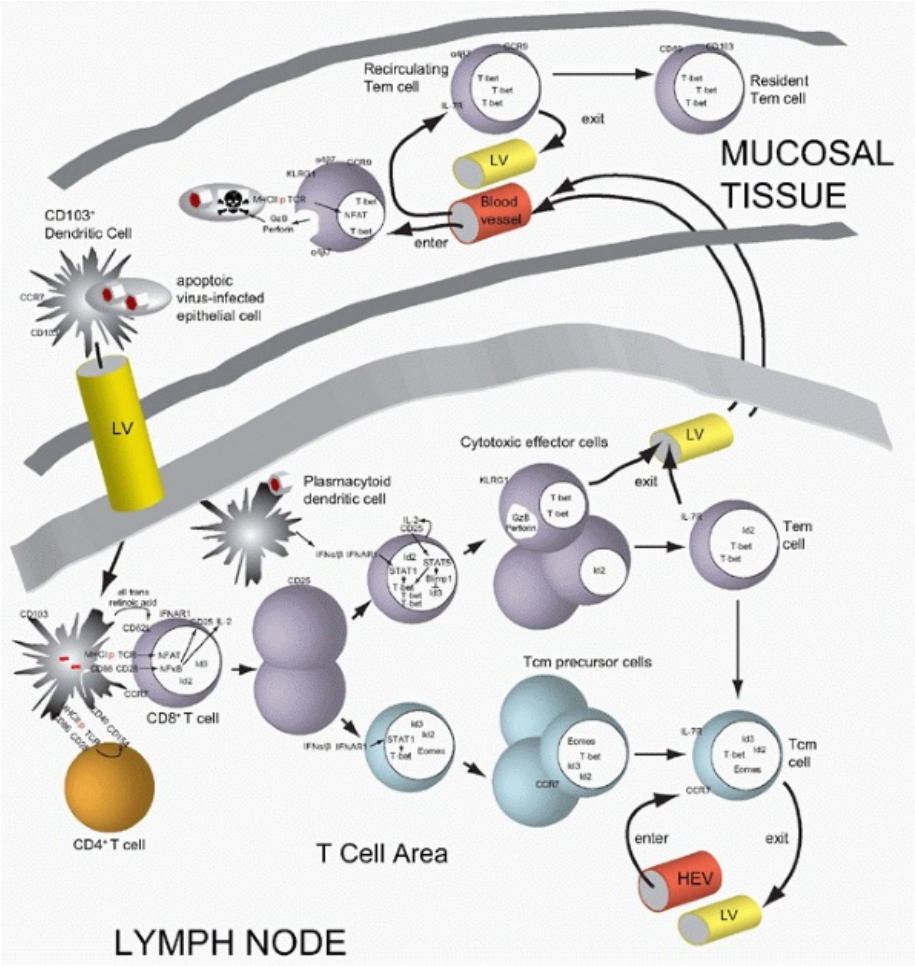

FIG. 14.2. CD8+ T-Cell Response to Viral Infection of a Mucosal Tissue. See the text for description. Virus particles are indicated with hexagons. Surface receptors are shown attached to the cell surface. Transcription factors are shown in the nucleus. Signals are shown with the *smallest arrows*. Sequential cell fates are shown with the *next largest arrows*. A virally infected cell killed by a cytotoxic clust of differentiation 8-positive T cell is indicated with a *skull and cross bones*. Migration routes are shown with the *largest arrows*. LV, lymphatic vessel; R, receptor.

The early CD25- progeny do not experience IL-2 receptor signaling and STAT5 activation, do not upregulate the IL-12 receptor β2 chain, and are left with a low amount of T-bet. Blimp-1 is also not turned on, allowing the cells to retain Bcl6 and express CXCR5. The CXCR5+ T cells then migrate toward the follicles.[103] If they interact with an antigen-specific B cell, then they receive TCR and ICOS ligand signals[98] and produce IL-21, which binds the IL-21 receptor and activates STAT3.[174] The combination of TCR, ICOS, and STAT3 signals then amplifies Bcl6 expression, stimulating the cells to express PD-1 and more CXCR5, and to commit to the Tfh lineage. The Tfh cells then migrate into germinal centers, interact with antigen-specific germinal center B cells, induce expression of CD154, which engages CD40 on the B cells and stimulates them to express activation induced cytidine deaminase, and undergo antibody isotype switching and somatic hypermutation.[98] If the early CXCR5+ T cells interact with B cells that are not specific for bacterial antigens, then they receive an

ICOS signal that maintains their survival.[92] However, without additional TCR signaling, the T cells do not further upregulate CXCR5, do not lose CCR7 or CD62L, and some of these cell become Tcm cells, eventually losing Bcl6.[92] These Tcm cells recirculate through secondary lymphoid organs like naïve cells.

Now consider the CD8+ T-cell response to viral infection of a mucosal tissue (Fig. 14.2). Local CD103+ dendritic cells with cross-presentation capacity take up apoptotic infected cells,[41] produce viral p:MHCI and p:MHCII complexes, upregulate CD28 ligands, produce all-trans retinoic acid,[121] and migrate through an afferent lymphatic vessel to the draining lymph node. Plasmacytoid dendritic cells are recruited to the lymph node and produce type I IFNs in response to PRR recognition of viral pathogen-associated molecular patterns.[42] Interaction with CD154+ virus p:MHCIIspecific CD4+ T cells increases the activation state of the CD103+ dendritic cells through CD40 signaling.[175,176] Naïve virus p:MHCI-specific CD8+ T cells interact with these dendritic cells and produce IL-2 and induce expression of CD25. Unknown T-cell growth factors and perhaps IL-2 then stimulate the CD8+ T cells to divide to produce progeny that express small or large amounts of CD25.[96] The $CD25^{high}$ cells experience IL-2 receptor signaling and STAT5 activation, which stimulates Blimp-1 expression, which cooperates with STAT1 activation from the type I IFN receptor to upregulate T-bet.[177] T-bet and Blimp-1 drive the cells to become terminally differentiated KLRG1+ cytotoxic effector cells loaded with granzyme B and perforin-containing granules.[170,178] Blimp-1 represses another transcription factor Id3, which is required for Tcm cell formation,[162] thereby reinforcing effector cell formation. The effector cells also express α4β7 integrin and CCR9 due to activation in the presence of all-trans retinoic acid,[121] and migrate to the site of infection through mucosal blood vessels displaying mucosal addressin cell adhesion molecule-1 and CCL25.[179] After extravasating into this site, the cytotoxic effector cells interact with infected cells displaying virus p:MHCI ligands. TCR signaling then causes the T cells to expel granzyme B and perforin, which enter the target cell and kill it.[180] Some of the KLRG1+ effector cells in the lymph node survive the contraction phase, perhaps through the action of Id2,[161] and then either become CD103- Tem cells that recirculate through the mucosal tissue or CD103+ Tem cells that enter the tissue and never leave.[129] The recirculating Tem cells may convert to Tcm cells over long periods of time.[141]

The early CD25- progeny do not experience IL-2 receptor signaling and STAT5 activation and do not turn on Blimp-1.[178] Without Blimp-1, the cells retain Id3 expression[162] and are prevented from becoming terminally differentiated $Tbet^{high}$ cytotoxic effector cells. Instead, type I IFN receptor signaling facilitates expression of the Eomes transcription factor,[156] retention of CCR7 expression, and survival as Tcm cells, which recirculate through the secondary lymphoid organs like naïve cells.

Chapter 15

The Innate Immune System

Luke A. J. O'Neill

INTRODUCTION

Every organism has to contend with infection by microbes. Infectious agents such as bacteria, viruses, and fungi threaten health and viability by competing for nutrients or more dangerously by killing the infected host as a consequence of infection or in order to spread to another host. This threat occurs largely because microorganisms divide at a faster rate than the host and because of the production of toxins that the microorganism uses for its own viability. The job of the immune system is firstly to sense the danger posed and secondly to mount an appropriate response. This response can be to tolerate the microorganism or to resist it such that at best sterilizing immunity occurs.

The immune system is traditionally split into two categories: innate and acquired (or adaptive) immunity. The term “innate” refers to the feature that the sensors involved are encoded by genes that do not undergo any rearrangement to generate variants. Adaptive immunity, on the other hand, refers to host defense proteins encoded by genes that undergo rearrangement to generate great diversity. This rearrangement process is not driven by the infectious agent, but happens by genetic programming. Antigens then lead to an expansion of antigen-specific B cells or T cells that help clear the infection and importantly persist in the form of memory cells. This means that when the host is re-infected, there are substantially greater numbers of the specific B- and T-cell populations that lead to clearance of the infectious agent. There are therefore insufficient numbers of microbes to trigger substantial systemic symptoms.

It is estimated that more than 99% of life on earth only has innate immunity.[1] What advantage would the evolution of adaptive immunity bestow on an organism? The answer lies in part in the nature of innate immunity. As will be discussed, the effector mechanisms here involve the inflammatory process, which when out of control can harm the host. In mammals, a “sickness behavior” also occurs, which includes processes such as fever, aches and pains, and drowsiness, which are thought to allow the infected host to rest and recuperate.[2] They also present a disadvantage, however, because they leave the host vulnerable to predators and decrease reproductive potential. Adaptive immunity occurs later in the cycle of infection, typically becoming evident several days after infection, and probably only after innate immune defenses have been breached. It is needed for sterilizing immunity. The fact that memory is a key feature of adaptive immunity, however (which is evident because of the expansion of specific B and T cells), means that upon re-infection, the innate response is limited because the pathogen is more rapidly cleared and there are therefore fewer microbial products present to activate innate immunity. In addition, there is evidence that adaptive immune cells

actually inhibit the innate immune response, which in the first infection acts in a negative feedback manner.[3] In subsequent infections, the memory cells probably inhibit innate immunity from the start of the infection. In essence, therefore, it appears that adaptive immunity evolved to promote sterilizing immunity and also to prevent innate immunity happening upon reexposure to pathogen, given its potential disadvantages in terms of systemic inflammation. Figure 15.1 illustrates this principal.

Previously thought to be crude and nonspecific, innate immunity is now known to involve a range of receptor families that recognize diverse microbial products. Importantly, these receptors program gene expression changes in target cells. The products of these genes drive inflammation and are also required for adaptive immunity. These proteins include cytokines that promote expansion of B and T cells. Other innate immune proteins have direct antimicrobial effects or act as opsonins, coating bacteria and promoting phagocytosis. Innate immunity has therefore gone from being viewed as a process lacking sophistication, to one determining for both inflammation and adaptive immunity.[4]

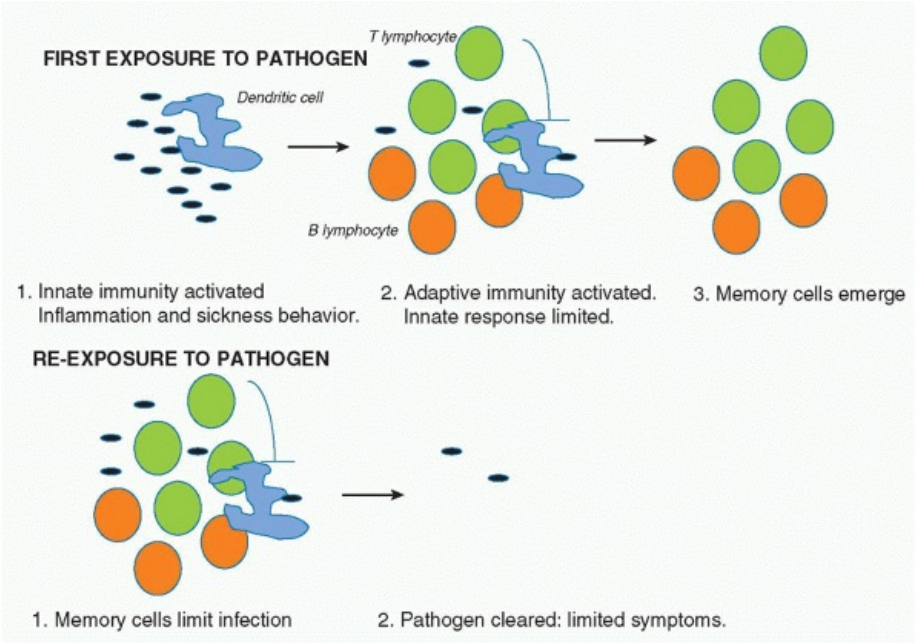

FIG. 15.1. The Relationship between Innate and Adaptive Immunity. A: Upon exposure to a pathogen, the innate immune response is triggered mainly by phagocytes and dendritic cells. Inflammation ensues, which leads to sickness behavior and host defense. The adaptive immune system is then triggered leading to effector T- and B-lymphocytes, some of which become memory cells. Adaptive immunity also has a negative feedback effect on innate immunity, preventing damage. **B:** When an organism is exposed to the same pathogen again, the memory cells can handle the infection, limiting innate immunity such that there are only minor symptoms. The evolution of adaptive immunity therefore provides an advantage to the host: adaptive immunity evolved to clear pathogens and limit innate immunity.

THE FRONTLINE OF INNATE IMMUNITY

The Skin

Innate immunity at its simplest involves barriers that prevent entry of microorganisms in the first place. In mammals, the skin is an obvious barrier that when broken in injury allows pathogens to enter. Many pathogens use insects that can deliver them across the skin into the bloodstream. A good example here is *Plasmodium falciparum*, which causes malaria. It is transmitted by mosquitoes feeding on blood. If the skin is broken, pathogens can enter. The importance of the integrity of the skin barrier can be seen in atopic dermatitis, an inflammatory skin disease. Mutations in the gene encoding fillaggrin, which is important for skin integrity, associate with atopic dermatitis.[5] The altered fillaggrin is less able to maintain the skin barrier, and the dermatitis is likely to be caused by microorganisms penetrating the skin or environmental irritants that provoke allergy.

The Epithelial Barrier

Equally important is the epithelial barrier that lines surfaces inside the body in the respiratory, gastrointestinal, and urogenital tracts. Microbes gain access to these surfaces via processes such as inhalation and digestion. The epithelial cells that make up the epithelium form tight junctions that keep the microorganisms out.[6] Specialized structures called cilia also expel microbes, and damage to cilia, for example caused by cigarette smoke, promotes respiratory tract infections.[7]

DIRECT-ACTING ANTIMICROBIAL FACTORS

The epithelia also produce a range of chemicals that limit microbial growth. Mucus is a key substance that traps microbes and is expelled. The importance of mucus can be seen in cystic fibrosis, where unusually thick mucus is made in lungs that limits expulsion and gives rise to growth of bacteria in the airways.[8] This chronic infection in turn leads to the lung pathology in this disease. In the stomach, acid production by the epithelium leads to low pH that limits growth of microbes. Enzymes that digest microbial proteins are also produced, including pepsin in the gut. A phospholipid-based substance termed pulmonary surfactant is made in the lungs that acts to trap microbes and can also directly lyse bacteria. Similarly, in skin the production of fatty acids in sebum limits bacterial growth. Lysozyme is a prominent enzyme in tears and saliva that breaks down peptidoglycan in the cell walls of gram-positive bacteria. Lysozyme is in fact a prototype of an innate immune protein because it does not affect the host cells, as they lack peptidoglycan. It is made by epithelial cells, but also phagocytes and Paneth cells in the crypts in the small intestine.

Antimicrobial Peptides

Another important example of innate immune proteins produced at barriers is antimicrobial peptides.[9] Epithelial cells are a major source of these peptides, but phagocytes can also make them. They are an ancient form of defense because they are found in most species, including insects and plants. There are three classes: defensins, catelicidins, and histatins. Defensins are 30 to 40 amino acid peptides that usually have three disulphide bonds. Their key property is amphipathicity (they contain both polar and nonpolar properties), and it is this property that is thought to underly their specificity for the membranes of bacteria, fungi, and

certain viruses. Their hydrophobic part inserts into these membranes, which are more positively charged than host cell membranes. A pore is formed, rendering the membrane leaky and leading to lysis.

There are three subfamilies of defensins-: α, β, and θ, which have different specificities in terms of target microorganisms.[10] They are produced as propeptides that require processing by proteases. Neutrophils produce α-defensins and store them in so-called primary granules from which they are secreted upon neutrophil activation. Paneth cells in the gut produce a class of α-defensins called cryptidins, which are processed by trypsin prior to secretion into the gut., β-defensins are made in the urogenital and respiratory tracts, skin, and tongue. Keratinocytes in skin are also a key producer of β-defensins.

Catelicidins lack the disulphide bonds in the α-defensins and are produced by epithelial cells, phagocytes, and keratinocytes. They are also produced as propeptides and in neutrophils are processed by elastases in secondary granules and then secreted in response to microbial stimulation. Histatins are produced in the parotid, sublingual, and submandibular glands in the oral cavity. They are histidine-rich and target fungal membranes.

Phospholipase A2

Phospholipase A2 (PLA2) is another antimicrobial protein found in primary granules of neutrophils and similar to defensins, is secreted during degranulation in response to bacterial activation. It is also secreted by epithelial cells and Paneth cells. PLA2 can directly kill gram-positive bacteria by hydrolysing phospholipids in the microbial membrane.[11] The means by which it distinguishes host membranes from bacterial membranes is because its effect on phospholipids is strongly potentiated by another protein termed bactericidal permeability increasing (BPI), which binds to lipopolysaccharide (LPS) in gram-negative bacterial membranes.[12] As will be discussed subsequently, LPS is one of most potent innate immune activators known; it is sensed by a protein termed toll-like receptor-4 (TLR4). LPS does not occur in host membranes, and so BPI only facilitates the effect of PLA2 on bacterial membranes. BPI disrupts the integrity of the bacterial membrane and presumably allows PLA2 to gain access to phospholipids, where it cleaves fatty acids from the sn-2 position, leading to lysis. Similar to PLA2, BPI is found in primary granules in neutrophils.

Lactoferrin

Lactoferrin is an 80 kDa protein that belongs to the transferrin family and therefore acts to sequester iron. This effect is thought to limit the availability of iron to bacteria, altering their metabolism and thereby compromising their ability to replicate.[13] Lactoferrin is found in the secondary granules of neutrophils and occurs at a high level in breast milk, its cellular origin there being epithelial cells. Lactoferrin can also be processed to generate an antimicrobial peptide called lactoferricin that, similar to other such peptides, can lyse bacterial membranes.

The Microbiota

A final front-line mechanism to keep microbes at bay is commensal bacteria in the healthy intestine. Commensal bacteria live in our intestines and serve several functions, including providing vitamin B_{12} and other nutrients. However, they also maintain epithelial barrier integrity, most likely because they are sensed by innate immune receptors that will be

described in subsequent sections, and these receptors seal the epithelial barrier against infection.[14] However, importantly they also compete with any pathogenic bacteria in the intestines limiting their growth. Similarly, on skin and in the urogenital tract, there are competing microbes.

THE INITIAL RESPONSE ONCE BARRIERS ARE BREACHED

What happens when skin or epithelial barriers are breached? Pathogens have mechanisms to get across the barriers, or if the barrier is damaged by trauma, pathogens will traverse the broken barrier. Two important cascades are triggered in blood that will generate inflammatory factors or act to wall off pathogens and prevent them from spreading. The first cascade to be characterized in detail is the complement cascade, described in detail elsewhere in this volume. Complement generates the membrane attack complex that will lyse bacteria. Complement factors such as C1q also bind to pathogen surfaces and act as opsonins, promoting uptake by neutrophils and phagocytes. The complement cascade also generates chemotactic factors such as C5a, which attracts neutrophils to the site of infection. Coagulation is the other cascade that is triggered, largely by bacteria. This will form clots that prevent bacteria from spreading.

The Neutrophil

A key cell type, however, that is engaged early in infection is the neutrophil, again described in detail elsewhere. Chemotactic peptides present in bacteria, termed fMLP, act as chemoattractants for neutrophils. Both C5a and fMLP also trigger an important process in the neutrophil termed the respiratory burst.[15] This involves an enzyme complex termed the nicotinamide adenine dinucleotide phosphate-oxidase. This is also present in macrophages and is activated either by the G-protein coupled receptors that bind fMLP or C5a, or by the process of phagocytosis. It is a multicomponent enzyme complex that contains three cytosolic subunits: p40phox, p47phox, and p67phox. It also contains a membrane-associated flavocytochrome complex comprising p22phox and p91phox. The subunits form the enzyme complex following activation of the low molecular weight G protein Rac. The nicotinamide adenine dinucleotide phosphate-oxidase generates reactive oxygen species by transferring an electron from its flavin adenine dinucleotide cofactor to molecular oxygen forming the superoxide anion and other oxygen radicals. This all occurs in the so-called phagolysosome, which comprises a fusion between the phagosome that contains the ingested bacteria with the lysosome. The oxidizing environment will be antibacterial, but in addition, will lead to acidification of the phagolysosome due to potassium and hydrogen ions being drawn in to neutralize the charged superoxide ion. The acidification, however, has been shown to lead to dissociation of proteolytic

enzymes such as elastase from the proteoglycan matrix in the phagolysosome.[16] These proteases will also have a direct effect on bacteria.

In addition, superoxide is a substrate for myeloperoxidase, which is stored in primary granules and generates hypochlorous acid and chloramines, as well as other reactive oxygen species that are bactericidal and fungicidal. A final oxygen radical generated in neutrophils is nitric oxide. It is produced by the enzyme nitric oxide synthase, which is induced by cytokines such as interferon-γ. Nitric oxide is also microbicidal.

THE CONCEPT OF PATTERN RECOGNITION: HISTORICAL PERSPECTIVE

Much of the forgoing components of innate immunity had been worked out at least in broad terms by the mid-1990s. However, the issue of the exact recognition mechanism during innate immunity by the host was poorly understood. In 1989, Janeway made the point that the continued focus on adaptive immunity, which was evident at the time, would lead to an asymptote being approached in our understanding of immunity.[17] He speculated that receptors must exist for microbial structures that were known to be proinflammatory, such as LPS from gram-negative bacteria. Receptors such as mannan-binding lectin (MBL), which binds mannose in microbial membranes (and which does not exist in host membranes) and CD14 (which binds LPS), had already been described at that stage, but importantly these proteins did not signal because they possessed no intracellular domains. MBL was shown to be an opsonin, and CD14 had no clear function. Janeway therefore proposed that pattern recognition receptors (PRRs) must exist that recognize microbial "patterns" such as LPS, termed pathogen-associated molecular patterns (PAMPs), and trigger activation of cells such as dendritic cells, which are prodigious producers of cytokines and also present antigen to T cells. At around the same time, Matzinger was proposing that the job of the immune system is to sense "danger."[18] The danger can be in the form of a microbe or in the form of tissue injury. Again, the idea that specific receptors would exist to recognize products of damaged tissue was proposed. In essence, what was being hypothesized was the existence of receptors that would drive the production of cytokines, as several cytokines had been found that could provoke inflammation and also adaptive immunity. LPS was a powerful inducer of such cytokines and yet no receptor had been convincingly described for LPS that would activate transcription factors such as NF-kB, which was known to be required for increased transcription of genes such as that encoding the potent proinflammatory cytokine tumor necrosis factor (TNF).

How did Janeway's insight that PRRs and PAMPs would form the core of innate immunity lead to the discovery of the TLRs, which became the prototypical PRRs? Five important findings were made.

1. The receptor for the proinflammatory cytokine interleukin (IL)-1, which is a key mediator of many aspects of inflammation and which, similar to LPS, could activate NFκB, was shown to have a signalling domain similar to a *Drosphila melanogaster* protein Toll.[19] The Toll protein had been discovered as being important in the generation of dorsal-ventral polarity in the developing *Drosophila* embryo. At first glance, this seemed odd. What was a receptor important for inflammation doing with a signaling domain highly similar to a protein in fruit fly development? Toll drives a transcription factor termed dorsal, however, which is highly similar to NFκB so it seemed as if a similar "machine" was being used in two different contexts: one for inflammation in the case of IL-1 and the other for development in the fruit fly.
2. In 1994, a protein termed N protein was described in tobacco by Whitham and colleagues, which provided resistance to tobacco mosaic virus.[20] This protein also had the domain found in the type I IL-1 receptor and Toll, which was then named the Toll-IL-1 receptor - resistance (TIR) domain. Clearly, the TIR domain was therefore important for innate immunity in very diverse species.

3. This was confirmed when in 1996, Lemaitre and colleagues reported that Toll also has a role in innate immunity in *Drosophila*, being activated in response to fungi and driving the antifungal peptide drosomycin.[21]
4. Mammalian proteins even more similar to Toll than the IL-1 receptor, and termed TLRs, were then reported[22] and one, termed Toll (subsequently renamed TLR4) when overexpressed in dendritic cells, was shown to drive costimulation of T cells, as reported by Medzhitov and colleagues.[23]
5. In 1999, Poltorak and colleagues reported that the lack of responsiveness of a strain of mouse termed C3H/HeJ to LPS was due to a mutation in the gene encoding TLR4, such that a proline in the signaling domain was converted to a histidine.[24] This rendered TLR4 unable to signal, identifying TLR4 as the longsought signaling receptor for LPS. It was therefore clear that TLRs were ideal examples of the PRRs proposed by Janeway. Subsequently,[10] TLRs were described in human, although other species have very many more, notably the sea urchin, which has over 150.[25] TLRs were shown to recognize a diverse range of PAMPs and also in some cases products of damaged tissue, termed danger-associated molecular patterns (DAMPs). Complex signaling pathways were elucidated and links to disease established. The discovery of TLRs also galvanized researchers to seek other PRR types, and there are now several families, notably the retinoic acid-inducible gene I (RIG-I)-like receptors (RLRs), which sense viral ribonucleic acid (RNA), the nucleotide oligomerization domain (NOD)-like receptors (NLRs), which sense bacteria and DAMPs, and the C-type lectin receptors, which sense fungi.[26] Figure 15.2 illustrates the main families of PRRs. A level of complexity in innate immunity was therefore revealed that has provided great insight into the overall workings of the immune systems of many organisms.

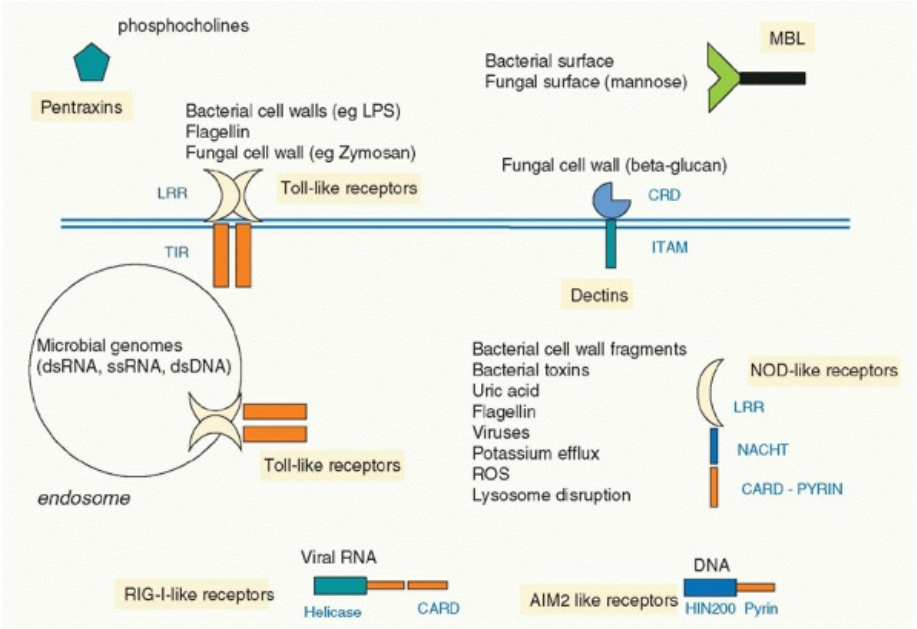

FIG. 15.2. Innate Immune Sensors. Several classes of innate immune sensors have

been found. Soluble factors such as pentraxins and mannoan-binding lectins bind pathogen structures and promote phagocytosis. Toll-like receptors (TLRs) sense bacteria, fungi, and protozoans from the plasma membrane, whereas endosomal TLRs sense microbially derived nucleic acids. C-type lectin receptors sense fungal cell wall components and mycobacteria. In the cytosol nucleotide oligomerization domain-like receptors sense microbial products and also, in the case, of Nlrp3 particles such as uric acid and IAPP. Retinoic acid-inducible gene I-like receptor sense viral ribonucleic acid, whereas AIM-2-like receptors sense microbial deoxyribonucleic acid. All lead to signaling pathways culminating in the induction of immune and inflammatory genes.

Toll-Like Receptors

TLRs are type I transmembrane receptors that have leucinerich repeats (LRRs) and a TIR domain. LRRs are found in many proteins, and that they occur in TLRs is of interest given their capacity to interact with different kinds of ligands. Also of note is that in agnathans, the LRR is used to build a repertoire of variable lymphocyte receptors, which are analogous to the antibody repertoire in human.[27] The LRR domain is therefore of evolutionary interest in that it is used for TLRs but also generation of diversity in the lamprey and the hagfish. The immunoglobulin domain serves this purpose in vertebrates and in fact is fused to the TIR domain in the type I IL-1 receptor. Figure 15.3 illustrates the relationship between these domains.

The 10 TLRs in human have different ligand specificities, and several ligand/TLR structures have been solved.[28] Broadly speaking, TLRs can be split into two families. TLRs 1, 2, 4, 5, and 6 are expressed in the plasma membrane, and their job is to sense bacterial, fungal, and protozoal products. TLRs 3, 7, and 9 are all expressed in endosomal membranes with their LRRs in the lumen and their TIR domains pointing into the cytosol. Their role is to sense viral nucleic acids. There are also differences in relation to signaling,[29] with all of the TLRs with the exception of TLR3 signalling via MyD88, to NF-κB and mitogen-activated protein (MAP) kinases such as p38. TLR2 and especially TLR4 require a bridging adapter termed Mal to recruit MyD88. TLR3 signals via Trif to NF-κB and another transcription factor IRF3. TLR4 can also signal via Trif and does so via the second bridging adapter Tram.

Toll-Like Receptors 2, 1, and 6

TLR2 recognizes multiple ligands. From bacteria, these include lipopeptides, lipoproteins, lipoteichoic acid, and mycobacterial lipoarabinomannan. From yeast, TLR2 recognizes the cell wall structure zymosan. TLR2 also recognizes glycosylphosphoinositol from the parasite *Tryanosoma cruzi*. Alone amongst the TLRs, TLR2 can heterodimerize with other TLRs, and this provides a degree of specificity in ligand recognition.[30] The TLR1/TLR2 dimer binds triacylated lipopeptides whereas TLR2/TLR6 recognizes diacylated lipopepides. In the case of TLR2/6, one acyl chain fits into a hydrophobic pocket in one TLR, whereas the second acyl chain fits into the other TLR.[31] This allows the TLRs to dimerize, an important event for signaling. There is also a coreceptor for TLR2/6 in the form of CD36, which appears to deliver the

lipopeptide to the TLR dimer.[32] TLR2 is expressed on macrophage, dendritic cells, B cells, and also on regulatory T cells.

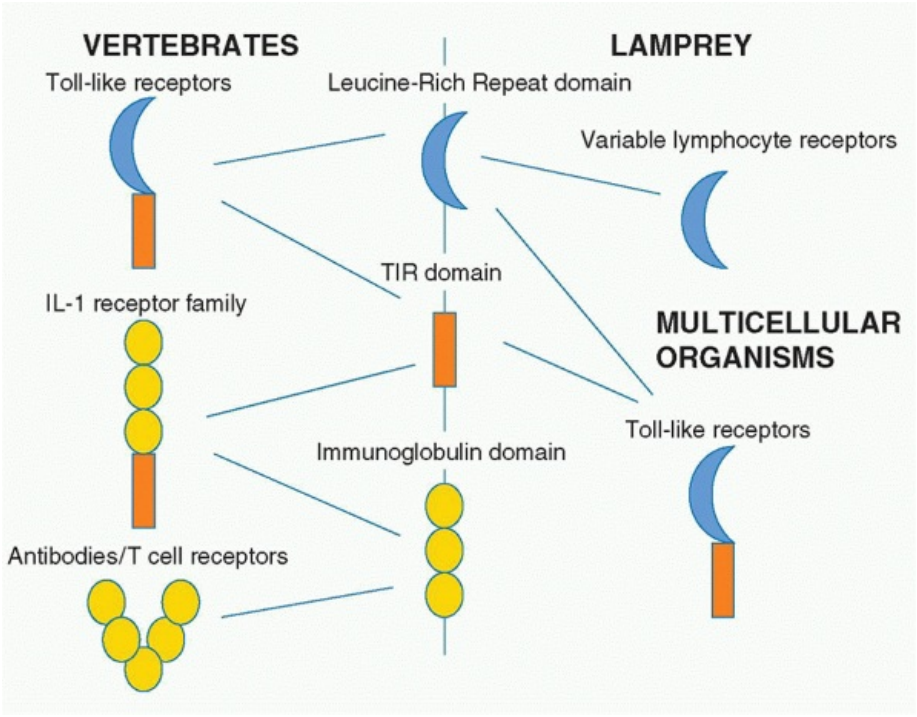

FIG. 15.3. Protein Domains in Innate and Adaptive Immunity. Three protein domains occur in several immune system proteins. The leucine-rich repeat occurs in toll-like receptors in vertebrates and all multicellular organisms combing with the toll-IL-1 receptor-resistance (TIR) domain. The leucine-rich repeat also forms the basis of the repertoire of variable lymphocyte receptors in the hagfish. The immunoglobulin domain only occurs in vertebrates and is found in antibodies and T-cell receptors. However, it also combines with the TIR domain to form interleukin-1 receptor family members.

Toll-Like Receptor 4

TLR4 is the receptor for LPS and is the most studied TLR. It acts as a homodimer but on its own is unable to recognize LPS. Similar to TLR2 and CD36, a coreceptor is needed, termed MD2.[33] LPS is a hexacylated lipid, and five of the acyl chains are buried in MD2, whereas the sixth is on the surface and interacts with TLR4.[34] However, two other proteins are needed to deliver LPS to MD2. LBP occurs in serum and binds LPS monomers, transferring them to CD14.[35] CD14 can occur as a soluble protein or as a glycerophosphatidylinositol anchored protein.[36] The job of CD14 appears to be to concentrate LPS and deliver it to MD2. In B cells, there are two other accessory molecules: RP105 and MD1.[37] These appear to serve an analogous function to CD14 and MD2. Recognition of LPS is therefore highly complex. This is presumably because once TLR4 is activated, there can be lethal consequences in the form of septic shock; therefore, several proteins are needed for LPS recognition. Similar to TLR2, a dimerization event occurs upon ligand binding that allows the intracellular TIR domains to come into juxtaposition and trigger signaling pathways. TLR4 has

been shown to recognize other ligands, notably F protein from respiratory syncytial virus,[38] although the basis for this recognition is not known. Another example is the metal nickel. In contact dermatitis, there is an inflammatory reaction to nickel, and it has been shown that nickel coordinates two key histidines on different TLR4 proteins, causing a cross-linking event that activates TLR4 and drives the inflammatory process in skin.[39] TLR4 is expressed on multiple cell types, notably on macrophages and dendritic cells but also on neutrophils and in the endothelium.

Toll-Like Receptor 3

TLR3 is the receptor for double-stranded RNA, found in viruses or more commonly in the form of the viral RNA analogue polyIC. PolyIC had been known for some time to be a potent inducer of the antiviral type I interferons. Similar to LPS, therefore, the discovery of TLR3 as the receptor for polyIC provided a molecular explanation for how polyIC induces this response. TLR3 is expressed on macrophages and dendritic cells and importantly on CD8+ dendritic cells, which are potent type I interferon producers.

Toll-Like Receptor 5

TLR5 is the receptor for bacterial flagella.[40] Flagellin is a key protein in flagella, which occur in multiple bacteria species. Flagellin is in many ways a prototypical PAMP because it does not occur in humans and can bear few mutations in bacteria. TLR5 is therefore required for host defence against flagellated bacteria such as *Legionella* and *Salmonella*.

Toll-Like Receptor 7

TLR7 recognizes single-stranded RNA from viruses. It is highly expressed in plasmacytoid dendritic cells, where when activated it induces type I interferons. TLR7 was first described as the receptor for a small molecule termed imiquimod, which is used to treat genital warts. This effect is mediated by type I interferons. TLR7's expression on plasmocytoid dendritic cells reveals a key function in antiviral immunity.

Toll-Like Receptor 9

TLR9 is the deoxyribonucleic acid (DNA) sensing TLR that, similar to TLR3 and TLR7, is found in endosomes. The type of DNA recognized is of interest as it binds to hypomethylated CpG-rich DNA, commonly found in bacteria and viruses. TLR9 is also expressed in plasmacytoid dendritic cells as well as in macrophages and in the epithelium. Once activated, again by dimerization, TLR9 induces a strong proinflammatory signal, increasing TNF production as well as type I interferons. A protein termed Unc93b is required to traffic TLR9 from the Golgi to intracellular vesicles. The CpG-rich DNA

from pathogens is taken up by cells in an endosome, which fuses with the TLR9-expressing endosome. In this way, the receptor can interact with its ligand. TLR9 has no known coreceptors, but it has been shown that it requires cleavage by cathepsins for full activation.[41]

The Recognition of Danger-Associated Molecular Patterns by Toll-Like Receptors

TLRs have also been implicated in the recognition of products of damaged tissues.[42] This is an important area as the inflammatory process can occur under conditions where there is apparently no infection. DAMPs include a range of factors released by damaged cells and include high-mobility group protein 1, heat shock proteins such as hsp90, products of damaged connective tissue such as hyaluronic acid fragments, versican and tenascin-C, the acute-phase reactant serum amyloid A, pyrrole-based lipids such as CEP, and coagulation products such as fibrinogen. This area has been somewhat controversial, as in vitro there is a risk of LPS contamination. However, the consensus has emerged that at least some of these are indeed sensed by TLRs although what the mechanism might be is not fully understood. Many of these are sensed by TLR4, notably high-mobility group protein-1, hsps, hyaluronan fragments, and tenascin-C. TLR2 has been shown to sense versican and CEP. Importantly, these factors are only produced by damaged cells, as would occur during tissue injury. There may be coreceptors involved here, which explains the recognition process, because it is difficult to imagine how a single TLR can recognize multiple ligands. A clearer example is the sensing of host nucleic acids in the case of cell damage. Necrotic cells have been shown to release double-stranded RNA, which is sensed by TLR3. TLR7 can sense host RNA, and TLR9 can sense host DNA in the context of immune complexes. This has particular relevance to autoimmune diseases such as systemic lupus erythematosus (SLE).[43]

Toll-Like Receptor Signaling Pathways

The key output from TLR signaling is cytokines, and TLRs filled the missing gap in our understanding of what actually induces cytokines. Because they bind directly to microbial ligands, TLRs bring us close to the initiation of host defense.

The type of cytokine being induced is dependent on the TLR. TLR4 is the most prodigious activator of macrophages known, with many genes induced by TLR4. Other TLRs are less prolific but all share the feature of driving inflammation. Cytokines such as IL-6, TNF, and the chemokine IL-8 are typical responses for plasma membrane receptors. For the endosomal TLRs, type I interferons are the typical readout. What gives rise to signaling specificity? As stated previously, TLRs use different adapter proteins. All have a TIR domain, and upon TLR dimerization, adapter TIR domains are likely to be recruited to the interface formed between two TLRs. This then launches the signaling pathways.

Broadly speaking, TLR signaling pathways can be divided into two: MyD88-dependent and MyD88-independent. All TLRs, with the exception of TLR3, signal via MyD88. IL-1 receptor family members, including the receptor for IL-18, also signal via MyD88.[44] The MyD88 dependent pathway involves the IL-1 receptor-associated kinases (IRAKs). There are four of these: IRAK-1, IRAK-2, IRAK-4, and IRAK-M. They interact with MyD88 via their death domains, because along with the TIR domain, MyD88 has a death domain. The structure of this multicomponent signaling machine, termed the MyDDosome, has been solved.[45,46] Strikingly, it has a stoichiometry of 14. SIx MyD88 subunits assemble and bring four IRAK-4s to the complex. These sit on top of the assembled MyD88 subunits in a helical structure. Four IRAK-2s or IRAK-4s are then recruited. All of the death domain interfaces in this complex have been solved, and it is predicted to have a high degree of cooperativity. The so-called MyDDosome launches signaling pathways activated by TLRs.

Once assembled, IRAK-4 phosphorylates IRAK-1, and this event appears to be key for

signaling. The IRAKs then dissociate from the complex, and IRAK-1 and/or IRAK-2 then interact with the ubiquitin ligase Traf6, a member of the Traf family. Once activated, Traf-6 signals in association with two noncanonical E3 ubiquitin ligases, Ubc13 and Uev1A.[47] This results in polyubiquitination of Traf6. This is a type of ubiquitination termed K63-linked ubiquitination. This covalently modifies Traf-6 causing oligomerization and downstream activation. This activation involves the IkappaB kinase (IKK) complex for the NF-κB pathway. The main form of NF-κB in cells is a p50/p65 dimer. It is, however, kept in check by an inhibitory protein I-κB. Traf6 activates the kinase TAK-1, which in turn activates the IKK complex leading to I-κB degradation (via K48-linked polyubiquitination). This releases the p50/p65 dimer, exposing a nuclear localization sequence and allowing NF-κB to bind its consensus site in target genes. In addition, TAK-1 can activate MAP kinase cascades, notably via MKK3/6, which leads to p38 MAP kinase activation, and MKK7, which leads to activation of Jun N-terminal kinase. Both of these MAP kinases can activate transcription factors, such as ATF3 in the case of p38 and Jun in the case of Jun N-terminal kinase. This in turn will modulate inflammatory gene expression.[48]

MyD88 is also involved in activation of IRF7 by TLR7 and TLR9.[49] This is an important transcription factor for the induction of interferon-alpha, a key antiviral cytokine but also a cytokine implicated in the pathogenesis of SLE.

The importance of the MyD88 pathway can be seen in MyD88-deficient mice, which are unable to mount an effective host defense response to multiple pathogens, including a wide range of bacteria, as well as fungi, protozoans, and certain viruses.[50] In addition, MyD88-deficient mice are resistant to inflammation in a number of disease models including models of SLE and arthritis. However, in the case of humans, the situation is not as clear-cut. This is because of reports of MyD88 deficiency in human.[51] People with this deficiency show higher mortality in childhood but susceptibility to a restricted set of pathogens, the main defect in host defense being against pyogenic infections such as *Streptococci*. This is also the case in subjects with IRAK-4 deficiencies.[52] Once people with these deficiencies reach adulthood, however, no immunodeficiencies are evident. It is likely, therefore, that the MyD88 pathway is somewhat redundant in children and is not required in adults probably

because of the emergence of adaptive immunity. This supports the concept raised at the start of this chapter, that once memory is established, innate immunity is not as important.

The second TIR domain adapter to be found was Mal (also termed TIRAP).[53,54] This protein is required for MyD88-dependent signaling specifically by TLR2 and especially TLR4. It appears to act as a bridging adapter for MyD88 to be recruited to the receptor TIR domains and has a PIP2 binding domain which localizes it to the plasma membrane.[55] It is also a substrate for IRAK-1 and IRAK-4, and upon phosphorylation undergoes ubiquitination and degradation,[56] providing a negative feedback loop in TLR signaling.

The MyD88-independent signalling pathway involves the third adapter, Trif.[57] This adapter is used by TLR3 to signal and activates NF-κB as well as another transcription factor IRF3 via activation of the kinase TBK-1.[58] TLR4 can also activate Trif, but this happens in endosomes. The fourth adapter, Tram, mediates this effect, acting as a bridge for Trif in a

manner similar to Mal acting as a bridge for MyD88.[59] Tram has a myristoylation motif that localizes it to the plasma membrane.[60] However, upon activation of TLR4, Tram undergoes phosphorylation by protein kinase C-epsilon.[61] This leads to dissociation of Tram from the plasma membrane, and it is likely that a TLR/Tram complex localizes to the endosome, where Trif is then recruited, again leading to TBK-1 activation and induction of type I interferons. The TLR4 signal is terminated by a splice variant of Tram termed TAG, which displaces the Trif/Tram complex.[62] It is this dual pathway, Mal/MyD88 and Tram/Trif, occurring at different subcellular localizations, that probably make LPS such a powerful innate immune activator, as a wide range of genes can be induced. Figure 15.4 illustrates the TLR4 signaling pathway.

The final TIR domain adaptor to be found is SARM. This is a large protein with a TIR domain and SAM and ARM domain. SARM is a negative regulator of Trif-dependent signaling, acting as another modulator of TLR4 action.[63] It is of interest that there are several mechanisms to inhibit TLR signaling, including microRNAs, decoy receptors, ubiquitin regulators (eg, A20), and splice variants of MyD88 and IRAK2 that are inhibitory.[64] This tells us that TLRs, and in particular TLR4, must be kept under control otherwise the host can be damaged or even succumb.

Viruses have also been shown to target TLRs. The best examples are two vaccinia virus proteins A46R and A52R.[65] A46R has been shown to block recruitment of TIR domain-containing adapters, particularly Mal and Tram.[66] A52R inhibits activation of the IRAKs.[67] Deletion of A52R leads to attenuation of the virus, confirming its importance for viral evasion.[68]

Conservation of the Toll-Like Receptor System Across Nature

Every multicellular organism has proteins with TIR domains, attesting to their evolutionary importance. A particular case is in plants, which have a number of TLRs.[69] As mentioned previously, N protein from tobacco has a TIR domain and is required for antiviral immunity. Similarly, L protein from flax has a TIR domain and is required for resistance to flax rust. Plants also have IRAK-like kinases activated by these receptors, notably BAK1 and BIK1 in Arabidopsis. The receptor for flagellin in Arabidopsis is sensed by a leucine rich repeat protein termed FLS-2. This receptor has an IRAK-like kinase domain actually attached and also activates BAK-1 and BIK-1. FLS-2 activates MAP kinases such as MEKK1, which probably lead to activation of the AtWRKY family of transcription factors. In addition, ubiquitin ligases termed PUBs ubiquitinate FLS-2, downregulating it.[70] The parallel in human is Triad3a, which ubiquinates TLR4 leading to its degradation.[71] These conserved elements confirm the importance of the TLR pathways across evolutionary time. Table 15.1 illustrates the conservation between mammals, insects, and plants.

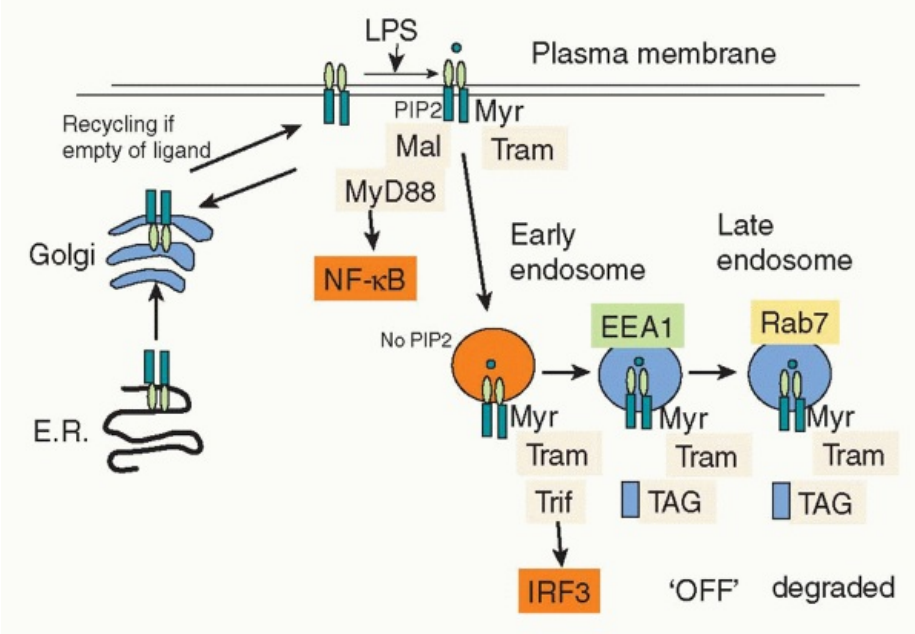

FIG. 15.4. Subcellular Toll-Like Receptor 4 Signaling. The signaling pathway, activated by lipopolysaccharide (LPS) via toll-like receptor-4 (TLR4), is highly complex. In resting cells, TLR4 recycles from the endoplasmic reticulum to the plasma membrane. An LPS/MD2 complex binds TLR4, stabilizing it transiently at the plasma membrane. The activated TLR4 dimer recruits the adapters Mal and MyD88, which then lead to activation of NF-κB, which induces multiple immune and inflammatory genes, such as tumor necrosis factor, interleukin-1beta, and interleukin-6. Mal is retained in the membrane by binding the phospholipid PIP2. Th adapter Tram is also membrane-localized via a myristate in its N-terminus. Tram then undergoes phosphorylation by protein kinase C-epsilon. TLR4 then internalizes in combination with Tram and localizes to an early endosome where it encounters Trif. This adapter activates TBK-1 and promotes IRF3 activation, which regulates the expression of type I interferons and other gene products. The endsome containing TLR4 then matures to a late endosome where TAG is engaged. This protein displaces Trif from Tram, and TLR4 is ultimately degraded.

Therapeutic Targeting of Toll-Like Receptors

TLRs are being targeted clinically, either in the form of new vaccine adjuvants or with inhibitors that would be anti-inflammatory.[72] The best example of an adjuvant approach is imiquimod, a compound found to be antiviral by activating TLR7. This induces type I interferons, and imiquimod is used to treat genital warts. Another example of an adjuvant approach is the use of monophosphoryl lipid A in vaccines for such pathogens as human papilloma virus. This acts via TLR4 but is not as toxic as LPS. In terms of anti-inflammatory

approaches, eritoran, an antagonist toward TLR4, has been tested in septic shock, but with only limited success. As referred to previously, TLR4 has also been implicated in the pathogenesis of contact dermatitis. It is also implicated in rheumatoid arthritis and inflammatory bowel disease. TLR2 has been shown to be important for ischemia/reperfusion injury and may prove interesting as a target to limit this process in transplantation.[73] There is

promise that targeting TLR7 and/or TLR9 might be effective in SLE, as in this disease TLR7 senses host ribonucleoprotein complexes (known to be implicated in SLE) while TLR9 senses DNA/chromatin complexes (again implicated in SLE). Whether inhibiting TLRs will be prove to be to immunosuppressant remains to be seen, although given the redundancy in the TLR system in relation of host defense, this may not pose a problem, particularly if a given TLR has a nonredundant role in inflammatory disease.

TABLE 15.1 Conservation of Innate Immunity across Species

	Human	Fruit Fly	Plant
Receptor (TIR domain)	Toll-like receptors	Toll	Tobacco: N protein Flax: L6
Adapter protein (TIR domain)	MyD88, Mal, Trif, Tram	dMyD88	
Non-RD kinase	IRAK-1	Pelle	Rice: XA21
RD kinase	IRAK-4		Arabidopsis: BIK1
Ankyrin repeat	IkappaB NF-κB	Cactus Relish	Rice: NH

RD, Arginine-Aspartic acid; TIR, toll-IL-1 receptor-resistance.

Notes: Each receptor senses microbial products and activates the adapters and kinases indicated. Human and insects have the NF-κB family transcription factors on these pathways. Plants lack NF-κB but have other transcription factors such as the WRKY family.

NOD-Like Receptors

The second major family of PRRs are the NLRs.[74] Nod-like receptors undergo oligomerization in response to activation. They also have LRRs, similar to TLRs. There are several subfamilies that can be defined by additional domains. The main members are summarized in Table 15.2. Of particular interest are the NLRC family, which have antibacterial NOD1 and NOD2 as members and are defined by the caspase recruitment domain (CARD). The Nlrp subfamily contains a pyrin domain, and the prototypical member is Nlrp3, which is a key component of the inflammasome multiprotein complex that regulates caspase-1 and drives production of the proinflammatory cytokine IL-1beta. The NAIP subfamily contains a Bir domin. All NLRs are intracellular proteins, implying that ligands have to be endocytosed in order to activate them.

Nucleotide Oligomerization Domain 1 and Nucleotide Oligomerization Domain 2

NOD1 and NOD2 sense breakdown products of peptidoglyan, which is a major component of the cell wall of gram-positive and gram-negative bacteria. The finding that NOD2 mutations strongly associate with Crohn disease was an important finding. It supported the hypothesis that aberrant sensing of intestinal microbes is important for the pathogenesis of inflammatory bowel disease.[75] NOD2 detects muramyl dipeptide, whereas NOD1 detects *meso*-diaminopimelic acid. This latter component is more common in gram-negative bacteria. Peptidoglycan is constantly remodeled during bacterial growth, and the component parts are produced constantly, making them ideal PAMPs. How the ligands get into the cytosol is not wholly clear, however. Transport systems such as pannexin, PepT1, and PepT2 have been shown to carry muramyl peptides across the plasma membrane, and there is also evidence of endocytosis.[76] NOD1 and NOD2 signaling leads to NF-κB and MAP kinase activation in a manner similar to TLRs. There are no adapters, however, and they recruit RIP2 kinase to activate these downstream pathways. NOD1 and NOD2 agonists can synergise with TLRs, which is likely to be important in vivo.[77]

Role of Nucleotide Oligomerization Domain 1 in Antimicrobial Responses

The first pathogen shown to be sensed by NOD1 in vivo was *Helicobacter pylori* ; NOD1-deficient mice were demonstrated to be more susceptible.[78] Key outputs from NOD1 in this model are chemokines, antimicrobial peptides, and type I interferons. NOD1 has also been shown to be important in the host defense response to other pathogens,

including *Clostridium difficile*, *Legionella pneumophilia*, and *Listeria monocytogenes*.[79] In all cases, impaired recruitment of neutrophils was a feature of the NOD1-deficient mice, highlighting again the importance of neutrophils in antibacterial host defense. NOD1-deficient mice have also been shown to be impaired in their response to the intracellular parasite *Trypanosome cruzi*.[80] Although the *T. cruzi* ligand is not known, macrophages from the deficient mice have an impaired ability to kill intracellular parasites.

TABLE 15.2 Notable Nucleotide Oligomerization Domain-Like Receptor Family Members

Subfamily	N-terminus	Function
NLRB (NAIP)	BIR	Binds flagellin
NLRC		
NOD1	CARD	Binds ieDAP

NOD2	CARD	Binds MDP
NLRC4	CARD	Binds flagellin/NAIP
NLRP		
NLRP1	Pyrin domain	Binds anthrax lethal toxin
NLRP3	Pyrin domain	Mutiple activators (eg, uric acid, IAPP, cholesterol crystals)

BIR, Baculo Virus Repeat; CARD, caspase recruitment domain; IAPP, islet amyloid polypeptide; ieDAP, Diaminopimelic acid; MDP, Muramyl Dipeptide; NAIP, Neuronal Apoptosis Inhibitory Protein; NLRB, Nod-like receptor with BIR domain; NLRP, Nod-like receptor with Pyrin domain; NOD, nucleotide oligomerization domain.

Role of Nucleotide Oligomerization Domain 2 in the Antimicrobial Response

Similar to NOD1, NOD2 has been shown to be important for host defense against multiple bacteria. One interesting aspect, however, was that NOD2 was only shown to be required for host defense against *L. monocytogenes* when given by the oral route.[81] Intravenous and intraperitoneal infections were handled normally in NOD2-deficient mice. This suggests that other PRRs can compensate for the lack of NOD2 depending on the route of infection. There is also redundancy in relation to NOD1 in the response to *Salmonella typhiurium* infection. NOD1- or NOD2-deficient mice are normal in their response, but the double knockout is impaired, with decreased inflammation and enhanced colonization of the intestine.[82]

Autophagy, Adaptive Immunity, and Nucleotide Oligomerization Domain 1 and Nucleotide Oligomerization Domain 2

Another interesting aspect of NOD1 and NOD2 biology concerns a process termed autophagy. This is a process whereby an organelle called the autophagosome digests material in the cytosol of cells. Autophagosomes are related to lysosomes and were originally shown to be important in development and in starvation where in effect a cell will digest some of its own contents to provide nutrients. Autophagy has also been found to be important in antimicrobial immunity. It is an important part of intracellular innate immunity and may in fact be the means by which cells such as macrophages clear bacteria in a process that was originally thought to involve the lysosome. Autophagosomes can be viewed as a subtype of lysosome. These insights came from the uncovering of proteins required for the formation of the autophagosome, notably ATG16, which is recruited to membranes and allows formation of the autophagosomal double membrane structure. NOD1 and NOD2 activation have been shown to lead to recruitment of ATG16L to the plasma membrane sites where *S. typhimurium* and *Shigella flexneri* intrude.[83] This leads to degradation of bacteria in autophagosomes and importantly to the processing of bacterial antigens for presentation on major histocompatibility complex class II molecules. This is a classic example of the link between

innate and adaptive immunity. Also of interest is the observation of mutations in ATG16L in Crohn disease and the observation that the mutant NOD2 also in Crohn disease is less able to drive ATG16L recruitment.[84] This could mean that impaired antigen presentation to T cells (eg, regulatory T cells that produce IL-10) might be important in Crohn disease pathogenesis.

There is additional evidence that NOD1 and NOD2 promote adaptive immunity. This was first observed when it was realized that muramyl dipeptide was a key component in Freund's adjuvant, a standard adjuvant used in experimental immunology to drive antibody production. This is probably due to NOD2 inducing important T-cell-activating cytokines, but there is also evidence for NOD2 in T cells themselves where it promotes interferon-gamma production.

Inflammasomes

There are 14 members in the Nlrp branch of the NLRs, and those with a known function are components in inflammasomes. The term inflammasome comes from the fact that the regulation of caspase-1 was shown to be due to assembly of a multiprotein complex involving Nlrps and also the scaffold protein Asc.[85] This complex is needed for the activation of caspase-1, the enzyme that processes the pro-forms of IL-1beta and IL-18. Given the importance of these cytokines in inflammation and inflammatory diseases, much attention has focused on inflammasome regulation.

Nlrp3

The Nlrp3 inflammasome has been characterized in detail. Nlrp3 has a carboxy-terminal LRR domain, a central NOD domain, and an amino terminal pyrin domain. The pyrin domain mainly interacts with the key scaffold protein Asc. It is triggered by agents phagocytosed by macrophages, including bacteria and viruses, but also particles such as uric acid, silica, asbestos and cholesterol crystals, and amyloidcontaining proteins such as beta-amyloid and islet amyloid polypeptide (IAPP).[86] Uric acid, cholesterol crystals, betaamyloid, and IAPP all constitute DAMPs. Activation mechanisms are not fully worked out, although potassium efflux is a common event that is required for oligomerization of the Nlrp3/Asc complex. Roles for reactive oxygen species and cathepsins have also been suggested.[87,88] CARD domains in Asc and caspase interact, whereas the pyrin domain in Nlrp3 interacts with the pyrin domain in Asc, allowing for the complex to assemble. This is needed to activate caspase-1. Extracellular adenosine triphosphate is also able to activate the Nlrp3 inflammasome. Also of note is the fact that the system must be primed by other innate receptors, notably the TLRs, which induce Nlrp3 and also pro-IL-1beta expression.

The effect of uric acid on Nlrp3 is of interest because uric acid may be a common danger signal from damaged cells, as well as having a clear role in gout.[89,90] Similarly, the inflammation associated with silica and asbestos is likely to be due Nlrp3 activation.[91] The effect of cholesterol crystals, which form in atherosclerotic plaques, on Nlrp3 implicates the inflammasome in heart disease.[92] Similarly, the effect of beta-amyloid suggests a role in Alzheimer disease.[93] In the case of IAPP, a role in type 2 diabetes is suggested.[94] IL-1 has been implicated in insulin resistance and beta cell loss in type 2 diabetes, but s there is no infection, what drives IL-1beta is not clear. Hyperlipidemia is now known to activate the Nlrp3 inflammasome in adipose tissue.[95] This will

lead to IL-1beta release, which causes insulin resistance. The beta cells in the pancreas respond by secreting insulin, but also IAPP, which modulates insulin action. However, IAPP can form amyloid, and macrophages in the pancreas take up IAPP; the Nlrp3 inflammasome is activated leading to IL-1beta production. These findings support the clinical targeting of IL-1beta in several diseases notably type 2 diabetes and atherosclerosis.[96]

Another important aspect of the Nlrp3 inflammasome concerns genetic mutations. Activating mutations in Nlrp3 lead to autoinflammatory diseases such as Muckle Wells disease and familial Mediteranean fever.[97] Autoinflammatory diseases such as these are prototypical genetic diseases of innate immunity because there are only inflammatory symptoms with no roles for T and B cells and autoimmunity. The diseases are systemic, involving skin inflammation, arthropathy, and amyloidosis. They are treatable with anti-IL-1beta blocking agents, attesting to the potency of this proin-flammatory cytokine.

Nlrp3 in Host Defense

Several bacteria have been shown to activate the Nlrp3 inflammasome. A common feature is pore-forming toxins that cause potassium efflux. *Listeria* produces a toxin called listeriolysin that is required for Nlrp3 activation.[98] Secretion of pneumolysin by *S. pneumoniae* or streptolysin O from *S. pyogenes* both result in activation of the Nlrp3 inflammasome.[99]

Nlrp3 is also activated by viruses. Influenza is a potent Nlrp3 activator, and Nlrp3-deficient mice are less able to survive influenza infection.[100] Viral RNA was shown to prime the inflammasome via TLR7, whereas activation of Nlrp3 was mediated by the influenza-encoded M2 ion channel, which led to potassium efflux.[101] Other viruses such as the DNA viruses vaccinia and varicella zoster, and RNA viruses such as encephalomyocarditis virus and vesicular stomatits virus all activate the Nlrp3 inflammasome.[102] It is therefore likely that the Nlrp3 inflammasome is key for the fever response to all these viruses, as IL-1beta is a key pyrogen during infection.

The Nlrp3 inflammasome can also be activated by fungi, notably *Candida albicans* and *Saccharomyces cerevisiase*.[103] Again, there is interplay with TLRs, as zymosan (a PAMP in the cell wall of yeast) acting via TLR2 primes the Nlrp3 inflammasome for activation. *Aspergillus fumigatus* can also activate the inflammasome.[104]

Finally, parasites can also activate the Nlrp3 inflammasome. *Plasmodium falciparum*, the causative agent of malaria, secretes a crystal called hemazoin, which activates Nlrp3.[105] Malaria severity is less in Nlrp3-deficient mice. Schistosomes have also been shown to activate Nlrp3.

Overall, therefore, fever, a common response to infection, is likely to involve the Nlrp3 inflammasome in many cases.

IPAF

Another inflammasome complex comprises the NLR IPAF, also known as NLRC4. IPAF contains an N-terminal CARD, a central NOD domain, and a C-terminal LRR. It responds to bacterial flagellin, which activates caspase-1 via IPAF.[106] Bacteria such as *Salmonella* are

sensed by IPAF. The interaction between IPAF and caspase-1 again involves CARD domains. More generally, IPAF is activated mainly by gramnegative bacteria that contain bacterial type III or type IV secretion systems. These include *Salmonella*, *Legionella*, *Shigella*, *Pseudomonas*, and *Yersinia*.[107] Several of these strains when deficient in flagellin do not activate caspase-1. Flagellin added extracellularly does not activate the IPAF inflammasome and is likely to enter the cytosol via the type III or type IV secretion systems. IPAF has a coreceptor that is another NLR family member NAIP5. This protein interacts directly with flagellin and is the actual sensor, the signaling occurring via IPAF.[108] Similar to NODs and TLRs, there is also evidence for an interaction between IPAF and TLR5. In a model of immunization with ovalbumin and flagellin, it was shown that IPAF- or TLR5-deficient mice are normal in the humoral response, but a double knockout mouse was deficient in its response.[109] This implies that both IPAF and TLR5 are acting in a redundant manner in this system. More generally, it is no surprise that innate systems would be redundant in terms of host defense, as a lack of redundancy would leave the host open to manipulation by pathogens.

Nlrp1

The Nlrp1 inflammasome was the first to be characterized biochemically, but its activators are not fully understood. It is expressed in many cell types, including granulocytes, monocytes, dendritic cells, B cells, T cells, and neurons. It also interacts with Asc, and there is evidence for both caspase-1 and caspase-5 in the Nlrp1 inflammasome. Anthrax toxin has been shown to be sensed by Nlrp1, and in mice the Nlrp1b isoform has been shown to be a key determinant of susceptibility to infection by *Bacillus anthracis*.[110] A role for Nlrp1 in antiviral immunity is suggested from the observation that Kaposi sarcoma herpes virus encodes a protein called Orf63 that blocks Nlrp1-dependent responses and is required for reactivation and generation of progeny virus.[111] Finally, mutations in Nlrp1 are associated with the skin disease vitiligo.[112]

AIM2

The final inflammasome to be characterized contains AIM2, which also couples to caspase-1 via Asc. AIM2 is a member of the PYHIN family of proteins, which contain a pyrin domain and HIN200 domain, which binds DNA.[113] The pyrin domain in AIM2 allows it to interact with Asc. It is activated directly by DNA and has been shown to be activated by DNA from bacteria such as *Listeria monocytogenes* and *Francisella tularensis*, and viruses such as vaccinia virus and cytomegalovirus.[114] Responses to these pathogens in vivo are all impaired in AIM2-deficient mice.

Retinoic Acid-Inducible Gene I-Like Receptors

RLRs are a family of RNA helicases that contain a DExD/H box as the defining protein domain.[115] They occur in the cytosol of most cell types and sense viral RNA. The key output from RLRs is type I interferons. There are three RLRs: RIG-I, melanoma differentiation associated factor 5 (Mda5), and laboratory of genetics and physiology 2.

Figure 15.5 illustrates RIG-I signaling. RIG-I and Mda5 sense a wide range of viruses and

have shared structural features. They both have two CARD domains, a DEAD box Helicase domain, a repressor domain, and a C-terminal domain. Structural insights have revealed that upon binding RNA, a major conformational change occurs releasing the repressor domain and shifting the two CARDs out of the protein to engage with the downstream signaling molecule MAVS.[116,117,118] Laboratory of genetics and physiology 2 lacks the CARDs and is thought to function as a regulator of RIG-I and Mda5 signaling.

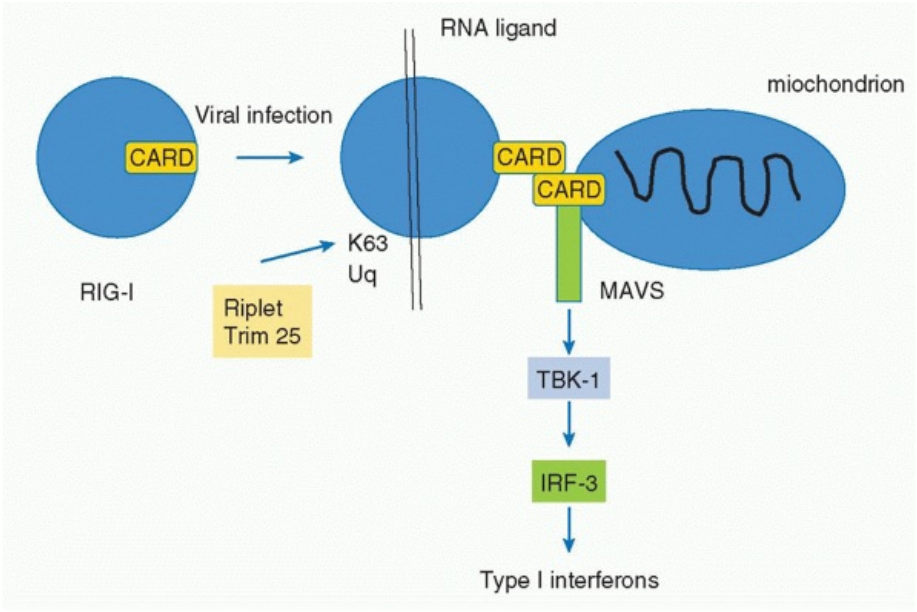

FIG. 15.5. Retinoic Acid-inducible Gene I (RIG-I) Signaling. In response to viruses such as influenza, RIG-I is activated by viral ribonucleic acid. This leads to a dramatic conformational change, such that the caspase recruitment domain (CARD) domains (*orange*) move out from the protein structure and engage with the CARD domain in MAVS, which is in the mitochondrial outer membrane. RIG-I also undergoes K63-linked ubiquitination by Riplet and TRIM25, an event required for activation. MAVS then activates TBK-1, which phosphorylates IRF3, leading to induction of type I interferons and an antiviral response.

Viruses detected by RLRs include Sendai, respiratory syncytial virus, measles, rabies, influenza, Ebola, hepatitis C, myxoma, West Nile virus, dengue, and vaccinia. RIG-I preferentially recognizes RNA sequences that contain 5′triphosphorylated ends, which serves to distinguish them from host RNA sequences.[119] Polyuridine motifs in the RNA are also important for recognition, and such motifs occur in hepatitis C, Ebola, and influenza virus.

Retinoic Acid-Inducible Gene I-Like Receptor Signaling

The key process in the RLR signaling mechanism is the recruitment of the adapter protein MAVS (also known as IPS-1, Visa, and Cardif). MAVS is a membrane-bound CARDcontaining protein that occurs in the outer mitochondrial membrane and also on the membrane of peroxisomes.[120] Activation of RIG-I and Mda5 leads to a translocation to these membranes via the interaction with MAVS. The transcription factors IRF3 and IRF7 are activated by MAVS

via the kinases TBK-1 and IKK-epsilon.[121] These in turn lead to induction of type I interferons and other anti-viral genes, with the type I interferons then activating subsequent antiviral responses via the JAK/STAT signaling pathway. RIG-I can also interact with Asc and activate caspase-1, placing RIG-I as another inflammasome component.[122] Another key protein that interacts with RIG-I is STING. This protein was found to be involved in DNA-dependent signaling but also appears to be involved in RNA-dependent signaling via RIG-I.[123]

An excellent example of immune evasion by viruses is the targeting of MAVS by the hepatitis C protease NS4.[124] This leads to MAVS degradation and impaired RIG-I signaling. NS4 is currently the focus of targeting by a protease inhibitor, which could have utility in the treatment of hepatitis C.[125]

RIG-I signaling is a tightly controlled process as overactivation could kill the host; in fact, this may be the reason for the lethal effects of influenza and other viruses. Ubiquitination is a key process here. K63-linked ubiquitination of RIG-I by the ubiquintin ligase Riplet is required for RIG-I signaling.[126] TRIM25 also causes K63-linked ubiquitination, and this has been shown to enhance the interaction with MAVS.[127] RNF125, on the other hand, causes K48-linked ubiquination of RIG-I, leading to its degradation in the proteosome.[128] The deubiquitinase CYLD removes the K63-linked ubiquitin from RIG-I, inhibiting RIG-I activity.[129] Reversible ubiquitination is therefore a key control mechanism for RIG-I.

Cooperation between Retinoic Acid-Inducible Gene I-Like Receptors and Other Pattern Recognition Receptors in Antiviral Immunity

As is the case with NLRs and TLRs, RLRs and other PRRs also cooperate in host defense, in this case against viruses. A good example is the response to West Nile virus. This virus is transmitted by mosquitoes; upon injection into skin, RIG-I triggers an interferon response from resident Langerhans cells and skin fibroblasts.[130] Some virus will then disseminate to the draining lymph node where it infects resident macrophages and dendritic cells. The TLRs are then engaged, particularly TLR7, and induce cytokines to promote adaptive immunity.[131] Some virus will escape to the spleen, and RIG-I will again be engaged here. The situation for TLR3 is more complex because TLR3-deficient mice have improved survival rates.[132] SARM knockout mice, on the other hand, have increased lethality,[133] consistent with the inhibitory effect of SARM on TLR3 signaling.

Retinoic Acid-Inducible Gene I-Like Receptors and Adaptive Immunity

As with other PRRs, RLRs have also been shown to be key for adaptive immunity via the induction of cytokines, in this case type I interferons. Interferons are key regulators of T cells, promoting their survival and clonal expansion after antigen presentation. Interferons also promote the activity of cytotoxic T cells and promote antibody production in B cells. They also promote major histocompatibility complex class I expression as well as costimulatory molecules on dendritic cells.

PKR, 2′-5′-Oligoadenylate Synthase, and RNaseL

Prior to the RLRs, PKR and 2′-5′-oligoadenylate synthase were known to sense viral RNA. PKR is a serine/threonine protein kinase that contains three double-stranded RNA binding domains in the N terminus and a kinase domain in the C terminus.[134] It is activated by double-stranded RNA and therefore acts as an intracellular PRR. A key substrate for PKR is the translation initiation factor eIF-2alpha.[135] This directly restricts both cellular and viral protein synthesis. PKR can also induce apoptosis in virally infected cells.

Oligoadenylate synthase (OAS) is another doublestranded RNA sensor.[136] It is highly induced by Type I interferons. Oligoadenylate produced by OAS activates RNAseL.[137] This enzyme degrades viral RNA but can also degrade ribosomal RNA, limiting translation of host and viral mRNAs. Of particular note is the observation that RNAseL can also generate ligands for RIG-I from viral RNA.[138] This indicates that the OAS/RNAseL axis can serve to amplify antiviral responses triggered by double-stranded RNA. There is also evidence that RNAseL can also promote Mda5 activation. Based on the nature of RNAseL-generated products, both RIG-I and Mda5 can therefore recognize fragments of RNA that are specific cleavage products from viral RNA.

Cytosolic Sensors of Dexoyribonucleci Acid that Induce Type I Interferons

The process of DNA sensing in the cytosol that leads to type I interferons is not as well understood as RNA sensing. As mentioned previously, TLR9 can sense hypomethylated CpG motifs in DNA, but this occurs in endosomes. Intracellular delivery of mammalian or bacterial DNA can, however, induce type I interferons in a TLR9-independent manner. The pathway was shown to involve IRF3 and TBK-1, as with RLRs. Three mechanisms have been proposed. The first is DNA-dependent activator of IFN-regulatory factor (DAI) that interacts with DNA and enhances type I interferons.[139] The precise role of DAI, however, is not clear because DAI-deficient mice have a normal response to infection with DNA viruses.[140] The second mechanism involves RNA polymerase III. This host enzyme has been shown to convert viral DNA into RNA, which can then be detected by RIG-I.[141] This process has been shown to occur during infection with Epstein-Barr virus, herpes virus. and the bacterium *Legionella pneumoniea*. The third process involves DNA sensing with IFI16.[142] This protein was identified as the product of an interferon-inducible gene and was then shown to bind a 70-base-pair double-stranded DNA sequence from vaccinia. Of particular interest is the structure of IFI16 because, similar to AIM2, it also senses DNA but activates caspase-1. IFI16 has a pyrin domain and two HIN200 domains, placing it in the PYHIN family. AIM2 and IFI16 are therefore part of the AIM2-like receptor family.

IFI16 signals via a protein termed STING, which is found in the endoplasmic reticulum membrane.[143] DAI has also been found to signal via STING. The function of STING is to interact with TBK-1 and promote IRF3 activation. STING is in fact essential for TBK-1 activation. STING-deficient mice have impaired interferon induction in response to bacterial, viral, and mammalian DNA, as well as to several DNA viruses, including herpes simplex virus-1, human cytomegalovirus, vaccinia virus and baculovirus, and *Plasmodium falciparum*.[144,145] STING is also required for the immune response to DNA vaccines, presumably because of the essential role it plays in the induction of interferons.

STING also plays a role in the induction of interferon by *Francisella tularensis* and *Listeria monocytogenes*. Cyclic dinucleotides produced by *Listeria* have been shown to be directly sensed by STING, implying that it is actually a PRR for these dinucleotides.[146]

There is also evidence for viral evasion of DNA-sensing pathways. Cytomegalovirus encodes a protein termed M45 that blocks DAI signaling.[147] Another cytomegalovirus protein is pUL83, which inhibits IFI16.[148] The pox virus protein M13L has been shown to target AIM2.[149]

C-Type Lectin Receptors

The term C-type lectin was first used to describe a family of calcium (hence "C")-dependent carbohydrate-binding (lectin) proteins.[150] The carbohydrate binding region was in a carbohydrate recognition domain and the more general term C-type lectin domain is used to describe this family of receptors. Dectin-1 is the best characterized member. It recognizes β-1,3-linked glucans, which occur in the cell wall of fungi, some bacteria, and plants.[151] It binds a range of fungal pathogens, including *Candida*, *Aspergillu*, *Coccidiodes*, *Pneumocystis*, and also bacterial pathogens such as *Mycobacteria*.[151] Two related proteins are CLEC-2 and DNGR-1.[152,153] CLEC-2 has been shown to bind HIV, whereas DNGR-1 has been shown to bind an unknown ligand sequestered in living cells and exposed upon cell death. All three of these C-type lectin receptors (CLRs) signal via a tyrosine kinase termed Syk.[154] This protein couples to CARD9, which in turn can activate NF-κB and promote inflammatory gene expression. It has also been shown to activate Nlrp3 and promote IL-1beta production,[155] These CLRs can also promote phagocytosis. Similar to other PRRs, there are also synergies. Dectin-1 and TLR2 when both activated strongly promote the production of proinflammatory cytokines.[156]

DC-SIGN is another CLR but instead of signaling via Syk, it activates Raf-1 and promotes MAP kinase activation.[157] It binds to mannose and fucose and has been shown to bind HIV, measles virus, severe acute respiratory syndrome, dengue virus, and mycobacteria. Raf-1 is able to modulate the

NF-κB pathway by regulating phosphorylation of the p65 subunit of NF-κB.

Phagocytic Receptors

The PRRs clearly form a major class of innate immune receptors. What distinguishes them from other innate recognition systems is their ability to change gene expression in target cells, the complexity of the gene expression profiles ultimately giving rise to the specific effector mechanisms required to clear the provoking pathogen. Another group of pathogen sensors, however, are proteins that recognize the pathogen but whose function it is to promote phagocytosis.

Scavenger receptors. Scavenger receptors (SRs) are in the plasma membrane and are defined by their ability to bind modified low-density lipoprotein.[158] Six classes are known but most is known about two: SR-A and macrophage receptor with collagenous structure. Both contain a collagenous region and an SR cysteine-rich domain. Both are trimers. They have a

role in low-density lipoprotein uptake, but also recognize LPS and lipoteichoic acid from bacteria. SR-A-deficient mice are more susceptible to infection by *Listeria monocytogenes*, herpes simplex, and malaria.[159] They are also more susceptible to LPSinduced sepsis, implying a role in LPS clearance. Macrophage receptor with collagenous structure can bind gram-positive and gram-negative bacteria and promote their phagocytosis.[160]

Macrophage mannose receptor. The macrophage mannose receptor (MR) is a protein found in the plasma membrane of macrophages and contains cysteine-rich and fibronectin type 2 domains, followed by eight carbohydrate recognition domains of the C-type lectin family.[161] MR recognizes mannose-rich carbohydrates from bacteria but can also promote phagocytosis of high-mannose glycoproteins from the host. MR has been shown to be required for phagocytosis of multiple bacteria, fungi, and protozoans. There is evidence that MR can complex with TLRs and promote TLR signaling,[162] yet another example of cooperation between PRRs.

Secreted pattern recognition molecules. There are also a range of secreted pattern recognition molecules that have various functions, although a unifying feature is opsonization. They are secreted into the circulation during infection and can reach high concentrations, effectively acting as acute phase proteins. Three classes have been particularly well-studied.

Mannan-binding lectin. MBL is the best characterized of the collectin family, which have a C-type lectin domain.[163] It binds to the terminal mannose and fucose residents on microbial carbohydrates and importantly can recognize the spatial arrangement of these sugars, which differs according to the host forms. It recognizes a wide range of pathogens, including *Staphylococci*, *Streptococci*, *Pseudomonas*, *Klebsiella*, *Salmonella*, *Mycobacteria*, *Candida*, influenza, human immunodeficiency virus, and trypanosomes. As can be seen from this list, MBL can therefore recognize all classes of pathogens. The main function of MBL is to activate the lectin pathway of complement. It is associated with two serine proteases, MASP-1 and MASP-2.[164] These proteases, when activated by ligand-bound MBL, cleave the C2 and C4 complement proteins initiating the complement cascade. MBL can also act as an opsonin, binding to C1qRp. MBL deficiency has been found in humans and leads to increased susceptibility to various infections.[165]

Pentraxins. C-reactive protein (CRP) and serum amyloid P both belong to the pentraxin family.[166] They are acute phase protein in human and mouse, respectively. They are produced mainly by hepatocytes in response to cytokines such as IL-1 and IL-6. They bind to bacterial surfaces and recognize phosphorylcholine. They promote opsonization and can activate the classical complement pathway via C1q. CRP is a classical diagnostic indicator of inflammation. Another pentraxin is PTX3, which plays an important role in host defense against bacteria and fungi.[167] It is expressed on multiple cell types, including dendritic cells, macrophages, and neutrophils. It is strongly induced by TLRs. Similar to CRP and serum amyloid P, it binds directly to bacterial and fungal membranes and promotes phagocytosis.

Peptidoglycan recognition proteins. Peptidoglycan recognition proteins are a family of PRRs that bind peptidoglycan.[168] They are conserved across evolution and were first described in *Drosophila*. They all contain a highly conserved peptidoglycan domain, and some also have transmembrane domains. Most are secreted, however. Four have been described in humans.

Their functions have yet to be fully elucidated, although they can clearly bind peptidoglycan. There is some evidence that they might compete with other peptidoglyan recognition PRRs, such as TLR2, possibly acting to limit inflammation, although this has to be demonstrated.

CONCLUSION

Clearly our knowledge of innate immune processes has greatly improved in the past few years. Multiple mechanisms exist that keep pathogens at bay, and several receptor classes can drive innate defence mechanisms via the production of effector cytokines and other mediators. The innate immune system provides an important link to the adaptive response, mainly via the activation of dendritic cells. Other cell types that participate include mast cells, basophils, and natural killer cells, which are discussed at length elsewhere. Innate immunity therefore provides us with a first line of defense, but via the inflammatory response and the activation of adaptive immunity orchestrates the major mechanisms that lead to restoration of the host after infection.

Chapter 16

Dendritic Cells

Kang Liu

Michel C. Nussenzweig

INTRODUCTION

Immunology interfaces with medicine at many points, the most prominent being infectious diseases, cancer, transplantation, allergy, and autoimmunity. Antigen-specific immunity is critical for vaccination and for protective immunity against pathogens and tumors. Moreover, when control over immune responses is lost, the result is autoimmune disease. T cells are an essential element that regulates the balance in immunity by killing infected cells, helping antibody formation, and suppressing autoimmune responses. However, T cells are incapable of recognizing native antigens. Instead, they recognize processed peptides presented by major histocompatibility complex (MHC) molecules. Dendritic cells (DCs) are professional antigen-presenting cells that inform the fight against invasive pathogens while enforcing tolerance to self- and harmless environmental antigens. They capture pathogens and receive signals from pathogens that influence the outcome of immune responses. On the basis of these signals, DCs orchestrate antigen-specific T-cell differentiation toward Th1, Th2, Th17, or Tfh pathways. Alternatively, they can silence self-reactive T cells by inducing deletion, anergy, or active regulation (via regulatory T [T_{reg}] cells). This chapter will focus on the discovery, function, and development of DCs, and the mechanisms by which they link innate immunity to adaptive immunity.

DISCOVERY

DCs were discovered as part of an effort to understand the initiation of immunity. The mouse as an experimental animal was critical because of a system, developed by Mishell and Dutton,[1] in which mouse spleen cell suspensions could be stimulated to generate antibody responses in culture. One of the early observations was that lymphocytes alone were not sufficient to induce antibody-forming cell responses and that an adherent accessory cell was required. The search for the accessory cell led to the discovery of DCs. In this section, we will review the early methods used to identify and study DCs.

Identification and Isolation

DCs were discovered by Steinman and Cohn when they examined spleen adherent cells by phase contrast microscopy.[2] They then employed physical techniques to fractionate spleen cells and purify DCs. These cells were found to adhere to plastic or glass, had low buoyant density, and did not bind to erythrocytes coated with antibody. Sequential steps of density

centrifugation in bovine serum albumin gradients and adherence to glass were originally used to purify DCs.[3]

At the time, macrophages were thought to be the key accessory cell because they composed a major population of adherent cells and also because their role in innate immunity had been long appreciated. Moreover, purified antigen loaded macrophages induced immune responses when reinjected into their hosts.[4] However, macrophages failed to show robust activity in induction of antibody responses in vitro, and they rapidly degraded ingested antigens suggesting that they would be unable to present it to lymphocytes.[5,6,7]

Dendritic Cells Initiate T-Cell Responses

In addition to their morphology, the cell surface composition of the newly discovered DCs proved to be distinct. DCs were found to express high levels of MHC antigens.[8,9] At the time, the precise function of the MHC in antigen presentation was not known, but it was already clear that the MHC was a key genetic determinant of immune responses and that it encoded many of the antigens involved in graft rejection.

The mixed leukocyte reaction (MLR) was considered an in vitro model system to study graft rejection and was used by Steinman and Cohn to examine the function of DCs.[10] They found that DCs were nearly two orders of magnitude more potent than unfractionated spleen cells, B cells, or macrophages in stimulating allogeneic T cells in the MLR.[10,11] On the basis of these experiments, they speculated that DCs were the accessory cells that present antigen to T cells to initiate immune responses.[12] However, their conclusions were not widely accepted by immunologists because unlike traditional immune responses, the MLR did not require priming.[13]

Proof that DCs are antigen-presenting cells came from experiments performed by Nussenzweig and Steinman who cocultured DCs with responding T cells and hapten-modified thymocytes. They showed that DCs induced MHC-restricted cytotoxic T cells specific to the hapten and that macrophages and other purified populations of lymphoid cells were nearly inactive as accessory cells.[14]

Monoclonal Antibodies to Dendritic Cells

Although the morphologic and functional differences between DCs and other leukocytes were striking, few immunology laboratories were equipped to perform the purification procedures required to study DCs until monoclonal antibodies to DCs became available. A series of

mouse DC-restricted monoclonal antibodies were produced by Steinman and others starting in 1980s, including 33D1 (specific for the cell surface receptor DCIR2/Clec4a4),[15] NLDC-145 (specific for the adsorptive endocytosis receptor, DEC205/cluster of differentiation [CD]205),[16] and N418 (specific for the CD11c integrin).[17] These monoclonal antibodies were used to establish the unique functions of DCs within heterogeneous mixtures of leukocytes and to identify DCs in situ. For example, 33D1 was used to selectively deplete DCs from mouse spleen suspensions and shows that this depleted MLR stimulating activity[12] and accessory function in the Mishell-Dutton system.[18]

Dendritic Cell Subsets

Shortman and colleagues first showed that DCs are heterogeneous and suggested the existence of DC subsets.[19,20] These subsets differ in their anatomic distribution, cell surface marker expression, and function. In the mouse, three major groups of DCs exist in the steady state: plasmacytoid DCs (pDCs), conventional DCs (cDCs), and migratory DCs (mDCs). pDCs are important mediators of antiviral immunity through their ability to produce large amounts of type I interferons (IFNs) upon viral infection (see following discussion). cDCs are composed of two major subsets, namely CD8α+ and CD8α-.[21] mDCs are present in nonlymphoid tissues such as the liver, gut, skin, lung, and aorta, and they are composed of two main subsets CD103+ and CD103-.[22] These nonlymphoid tissue DCs are referred to as mDCs because they transit from tissue to lymphoid organs.[21,23]

The two major subsets of mouse spleen cDCs have some overlapping functions. Both can process and present antigens to T cells and also secrete cytokines such as interleukin (IL)-12, which can influence the ultimate polarization of the T-cell response to pathogens. However, the two subsets also have unique functions in vivo and are not redundant.[24,25,26]

Some of the differences in cDC subset function may be accounted for differential expression of toll-like receptors (TLRs) or other mediators of cDC activation. For example, spleen CD8α+ cDCs express TLR3 (recognizing doublestranded ribonucleic acid [RNA]) but lack TLR5 (recognizing flagellin) and TLR7 (recognizing single-stranded RNA), whereas CD8α- cDCs express TLR5 and TLR7 but have low levels of TLR3.[27] Comparative analysis of messenger RNA expression profiles between the two DC subsets revealed that the two are as different from each other as are T- and B-lymphocytes.[28] This is in part reflected in the antigen processing capacity of the two cDCs types. CD8α+ cDCs are specialized for MHCI cross-presentation, and enriched in Tap1, Tap2, calreticulin, calnexin, Sec61, ERp57, ERAAP, as well as cystatin B and C, all of which are involved in MHCI presentation or inhibition of enzymes that process peptides for MHCII presentation. In contrast, CD8α- cDCs, which are biased for MHCII presentation, were enriched in cathepsins C, H, and Z, asparagine endopeptidase, GILT, and H2-Mbeta 1, all of which are implicated in the MHCII antigen-processing pathway.[28] The immunologic consequences of this specialization can be seen after immunization with antigens targeted to one or the other cDC in vivo. Antigens targeted to CD8α+ and CD8α- DCs by chimeric monoclonal antibodies that bind endocytic receptors Dec205/CD205 or DCIR2/Clec4a4 are biased to strong CD8 or CD4 T-cell responses, respectively.[28]

In conclusion, the two major subsets of DCs have distinct microanatomic locations, gene expression profiles, and functions. However the CD8α+ cDC in lymphoid tissue and CD103+ subset in nonlymphoid tissue DCs subsets are far better characterized than the CD8α- cDC or CD103- subset, which are heterogeneous and difficult to distinguish from activated monocytes.

ANATOMIC DISTRIBUTION

Lymphoid Organs

Peripheral lymphoid organs (ie, spleen, lymph nodes, and mucosal associated lymphoid tissues) are the sites where primary immune responses develop, including activation of helper, killer, and antibody-forming cells. Initiation of immune responses is facilitated by the highly organized structure of the peripheral lymphoid organs, with lymphocytes segregated into B- and T-cell areas. In addition to lymphocytes, the T-cell area also contains large interdigitating cells that were initially thought to be macrophages. However, cytologic and functional studies of spleen and lymph nodes in rat and mice revealed that interdigitating cells lack phagosomes and lysosomes, and are poorly phagocytic.[29,30,31] These features distinguished interdigitating cells from macrophages and suggested that they might be related to the cDCs isolated from mouse spleen.

Mouse interdigitating cells were later proven to be cDCs based on immunohistochemistry using DC-specific monoclonal antibodies. In human lymphoid organs, interdigitating cells in the T-cell area express CD83, a member of immunoglobulin superfamily. This marker is not conserved in the mouse where the interdigitating cells in the T-cell area of lymph nodes express CD11c and DEC205/CD205. In contrast, the two cDC subsets in the mouse spleen segregate into distinct microanatomic compartments. CD8α+ cDCs in spleen T-cell areas resemble those in the lymph nodes in that they express DEC-205, whereas those in the bridging channels and red pulp express DCIR2.[28]

In the T-cell area, cDCs form a dense network of cells that are primarily sessile but constantly protrude and retract large membrane folds into their environment.[32] T cells actively migrate through the DC network in search of antigen, and when they find a cDC presenting cognate antigen, they pause for a prolonged interaction.[33] The large DC membrane protrusions are thought to increase the surface area for antigen presentation and facilitate antigen detection by migrating T cells.[34]

Nonlymphoid Organs

In addition to the lymphoid organs, DCs are also found in most nonlymphoid organs and in all epithelial surfaces that contact the environment. In organs such as heart, lung, kidney, the dermal layer of skin, and meninges and choroid

plexus in the brain, they are found in interstitial spaces that are drained by lymphatics.[35,36,37] Like their lymphoid counterparts, interstitial DCs can be distinguished from macrophages by abundant expression of MHCII and low levels of lysosomal hydrolases. In comparison to macrophages, which are also abundant in the interstitial spaces, interstitial DCs are less phagocytic and more sensitive to radiation. Tissue macrophages and DCs can be distinguished by immunohistology; the former typically express F4/80 and lysosomal hydrolase, whereas the latter express MHCII and CD11c. The standard markers for distinguishing DCs and macrophages in interstitial tissues are listed in Table 16.1. Importantly, although these markers help to differentiate macrophage and cDCs in most tissues, they are not sufficient in defining cell lineages unless used in combination with functional and developmental analysis. This is because CD11c and MHCII can also be expressed by lung macrophages and induced on monocytes during inflammation.[38]

TABLE 16.1 Cell Surface Comparison between Dendritic Cells and Macrophage

	DC	Macrophage
MHC II	+	-/lo
FcR (CD16/CD32)	-	+
CD11b	-/lo	+
F4/80	-	+
CD115	-/lo	+

CD, cluster of differentiation; DC, dendritic cell; MHC, major histocompatibility complex.

Afferent Lymphatics

Afferent lymphatics in rats, rabbits, guinea pigs, sheep, and humans contain cells with motile processes that were named veiled cells because of their large membrane protrusions.[34,39,40,41] These cells were found to be poorly phagocytic, express high levels of MHCII, and are potent stimulators of the MLR in vitro. Lymphadenectomy and thoracic duct cannulation in larger animals such as rats and sheep made it possible to collect these cells from afferent lymph. Using this technique, Huang et al. revealed that veiled cells are constantly carrying intestinal epithelial contents via lymphatics to the cDC network in the T-cell area of the mesenteric lymph nodes.[42] Therefore, in the healthy individual, these veiled cells continually carry and present self- and harmless antigen to the adaptive immune system, thereby contributing to the induction of peripheral tolerance (see following discussion); during infection, they carry pathogen-derived antigens and induce specific T-cell activation. Thus veiled cells correspond to mDCs.

Dendritic Cells in the Skin and Other Body Surfaces

Several types of DCs, monocytes, and macrophages exist in the skin and at other body surfaces. Professional antigenpresenting cells in the skin include Langerhans cells (LCs) in the epidermis, and CD103+ and CD103- DCs in the dermis.

DENDRITIC CELL DEVELOPMENT

Origin of Conventional Dendritic Cells in the Lymphoid Organs

DCs, like all other leukocytes, develop from bone-marrow-derived hematopoietic stem cells. Monocytes, macrophages, granulocytes, megakaryocytes, and erythrocytes differentiate from a common myeloid progenitor (CMP) whereas B, T, and natural killer (NK) cells differentiate from a common lymphoid progenitor.[43,44,45] Although early cell transfer and genetic

experiments were interpreted to indicate that DCs originated from lymphoid and myeloid progenitors,[46,47,48,49] subsequent work showed that all DCs are derived from myeloid progenitors.[50]

Relationship between Dendritic Cells and Monocytes

In the steady state, DCs and monocytes can readily be distinguished based on cell surface marker expression. For example, DCs are CD11c+CD115-/loMHCII+ and monocytes are CD11b+CD115+F4/80+ (see Table 16.1). In contrast, under inflammatory conditions or in tissues such as lung and intestine, where they can be exposed to pathogenic and nonpathogenic microbes, monocytes develop many of the characteristic features associated with DCs, and the distinction becomes far more difficult. Moreover, the question of how DCs are related to monocytes and macrophages during development was a vexing problem that was only resolved very recently.

The idea that monocytes might be the direct precursors of DCs in vivo was suggested by elegant experiments with human CD14+ monocytes.[51] Monocytes undergoing reverse transmigration, which simulates their entry into lymphatic vessels from tissues, lose expression of monocyte markers CD14 and CD64 and upregulate human leukocyte antigen-DR and CD54.[51] Phagocytosis further stimulates expression of CD80, CD86, human leukocyte antigen-DR, DC-LAMP, and CD83, all of which are expressed by DCs.[51] Consistent with these cell surface changes, activated monocytes stimulate allogeneic T-cell proliferation in MLRs.

Similarly, in mice, microspheres injected intracutaneously are phagocytosed by CD11b+ F4/80+ monocytes that can then be found in the draining lymph nodes 3 to 4 days after the injection.[52] These cells display high expression of MHCII, MHCI, CD86, and stimulate allogeneic T-cell proliferation; however, unlike DCs, they express low levels of CD11c and no CD8α. Therefore, monocytes in the skin did not appear to become classical cDCs upon migration to lymph nodes; nevertheless, these activated monocytes shared many of the features associated with DCs. Finally, activated monocytes that appear in the spleen during *Listeria monocytogenes* infection expressed many of the cell surface features of cDCs.[53] These cells produce tumor necrosis factor (TNF) and inducible nitric oxide synthase (iNOS) and were named TNF/iNOS-producing DCs (Tip-DCs).[53] Tip-DC deficiency led to lethal *L. monocytogenes* infection; however, this effect was independent of the development of adaptive CD8 T-cell immunity.[53]

The idea that DCs develop from monocytes was tested by several laboratories in direct transfer experiments in

mice without clear success.[54,55,56,57] Indeed, it was always the nonmonocyte fraction of the bone marrow that produced cDCs.[54,56] The only exception to this rule occurred after inflammation induced by Freund's Complete Adjuvant (CFA), when monocytes differentiated into CD11c+CD11b+Mac3+ cells, which again are phenotypically distinct from cDCs.[56]

The inability of monocytes to produce cDCs in steadystate lymphoid organs was further confirmed in a series of elegant genetic studies using reporter mice carrying Rosa26-

$Stop^{flox}EGFP$.[58] In these mice, a lox-flanked Stop transcription signal must be deleted by Cre expression before GFP can be transcribed. Breeding LysM-Cre and Rosa26-$Stop^{flox}EGFP$ mice results in lysozyme promoter-driven Cre expression in monocytes and neutrophils, as well as deletion of the Stop sequence from Rosa26-$Stop^{flox}EGFP$ in these cells. As a result, monocytes and their progeny are irreversibly marked with enhanced green fluorescent protein expression. Classical DCs in the peripheral lymphoid organs remained enhanced green fluorescent protein negative in these mice; therefore, they cannot be derived from monocytes.[58]

In conclusion, experiments in humans and mice show that monocytes can develop some of the features of DCs under conditions of inflammation in vivo, or when cultured with cytokines in vitro, but they are not precursors of cDCs.

Dendritic Cell Progenitors in the Bone Marrow

If monocytes do not produce DCs, the question remains: what is the origin of DCs and where does commitment to this lineage occur? The first clue in solving this problem came from the identification of a common precursor for monocytes, macrophagesm and classical DCs (macrophage-DC progenitors [MDPs][54]). MDP are Lin-CX3CR1+CD11b-CD 115+cKit+CD135+ and account for 0.5% of all bone marrow mononuclear cells in mice.[54,59] When cultured with granulocyte-macrophage-colony stimulating factor (GM-CSF) in vitro or adoptively transferred into mice, these cells produced macrophages and DCs, but not neutrophil granulocytes, B-or T-lymphocytes, or NK cells.[54,59,60] Therefore, MDPs are more restricted than CMPs, from which they are derived.

A DC-restricted progenitor that produces cDCs and pDCs but not monocytes in vitro[61] or in vivo[62] was then identified based on reduced cKit (CD117) and residual Flt3 expression and named common-DC progenitor (CDP; Lin-CD115+Flt3+CD117lo). The CDP is downstream of CMP and MDP because adoptive transfer of either CMP or MDP gives rise to CDP and monocytes.[60] More importantly, these experiments showed that the split between the monocyte and DC lineages occurs in the bone marrow between the MDP and CDP stages of development.[60]

Migratory Pre-Dendritic Cells

cDC precursors must migrate from the bone marrow to the lymphoid organs through the blood. However, MDPs and CDPs are restricted to the bone marrow.[60] The identity of the DC precursor was suggested by the finding that lowdensity CD11c+MHC II-SIRPα^{lo} cells isolated from blood, bone marrow, and periphery had the potential to produce cDCs.[56,63,64] Although this group of cells was heterogeneous, the combination of these markers and persistent expression of Flt3 defined pre-DCs and allowed for their isolation in mice.[60]

Pre-DCs migrate from the bone marrow to the blood and then to peripheral lymphoid organs and nonlymphoid tissues.[60] These cells comprise ˜0.5% of all leukocytes in bone marrow, 0.02% in blood, 0.05% in the spleen, and 0.03% in the lymph nodes. Pre-DCs have a short half-life in the blood of < 1 hour[65]; this, together with the small number of these cells in blood

and tissues, may explain why previous efforts to identify pre-DCs failed and why human pre-DCs have yet to be identified.

Pre-cDCs isolated from the bone marrow, blood, or spleen give rise to both CD8α+ and CD8α- cDCs in lymphoid and nonlymphoid organs.[60] Thus, the pre-DC is a progenitor with significant plasticity. In conclusion, the DC and monocyte lineages split in the bone marrow, where MDPs give rise to both monocytes and CDP; the latter produce pre-DCs, which migrate from bone marrow through the blood to the periphery to give rise to DCs (Fig. 16.1).

Origin of Nonlymphoid Tissue Dendritic Cells

Skin

The skin contains LCs in the epidermis and CD103+ and CD103- DCs in the dermis.

Epidermis. LCs were discovered in 1868 by Paul Langerhans. Although LCs were initially thought to be of neural crest origin,[66,67] this view was changed with the discovery that LCs are closely related to leukocytes,[68,69] express Fc receptors[70] and MHCII antigens,[71] and are competent to present antigen to primed T cells.[72]

Experiments using bone marrow chimeras and parabiotic mice demonstrated that LCs are long-lived cells that divide in situ in the skin.[73] These cells originate from fetal liver-derived progenitors in an Flt3L-independent manner, and they are only replaced by bone marrow-derived hematopoietic cells during inflammation.[73,74] Thus, the origin of the LCs is different from that of cDCs.

Nevertheless, mouse LCs have been valuable as models for studying the differentiation and migration of antigenpresenting cells.[75,76,77,78,79,80,81] LCs in the epithelial layer of the skin can take up particles[82] and contain distinct granules, known as Birbeck granules, which are a type of endocytic organelle enriched in langerin.[83,84] While LCs express Fc receptors and MHCII in situ, the expression of Fc receptors drops and MHCII molecules redistribute from intracellular compartments to the cell surface in cultured LCs that become more highly immunostimulatory.[75,76,85] Cells that resemble LCs are also found in other stratified squamous epithelia such as the vagina, cervix, anus, pharynx, and esophagus.

LCs show many of the phenotypic features of cDCs, including morphology, ability to redistribute large amounts of MHCII from the endocytic system to the cell surface, and capacity to stimulate allogeneic T-cell proliferation in vitro after activation.[75,78,86,87,88] Importantly, however, LCs differ from DCs in that they are resistant to irradiation, they are self-renewing in situ and not of pre-DC origin in the steady

state, and finally, like monocytes and macrophages, their development is dependent on macrophage-colony stimulating factor (M-CSF) and not on Flt3L.[89] LC precursors, which are CX3CR1+CD45+, colonize the dermis during late embryonic development.[90,91] In mice, these precursors complete their differentiation into LCs by postnatal d2, whereupon they undergo a burst of cell division between postnatal d2 and d7, which accounts for the dramatic increase in LCs during this developmental window. The LC precursor in skin appears to

resemble the MDP.[90] Recently, fate-mapping analysis revealed that LCs derive from primitive macrophages during yolk sac stage of embryogenesis, and not from postnatal hematopoietic progenitors.[91] These two lineages can be differentiated by their dependence of Myb gene. The absence of Myb impaired HSC development, but did not affect development of the yolk sac macrophage progenitor that gives rise to LCs, microglia and liver Kupffer cells. This finding places the LC in its own differentiation pathway distinctive from cDC and monocyte.[91]

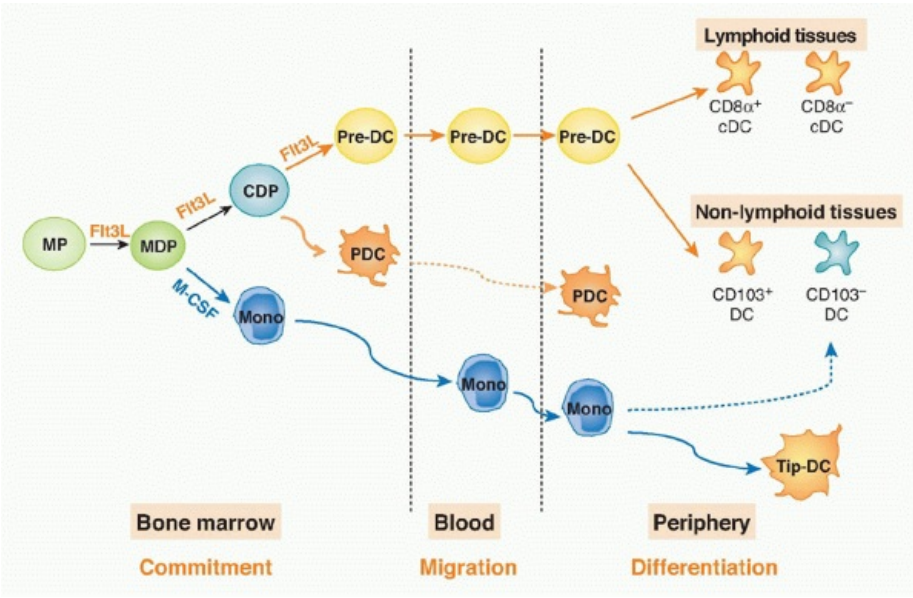

FIG. 16.1. Dendritic Cell and Monocyte Origin and Development.

Dermis. The dermal layer of the skin contains two subsets of DCs: CD103+ and CD103- DCs. CD103+ dermal DCs are langerin+CD11blo, whereas CD103- dermal DCs are langerin-CD11b+.[92,93,94,95] Although both LCs and CD103+ dermal DCs express langerin, CD103+ dermal DCs are more closely related to spleen CD8α+ cDCs than to LCs.[25,37,96] CD103+ dermal DCs, like spleen cDCs, are M-CSF-independent and Flt3-dependent.[37] Unlike LCs that can self-renew in situ, dermal CD103+ DCs are continually replenished from the same bloodborne pre-DCs that give rise to lymphoid organ DCs.[95] In addition, like CD8α+ splenic cDCs, development of CD103+ dermal DCs requires expression of the IFN regulatory factor (IRF)8, Id2, and Batf3 transcription factors (see following discussion). Finally, both dermal CD103+ dermal DCs and CD8α+ cDCs specialize in antigen cross-presentation.[28,96] The CD103- dermal DC compartment appears to be a heterogenous mixture of cells, some of which are Flt3 dependent and of pre-DC origin and others M-CSF-dependent and of monocyte origin.[37]

Skin-draining lymph nodes contain subpopulations of DCs that resemble CD103+ and CD103- dermal DCs.[92,95] Their migration from the skin to the draining lymph nodes is dependent on CCR7 but independent of CD62L. In the steady state, these cells account for 20% of lymph node DCs while the remainder of the DCs are derived from blood pre-DCs.[60]

Inflammation dramatically enhances the migration of dermal DCs to the lymph node.[52,58]

Gut, Kidney, Lung, and Liver

Similar to the skin, CD103+ and CD103- DCs are found in nearly all mouse nonlymphoid tissues.[37,97] However, the origin of these cells was not established until very recently. CD103+ nonlymphoid tissue DCs express Flt3, a marker expressed on most cells in the DC lineage but not on monocytes. Furthermore, mice deficient in Flt3L or its receptor, Flt3, showed significant decreases in CD103+ nonlymphoid tissue DCs but normal numbers of monocytes.[37,98] Finally, adoptive transfer of pre-DCs into naïve recipients, or mice in which CD11c cells had been depleted, resulted in reconstitution of the CD103+ nonlymphoid tissue DC compartment in the liver, lung, kidney, and intestine.[37,57] In contrast, adoptive transfer of 50 times more monocytes failed to show detectable DC progeny in naïve mice.[37,57] Thus, in the steady state, CD103+ DCs in all tissues tested are pre-DC

and not monocyte-derived. Only after depletion of endogenous CD11c+ cells were monocytes able to produce some CD103- DCs.[37,57] The idea that all CD103+ nonlymphoid tissue DCs are derived from pre-DCs and not from monocytes is further supported by genetic experiments that show a common requirement for Batf3, Id2, and IRF8 for lymphoid tissue CD8α+ DCs, and CD103+ nonlymphoid tissue DCs, but not monocytes or macrophages (see following discussion).[24,37,99,100]

In conclusion, in addition to DCs in the lymphoid organs, pre-cDCs also contribute to CD103+ DC development in nonlymphoid tissues. CD103- DCs appear to be more heterogenous; some of these cells are derived from pre-DCs while others may be of monocyte origin.

Plasmacytoid Dendritic Cells

pDCs were described by pathologists as a unique population of cells in the peripheral lymphoid organs that resemble plasma cells and monocytes and were referred to as plasmacytoid monocytes. In 1990s, Svensson et al. described a population of cells in human blood that produces large amounts of type I IFN upon exposure to herpes simplex virus, and they named these cells IFN-producing cells.[101] Both of these populations correspond to the pDCs described by Liu and colleagues.[102,103,104]

pDCs were first purified from human tonsil and blood on the basis of being CD4+CD3-CD11c-. They were then shown to develop DC-like morphology upon culture with IL-3 and anti-CD40. Liu and colleagues discovered that purified pDCs produced 100 to 1,000 times more type I IFN than the other blood cell types following viral activation.[104] Subsequently, pDCs were identified and isolated from lymphoid tissues in mice, and later in rats, monkeys, and pigs. In humans, the pDCs express CD4, MHCII, CD68, CD123, and blood DC antigen 2 (BDCA2), but do not express other lineage marker such as CD3 (T cell), CD14 (monocyte), CD19 (B cell), CD16 and CD56 (NK cell), or CD11c, BDCA1, and BDCA3 (cDC). They are identified as CD4+, CD11c-, and Lin- (CD3, CD14, CD16, CD19, CD56) cells.[105] In mice, pDCs express CD11c (lower levels than cDCs), Gr1, B220, and PDCA1; low levels of MHCII; do not express CD11b or CD19;and they are frequently isolated by virtue of CD11c and B220 expression.[106]

pDCs are closely related to cDCs; they originate from the same progenitor, the CDP. Development of pDCs is also critically dependent on Flt3L. Unlike cDCs, however, pDCs do not express high levels of MHC II in the steady state and therefore, their primary function is not antigen presentation to CD4 T cells. Instead, pDCs focus on sensing infection and producing type I IFN. Depletion of pDC blocks antiviral IFN responses but also results in loss of T_{reg} homeostasis, impaired differentiation of Th cells, and initiation of CD8 T-cell responses (see following discussion).[107,108]

Growth Factors for Dendritic Cells and Monocytes

GM-CSF, M-CSF and Flt3L are essential growth factors for myeloid cell development in vitro and in vivo. During the early stages in myeloid development, shared progenitors of lymphocytes, polymorphonuclear leukocytes, monocytes, and DCs express one or more of the receptors for these growth factors. For example, Flt3 is expressed very early in hematopoiesis on shared progenitors of lymphocytes and all myeloid cells.[109] However, with the exception of pre-DCs, Flt3 expression is lost by nearly all leukocytes by the time they enter circulation.[60] Conversely, M-CSF receptor expression is retained by cells in the monocyte lineage but lost on pre-DCs and DCs.[60]

As might be predicted from their patterns of expression, M-CSF and Flt3L are essential for normal development of the monocyte and DC lineages, respectively. For example, mice deficient in M-CSF or its receptor show deficiencies in monocyte, macrophage, and LC development but have normal spleen and lymph node DCs.[110] In contrast, DC development is impaired in mice deficient in either Flt3L or Flt3, but monocyte development is normal.[59,111] Consistent with these observations, administration or overexpression of Flt3L results in selective expansion of DC populations, including fully differentiated DCs in lymphoid organs.[59,112]

Dendritic Cell Cultures

In the early 1990s, Banchereau and Schuler and their colleagues established in vitro culture systems to produce human monocyte-derived DCs (moDCs), and Inaba and Steinman for the mouse equivalent.[76,113,114] These culture systems are widely used today for basic and clinical studies. Bone marrow cells from mice or monocytes from humans are cultured for 6 days in medium containing GM-CSF to produce cells with dendritic morphology that exhibit modest phagocytic activity, express CD11c and MHCII, and stimulate the MLR. Differentiation to moDCs is further stimulated by addition of lipopolysaccharide, which induces a series of changes that were originally described as maturation. Notably, monocytes do not give rise to DCs in the lymphoid organs in vivo (see previous discussion), and GM-CSF is entirely dispensable for DC development in vivo[115]; thus, the moDCs generated in GM-CSF culture are not entirely representative of the cDCs found in the lymphoid tissues. moDCs may be more closely related to activated monocytes than to steady-state DCs in the lymphoid organs.

Authentic cDCs can be produced in in vitro cultures of bone marrow cells supplemented with Flt3L, which is an essential growth factor for DCs in vivo.[116] Flt3L cultures produce all of the known subsets of DCs, including cells with features of pDCs, CD8α+/CD103+ cDCs, and

CD8α- cDCs.[116]

Transcriptional Regulation of Dendritic Cell Development

A number of different transcription factors are known to regulate DC development, but to date none of these are cDC specific. For example, signal transducer and activator of transcription (STAT)3 is required for cDC development in part because this transcription factor is downstream of Flt3.[117] Binding of Flt3L to its receptor on the surface of DC precursors or cDCs induces activation of the phosphoinositide 3-kinase-Akt-mammalian target of rapamycin signaling

pathway; this leads to activation of STAT3.[118] Activation of STAT3 is also regulated by the transcriptional repressor, Gfi-1, deletion of which leads to reduction of lymphoid DCs and increase of LCs.[119] PU.1, an E-twenty-six family transcription factor, is a third transcription factor that is downstream of Flt3 signaling.[120] Although PU.1 deficiency is lethal, mice reconstituted with PU.1-deficient hematopoietic cells show a number of hematopoietic defects, including strong reduction in CD8α+ and CD8α- cDCs.

The Interferon Regulatory Factors

IRF2, 4, and 8 are prominent transcription factors that regulate DC diversification. IRF2-/- mice exhibit reduced CD8α- cDCs, IRF4-/- mice display reduced CD8α-cDCs and slightly reduced pDCs, and IRF8-/- mice have reduced CD8α+ cDCs, pDCs, and LCs.[100,121,122,123]

NF-kB/Rel

Members of the NF-kB/Rel family also contribute to DC development. CD8α- cDC numbers are dramatically reduced in RelB-/- mice.[124] TRAF6 belongs to TNF receptor-associated factor family and acts upstream of the NF-kB cascade. Consistent with a role for NF-kB in cDC development, TRAF6-/- mice also show a defect in the CD8α- cDC compartment.[125]

Basic Helix-Loop-Helix Transcription Factors

Basic helix-loop-helix factors (E12, E47, HEB, E2-2) interact with helix-loop-helix Id (inhibitors of deoxyribonucleic acid [DNA] binding) proteins to control DC development. Loss of Id2 leads to a severe reduction of CD8α+ cDCs and absence of LCs. Another helix-loop-helix family member, E2-2, plays a crucial role in guiding pDC development and maintaining stability of the pDC lineage. Deletion of E2-2 in developing precursors blocked pDC development, whereas deletion in more mature cells reversed the development, suggesting differentiation plasticity that needs to be constantly reenforced.[126,127] Similar to mice, E2-2 haploinsufficient humans with Pitt-Hopkins syndrome show a pDC defect.[126]

TABLE 16.2 Transcription Factors Determine Dendritic Cell Development and Homeostasis in Vivo

		Classical DC		Tissue DC

Batf3

Batf3 is expressed at high levels in DCs and is specifically required for development of CD8α+ cDCs and CD103+ nonlymphoid tissue DCs.[24,128] Batf3-/- mice failed to mount antitumor and antiviral immune responses, demonstrating a key role of CD8α+ cDCs and CD103+ nonlymphoid tissue DCs in priming CD8 T cells.

Notch

Terminal DC differentiation appears to depend on signaling through Notch receptors and their transcriptional effector RBP-J. Inactivation of RBP-J in DCs results in severe reduction and functional impairment of splenic CD8α- cDCs.[129] In addition, Notch2 deletion leads to the loss of CD103+ nonlymphoid tissue DCs in the intestinal lamina propria and to a corresponding decrease of IL-17-producing CD4 T cells in the intestine.[130]

In conclusion, DC differentiation is dependent on a number of interacting transcription factors (Table 16.2). Together, they turn on expression of lineage-specific genes and suppress alternative developmental programs.

Human Dendritic Cell Development

Research on human DCs is difficult because it is largely limited to peripheral blood, whereas in the mouse, most of the work has been done on DCs residing in lymphoid or nonlymphoid tissues. As a result, human DC research has relied on peripheral blood monocytes cultured in the presence of cytokines, which generate moDCs and not cDCs.

Despite these obstacles, three different subsets of DCs have been found in human blood. These subsets are referred to as BDCA1, 2, and 3 based on their expression of cell surface markers.[131] BCDA1+ DCs resemble mouse CD8α- cDCs, BDCA2+CD11c- DCs are equivalent to mouse pDCs, and BDCA3+ DCs are equivalent to mouse CD8α+ cDCs (Fig. 16.2). These interspecies associations were initially based on similarities in gene expression between human and mouse DC subsets,[132] and were recently confirmed in functional experiments.[133,134,135,136,137] Moreover, human DCs can be obtained from cultures of human cord blood supplemented with Flt3L and GM-CSF.[134]

The human equivalents of the bone marrow-derived DC precursors, MDP, CDP, and pre-DC remain to be isolated. However, recent clinical studies revealed genetically defined syndromes associated with DC deficiency, which may shed some light on human DC development. Three different genetic lesions have been associated with the triad of DC deficiency, monocytopenia, and opportunistic infections. GATA2 mutation leads to a loss of DC, monocytes, B cells, and NK cells.[138,139] These patients have normal LCs and macrophages, suggesting that LCs and tissue macrophage have different origin from DCs and monocytes in humans. Mutations in IRF8 are associated with disseminated bacille Calmette-Guérin infection.[140] Two different mutations in IRF8 have been identified. The K108E variant is associated with an autosomal recessive severe immunodeficiency with a complete absence of circulating monocytes and DCs; the T80A variant is an autosomal dominant, milder immunodeficiency and is associated with selective depletion of circulating DCs. Loss of DCs due to IRF8 mutation also leads to myeloproliferation in humans and in mice due to increased serum Flt3L, which induces expansion of myeloid progenitors. In

humans, as in mice, loss of DCs is associated with loss of T_{reg} cells, confirming the existence of a homeostatic feedback loop these two cell types[141] (see following discussion).

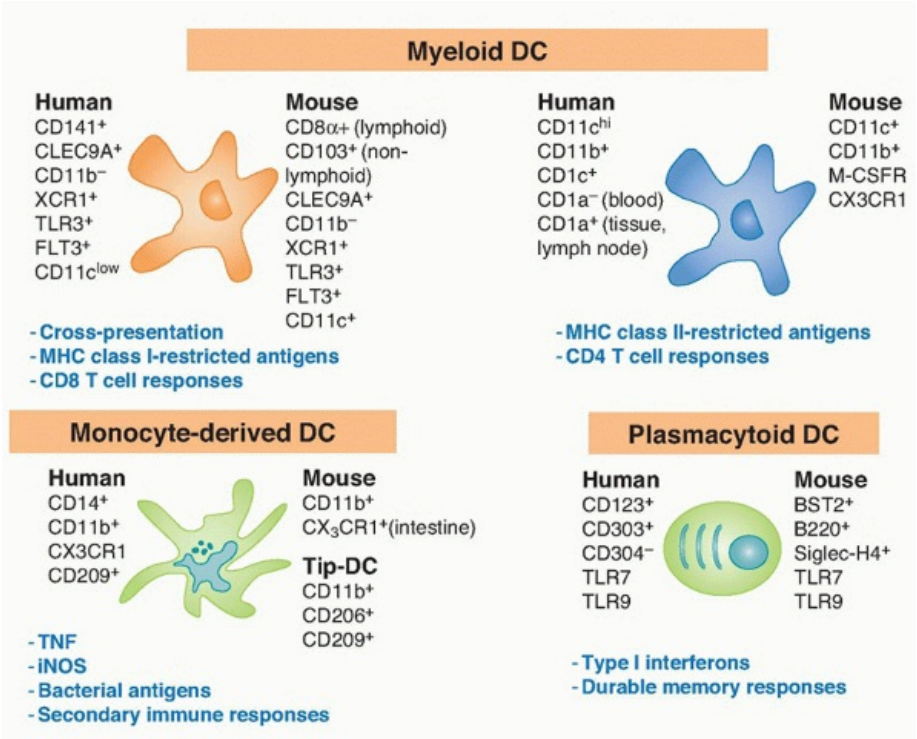

FIG. 16.2. Functionally Correlated Dendritic Cell Subsets in Human and Mouse.

DENDRITIC CELL HOMEOSTASIS

Lymphoid Organs

Based on their rapid labeling kinetics and loss of label in pulse chase experiments with BrdU, it was proposed that DCs have a very short half-life.[136,137] However, these early experiments are difficult to interpret in view of the more recent finding that DCs in lymphoid and nonlymphoid tissues divide in situ.[37,65,142]

The half-life of cDCs in tissues was measured in parabionts and shown to vary from 5 to 7 days in the spleen, lymph nodes, liver, and kidney, and as many as 25 days in the lung.[37,65] cDC homeostasis in all organs is maintained through a dynamic balance of three parameters: continuous input of pre-DCs from the blood, limited cDC division in situ, and cell death. Fitting BrdU incorporation and parabiosis separation data into mathematical equations produced a numerical estimate of the rate of DC precursor input (˜4,300/hour) and DC death (˜9,600/hour) in the mouse spleen.[65]

Regulation of Dendritic Cell Division

cDCs in mouse lymphoid and nonlymphoid tissues divide in situ for 10 to 14 days before being replaced by pre-DCs.[65] In the steady state, their division is regulated by

lymphotoxin-beta and Flt3L. Flt3L impacts nearly all stages of cDC development in lymphoid and nonlymphoid tissues, and is essential for their development.[59,112,143] In contrast, the effects of lymphotoxin-beta appear to be limited to CD4+ spleen DCs.[142] How the levels of circulating Flt3L are regulated is not known, but there appears to be a feedback loop between tissue cDCs and Flt3L that results in upregulation of Flt3L in the serum in response to cDC depletion,[144] loss of T_{reg}s,[60,145,146] or TLR ligand injection.[147] In all instances, increased Flt3L production leads to increased export of DC progenitors from the bone marrow and DC division in the periphery.

Conversely, increasing the number of DCs by Flt3L injection leads to an increase in the number of T_{reg} cells. Thus, the feedback loop between DCs and T_{reg}s is mediated by Flt3L, and that maintains the physiologic numbers of these two cell types in the steady state (Fig. 16.3).[146] Alterations in this mechanism lead to immune imbalance and can alter the course of autoimmune disease in mice.[146,148] For example, increasing the number of DCs in diabetes prone nonobese diabetic mice leads to increased numbers of T_{reg}s and a delay in disease onset. Similarly, Flt3L injection can protect mice from inflammatory bowel disease by increasing the number of cDCs and thereby the number of T_{reg}s. Thus, the Flt3Lmediated homeostatic feedback loop between T_{reg}s and DCs has clinical implication for vaccine design as well as the control of autoimmunity. Finally, this mechanism is entirely consistent with the proposed role of DCs in maintaining tolerance and regulating immunologic responses in vivo.[149]

Dendritic Cell Migration

DC migration from peripheral tissues into lymphoid organs is key to their sentinel and antigen trafficking functions. Upon microbial contact or stimulation by inflammatory cytokines, nonlymphoid tissue resident cDCs traffic through afferent lymphatics to the T-cell areas of the lymph node where they can participate in the initiation of immune responses. Migration is dependent on CCR7, which is upregulated by stimuli such as TLR ligands that activate DCs.

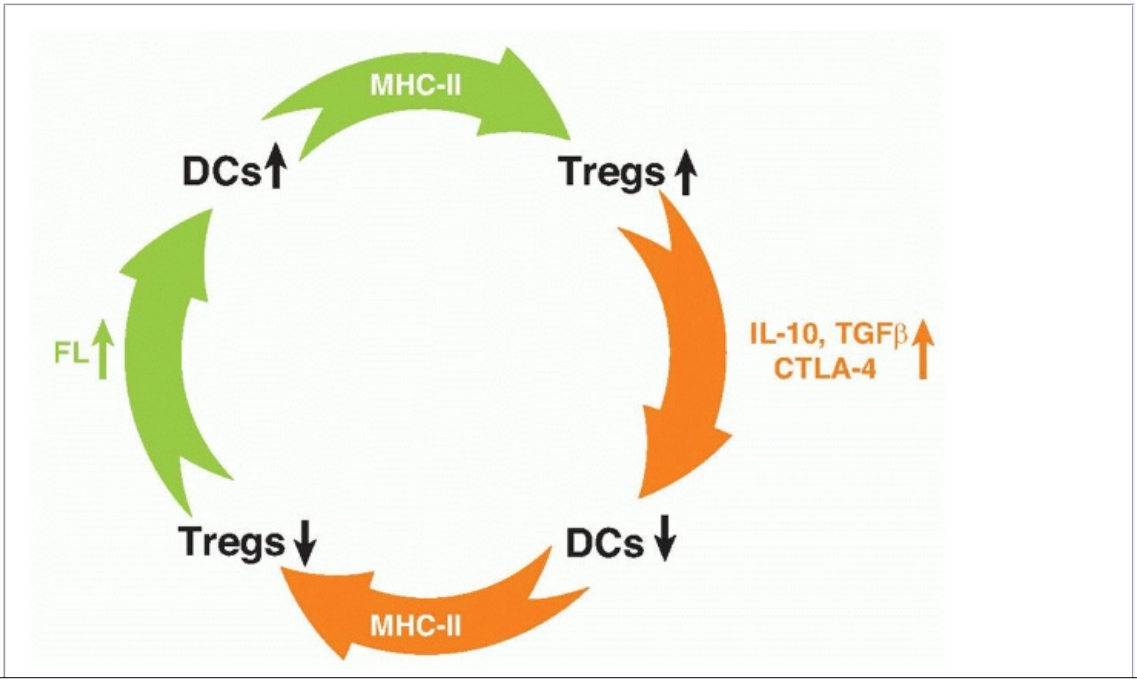

FIG. 16.3. Homeostatic Feedback Loop between Dendritic Cells and Regulatory T Cells.

Even in the absence of invading pathogens, some DCs are always migrating from tissues to lymph nodes. Studying afferent lymph is difficult in mice, but in rats, for example, DCs move along liver sinusoids in hepatic lymphatics to celiac lymph nodes,[150,151] and DCs from intestine migrate to mesenteric lymph nodes.[42,152] These cells are not found in the efferent lymph, indicating that most of the migrating DCs die after their arrival in lymphoid tissues. The DCs that migrate in the steady state might have several functions: to replenish immature populations, to transport self- or environmental antigens, or to be on patrol to identify invaders.

DC migration is a regulated process, controlled at the level of chemokine production and chemokine receptor expression and function.[153] Some immature DCs can express a repertoire of receptors (eg, CCR1, CCR2, CCR5, CCR6, and CXCR4) that bind inflammatory chemokines (eg, CCL5, CCL2, CCL3, CCL4, CCL20, and CXCL12). DC activation due to inflammatory signals is usually associated with downregulation of chemokine inflammatory receptors and the de novo expression of CCR7, the receptor for CCL19 and CCL21. In mice homozygous for an autosomal recessive mutation in CCL21 (paucity of lymph node T cells or plt/plt mice), naive T cells fail to home to secondary lymphoid organs. DCs in these mice also fail to accumulate in the spleen and in the T-cell areas of lymph nodes.[154] Similarly, CCR7-/- mice show defective secondary lymphoid organ architecture, defective homing of DCs and lymphocytes, and defective entry of DCs into lymphatic vessels at peripheral sites both in the steady state and inflammation conditions.[155] CCL19 and CCL21 also increase the maturation and proinflammatory differentiation of cDCs.[156] Therefore, chemokine/chemokine receptor interactions not only orchestrate the DC migration but also influence their immunogenic potential.

There are many other examples in which specific chemokines control the traffic of select populations of DCs (Table 16.3). In skin exposed to ultraviolet light, LCs disappear and are replaced in 2 weeks. The recruitment of LC precursors from blood is dependent on their expression of CCR2.[73] During murine listeriosis, CCR2 is also required for TNF-inducible nitric oxide synthase-producing DCs to migrate into the spleen.[53] Migration of pDCs into inflamed lymph nodes and their redistribution during inflammation depend on CXCR3 and CCR7. CCR6 is used by cDCs to populate epithelial surfaces during inflammation.[157,158,159] In the steady state, CXCL14 is important for LC progenitors to establish themselves in the skin.[160] All these findings indicate that the differential expression of chemokine receptors by DCs (and their subsets) at different stages of their life history determines their location in vivo.

ANTIGEN PRESENTATION

Antigen Capture

Macropinocytosis

DCs in culture continuously form 0.25 to 1.0 um pinocytic vesicles. These vesicles allow DCs to sample a large volume of extracellular fluid and soluble proteins that are present at low concentrations. Expression of aquaporin 3 and 7 on DCs may also contribute to macropinocytosis.[161]

TABLE 16.3. Animal Models Demonstrate Dendritic Cell Migration Depending on Chemokine Receptor

DC migration	
CCR2-/-, CCR5-/-	The recruitment of new Langerhans cells is dependent on their expression of the CCR2 chemokine receptor and on the secretion of CCR2-binding chemokines by inflamed skin.73 Recruitment of TNF/inducible nitric oxide synthase-producing DC subset in spleens of *Listeria monocytogenes*-infected mice is dependent on CCR2 and independent of CCR5.53,246
CCR6-/-	CCR6 mediates DC localization, lymphocyte homeostasis, and immune responses in mucosal tissue. In CCR6-/- mice, DCs expressing CD11c and CD11b are absent from the subepithelial dome region of Peyer patches.247
CCR7-/-, plt/plt (CCL19 and CCL21-/-)	CCR7 coordinates the primary immune response by establishing functional microenvironments in secondary lymphoid organs.155 Plt/plt mice lacking CCR7 ligands, CCL19 and CCL21, have defects in lymphocyte homing and DC localization.154 CCR7 also governs skin DC migration under inflammatory and steady-state conditions.248 CCR7 ligands, CCL19 and CCL21, induce a proinflammatory differentiation program in DCs.156
CCR8-/-	CCR7 and CCR8 pathways are used by monocyte-derived DCs during mobilization from skin to lymph nodes.249
CXCR3-/-	Plasmacytoid DCs migrate to inflamed lymph nodes, produce interferon-α, and help lymph node DCs to induce antiviral CTLs.250,251

Receptor-Mediated Phagocytosis

Phagocytosis is triggered by the attachment of extracellular particles to surface receptors, which mediate particle uptake. Multiple receptors on cDCs enhance recognition and ingestion of particulates including pathogens and dying cells. Importantly, many of the receptors also recognize molecular patterns on pathogens and as a result, activate DCs. In addition, DCs also express Fc receptors that mediate ingestion of opsonized particles and delivery to intracellular compartments that facilitate TAP-1-dependent cross-presentation to CD8 T cells. DCs express both activating and inhibitory forms of Fc receptors.[162] The inhibitory receptors help maintain DCs in an immature tolerogenic state. DCs that lack the FcγRIIB inhibitory receptor are more readily activated because the immunoreceptor-based tyrosine activation motif-associated FcγRIIA receptor is no longer subject to inhibition.[163] These observations have been extended in mice and humans through the identification of monoclonal antibodies that selectively block inhibitory receptors.[164,165]

Other than TLRs, DCs express many different types of pattern recognition receptors including those of the specific intercellular adhesion molecule-3-grabbing nonintegrin (SIGN) family, and multiple C-type lectins such as macrophage mannose receptor (MMR), DEC205, and DCIR2. MMR binds a range of bacteria, yeasts, and viruses through interactions between a mannose-type carbohydrate recognition domain and pathogen-associated high mannose structures. Notably, DCs deficient in any single C-type lectin receptor, such as MMR, DEC205, or DCIR2, develop normal adaptive immune response to dying cells, or pathogens, suggesting that this important class of receptors is redundant.

Dendritic Cell Maturation

DCs exist in two functionally distinct and phenotypically different stages. In the steady state, DCs in most tissues are equipped to capture and present antigens to T cells, but the outcome of antigen presentation by steady-state DCs is tolerance and not immunity. Steady-state DCs express high levels of pattern recognition and activation receptors, allowing them to sense changes in the environment, including pathogens and inflammatory cytokines. These signals induce extensive differentiation to a mature or activated state characterized by increased levels of cell surface MHC and coactivator expression, as well as cytokine secretion. In the activated state, DCs initiate potent and specifically polarized T-cell immune responses. Thus, pathogen sensing by DCs is an important mechanism that links innate pathogen recognition to the adaptive immune response.

Toll-Like Receptor Signaling

Microbes and viruses induce DC activation in part by engaging TLRs. DCs express nearly all known TLRs and also express additional cytoplasmic receptors that recognize pathogen patterns such as melanoma differentiation associated protein 5 (MDA-5), RIG-I, and DDX41, and nucleotide oligomerization domain-like receptors, although expression of specific receptors is restricted to distinct DC subsets.[166,167,168] In many cases, a single microbe will trigger several different TLRs expressed by DCs; therefore, a single TLR may be redundant for inducing immunity to many, but not all, pathogens. Thus, in humans, loss of TLR3 results in susceptibility to herpes simplex virus-1 infection but not to other microbes that also contain the TLR3 ligand.[169] Pathogen recognition by TLR ligation induces rapid DC activation and upregulation of MHC and costimulatory molecules, and also triggers secretion

of inflammatory cytokines such as IL-1α, IL-6, TNFα, IL-18, and IL-12, which are critical in driving T-cell differentiation.[170,171,172]

Cytokines, T, and Natural Killer T Cell Signals

DCs can also sense proinflammatory cytokines such as TNFα and IL-1β, and direct cellular contact with activated T or NKT cells by ligation of CD40, a TNF receptor family molecule that is highly expressed on the surface of DCs. Many of these receptors, including TLRs, IL-1R, and TNF receptors, activate DCs through the NF-κB pathway.

Antigen Processing

DCs process ingested antigens for presentation on both MHC class I and MHC class II. Although DCs are excellent MHCII antigen-presenting cells, they are not unique in this respect. Other cells, including activated B cells and monocytes, can also process and present antigens for presentation by MHCII efficiently. For example, in germinal centers, activated B cells are the key antigen-presenting cell.

Macrophages endocytose antigens and rapidly digest them. In contrast, DCs sequester and preserve the captured antigen for later presentation. Preservation of antigens is critical for immunogenicity and depends on two DC specializations. The first is low lysosomal protease activity. Macrophages contain high levels of lysosomal proteases, including cathepsin S, cathepsin L, cathepsin K, and asparagine endopeptidase. These proteases enable rapid degradation of internalized proteins to single amino acids. Compared to macrophages, DCs express low amounts of proteases, resulting in a limited capacity for lysosomal degradation.[173] This low-level proteolytic capacity appears to be crucial as the peptides loaded on MHC and recognized by T cells consist of peptides between 8 to 17 amino acids. Consistent with this idea, mutations in amino acids in antigens that increase their resistance to lysosomal proteolysis increase immunogenicity by decreasing the rate of proteolysis.[173]

A second feature of DC lysosomes that facilitates antigen presentation is that DC lysosomes are less acidic compared to those in professional phagocytes. In macrophages and neutrophils, the low pH of the phagosome and endosome activates lysosomal proteases delivered to these endocytic vesicles. In DCs, the pH in these compartments is less acidic because the assembly of V-ATPase, an adenosine triphosphate-dependent vacuolar proton pump, appears to be incomplete in the lysosome of steady-state DCs, leading to alkalinization of the endocytic compartment.[174] In addition, DCs show efficient recruitment of Nox2 to endosomes and phagosomes. Nox2 produces reactive oxygen species, which consumes protons and thereby reduces the acidification of the endocytic compartment. NOX2-defective DCs exhibit a higher level acidification of the phagosome and increased proteolysis and decreased antigen presentation.[175] Furthermore, Nox2-deficient patients, who suffer from chronic granulomatous disease, show impaired cross-presentation.[176] Together, the lower levels of proteolytic activity and decreased acidity in endocytic compartment lead to a decrease in the rate of antigen digestion and increased availability of partially processed peptides for loading on MHC. This unique feature of DCs may also help preserve the antigen during the migration of nonlymphoid tissue DCs from the site of antigen capture to the lymph nodes.

Antigens are actively taken up by immature DCs and targeted to MHCII-positive lysosomes. However, these antigens are sequestered in an intact form and are not efficiently utilized for formation of MHCII-peptide complexes. Immature DCs do form stable MHCII dimers, but their presence does not result in immunogenic complexes. DC activation by microbial products or proinflammatory cytokines results in redistribution of MHCII from intracellular compartments to the plasma membrane. In addition, DC activation reduces lysosomal cystatin C, which leads to increased activation of cathepsin S and more efficient processing of Ii.[85]

DENDRITIC CELLS LINK INNATE AND ADAPTIVE IMMUNITY

Plasmacytoid Dendritic Cells

Nucleic acid-sensing pDCs are activated when they sense pathogen or self-derived nucleic acids and are involved in antiviral immunity and autoimmune diseases. Whereas monocytes express TLR4 (lipopolysaccharide sensor) and cDCs express TLR3 (double-stranded RNA sensor), pDCs selectively express TLR7 (single-stranded RNA sensor) and TLR9 (DNA sensor). pDCs endocytose viruses and sense their nucleic acids using TLR7 and TLR9, both of which reside in the endosomal compartment. TLR7 detects single-stranded RNA viruses, such as influenza, respiratory syncytial virus, Sendai, and vesicular stomatitis virus, and synthetic singlestranded RNA analogs such as R848/Imiqimod; TLR9 detects DNA viruses, such as herpes simplex virus-1, herpes simplex virus-2, and murine cytomeglavirus, or cytosinphosphatidyl-guanosin oligodeoxynucleotides. Viruses that enter the cytoplasm of pDCs are detected after autophagy, a conserved cell-autonomous process involving lysosomal degradation of cellular organelles to deliver cytoplasmic RNA to TLR7-containing endosomal compartments. Both TLR7 and TLR9 use MyD88 as the adaptor protein for activation; thus, MyD88-deficient pDCs have defective responses to a wide range of viruses that enter the cytoplasm. Recruitment (binding) of MyD88 to the TLR leads to assembly of a signal-transducing complex that includes IRAK4, TRAF6, Bruton's tyrosine kinase, and IRF7.[177] This signaling complex is critical for IFN production by pDCs. In most cells, production of IFNα depends on binding of IFNβ to interferon-α/β receptor (IFNAR), which induces IRF7 expression. In pDCs, however, constitutive high-level expression of IRF7 facilitates a rapid IFNα response that is independent of IFNAR signaling.[105]

IFN production by pDCs is rapid, starting 4 hours after exposure to TLR ligands and peaking after 24 hours when pDCs become refractory. Type I IFN produced from activated pDCs not only directly inhibits viral replication, but also activates NK, B cells, and cDCs.[178] For example, human immunodeficiency virus (HIV) or herpes simplex virus infection stimulates pDCs to produce type I IFN and CD40L, which in turn activates cDCs and facilitates antigen presentation and development of antiviral immunity. Similarly, pDC nucleic acid sensing and cDC activation occurs in autoimmune diseases. In patients with systemic lupus erythematosus, pDCs are continuously activated by circulating immune complexes composed of self-DNA or RNA leading to high circulating levels of IFNα.[178]

Given the potential pathologic consequences of high-level IFNα production by pDCs, it is not surprising that this response is highly regulated. pDCs express an array of negative regulators to downregulate IFNα production. In humans, two surface molecules, BDCA2 and immunoglobulin-like

transcript 7 (also known as LILRA4), were found to suppress TLR-induced IFN production from pDCs. Both receptors mediate their inhibitory effects through cytoplasmic immunoreceptor-based tyrosine activation motifs, and both BDCA2 and immunoglobulin-like transcript 7 associate with the γ-chain of the high-affinity Fc receptor for immunoglobulin E (FcεRIγ).[179] Other immunoreceptor-based tyrosine activation motif-mediated inhibitors of pDC IFN production include NKp44 and sialic acid binding Ig-like lectin (Siglec)-H, which recruits DAP12.[180]

Interactions with Innate Lymphocytes

DCs interact with innate lymphocytes (eg, NK, NKT, and γδ T cells) in ways that enhance the functions of both cell types. DCs produce IL-12, IL-15, IL-2, and IFNα/β that affect different facets of NK cell function, whereas the innate lymphocytes induce DC activation.[181,182] Injection of activated cDCs leads to the recruitment of NK cells into the draining lymph nodes while exposure of cDCs to TLR stimuli induces IL-2 and IL-12 production, which in turn activate NK cells to produce IFNγ. DCs also present different glycolipids on CD1d molecules to the invariant T-cell receptor on NKT cells. These include endogenous lysosomal glycosphingolipids (eg, iGb3),[183] microbial lipids,[184,185] or synthetic glycolipids (eg, alpha-GalCer)[186,187] to activate NKT cells in vivo.

Type I IFN appears to be one of the essential mediators of DC activation in vivo. For example, antigen targeted to cDCs can elicit strong Th1 immunity in the presence of PolyI:C. PolyI:C binds to TLR3 on the cell surface and intracellular sensor MDA-5. However, PolyI:C does not directly stimulate DC maturation because deficiency of TLR3 or MDA-5 on DCs does not abrogate immunogenicity.[188] Instead, PolyI:C stimulates nonhematopoietic cells to produce large amounts of type I IFN.[188] High levels of systemic type I IFN stimulate functional maturation of cDCs, which consequently induce a robust Th1 response. Thus, microbial stimuli-induced DC maturation in vivo engages a cascade of cellular and molecular mechanisms, which may amplify the environmental signals to facilitate optimal immunity.

Initiating Adaptive T-Cell Immunity

In the steady state, DCs can endocytose a diverse array of antigens through multiple receptors on their cell surface. However, steady-state DCs typically express relatively low levels of surface MHC class I and II products and only low levels of costimulatory molecules (eg, CD80, CD86). Upon receipt of an activation stimulus, DCs undergo extensive differentiation, and they migrate in increased numbers to secondary lymphoid tissues.

DC-T-cell interactions in the lymph nodes have now been studied in the living state with two-photon microscopy.[33,189,190,191,192] Naïve antigen-specific T cells arrest on antigen-presenting DCs, and this stable interaction lasts for at least 18 hours. In the steady state, this stable DC-T-cell interaction leads to tolerance while an activation signal such as TLR ligation allow DCs to initiate immunity. cDC activation results in redistribution of MHCII from intracellular compartments to the plasma membrane; the upregulation of costimulatory molecules such as CD40, CD80, and CD86; and change in profiles of cytokine and chemokines such as TNFα and IL-12. All these changes likely contribute to the initiation of T-cell immunity.

The communication between DCs and T cells is a dialogue in which the DCs also respond to T cells. For example, CD40 and TRANCE/RANK receptor on DCs are ligated by the corresponding TNF family member expressed on activated and memory T cells (ie, CD40L and RANK-L).[193,194,195] This leads to increased DC survival and in the case of CD40 ligation, upregulation of CD80 and CD86, secretion of IL-12, and release of chemokines such as IL-8 and MIP-1α and β.

Controlling the Quality of the T-Cell Response

DCs are involved in critical T-cell fate decisions such as clonal selection, tolerance versus immunity, Th1 versus Th2, and even memory. In the presence of mature DCs producing IL-12 or IFNs (as might occur when DCs are ligated by CD40L or infected with viruses), CD4 T cells differentiate along a Th1 pathway for IFNγ production. The latter in turn activates the antimicrobial activity of macrophages and promotes killer T-cell differentiation. However, in the presence of exogenous IL-4, DCs induce T cells to differentiate into Th2 cells, which secrete IL-4, IL-5, and IL-13. These cytokines help B cells to make antibodies of the IgG1 and IgE isotypes, activate eosinophils, and stimulate fibrosis. A new and striking pathway that was first discovered with human monocyte-derived DCs involves the epithelial-derived cytokine thymic stromal lymphopoietin (TSLP). This cytokine stimulates DCs to induce "inflammatory Th2 cells" that produce TNFα (rather than IL-10) in addition to IL-4, IL-5, and IL-13.[196] Recent studies have shown that TSLP receptor knockout mice exhibit strong Th1 responses, with high levels of IL-12, IFNγ, and IgG2a, but low production of IL-4, IL-5, IL-10, IL-13, and immunoglobulin E.[197] DCs that are activated with either CD40L or TSLP are similar in appearance, being rich in MHCII and CD86 co-stimulatory molecules. However, they differ significantly in cytokine and chemokine production, and the functional consequences for T cells vary.[196]

Cross-Presentation by Conventional Dendritic Cells

CD8 T cells are critical for protective immunity against intracellular pathogens and malignant tumor cells. When autologous T cells are incubated with influenza-infected DCs, strong proliferative and cytotoxic T-lymphocyte (CTL) responses develop within a week. Thus, DCs present endogenous antigens on MHCI to prime CD8+ T cells. Interestingly, DCs can also present exogenous antigen on MHCI, an unconventional presentation path called "cross-presentation." The earliest experiment demonstrating the capacity of DCs in cross-presentation was done in vitro, when trinitrophenyl-modified cells were taken up by DCs. DCs can present trinitrophenyl, an exogenous antigen, and induce antitrinitrophenyl CTLs in vitro in a MHC-restricted manner.[14] Later, DCs were found to take up exogenous influenza

antigen in the form of nonreplicative virus or apoptotic cells, and present them on MHCI to prime CD8 T cells.[198] In the absence of DCs, mice are unable to process several different antigens through the exogenous pathway, indicating that DCs were a major cell type for cross presentation to CD8 T cells in vivo.[199] DCs cross present exogenous antigen taken up as soluble form or via multiple receptors, including FcR, CD91, Lox-1, DEC205/CD205, and DNGR1. CD8+ DCs in mice and their functional equivalent BDCA3+ DCs in humans excel in cross-presenting exogenous antigens.[24,134,200] Exogenous presentation or cross-

presentation is essential for protective immunity against viruses and tumors.

DENDRITIC CELLS CONTROL TOLERANCE

The mechanisms used by DCs to initiate immunity against pathogens pose a major risk for the development of autoimmunity, allergy, and chronic inflammatory disease. For example, infection frequently induces some cell death; therefore, DCs at the site of infection capture pathogens and dying cells, and the two are processed and presented similarly.[201,202] Likewise, at body surfaces, maturing DCs are also capturing environmental antigens to which the body must remain unresponsive. How do maturing DCs focus the immune response on antigens derived from the pathogen and avoid inducing immunity to self- and nonpathogenic environmental antigens?

Thymic Dendritic Cells Contribute to Central Tolerance

Self-reactive thymocytes are deleted by antigen-presenting cells during negative selection. The thymus contains two major populations of antigen-presenting cells that express MHCII, namely, medullary thymic epithelial cells and cDCs. Both cell types are required for efficient negative selection. Medullary thymic epithelial cells express a panoply of selfantigens under the control of the autoimmune regulator "AIRE."[203] Self-antigens for negative selection in the thymus also include antigens expressed by DCs, and antigens that enter the thymus through the bloodstream and are captured by DCs. In the absence of antigen presentation by DCs, negative selection of CD4+ thymocytes is impaired.[204] In addition to negative selection, thymic cDCs also support the development of Foxp3+ T_{reg}s.[205] Thus cDCs contribute to central tolerance in the thymus by more than one mechanism.

Dendritic Cells Mediate Peripheral Tolerance

DCs also mediate tolerance in the periphery. Because central tolerance alone is incomplete, the immune system must continually establish tolerance to harmless or "noninfectious" antigen in the environment. Therefore, the effective control of self-reactive T cells depends on peripheral tolerance. For example, mice and humans deficient in T_{reg}s, which suppress autoreactive T cells in the periphery, succumb to autoimmunity at an early age. DCs constantly carry innocuous antigens from the periphery (eg, from the skin, airways, stomach, intestine, and pancreas) and present them to T cells in lymphoid organs.[206] A critical observation was that bone-marrow-derived cells in the pancreatic lymph nodes present peptides derived from insulin-producing β cells from pancreatic islets, leading to tolerance.[207,208] Although DCs were not implicated directly, a direct role for DCs in maintaining tolerance was established by Hawiger and colleagues by targeting antigens directly to DCs.[209] Furthermore, CD8α+ cDCs are particularly efficient in capturing dying cells[201] and inducing tolerance.[202] Likewise, when DCs capture innocuous proteins from the airway, profound tolerance develops even though the T cells can initially proliferate extensively to the antigen-capturing DCs in the draining lymph nodes.[210]

Deletion and Anergy

Mechanisms for peripheral tolerance can be intrinsic (deletion and anergy) or extrinsic

(through suppressive T_{reg} cells). Interestingly, the former requires expression of B7 family members on the steady state DCs (eg, PD-L1 and CD86), which then ligate PD-1 and CTL antigen-4 on the T cells to be tolerized.

Regulatory T cells

Autoreactive T cells can remain quiescent in the presence of T_{reg} cells. There are two types of T_{reg}s: naturally occurring T_{reg}s derived from thymus (natural T_{reg}s) and T_{reg}s induced from Foxp3-CD4+ T cells in the periphery (induced T_{reg}s).[211]

The groups of Belkaid and Powrie found that a subset of gut DCs expressing CD103, the αEβ7 integrin, are specialized at inducing Foxp3+ T_{reg}s and maintaining oral tolerance.[212] CD103+ DCs from mesenteric lymph nodes or gut-associated lymphoid tissue produce transforming growth factor-β, a cytokine critical for induction of Foxp3+ T_{reg}s.[212] Additionally, CD103+ gut DCs use retinal dehydrogenase to metabolize vitamin A to bioactive retinoic acid, which acts as a cofactor for transforming growth factor-β to induce Foxp3+ T_{reg}s.[212,213] Similarly, skin DCs use vitamin D3 to induce T_{reg}s.[214,215] Therefore, DCs are able to employ environmental signals, vitamin A in the gut, and vitamin D3 in the skin to induce tolerance to harmless foreign antigens. The CD8+ and CD103+ DC subset appears to be specialized at T_{reg} induction. When antigens were targeted to CD8α+ DEC-205+ or CD8α- DCIR2+ DC subsets in vivo, only CD8α+ DEC-205+ DCs were able to induce Foxp3+ T_{reg}s from Foxp3- CD4+ T cells.[216]

DCs also maintain the homeostasis of T_{reg}s. Loss of DCs leads to a loss of T_{reg} cells, and the remaining T_{reg} cells exhibit decreased Foxp3 expression. The DC-dependent loss in T_{reg} cells leads to an increase in the number of T cells producing inflammatory cytokines, such as IFNβ and IL-17.[217] Conversely, increasing the number of DCs leads to increased T_{reg}-cell division and accumulation by a mechanism that requires MHCII expression on DCs.[146] Activation of β-catenin is essential for DC to control T_{reg} and peripheral tolerance. DCs lacking β-catenin show decreased production of immunosuppressive cytokines and a decreased ability to support the differentiation of naïve T cells into T_{reg}s in vitro.[218]

In summary, DCs have the capacity to induce tolerance by several mechanisms.

DENDRITIC CELLS IN CLINICAL IMMUNOLOGY

This section focuses on diseases in which DCs play a pathogenic role or can be targets for therapy.

Dendritic Cells in Transplantation

DCs play a key role in the outcome of organ and hematopoietic transplantation. In organ transplantation, both donor and recipient DCs contribute to graft rejection. Donor DCs in grafted organs migrate to lymphoid organs where they stimulate alloreactive T cells in the recipient to induce organ rejection[219,220]; recipient DCs can also capture antigens from the graft and elicit organ rejection. For example, in hematopoietic transplantation, recipient DCs

initiate T-cell-induced graft-versus-host reactions.[74,221]

Dendritic Cells in Autoimmune Disease

Several human autoimmune diseases appear to involve DCs. Abundant DCs are found in the synovial exudates of rheumatoid arthritis, and TNF-α produced by DCs contributes to the severity of the disease. Similarly, in psoriasis, DCs infiltrate lesional skin, produce TNF-α, and polarize T cells toward Th1/Th17[222,223]; additionally, pDCs in psoriatic lesion become activated to produce type I IFN, which also contributes to the inflammatory response.

In systemic lupus erythematosus, two subsets of DCs contribute to the onset and severity of the disease; pDCs in patients with systemic lupus erythematosus overproduce IFNα, which activates cDCs and interferes with their ability to maintain peripheral tolerance.[178] Finally, DCs have been implicated in mouse models of type I diabetes by carrying self-antigens from the pancreas to draining lymph nodes where diabetogenic T-cell responses are initiated. In addition, DCs cultured from nonobese diabetic mice show an activated phenotype with increased IL-12 and costimulatory molecule expression.[224]

Dendritic Cells in Viral Infections

DCs mediate antiviral immunity by priming T-cell responses. However, a number of viruses have evolved strategies to subvert DCs, and thereby, the immune system.

The interaction between HIV and DCs is a fascinating example of viral immune subversion. DCs carry HIV from peripheral tissues into draining lymph nodes where the virus is transmitted to CD4 T cells. HIV binds to DCs by CCR4, CXCR5, or DC-SIGN, but productive infection is restricted by SAMHD1, a protein encoded by an Aicardi-Goutières syndrome susceptibility gene.[225] Transmission to CD4 T cells is dependent on DC-SIGN, a C-type lectin pathogen-recognition receptor expressed on the surface of DCs that retains the attached virus in an infectious state. In the lymphoid organs, close interaction between DCs and CD4+ T cells facilitate HIV transmission.[226,227]

Interestingly, DC-SIGN also serves as receptor for several other viruses including hepatitis C virus, Ebola virus, cytomegalovirus, dengue virus, and the severe acute respiratory syndrome coronavirus.[228,229,230] Dengue is a mosquitoborne flavivirus that causes a disease that can be associated with hemorrhagic fever. Dengue virus targets DCs directly through DC-SIGN but also enters DCs as a passenger in immune complexes that are taken up by Fc receptors.[231,232] When infection occurs through antibody enhancement mediated by Fc receptor, the infected DCs are involved in induction of the T-cell cytokines that mediate the vascular leak syndrome associated with the infection.

Dendritic Cells in Cancer

Tumors can suppress immunity in part through their effects on DCs. DC differentiation and activation can be suppressed by cancer-derived cytokines, such as IL-6, vascular endothelial growth factor, and IL-10.[233] In contrast to their normal counterparts that activate immune responses, DCs derived from tumors induce Foxp3+ T_{reg}s[234] and IL-13-producing CD4+ T cells,[235] and suppress proliferation of CTLs[236] and NKT cells.

Dendritic Cell-Targeted Vaccines

DC-based vaccines are currently being used in the clinic, and DC-targeted vaccines are being tested.

DC-based immune therapy is currently available for treating prostatic cancer, but it is far from optimized and is not curative. Monocyte-derived DCs are generated ex vivo, loaded with tumor cells or tumor antigens, and reinjected into the patient.[237] Scientific and practical problems exist with this approach, including limited responses possibly due to inefficient migration of monocyte-derived DCs from injection site to the draining lymphoid organs and inefficient antigen presentation.

DC-targeted vaccines are based on the idea that antigens delivered specifically to DCs in conjunction with the appropriate adjuvants will produce strong and lasting immunity.[209] DC-targeted vaccines require that antigens be delivered specifically to endocytic receptors on DCs together with the appropriate stimuli to induce DC activation. For example, antigens have been incorporated into antireceptor monoclonal antibodies, which are then injected into the vaccine recipient.[209,238,239] This paradigm was established using antibodies to DEC205/CD205, which is abundant on DCs and delivers antigens to both MHC class I and II antigen-processing compartments.[240] In mice, antigens targeted to DEC205/CD205 on activated DCs induce strong immunity against tumors and a number of intracellular pathogens, including malaria and *Leishmania*.[238,241,242] Importantly, these responses are broad, often generating immunity against multiple epitopes[243] in mice of several MHC haplotypes and the responses elicit protection from mucosal infections.[244] Other potential DC targets include LOX-1/OLR1, MMR/CD206, DCIR/CLEC4A, DC-SIGN/CD209, DNGR1, langerin (CD207), and CD40.[28,245]

In conclusion, DCs play important roles in a number of different diseases. Moreover, they are excellent targets in designing new approaches to prevention and treatment of these diseases.

Chapter 17
Natural Killer Cells

Wayne M. Yokoyama

INTRODUCTION

Natural killer (NK) cells were initially described because they spontaneously kill certain tumor targets.[1,2,3,4] However, they are now recognized to play important roles in early innate immune responses, especially to viral infections. They interact with other innate immune components and modulate the subsequent adaptive immune response. These effects are due to NK cell responses to proinflammatory cytokines or susceptible targets, which stimulate NK cells to secrete other cytokines and/or kill targets. In this chapter, we will consider all of these issues in detail by describing how they differ from other lymphocytes, their functions, unique target recognition strategies, tolerance, development, and role in immune responses and human diseases. There will be an emphasis on their target recognition receptors because their discovery made it possible to understand NK cell biology more precisely.

GENERAL DESCRIPTION

Developmental studies have provided strong evidence that NK cells belong to the lymphocyte lineage (discussed in detail in the following). Morphologically, NK cells are typically large lymphocytes containing azurophilic granules.[5] However, the large granular lymphocyte morphology is not invariably associated with NK cells because small, agranular lymphocytes may display natural killing,[6] activated cytotoxic T-lymphocytes (CTLs) can display this morphology,[7] and human large granular lymphocyte leukemias contain NK- and T-cell variants.[8] Among lymphocytes, NK cells more closely resemble T cells than B cells. Thus, it is useful to compare and contrast these two lymphocyte populations as well as consider another enigmatic cell termed the “lymphokine-activated killer” (LAK) cell.

Natural Killer Cells versus T Cells

NK cells are most often confused with T cells because they may have similar morphologies, express several cell surface molecules in common,[9,10] and share functional capabilities. While this confusion was frequent before the molecular description of the T-cell receptor (TCR)/cluster of differentiation (CD)3 complex, their similarities remain a potential source of uncertainty. However, mature NK cells are clearly not T cells by several criteria.[11] Conventional NK cells do not require a thymus for development and are normal in athymic nude mice (though this is not the case for the newly described “thymic” NK cell subset, discussed subsequently). NK cells do not express the TCR on the cell surface, do not

produce mature transcripts for TCR chains, and do not rearrange TCR genes.[12,13] Mice with the *scid* mutation or deficiencies in *Rag1* or *Rag2* lack TCR gene rearrangements and mature T cells but possess NK cells with apparently normal function.[14,15,16,17] Several CD3 components may be found in the cytoplasm of NK cells, particularly immature NK cells, but they are not displayed on the cell surface[18] with the exception of CD3ζ. But CD3ζ is expressed in association with FcγRIII (CD16) and other NK cell activation receptors instead of the TCR/CD3 complex.[19,20] Whereas mice lacking CD3ζ lack most T cells, NK cell number and function are minimally affected.[21] On the other hand, NK cells are completely absent in mice with only partial defects in T-cell subsets, such as in mice lacking components of the IL-15R (see following discussion). NK cells do not require the presence of major histocompatibility complex (MHC) class I (MHC-I) molecules on their targets for lysis in an important functional distinction with CD8+ MHC-I-restricted T cells. Instead, NK cells kill more efficiently when their targets lack MHC-I expression. Thus, NK cells can be clearly distinguished from T cells, even from so-called CD3+ NKT cells that express NK cell markers (see following discussion).

Natural Killer Cells, Lymphokine-Activated Killer Cells, and Interleukin-15

Another area of overlap between NK and T cells concerns cytokine responses. When mouse splenocytes or human peripheral mononuclear cells are exposed to high concentrations of interleukin (IL)-2 (800 to 1000 U/mL), robust lymphocyte proliferation ensues (ie, LAK cells are generated).[22,23,24,25] Although most are CD3- NK cells, TCR/CD3+ T cells are also produced. To distinguish NK cells within this population, they are sometimes called "CD3$^-$ LAK" cells or "IL-2-activated NK cells."

In a related phenomenon, NK cells are activated when mice are injected with polyinosinic-polycytidylic acid (poly-lic) or other agents that trigger through Toll-like receptors (TLRs), often on plasmacytoid dendritic cells (DCs).[26] NK cells can also be activated in vitro with interferon (IFN)α/β, IFNγ, or low concentrations of IL-2 that are insufficient to induce proliferation.[3,4,27]

NK cells activated in these various ways, with or without proliferation, display enhanced killing of typical NKsensitive targets. They also kill a broader panel of targets, including those that are generally resistant to freshly isolated NK cells, such as the murine P815 mastocytoma cells and

freshly explanted tumors. Many agents that enhance killing by NK cells may also activate T cells, such that even T-cell clones may display promiscuous killing of targets that is no longer MHC-restricted.[28] This phenomenon was a frequent source of confusion between NK cells and T cells during the initial characterization of both cell types.

Why cytokine activation leads to enhanced killing is incompletely understood. Interestingly, mouse NK cells constitutively express messenger ribonucleic acid (mRNA) for cytotoxicity components, perforin, and granzymes, but no protein.[29] Cytokine activation enhances expression of mRNA for perforin and granzymes,[30] and translation into expressed proteins that contributes to more lytic capacity,[29,31] but this effect may not explain the capacity of

LAK cells to kill a broader panel of targets. Activated NK cells express additional receptors that may deliver stimulatory signals,[32,33] but their contribution to the LAK phenomenon remains unclear. In mice, cytokine activation of NK cells results in expression of an alternatively spliced form of a receptor termed NKG2D (see subsequent discussion), which may play a role,[34,35] and IL-15 contributes to LAK-like activity of CTLs, although how much this applies to conventional NK cells is not understood.[36] Enhanced killing may also be due to effects on adhesion molecules.[37,38] Nonetheless, it remains unclear how each of these factors contribute to the LAK phenomenon of enhanced and broader killing capacity as compared to resting NK cells.

It seems unlikely that high concentrations of IL-2 can be achieved, even locally, to stimulate NK cells in vivo. Furthermore, NK cells tend to be early responders in immune responses whereas the prime reservoir of large amounts of IL-2 is the activated T cell that produces it somewhat later. Although naïve T cells can make IL-2 soon after stimulation[39,40] and DCs can produce IL-2 to enhance NK lytic activity,[41] whether the resultant IL-2 concentrations are sufficient to generate LAK cells in vivo is unclear.

Interestingly, NK cells are apparently normal in mice with a targeted mutation in the IL-2 gene or the IL-2Rα chain,[42,43] indicating that IL-2 itself is not required for normal NK cell development. Paradoxically, NK cells are deficient in mice with a mutation in either IL-2Rβ or IL-2Rγ.[44,45,46] The discrepancy in NK cell dependence on IL-2 versus IL-2 receptor (IL-2R), as well as the LAK cell phenomenon, may be best understood by comparing the components of the IL-2 and IL-15 receptors.

In brief, the high affinity IL-2R is a heterotrimeric receptor complex comprised of α (p55), β (p75), and γ (p64) chains.[47] Though individual components may bind IL-2 with low affinity, only the intermediate-affinity βγ receptor (K_d ~1 nM) and the high-affinity αβγ receptor (K_d ~10 pM) are capable of signaling. Resting NK cells constitutively express IL-2Rβγ[47,48] and upon activation, may induce IL-2Rα and further upregulate IL-2Rγ chain expression.[47] In contrast, resting T cells generally do not express any functional IL-2 receptors, and most naïve T cells do not respond to high concentrations of IL-2.[49] The IL-2Rγ chain is also termed the common γ subunit (γc) because it is a required component of the multimeric receptor complexes for other cytokines, including IL-15,[50] that is particularly relevant to NK cells. IL-15 does not bind to IL-2Rα but instead utilizes a unique IL-15Rα chain to form a high-affinity complex with IL-2Rβγ.[51,52] The IL-15Rα chain does not directly signal. Its distribution is widespread on numerous cell and tissue lineages including NK cells.

IL-15 has a number of effects on NK cell biology. It is required for NK cell development; mice lacking IL-15 or any component of the trimeric IL-15R complex lack NK cells.[44,45,46,53,54] Not surprisingly, mice deficient in other components of the IL-15R complex and its signaling pathway (IL-2Rβ, Jak3, and STAT5α/β) exhibit similar defects in NK cell development.[44,55,56,57] Depending on its relative concentration, IL-15 has an antiapoptotic or proproliferative effect.[58,59] When NK cells are transferred to NK cell-deficient mice, they undergo “homeostatic” proliferation,[60,61] akin to T-cell homeostatic proliferation.[62] Like

memory CD8+ T-cell homeostasis, NKcell homeostasis is IL-15-dependent,[60,61] to a more or less degree.[63] Finally, LAK cells can be generated with IL-15.[64] These studies strongly suggest that LAK cells are generated because high-dose IL-2 acts through the IL-2Rβγ that is normally expressed with IL-15Rα as components of the constitutively expressed trimeric IL-15R complex on resting NK cells. Thus, the LAK cell phenomenon is related to the role of IL-15 and its receptor in NK cell biology.

Interestingly, IL-15 is expressed at very low levels and is difficult to detect in vivo.[65] The IL-15Rα chain can present IL-15 in *trans* to NK cells that can respond through IL-2/15Rβγ alone.[66] For example, IL-15Rα-deficient NK cells develop in bone marrow (BM) chimeric mice in which IL-15Rα-deficient BM was used to reconstitute IL-15Rα-sufficient animals,[67] indicating that IL-15Rα on another cell can allow IL-15Rα-deficient NK-cell development. In certain inflammatory situations in vivo, DC presentation of IL-15 in *trans* can enhance NK cell responses (also known as priming).[31,68] In DCs expressing both IL-15 and IL-15Ra, the IL-15Ra chain provides a chaperone function to stabilize receptor-cytokine complexes on the cell surface.[69] Taken together, *trans* presentation of IL-15 may be physiologically important to NK cell function.

SELECTIVE NATURAL KILLER CELL SURFACE MARKERS

The constitutive expression on NK cells of IL-15R complex with IL-2Rβ has practical usefulness because anti-IL-2Rβ (CD122) is sometimes used to identify naïve CD3- NK cells or deplete them in mice,[70] but anti-CD122 is less useful during an ongoing immune response and CD122 is expressed on regulatory T cells. Anti-IL-15Rα antibodies have not been widely used. Other markers have proven to be more useful for analysis of NK cells.

In the mouse, the NK1.1 molecule is an especially important marker on NK cells in C57BL strains.[11] NK1.1 is an activation receptor encoded by *Nkrp1c* (*Klrb1c*),[71] a member of the *Nkrp1* gene family (see following discussion). In FACS sorting experiments, the NK1.1+ fraction contained all of the natural killing activity in the spleen.[72] In vivo administration of the anti-NK1.1 mAb PK136[73] completely abrogated natural killing but did not affect adaptive immune responses[74]

(mAb PK136 is available from the American Type Culture Collection [ATCC], Manassas, VA [HB-191] and is an IgG2a isotype [ATCC, and data not shown], not IgG2b as originally described[73]). While mAb PK136 is very efficient at NK-cell depletion and is widely used for this purpose, unfortunately it recognizes an epitope on NK1.1 that is confined to C57BL/6, C57BL/10, and a few other strains.[73] Moreover, in Swiss, NIH and SJL/J mice, mAb PK136 recognizes another NKRP1 family member, NKRP1B.[75,76] However, there are now available NK1.1+ congenic strains, such as BALB.B6- *Cmv1*^{r} (catalogued as C.B6-*Klra8*$^{Cmv1\text{-}r}$ /UwaJ, stock number 002936 at The Jackson Laboratory, Bar Harbor, ME) in which the C57BL/6 allele of NK1.1 has been genetically bred onto the BALB/c background that otherwise lacks the NK1.1 epitope.[77] Similarly, the NK1.1 allele has been introgressed onto the nonobese diabetic (NOD) background.[78]

A subpopulation of T cells expresses NK1.1, described in detail in another chapter 18. These "natural killer T (NKT) cells" express the TCR/CD3 complex and typically are restricted by the nonclassical MHC-I molecule, CD1, which presents glycolipid antigens to NKT cells. NKT cells respond early during the course of an immune response and may potently activate conventional NK cells.[79] Nonetheless, NKT cells can be distinguished from conventional NK cells by expression of the CD3 complex (ie, conventional NK cells are NK1.1+ CD3-).

The NKG2D (Klrk1) activation receptor is expressed on all NK cells in human and all strains of mice examined.[80] In humans, NKG2D is also expressed on all γδTCR+ and CD8+ T cells, whereas in mice, NKG2D is expressed on most NKT and γδTCR+ T cells but not on resting CD8+ T cells.[81,82,83] However, essentially all activated mouse CD8+ T cells express NKG2D. In both humans and mice, CD4+ T cells do not express NKG2D, but it is found on a subset CD4+CD28- T cells in patients with rheumatoid arthritis.[84] Blocking anti-NKG2D mAbs and NKG2D-deficient mice have been described.[80,85,86,87] Regardless, conventional NK cells are NKG2D+ CD3-.

The NKp46 (Ncr1) activation receptor appears to be expressed on all CD3- NK cells in humans and all strains of mice. However, recent reports indicate expression of NKp46 on immune cells in the gut that may be developmentally distinct from conventional NK cells.[88,89,90,91,92] Moreover, depleting anti-NKp46 mAbs have not been described, limiting its usefulness for in vivo functional experiments. Nonetheless, recently developed mice may allow other approaches, such as a mouse where a green fluorescent protein (GFP) cassette was inserted into *Nkp46* and two different transgenic (Tg) mice with a *Nkp46* promoter contruct for expression of Cre or diptheria toxin receptor.[93,94,95]

The mAb DX5 recognizes a molecule that is coexpressed on most NK1.1+ CD3- cells and on small populations of splenocytes in NK1.1- strains, consistent with identification of NK cells in all strains. However, mAb DX5 recognizes the α2 integrin that is widely expressed on other leukocytes, not just NK cells,[96,97] and its expression is regulated.[98] Nevertheless, the DX5 epitope has been used to identify NK cells in mouse strains that do not express NK1.1, but it has been largely supplanted by other nonpolymorphic markers such as NKp46.

The glycolipid determinant asialo-GM_1 is expressed by most if not all murine NK cells and a subpopulation of T cells.[99,100,101] Although the functional significance of this molecule is unknown, polyclonal rabbit anti-asialo-GM_1 (Wako Chemicals USA, Richmond, VA) has been used to effectively deplete NK cells. In more recent studies, the anti-NK1.1 mAb PK136 has become the reagent of choice for NK-cell depletion because of an available defined mAb and its more restricted reactivity with NK cells.[11,72,73,74] However, anti-asialo-GM_1 remains in use for NK-cell depletion when anti-NK1.1 cannot be employed.[73]

In addition to NKG2D and NKp46, human NK cells selectively express CD56. Although it is also found on neural tissues and some tumors, CD56 is generally not expressed by other hematopoietic cells or lymphocytes.[102,103,104] This 140 kDa molecule is derived from alternative splicing of the gene encoding neural cell adhesion molecule (NCAM) involved in nervous system development and cell-cell interactions.[105,106] CD56 may be involved in adhesion between NK cells and their targets,[107] but this function is controversial. Curiously,

mouse CD56 is not expressed on hematopoietic cells,[108] indicating that its role on NK cells is not conserved. Nevertheless, CD56 is particularly useful as a pan-NK-cell marker in humans.

Human NK cells can be functionally divided according to the level of CD56 expressed.[103,109] Most human peripheral blood NK cells are $CD56^{dim}$, a phenotype associated with more cytotoxicity and less cytokine production than a smaller subset of NK cells that express CD56 at higher levels ($CD56^{bright}$). These cells also tend to differentially express receptors involved in target recognition as well as CD16. The $CD56^{bright}$ cells may undergo a maturation process to become $CD56^{dim}$ cells[110] and may be related to a subset of NK cells identified in mice, termed “thymic” NK cells.[111]

Other molecules selectively expressed on NK cells are better discussed below under the general topic of NK cell receptors because they are molecularly defined and their ligands are known.

A MOLECULAR DEFINITION OF NATURAL KILLER CELLS?

A precise molecular definition of NK cells has been elusive. There are no known molecules that are exclusively expressed on NK cells and are responsible for critical functions only displayed by NK cells. The NK cell is therefore still defined by function to the exclusion of other cells, a concept first articulated 25 years ago.[11]

The defining functional feature of NK cells remains their intrinsic ability to perform natural killing (ie, they spontaneously lyse certain tumor cells in a perforin-dependent manner). Unlike other lymphocytes, NK cells do not express surface immunoglobulin or the TCR/CD3 complex, and generally do not require MHC-I expression on targets for lysis. Therefore, a current working definition is that an NK cell is a sIg^-, $TCR/CD3^-$ lymphocyte that can mediate perforin-dependent natural killing against targets that may lack MHC-I expression.

It is noteworthy that T cells were historically defined by an awkward functional definition (thymus-derived, sIg^- lymphocytes responsible for cell mediated immunity).[112]

With the molecular definition of the TCR and coexpressed CD3 molecules, immunologists can now define a T cell as a cell expressing the TCR/CD3 complex.[113] The availability of molecular probes and mAbs directed against this complex provides precise definition even in pathologic tissue sections, without the need for functional analysis (cell mediated immunity, thymus dependence). Similarly, a molecular definition should permit unequivocal identification of NK cells to define their role in normal immune responses and pathologic settings.

Presumably, such a definition will require further knowledge of the molecular basis for NK-cell function, such as the receptors involved in natural killing. On the other hand, one difficulty is that the function that is most attributed to NK cells, natural killing, can be displayed by other cells, such as cytokine-treated T cells. Moreover, NK cells can utilize more than one receptor for target recognition, and individual NK cells can simultaneously express several of these receptors. Thus, there is, as yet, no consensus on the elusive “NK-cell receptor” analogous to the TCR, and the general sentiment in the field is that there is unlikely to be such a receptor.

In the absence of a precise definition, most investigators currently consider the following phenotypes to be surrogate markers of bona fide NK cells. Mouse NK cells are typically NK1.1+ (in appropriate strains), FcγRIII+ (CD16), CD122+, and CD3-. Human NK cells are generally CD56+ and CD3-. In general, mouse and human NK cells also express NKG2D and NKp46, with caveats as elaborated previously.

Note that these markers are generally correlated with cells having natural killing capacity but the markers themselves are not required for natural killing. It should be emphasized that these phenotypes can lead to some confusion due to expression of other molecules on NK cells that are used to help define other immune cells. For example, NK cells express B220 (CD45R) that is often used as a B-cell-specific marker; CD19 is more reliable to distinguish B cells from NK cells.[114] Similarly, NK cells express CD11b, first described as Mac-1 on macrophages.[98] Moreover, NK cells express CD11c, a marker used to define certain DC populations, leading to publications describing a novel type of DC, termed killer DCs.[115,116] However, detailed investigation suggests that these cells are developmentally unrelated to DCs and are actually activated NK cells.[117,118,119] Therefore, markers associated with NK-cell function have been extremely useful in shaping our current concepts of NK cell biology and elaborate their effector functions, but caution may be necessary to avoid confusion with other immune cells.

EFFECTOR FUNCTIONS OF NATURAL KILLER CELLS

Cytotoxicity

A hallmark of NK-cell effector function is target killing, mediated by a process termed granule exocytosis that can be initiated by exposure to susceptible targets or cross-linking of specific activation receptors. Like CTLs, NK cells possess preformed cytoplasmic granules that resemble secretory lysosomes with properties of both secretory granules and lysosomes.[120] Granule formation is affected by Lyst, the molecule defective in humans with Chediak-Higashi syndrome[121,122] in which enlarged lysosomes are observed apparently due to decreased lysosome fission.[123] Normal granules contain perforin and granzymes (granule enzymes). Perforin, a pore-forming protein, is rendered inactive by association with calreticulin and serglycin, and is activated by a cysteine protease.[124] Granzymes are first produced as inactive proenzymes that are activated by N-terminal cleavage by dipeptidyl peptidase I, also known as cathepsin C. However, granzymes are rendered inactive by the acidic pH of the granules. Upon activation by a sensitive target, NK (and T) cells are triggered to rapidly polarize the granules and reposition the microtubule organizing center toward the target in a dynein-dependent manner.[125] The granule membrane ultimately fuses with the plasma membrane, and externalizes, releasing granule contents. Calcium-dependent polymerization of perforin results in “perforation” of the target cell plasma membrane, and granzyme entry by an as yet incompletely understood process. A recent study suggests that perforin induces a plasma membrane repair process that results in endocytosis of perforin and granzymes into enlarged endosomes, called “gigantosomes.”[126] Perforin pores in the gigantosome membrane then allow delivery of granzymes that mediate cleavage of caspases and Bid, ultimately leading to target cell apoptosis.[127]

Recently, many details of the granule exocytosis pathway have come from studies of the heterogeneous human disorder, hemophagocytotic lymphohistiocytosis (HLH).[128,129] In particular, genetic studies of heritable HLH, termed familial HLH (FHL), led to identification of the first described FHL mutation in the perforin gene (*PRF1*), responsible for FHL2. Studies of patients with FHL without *PRF1* mutations led to discovery of other genes whose products (MUNC13-4, syntaxin 11, MUNC18-2) affect granule exocytosis by cytotoxic lymphocytes. Fusion of the cytolytic granule with the plasma membrane requires vesicular RAB27a, a member of the small GTPase superfamily. Defects in RAB27a are associated with the human disorder Griscelli syndrome, type 2. Mice have been described with defects in granule exocytosis components including LYST (*beige*), perforin (*Pfn1-/-*), Unc13d (equivalent to MUNC13-4, also known as *Jinx*), and Rab27a (*ashen*). As highlighted by the names of the mutant mice, many mutations of molecules in the granule exocytosis pathway are associated with skin pigment changes because these molecules also affect melanosomes in melanocytes.[130]

Human T and NK cells also express another pore-forming molecule, granulysin, that is related to a family of saposin-like proteins.[131] Based on crystallographic studies, these molecules appear to be active against bacteria, fungi, and tumor cells by charge association with target membranes and subsequent disruption, leading to target cell lysis.[132] Granulysin is contained in cytolytic granules containing the other cytolytic proteins, such as granzymes.[133] In a perforindependent manner, granulysin causes target apoptosis but is not expressed in mouse cytotoxic lymphocytes.[134]

NK-cell cytotoxcity can be demonstrated in several related ways. Natural killing refers to the process by which NK cells kill certain tumor targets without need for prior host sensitization with the target. Natural killing was first

assessed with a simple in vitro assay for target membrane integrity that is still used today, the standard ^{51}Cr-release assay.[135] The prototypical NK-sensitive tumor target for mouse NK cells is YAC-1 (TIB-160 from ATCC), a thymoma derived from Moloney virus-infected A strain mice, whereas the standard human target is K-562 (CCL-243 from ATCC), an erythroleukemic cell line derived from a human patient with chronic myelogenous leukemia in blast crisis.[136] Maximal killing by enriched, IL-2-activated NK cells usually occurs with effector:target (E:T) ratios of <10:1 whereas unfractionated, freshly isolated peripheral blood or splenocyte preparations usually require E:T ratios of >100:1. Even at high E:T ratios, not all targets are killed, with percentagespecific cytotoxicity typically ranging from ~10% with fresh NK cells to ~80% with activated NK cells. Note that perforin-dependent leakage of ^{51}Cr from the targets is mostly complete within about an hour; 4-hour assays are standard. Longer periods may reflect other apoptotic processes, such as Fas-induced apoptosis.

While ^{51}Cr release is still the gold standard, there are also numerous nonradioactive tests for perforin-dependent killing, including release of intracellular enzymes or use of fluorochromes for target labeling.[137,138,139] The release of granule components, including granzymes, into the supernatant can be determined by conversion of an appropriate substrate, such as granzyme A-mediated cleavage of alpha-N-benzyloxy-carbonyl-L-lysinethiobenzyl ester (also

known as BLT-esterase activity).[140]

A particularly useful new flow cytometric assay exploits the orientation of lysosomal-associated membrane protein-1 (LAMP-1, CD107a) on the luminal side of cytotoxic granules in unactivated NK cells. During granule exocytosis, the granule fuses with the plasma membrane, resulting in externalization of the granule membrane and exposing CD107a on the external surface of the plasma membrane as an indicator of NK-cell activation.[141,142,143] By contrast to other methods, the CD107a assay provides the opportunity for measuring NK-cell responses at the single cell level, isolating triggered NK cells,[144] and possibly simultaneously assessing other NK-cell functions.

Activated NK cells and CTLs also induce perforin-independent target cell killing by expressing Fas ligand (tumor necrosis factor [TNF] superfamily 6) that binds Fas (TNF receptor superfamily 6, TNFRSF6) on the target, triggering apoptosis.[145,146,147,148,149,150] Similarly, other TNF superfamily members, such as TNF-related apoptosis-inducing ligand (TRAIL TNFSF10), can be involved in related processes.[151] However, mice deficient in TNF family members or their receptors may manifest significant alterations in lymphoid organogenesis and splenic architecture, and NK cell number and function,[152,153,154] such that the relative contributions of these pathways to NK-cell function are incompletely understood. Moreover, NK cells from mice deficient in perforin, granzymes, or molecules involved in granule formation or exocytosis demonstrate profound defects in natural killing in vitro.[155,156,157,158] Similar defects have been found with NK cells derived from patients with deficiencies in granule exocytosis.[128] Thus, the available data strongly suggest that granule exocytosis is the predominant mechanism for natural killing.

In addition to natural killing, cytotoxicity by NK cells can be triggered by deliberate cross-linking of activation receptors (discussed in greater detail in the “Activation Receptors” section). Plant lectins can also trigger target killing.[159] In general for all stimuli, cytotoxicity occurs via granule exocytosis and can be measured with the same assays for natural killing.

Cytokine Production

When exposed to NK-sensitive targets or cross-linking of receptors, NK cells also produce cytokines, including IFNγ, TNFα, and granulocyte-macrophage colony stimulating factor (GM-CSF).[160,161,162] They can also be similarly triggered to produce chemokines, such as RANTES, lymphotactin, MIP-1α, and MIP-1β.[163] Moreover, NK cells produce cytokines in response to other cytokines. For example, in response to IL-12, NK cells produce IFNγ.[164] Similarly, NK cells respond to type I IFNs (IFNα/β) produced by DCs stimulated by in vivo administration of poly-I:C and other ligands for TLR and nucleic acid sensors.[165] Cytokine-stimulated responses may obscure detection of specific activation by activation receptors in vivo.[163,166]

While cytokine production can be indirectly measured with RT-PCR for mRNA, it should be noted that resting NK cells typically already express abundant levels of cytokine mRNA even though the proteins are not synthesized,[167] as described previously for granule components

in mouse NK cells.[29] Enzyme-linked immunosorbent assays (ELISA) of tissue culture supernatants are often used, but recent studies have utilized intracellular staining of cytokines, such as IFN, for analysis of individual NK-cell responses that may be more informative, akin to use of the CD107a degranulation assay.[168]

In immune responses, NK-cell production of cytokines should occur relatively early and may thereby influence the subsequent adaptive immune response. Moreover, their responses to cytokines are regulated by complex interacting pathways.[169] A fuller description of NK-cell cytokine responses and production is provided in the following sections on NK cell responses during infections and interactions with DCs.

NATURAL KILLER CELL RECOGNITION OF TARGETS

Molecular dissection of NK-cell recognition of their targets opened new frontiers in NK-cell biology because it not only explained target recognition but it led to identification of receptors that are selectively expressed on NK cells. In addition to providing molecular tools for detailed studies of NK cell function, this analysis yielded several surprises. In contrast to CTL recognition: 1) NK cell receptors are germline encoded and are not strictly "clonotypic" as defined in terms of clonotypic TCRs (unique receptor only expressed by the rare effector clone and its progeny); 2) individual NK cells express both inhibitory and activation receptors for target recognition, and often simultaneously express several different receptors of each type; 3) the receptors are often promiscuous and may have overlapping ligand specificities; and 4) NK-cell receptors specifically bind MHC-I molecules but they are functionally and structurally distinct from other

receptors that bind MHC-I (ie, TCR and CD8). In the following sections, we will discuss NK-cell receptors involved in target recognition by first considering the relationship between target susceptibility to natural killing and expression of MHC-I.

Target Cell Major Histocompatibility Complex-I and Natural Killer Cells: The "Missing-Self" Hypothesis

Whereas initial studies suggested that natural killing was "non-MHC-restricted,"[11] substantial progress in understanding NK-cell recognition began with ascertaining the role of MHC-I molecules in natural killing (Fig. 17.1). Kärre and colleagues discovered that MHC-I-deficient tumors remained susceptible to in vivo rejection, apparently by NK cells.[170] Conversely, target cell expression of MHC-I molecules appeared to have a protective effect against NKcell -mediated lysis in vitro. A number of methods, such as IFNγ treatment, to upregulate MHC-I correlated with target protection but other effects could not be excluded.[171] There was significant variability in capacity of specific MHC-I molecules to protect targets[172,173]; in vitro culture conditions could influence NK-cell specificities,[174] and the specificities of individual human NK cell clones were not easily assignable to specific MHC-I alleles.[175] Thus, the MHC-I effect on natural killing was controversial for some time.

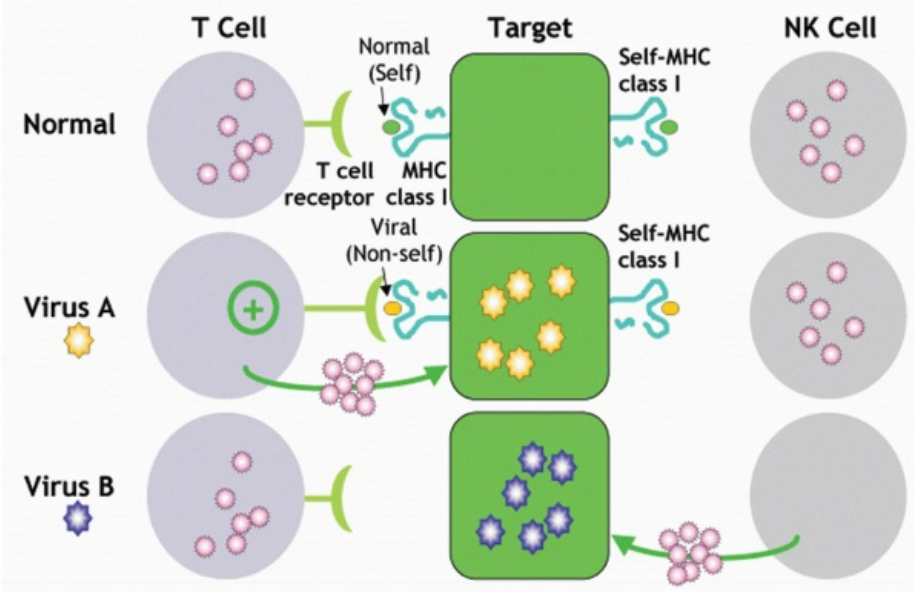

FIG. 17.1. Major Histocompatibility Complex (MHC)-I Expression on Targets is Inversely Related to Natural Killing. Targets expressing MHC-I are more resistant to lysis by natural killer (NK) cells than targets lacking MHC-I expression. This is the exact opposite of the requirements for MHC-I-restricted cyotoxic T-lymphocytes that recognize foreign peptides presented by MHC-I. As depicted, T cells can recognize virus-infected cells, but some viruses may evade T cells by downregulating MHC-I. These infected cells then become more susceptible to NK cells, which generally tend not to discriminate between self- and viral-peptides, though there are some peptide contributions to NK recognition as described in the text.

Several groups, however, observed that MHC-I-expressing parental targets were resistant to natural killing, whereas mutants selected for absence of MHC-I expression became susceptible. The parental (resistant) phenotype could be restored by reconstitution of MHC-I expression by transfected expression of molecules to correct the defect, be it β_2-microglobulin (β2m)[176] or transporter associated with processing (TAP).[177,178] Studies utilizing mice with a targeted mutation in the β2m gene added substantial support to the MHC-I protective effect, as normal expression of MHC-I heavy chains requires β2m.[179,180] β2m-deficient lymphoblasts were susceptible to lysis by normal NK cells. Moreover, β2m-/- BM transplanted into otherwise syngeneic normal hosts was rejected by recipient NK cells.[180,181] These results resembled hybrid resistance whereby NK cells in irradiated F_1 hybrid mice reject parental BM transplants.[182] Hybrid resistance is regulated by parental determinants that are genetically linked to the MHC-I region, H-2D.[183] Thus, in several distinct NK-cell recognition systems, the target cell expression of certain MHC-I molecules correlated with resistance to

natural killing whereas absence of MHC-I was associated with susceptibility to NK cells.

NK cells, therefore, have a different relationship to target cell MHC-I molecules than MHC-I-restricted CTLs (see Fig. 17.1). Strictly speaking, NK cell lysis is “non-MHC-restricted,”[11] at

least as far as MHC restriction is precisely defined for T cells having a requirement for specific self-MHC molecules presenting a given peptide antigen.[184] However, the term "non-MHC-restricted" (and its synonyms) is now somewhat outdated because it implies, when viewed in a broader sense, that MHC plays no role in NK-cell cytotoxicity. Avoidance of these terms will minimize confusion concerning the relationship of target cell MHC-I molecules with NK-cell specificity.

As initially observed and discussed by Kärre in the "missing-self" hypothesis, the relationship between target expression of MHC-I and resistance to natural killing highlights a fundamental distinction between NK and T cells[185] (see Fig. 17.1). Whereas T cells are triggered by detection of "foreign" epitopes, Kärre proposed that NK cells are equipped to detect the absence of "self" epitopes. The [missing-self] hypothesis suggests that NK cells survey tissues for expression of MHC-I molecules that are normally ubiquitously expressed and that somehow prevent NK-cell activity. If MHC-I molecules are downregulated or mutated, NK cells can then lyse the target. The generally opposite requirements of NK and T cells for target cell MHC-I expression may be physiologically important. Several pathogens, including herpes viruses, possess mechanisms that prevent the normal expression of MHC-I molecules on infected cells, providing means to avoid MHC-I-restricted T cells.[186] Moreover, tumorigenesis is frequently associated with alterations in MHC molecules, either mutation in structural genes or decreased expression, again leading to escape from T-cell surveillance.[187,188,189] In either case, however, the MHC-I-deficient cells should become more susceptible to natural killing. The host, therefore, is endowed with two components (T and NK cells) with opposing requirements for self-MHC-I expression. This fail-safe system should eliminate pathologic processes that might otherwise evade immune responses by any alteration of MHC-I expression (either increased to avoid NK cells or decreased to avoid T cells). The missing-self hypothesis thus provided a tentative physiologic explanation for MHC-I-associated resistance, creating a framework for initial attempts to define NK-cell recognition of their targets.

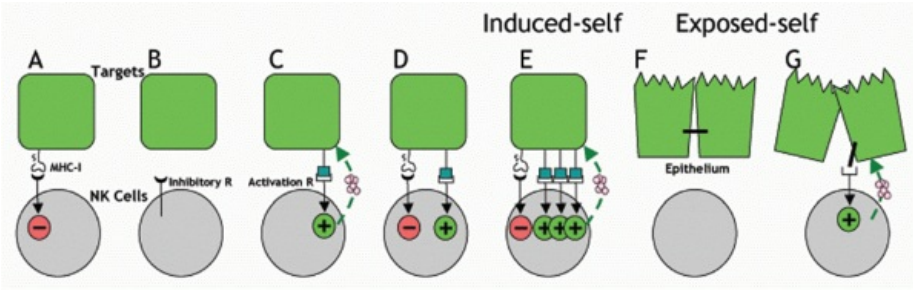

FIG. 17.2. Current Principles of Target Recognition by Natural Killer (NK) Cells. Pictured are several scenarios of interactions between ligands on targets (*top row*) and receptors on NK cells (*bottom row*). Successful activation of NK cells is shown by the *dashed upward line*. **A:** Targets expressing majoe histcompatibility complex (MHC)-I are resistant to lysis by NK cells because of MHC-I-specific inhibitory receptors. **B:** The absence of MHC-I (or lack of receptors specific for target MHC-I, not depicted) does not

automatically result in target killing. **C:** Activation receptor engagement is required to trigger target killing in absence of MHC-I. **D:** In the situation where both inhibitory and activation receptors are engaged, the inhibitory receptor effect often dominates and no killing occurs. **E:** In the induced-self model, induced expression of NKG2D ligands can overcome the inhibitory influence of MHC-I, resulting in NK cell activation. **F:** Normal epithelium masks ligands for NK-cell activation receptors at the tight junctions. **G:** Under pathologic situations, the epithelial architecture may be disrupted, leading to ligand exposure. (Not depicted are inhibitory ligands at the epithelial tight junctions that may inhibit NK cells when they transmigrate through epithelial barriers.) NK cells can also recognize pathogen encoded ligands on infected cells (not shown, but similar to *C* or *E*).

Current Principles of Target Recognition by Natural Killer Cells

The MHC-I-associated resistance to natural killing inspired a panoply of models and their variants to explain not only resistance but also natural killing.[172] The *target interference* or *masking* model predicted that a single NK-cell receptor activates natural killing when it engages its putative target cell ligand.[185] MHC-I molecules mask the putative target cell ligand and block its recognition by the NK-cell receptor. This hypothesis was initially favored because it was the simplest.[190] Moreover, it made the most sense if one considered that NK cells should have only one defined receptor analogous to the TCR. The *effector inhibition* or *inhibitory receptor* model suggested that NK cells are inhibited from natural killing by an NK-cell receptor that binds MHC-I on the target and delivers negative signals overriding a default pathway of activation.[185]

Although the target interference model has not been refuted, it is now known that NK cells express inhibitory receptors that physically bind MHC-I in a manner that may be influenced by MHC-bound peptides[191] (Fig. 17.2).

All known inhibitory receptors contain cytoplasmic immunoreceptor tyrosine-based inhibitory motifs (ITIMs) consisting of V/I/L/SxYxxL/V (single amino acid code where x is any amino acid).[192] Ligand engagement leads to phosphorylation of the ITIM, which leads to inhibition, traditionally thought to be due to recruitment and activation of intracellular phosphatases, although recent evidence suggests more complexity.

MHC-I inhibitory receptors on NK cells have either of two general structures[193]: 1) C-type lectin-like receptors that are disulfide-linked dimers with type II transmembrane topology (extracellular carboxyl termini). These receptors are encoded in the NK gene complex (NKC) and were first described in mice. 2) Immunoglobulin (Ig)-superfamily receptors that have type I transmembrane orientation. These molecules are encoded in a different genetic region, termed the leukocyte receptor complex (LRC), and were first described in humans. Although ongoing studies indicate that both structural types of receptors are expressed on mouse and human NK cells, the lectin-like receptors (Ly49 receptors) are the major MHC-specific inhibitory receptors in mouse whereas the Ig-like receptors (killer Ig-like receptors [KIRs]) predominate in human.

The absence of MHC-I does not always result in killing, indicating that release from inhibition

does not result in activation by default (Fig. 17.2B). Instead, it was suggested that NK cells express two functionally different receptors for target cell ligands.[194,195] In this *two receptor model*, one receptor triggers activation upon ligand binding (Fig. 17.2C) whereas the MHC-I-specific receptor inhibits activation by negative signaling. In many circumstances, the inhibitory receptor effect dominates over the activation receptor (Fig. 17.2D), but the outcome usually reflects the integration of signals from both types of receptors, which can be affected by ligand expression or affinities (not shown).

Many, but not all, NK-cell activation receptors are encoded in the NKC and LRC, having similar structural properties as their inhibitory receptor counterparts except for absence of cytoplasmic ITIMs. The activation receptors typically do not have signaling motifs in their cytoplasmic domains but contain charged transmembrane residues that facilitate association with reciprocally charged residues in the transmembrane domains of signaling chains having immunoreceptor tyrosine-based activation motifs (ITAMs) analogous to ITAMs in TCR and B-cell receptor (BCR) complexes (D/ExxYxxL/Ix$_{6-8}$YxxL/I). NK cells express three ITAM-containing signaling chains: CD3ζ, FcεRIγ, and DAP12 (DNAX associated protein of 12 kDa, also known as killer activating receptor-associated protein, KARAP; Ly83; tyrosine kinase binding protein, Tyrobp). NK cells also express DAP10 (hematopoietic cell signal transducer, Hcst) that lacks ITAMs and instead contains a motif for recruitment of phosphatidylinositol 3-kinase (PI3K) and Grb2. The signaling chains typically provide two major functions: facilitate cell surface expression of the associated activation receptor, and transduce signals.

To date, the ligands for activation receptors fall into several major groups. One group is encoded by the host and is expressed normally. Presumably, NK-cell attack against cells expressing these ligands is limited by inhibitory receptors (Fig. 17.2D). Another group of ligands is characterized by their relatively low expression on normal tissues and induced expression under “stress” conditions (Fig. 17.2E). Other ligands become exposed when tissue architecture is altered (Fig. 17.2F,G). Because the ligands are encoded in the normal host genome, they would be recognized by the NK cell as indicators of pathologic conditions, either as “induced-self” or “exposed-self,” respectively. Another group of ligands is found on infected cells and is encoded by the pathogen (not shown but similar to Fig. 17.2C or E).

Finally, many other NK-cell receptors have been discovered that do not fall neatly into the categories described here. Some appear to have similar inhibitory function as the MHC-specific inhibitory receptors but bind non-MHC ligands, strongly suggesting MHC-independent self-recognition. The function of these and other receptors remains under intense investigation.

NATURAL KILLER CELL RECEPTORS

In the following sections, we will describe the major receptors on NK cells in detail by first discussing the MHCspecific inhibitory receptors that helped elucidate NK recognition paradigms before delving into MHC-independent inhibitory receptors, activation receptors, and other receptors found on NK cells. Given the large number of receptors now identified (Table 17.1), this section will primarily discuss work on the receptors that have been studied most extensively. This summary will illustrate the experimental approaches that led to identification of these receptors, their features, and outline general principles applicable for study of other receptors that will not be discussed in detail due to space constraints. Nonetheless, description of the major activation receptors and their ligands help illustrate and

provide molecular handles on the various functions of NK cells.

Inhibitory Natural Killer-Cell Receptors Specific for Major Histocompatibility Complex-I Molecules

The mouse and human MHC-specific inhibitory receptors are remarkably different in protein structure. Each will be discussed separately.

Mouse Ly49

The Ly49A receptor was the first inhibitory MHC-I-specific NK-cell receptor to be described in molecular terms.[191,196] Ly49A was originally identified as a molecule of unknown function on a T-cell tumor.[197,198] It is a disulfide-linked homodimer (44 kDa subunits) with type II membrane orientation, and C-type lectin superfamily homology.[199,200] Previously termed Ly49, it is now appreciated that Ly49A (Klra1) belongs to a family of highly related molecules.[195,201,202,203] Indeed, genetic analysis revealed that the genes for Ly49A and NK1.1 are linked in the NKC (Fig. 17.3), leading to studies indicating that Ly49A is constitutively expressed on a distinct subpopulation (20%) of NK cells in C57BL/6 mice.[203]

CD96	X		A	Tactile	necl-5

CRTAM	X	A	necl-2
TIGIT	X	I	PVR, PVRL2

AICL, activation-induced C-type lectin; AIRM1, adhesion inhibitory receptor 1; CRTAM, class I-restricted T-cell-associated molecule; LGL, large granular lymphocyte; NK, natural killer; TIGIT, T-cell immunoglobulin and immunoreceptor tyrosine-based inhibitory motif domain.

a These are the major receptors discovered on NK cells in humans and mice, listed in order of appearance in the text.

Multiple lines of evidence indicate that Ly49A is an inhibitory receptor specific for MHC-I, particularly $H2D^d$: 1) Functional analysis: the Ly49A+ NK-cell subset were equivalent to Ly49A- NK cells in killing several targets, but they could not lyse a large panel of targets that were readily lysed by Ly49A- NK cells. This phenotype was related to MHC-I expression of certain H2 haplotypes on target cells.[191,204,205] Transfected expression of $H\text{-}2D^d$ selectively rendered a susceptible target resistant to natural killing by Ly49A+ NK cells. Moreover, killing through disparate stimuli by Ly49A+ NK cells was also inhibited. 2) Cell binding: Ly49A+ tumor cells bound specifically to immobilized MHC-I molecules[206] and to $H\text{-}2D^d$-transfectants.[207] 3) Antibody blocking: $F(ab')_2$ fragments of mAb directed against either Ly49A or the α1/α2 (but not the α3 domain) of $H\text{-}2D^d$ reversed resistance in killing experiments (permitted lysis) and blocked the cell binding assay.[191,204,206,207] 4) In vivo expression: the apparent level of Ly49A expressed per NK cell was downregulated in MHC congenic and Tg mice expressing $H\text{-}2D^d$.[208,209,210] This was not due to negative selection because the percentage of Ly49A+ NK cells was unchanged. 5) Gene transfer: primary NK cells and T cells expressing a Ly49A transgene and a Ly49A-transfected NK cell line were specifically inhibited by $H\text{-}2D^d$.[211,212] 6) Inhibition by Ly49A is ITIM-dependent, based on gene transfer of mutant Ly49A molecules.[212] 7) $H2D^d$ tetramers bind Ly49A transfectants.[213] 8) Ly49A tetramers bind $H2D^d$ on transfected cells.[214,215] 9) Biophysical studies: recombinant Ly49A binds recombinant $H2D^d$ in surface plasmon resonance (SPR) studies with K_D = ~2.0 μM.[216]

10) Crystallography: the structure of Ly49A complexed with $H2D^d$ was determined.[217] 11) Less extensive studies also indicate that Ly49A recognizes $H\text{-}2D^k$, $H2D^p$, and alleles in $H2^r$ and $H2^q$.[191,208,213,218,219] Therefore, Ly49A is an MHC-I-specific receptor for $H\text{-}2D^d$, $H\text{-}2D^k$, and $H2D^p$, and alleles in $H2^r$ and $H2^q$.

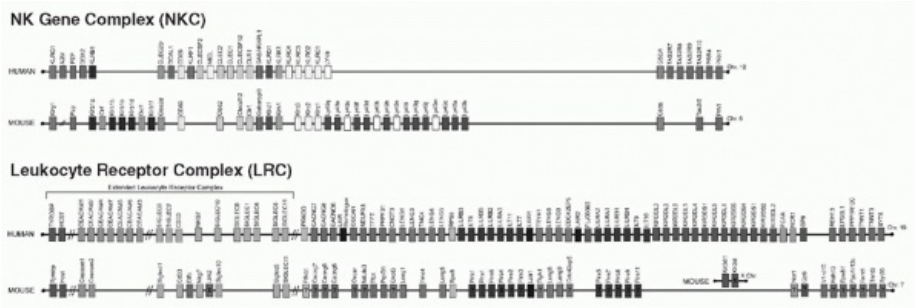

FIG. 17.3. The Genomic Organization of the Natural Killer (NK) Gene Complex and Leukocyte Receptor Complex in Humans and Mice. The figures are not drawn to scale with precise gene locations being modified as new sequence information becomes available (genome.ucsc. edu/ and www.ebi.ac.uk/ipd/kir/). The *grey shading* is coordinated to represent related genes. *Question marks* indicate genes whose precise location is not known. An "*X*" indicates genes not homologous to other aligned genes. *Double slashes* represent large genomic distances. Note that most but not all genes are expressed on NK cells. Many remain orphan genes because the functions of their gene products have not been determined. Modified from Kelley et al.[312]

The nature of the Ly49A interaction with MHC-I, however, is fundamentally different from TCR/MHC-I interactions because the former appears to be relatively independent of the specific peptide bound by $H2D^d$.[220,221] However, bound peptides are required for appropriately folded MHC-I molecules that can be recognized. Despite its structural homology to C-type lectins that are carbohydrate-binding proteins,[222,223] Ly49A does not have the residues for coordinate binding to calcium that is required for lectin binding. Moreover, Ly49A binding to its MHC ligands is not carbohydrate-dependent based on functional, SPR, and crystallographic analyses.[216,224] In the crystallographic structure of Ly49A complexed to $H2D^d$ (2.3Å resolution), the lectin-like structure of Ly49A was confirmed[217] (Fig. 17.4). Two interaction sites were seen between the lectin-like domain of Ly49A and $H2D^d$: site 1 involved the "left" side of the peptide-binding cleft of $H2D^d$ and a wedge-like site 2 involved the undersurface of the peptide-binding cleft. The residues in Ly49A involved in binding either ligand site are overlapping. Mutational analysis revealed that Ly49A binds site 2 where it contacts α1, α2, and α3 of $H2D^d$ and β2m.[214,216,225] This site is near Asn80, an Asn-linked glycosylation site conserved in all MHC-I molecules, leaving open the issue of whether carbohydrates could affect the interaction, such as affinities or kinetic parameters, but this has not been studied in depth. These studies also provide a structural explanation for species-specific β2m requirements as revealed by functional studies.[226] Thus, Ly49A recognizes site 2 in the MHC molecule in terms of *trans* recognition between the NK-cell receptor and target cell MHC-I molecule.

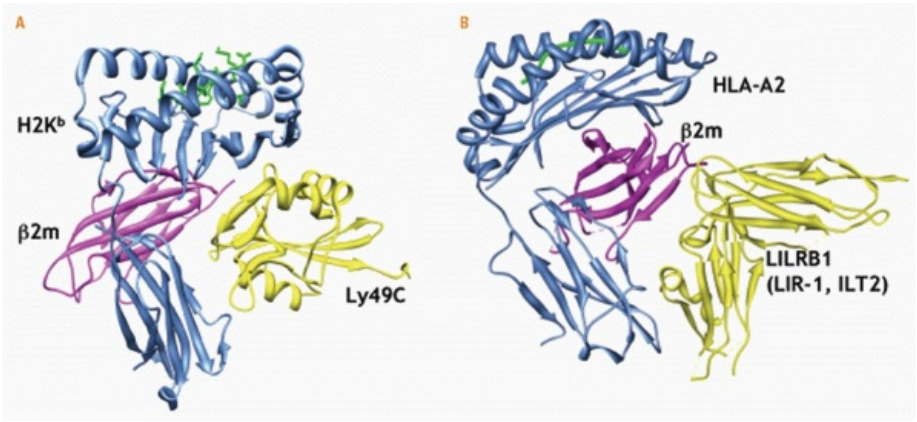

FIG. 17.4. Crystal Structures of Natural Killer (NK)-Cell Receptors in Complex with Their Ligands. A: Mouse Ly49C bound to $H2K_b$ at site 2 (PDB ID = 3C8K).[193,235] Ly49A interaction with site 2 of $H2D^d$ is very similar.[170] Site 1 of Ly49A-$H2D^d$ interaction is approximately located where the $H2K^b$ label is placed. **B:** Human LILRB1 (LIR1, ILT2) bound to human leukocyte antigen-A2 (PDB ID = 1P7Q).[266] Figures were produced using the University of California, San Francisco Chimera package from the Resource for Biocomputing, Visualization, and Informatics at the University of California, San Francisco (www.cgl.ucsf.edu/chimera).[1030] The structures are viewed from the side with the NK cell positioned at the top of the figure and the target cell surface at the bottom. The major histocompatibility complex molecules are oriented similarly.

Most but not all other Ly49 receptors are MHCI-specific inhibitory receptors. First noted by Southern blot analysis and cDNA cloning, genome sequence analysis revealed 15 complete Ly49 genes in C57BL/6 mice.[199,200,201,202,227] There is evidence for alternative splicing and alternative transcriptional start sites for the Ly49 genes, though their importance has not been elucidated.[202,228,229] Notably, Ly49C has broad specificity for H2 alleles, as revealed by tetramer staining, and is the only known inhibitory NKcell receptor specific for an $H2^b$ haplotype allele ($H2K^b$) in C57BL/6 mice, notwithstanding unconfirmed reports that Ly49I also binds $H2K^b$.[168,213,230] Ly49C is recognized by two mAbs: 5E6, which also binds Ly49I, and 4LO3311, which has exquisite specificity for Ly49C.[231,232,233] X-ray crystallographic studies have indicated that Ly49C binds $H2K^b$ in a manner similar to Ly49A interaction with $H2D^d$ (see Fig. 17.4).[234,235] Only a site 2 interaction was seen with the contact residues, showing a similar but distinct topology to the Ly49A-$H2D^d$ interaction. Interestingly, however, peptides bound to $H2K^b$ clearly affect functional interactions with Ly49C[236] and affinities as measured by SPR.[234] However, Ly49C does not directly engage the peptide, indicating long-range effects. Finally, both Ly49A and Ly49C

appear to undergo conformational changes upon ligand binding, and a Ly49 dimer can engage two MHC-I molecules.[235,237] Thus, Ly49 receptors bind their MHC ligands in a

structurally related manner.

Recent studies suggest that Ly49 molecules also can bind MHC in a *cis* interaction between receptor and ligand on the NK cell itself.[168,238] For example, an MHC ligand for Ly49A or Ly49C on the same cell prevents binding of MHC tetramer.[168,238] If the cells are briefly exposed to mild acidic conditions, MHC-I expression is lost (due to disruption of the noncovalently linked MHC-I heterotrimer), and Ly49A binding to cognate MHC-tetramers is restored. This *cis* interaction is dependent on site 2 residues in the MHC molecule. These findings may help explain the observation that the presence of self-MHC ligands leads to downregulation of Ly49 expression, as previously noted on primary NK cells in MHC congenic mice.[208,209,210] *Cis* interactions may also explain functional differences in NK cells in MHC-congenic mice or NK cells that do or do not express MHC ligands in Tg mice that are mosaic for MHC expression.[239,240,241] Finally, there are biophysical data supporting a role for the relatively long, flexible stalk region of Ly49 receptors in allowing either *trans* or *cis* interactions.[242] At the moment, the physiologic importance of *cis* interactions is incompletely understood but may be relevant to NK-cell tolerance and education, as discussed below.

Although they have not been studied as extensively as Ly49A and Ly49C, other inhibitory Ly49 receptors and their ligands have been identified[202,230] and characterized with other MHC allele specificities, as detailed in a recent review.[243] Moreover, they are structurally related.[235,244] Individual NK cells may express multiple Ly49 receptors simultaneously,[210,233,245] often (but not always) two or more, suggesting that individual NK cells may be inhibited by more than one MHC-I molecule.

Ontogenetic studies demonstrate that the total repertoire of Ly49 expression does not reach adult levels until sometime after 3 weeks of age, concomitant with attainment of full NK-cell cytolytic activity.[246] Thereafter, the expression of Ly49 receptors is generally thought to be fixed and stable on an individual NK cell. Ly49E is expressed only on fetal NK cells, but NK cells in mice deficient in Ly49E are otherwise normal.[247] In adult mice, developmental studies indicate that Ly49 receptors are first expressed on immature NK cells in the BM, before a phase of constitutive proliferation[98] that appears to be modestly affected by MHC haplotype.[168] There are only modest effects on the final “repertoire” of MHCspecific receptors expressed by splenic NK cells in different MHC environments.[210,248]

The expression of inhibitory Ly49 receptors appears to occur in a stochastic manner. There is evidence for monoallelic expression of Ly49 receptors (expression from one chromosome), initially described as “allelic exclusion,” a term that has fallen out of favor because it has a specific meaning and mechanism for TCRs and BCRs.[249] At least some Ly49 genes possess bidirectional, overlapping promoters directed in opposite orientations.[250] Transcription factors driving transcription in one direction prevent binding of other factors driving transcription in the opposite direction. Directionality and monoallelic expression may also be controlled by DNA methylation.[251] A “probabilistic” model has been proposed to explain these findings that may also explain the stochastic expression of Ly49 genes and their stable expression. However, recent studies of *Ly49* indicate highly variable transcriptional start

sites, suggesting that the probabilistic model may not be correct.[229] Other data indicate that TCF-1 but not LEF-1 in the T-cell factor/lymphoid enhancer family of DNA-binding proteins affects some but not all Ly49 receptor expression.[252,253,254] Thus, the elements controlling Ly49 gene expression are incompletely understood.

Analysis of the Ly49 receptors thus far is largely based on examination of the C57BL/6 alleles, but the Ly49 receptors display extensive polymorphism. The Ly49 family is encoded in the NKC located on mouse chromosome 6 with the syntenic human region being chromosome 12p13.2[195,203,255,256] (see Fig. 17.3). While the NKC also contains genes for other lectin-like receptors, the Ly49 genes are clustered with the exception of *Ly49b*. Corresponding to restriction fragment length polymorphic (RFLP) variants originally detected with the Ly49A cDNA,[203] there is significant allelic polymorphism of the Ly49 cluster between inbred mouse strains with differences in gene number as well as alleles for the *Ly49* genes.[227,257,258,259] In contrast to C57BL/6J mice, genomic sequence analysis shows 8 putative *Ly49* genes in BALB/c mice, 19 in 129 mice (of which at least 9 appear to be pseudogenes) and 22 in NOD mice. Array-based comparative genomic hybridization analysis of 21 mouse strains compared to the reference C57BL/6J strain indicated that these mice could be grouped into five clusters that correspond to or are predictive of restriction fragment length polymorphic patterns on Southern blot analysis.[203,260] There are also multiple alleles for individual *Ly49* family members.[227,249,257,258,261] Thus, there is significant polymorphism of the *Ly49* molecules at both the haplotype (gene numbers) and individual gene (alleles) levels, not unexpected because the Ly49 molecules bind highly polymorphic MHC-I molecules.

The MHC-I specificities have generally been well characterized for only a few Ly49 alleles. Interestingly, mAbs specific for one Ly49 allele may bind another molecule with a different function or specificity in another mouse strain,[262,263,264] similar to what was recognized for mAb reactivity with different MHC alleles.[265] Thus, the polymorphisms also raise practical issues when studying Ly49 molecules in different mouse strains.

Finally, it should be noted that Ly49 receptors may be expressed by other cells; some are selectively expressed on non-NK cells and some may have specificities for non-MHC ligands. NKT and other T-cell subsets may express Ly49 receptors but they have not been thoroughly studied.[266,267] Ly49B and Ly49Q are not expressed on NK cells; rather, they are expressed on myeloid cells.[268,269] Interestingly, Ly49Q recognizes $H2K^b$ and positively regulates TLR signaling.[270,271] On the other hand, Ly49E appears to recognize urokinase plasminogen activator, though physical binding has not been established.[272] Interestingly, Ly49B, Ly49E, and Ly49Q are predicted to be distinct in fine structure from the

known MHC-I-specific Ly49 receptors on NK cells.[235] Thus, while Ly49 receptors are predominantly NK-cell inhibitory receptors for MHC class I, they may have other roles that are less well understood; still other Ly49 receptors have activation function, as discussed subsequently.

Human Killer Immunoglobulin-like Receptors

In contrast to mouse NK cells, human NK cells can be cloned by limiting dilution in the presence of irradiated feeder cells, phytohemagglutinin, and IL-2, leading to establishment of short-term NK-cell clones that have differences in target killing and surface molecules. mAbs were isolated that reacted specifically with these clones; reactivity correlated with the capacity of the clones to kill certain tumors, and the mAbs affected cytotoxicity. This general approach led to the identification of the human NK-cell receptors.

A series of studies[273,274,275] showed that the mAbs GL183 and EB6 identify serologically distinct 55 kDa or 58 kDa molecules, initially termed p58. These molecules had several features: 1) selective expression on overlapping NK cell subsets; 2) expression on NK cell clones correlated with expression of certain human leukocyte antigen (HLA) class I alleles on resistant targets; 3) a target susceptible to a given NK-cell clone bearing p58 molecules reactive with either mAb was made resistant by transfection of cDNAs encoding certain HLA-C molecules; 4) the otherwise resistant, HLA-C-transfected targets could be lysed in the presence of the appropriate anti-p58 mAbs. The mAb effect occurred with $F(ab')_2$ fragments, suggesting that the interaction between p58 and an HLA class I molecule on the target cell inhibits the NK cell. Thus, the p58 molecules displayed features consistent with a role as inhibitory human NK-cell receptors specific for MHC-I, analogous to the mouse Ly49A receptor that was being studied in parallel, as described previously.

Other studies noted that NK-cell specificity was skewed when the NK cells were grown in the presence of cells bearing allo-MHC determinants.[276,277] This specificity correlated with reactivities that mapped to paired residues at position 77 and 80 in the .α1 domain of HLA-C. All known HLA-C molecules could be divided into two groups, one with Asn77-Lys80 (HLA-Cw2, -Cw4, -Cw5, -Cw6) and the other with Ser77-Asn80 (HLA-Cw1, -Cw3, -Cw7, -Cw8). Indeed, transfection analysis showed that p58 specificity for HLA-C molecules was related to expression of the EB6 epitope for the former (specificity 1, now termed HLA-C1), whereas the latter was related to the GL183 epitope (specificity 2, HLAC2) on the NK-cell clones.[276,278,279] Thus, human NK-cell receptors showed promiscuous specificity that was dependent on residues 77 and 80 in HLA-C.

The NKB1 (p70) molecule was serologically similar to p58 molecules with regard to subset expression, and correlation of expression on NK-cell clones to specificity for HLA class I.[280,281] In contrast to p58 molecules, however, NKB1 had a distinct M_r (70 kDa) and specificity for HLA-B. The NKB1+ clones were specifically inhibited by targets expressing transfected HLA-Bw4 molecules, and the anti-NKB1 mAb reversed the inhibition. Analysis of informative HLA-B alleles showed that this specificity was conferred by a region in the α1 domain overlapping the area on HLA-C recognized by p58 molecules.[282] Finally, HLA-A3, -A11-specific receptors have similar properties to p58 and NKB1 except that they appear to be disulfide-linked dimers termed p140,[283] whereas others have found that a monomeric HLA-A3-specific receptor resembles NKB1.[284] Thus, representative alleles of all classical HLA class I loci are capable of inhibiting NK cells through p58/NKB1/p140 receptors although HLA-B and -C alleles dominate human NK-cell specificities, and it is not yet known if there are receptors reactive with each HLA allele.

When the cDNAs for the p58 and NKB1 molecules were cloned, they were surprisingly found to encode type I integral membrane proteins with Ig-like domains[285,286,287] unlike the

lectin-like Ly49 family of type II receptors. The Ig-like receptors are now collectively known as killer Iq-like receptors (KIRs) or CD158.[288,289] The KIR nomenclature is based on whether the receptor has two or three Ig-like external domains (KIR2D or KIR3D, respectively), and possession of a long (L) or short (S) cytoplasmic domain. In general, the L forms are inhibitory because they contain ITIMs, whereas the S forms appear to be activation receptors (see following discussion). Each distinct receptor is also designated by a number. The KIR2DL1 (CD158a, p58.1) molecule bears the original EB6 epitope and is specific for HLA-C (Lys80, specificity 2), whereas KIR2DL2 (CD158b1, p58.2) and KIR2DL3 (CD158b2, p58) have the GL183 epitope and are specific for HLA-C (Asn80, specificity 1). (As detailed in the following, structural analysis supports grouping of HLA-C alleles into two mutually exclusive groups, HLA-C1 and HLA-C2, based on direct interaction of KIR2DL2/3 and KIR2DL1, respectively, with residue 80 of HLA-C, validating original functional groupings but simplifying HLA-C groupings to just residue 80.[276,277]) KIR2DL4 (CD158d, p49) reportedly binds HLA-G[290] but displays both inhibitory and activation functions.[291,292,293] KIR3DL1 (CD158e1, NKB1, NKAT3) is specific for HLA-A and HLA-B molecules with the Bw4 epitope.[282] KIR3DL2 (CD158k, p140, NKAT4) has HLA-A3 and HLA-A11 specificity.[283,284]

There is unequivocal evidence that the KIR2DL and KIR3DL molecules are inhibitory HLA class I-specific receptors. In addition to the data with NK cell clones and mAbs mentioned previously, the following have been described: 1) KIR bind directly to HLA class I: soluble KIR2DL-Fc fusion proteins bind cells expressing the appropriate transfected HLA class I alleles.[294,295] In addition, a soluble KIR2DL molecule containing only the extracellular domain binds specifically to its HLA-C ligand in solution.[296] 2) Gene transfer of KIR: KIR2DL specificity and inhibitory function were transferred when KIR2DL cDNAs were transiently expressed with vaccinia constructs in human NK-cell clones.[294] Similarly, Tg expression of KIR2DL2 in mice conferred inhibition of rejection of BM expressing Tg HLA-Cw3.[297] 3) SPR measurements indicate that the KIRs bind their HLA ligands with K_d = ˜10 μM.[298,299,300,301] Binding is affected by peptide bound by HLA molecule.[300,301] Through histidine-rich domains, the KIRs bind Zn++, which affects KIR multimerization and binding kinetics to HLA ligands.[302,303] 4) Crystallographic studies demonstrate

KIR2DL1 (2.8 Å resolution) and KIR2DL2 (3.0 Å resolution) interactions with their cognate HLA ligands.[299,304] Thus, KIR molecules are clearly MHC-I-specific inhibitory receptors on NK cells.

Interestingly, structural studies indicate that KIR molecules bind HLA class I molecules in a manner analogous to recognition of MHC by TCRs (Fig. 17.5). In particular, both KIR2DL1 and KIR2DL2 use surface loops near their interdomain hinge regions to bind their cognate HLA-C ligands (Cw4 and Cw3, respectively) with a footprint overlying the “right” side of the peptide-binding cleft (when viewed from the “top” in standard depictions of MHC-I molecules).[299,304] The receptors bind both α1 and α2 helices with interactions between KIR2DL1 and Lys80 of HLA-Cw4 and between KIR2DL2 and Asn80 of HLA-Cw3. These interactions with residue 80 of the HLA-C molecules were lost when the reciprocal residues were swapped, accounting for the previously described HLA-C groupings and KIR

specificities in functional studies[276,277] and mutational analysis indicating that residue 80 is more significant for KIR interaction than residue 77.[305,306,307,308] Although neither KIR2DL molecule has extensive contacts with peptides bound to HLA-C, KIR2DL interactions with HLA-C imposes physical constraints on the p8 position of the peptide. This may account for observed peptide preferences in functional studies and antagonism of certain peptides on KIR inhibitory function.[309,310] A recent structure (1.8 Å resolution) of KIR3DL1 complexed to HLA-B*5701 revealed a similar recognition strategy.[301] Thus, KIRs and Ly49s bind their MHC ligands in markedly different ways, despite their analogous functions as MHC-specific inhibitory receptors.

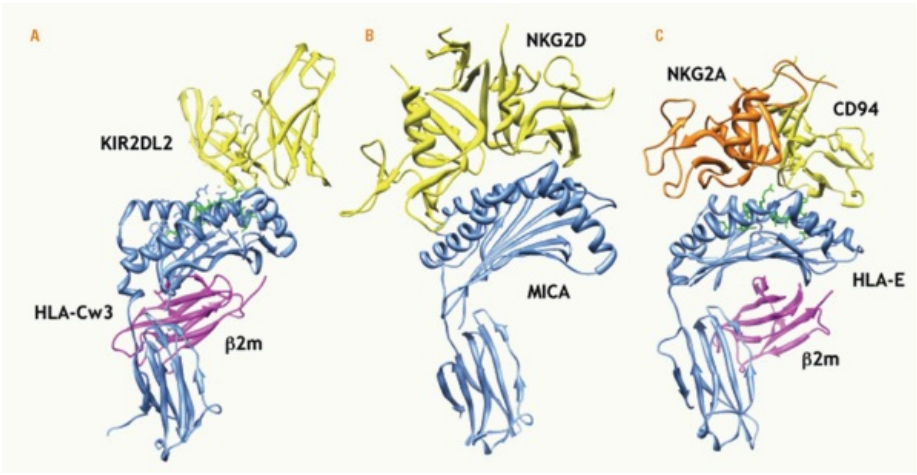

FIG. 17.5. Additional Structures of Natural Killer-Cell Receptors in Complex with Their Ligands. A: Human KIR2DL2 with HLA-Cw3 (PDB ID = 1EFX).236 Two KIR molecules are apparent in the crystal structure with only one molecule (killer Ig-like receptor [KIR] A) contacting the human leukocyte antigen (HLA) molecule. In this view, KIR B molecule is not shown. **B:** Human NKG2D with MICA (PDB ID = 1HYR).[412] **C:** Human CD94/NKG2A with HLA-E (PDB ID=3CDG).[382] The figures were produced and oriented as described in Figure 17.4.

Also unlike the Ly49s, the KIRs are encoded in the LRC on human chromosome 19q13.4 that encodes many other Ig-like receptors (see Fig. 17.3)[311]; the KIR genes are clustered toward the telomeric end of the LRC.[312] Interestingly, the mouse LRC on chromosome 7qA1 does not include genes for KIR-like molecules that instead are encoded on the X chromosome.[313,314] On the other hand, like the Ly49s, the KIRs display remarkable polymorphism with at least 11 genes[315,316,317] (see www.ebi.ac.uk/ipd/kir/index.html for updated database).

The human *KIR* locus also demonstrates considerable haplotype diversity with at least 27 different haplotypes,[315,316,318] recently defined at the sequence level.[317] While there has not been a consensus definition, two major types of haplotypes have been described.[289] Group B contains one or more of the following: *KIR2DL5*, *KIR2DS1*, *KIR2DS2*, *KIR2DS3*,

KIR2DS5, and *KIR3DS1*, whereas group A haplotypes have none of these genes. Reflecting extensive allelic polymorphism of individual genes, a large number of different KIR genotypes have been described, and they are distributed differently in the various ethnic populations.

As with the Ly49s, only a few KIR alleles have been well characterized with respect to HLA class I specificities. Nonetheless, these genetic variants have not only provided clues to new receptors and ligand specificities but also valuable links to the role of NK cells and their receptors in

disease pathogenesis (discussed in the subsequent clinical section), and more broadly, human evolution.

Convergent Evolution of Major Histocompatibility Complex-Specific Natural Killer-Cell Receptors

Despite the controversy surrounding the initial cloning of mouse Ly49s and human KIRs and leukocyte Ig-like receptors (LILRs), additional data have provided new interpretations of the distinctly different receptors used by mouse and human NK cells, respectively, to recognize MHC-I. Detailed genome sequence information is available on the NKC and LRC in mice, humans, and other species. In the mouse, MHC-specific NK-cell receptors with Ig-like domains have not yet been described, although there is conservation of several genes in the broader LRC on mouse chromosome 7[312] (see Fig. 17.3). Activated mouse NK cells do express gp49b (Lilrb4), an Ig-like inhibitory receptor also expressed on other leukocytes, including mast cells.[319,320,321,322] However, it is not expressed by resting NK cells and is not specific for MHC-I. Instead, it binds the integrin αvβ3 and appears more important for responses of other cells, such as neutrophil, eosinophil, and DCs.[323,324,325,326,327,328] Mouse *Kir3dl1* is on the X chromosome (see Fig. 17.3) and expressed in NK and T cells, but its function and ligand remain unknown.[313,314] The Ly49 locus in humans consists only of *LY49L* (*KLRA1*) that is a pseudogene because of a point mutation that gives rise to a splicing abnormality.[329] Thus, current data indicate that mouse NK cells do not express functional KIR orthologues while human NK cells do not express functional Ly49 orthologues.

One reason for this discrepancy may be that the corresponding orthologue is present in the genome but has not been identified. Indeed, genomic sequencing has revealed a multitude of candidate orphan receptors in the genome and specifically the LRC and NKC that have yet to be studied carefully.[311,330] In that regard, identification and functional analyses of NK cell receptors led to the recognition that they are encoded in genomic regions containing gene clusters for related receptors that are expressed on other leukocytes, not just NK cells. Dissection of the expression and function of these receptors is a rich area of research that is beyond the scope of this chapter.

The alternative and currently favored view for the discrepancy is that mice and humans independently evolved analogous receptors to serve the same function. While both human and mouse NK cells express a conserved relatively nonpolymorphic lectin-like receptor, CD94/NKG2, it does not possess many of the features that are shared by mouse Ly49 and human KIRs:

1. both Ly49s and KIRs are constitutively and selectively expressed on naïve, unstimulated

NK cells (with exceptions for rare populations of T cells);

2. both bind MHC-I molecules with intermediate affinity (K^D = 2-10 μM);
3. binding to MHC is promiscuous;
4. MHC-bound peptides have only a modest effect, if at all, on recognition;
5. both use ITIMs to inhibit NK-cell activation;
6. they are expressed in a stochastic fashion on overlapping subsets of NK cells;
7. a single NK cell simultaneously expresses one or more of either type of inhibitory receptor (each may be functional);
8. once they are expressed, their expression appears to be stable;
9. both are germ-line encoded by small families of genes that are clustered in the genome;
10. both display impressive polymorphism, in terms of gene number and alleles for each gene;
11. both are related to molecules that lack ITIMs and instead are activation receptors; and
12. both are involved in NK-cell education by self-MHCI (see following discussion).

Thus, the mouse Ly49 receptors and human KIRs are analogous receptors in an apparently striking example of convergent evolution,[331] whereby each species came up with a different genetic solution to provide extremely important functions for species reproduction and survival.

In other species, *Ly49* and *KIR* genes have been analyzed primarily with respect to sequence and gene number.[332] For example, the *LY49L* gene in baboons appears to be functional but the putative polypeptide lacks an ITIM.[333] In rats, the *Ly49* cluster appears to have markedly expanded with at least 25 genes,[334,335] demonstrating one of the most rapid rates of gene expansion.[336] Dog, cat, and pig appear to have only one *Ly49*, whereas horse represents the only known nonrodent mammal with several *Ly49* genes.[337] The chicken genome has several lectin-like receptor genes that are genetically linked to the MHC.[338,339,340] On the other hand, multiple KIR genes have been described in primates and cattle.[341,342,343,344] Rhesus macaques have a profound plasticity of KIRs with multiple genotypes and haplotypes[345] encoding receptors that bind MHC-I.[346,347] In rat, a KIRlike sequence has been reported,[314] and dogs and cats lack functional KIRs.[348] Interestingly, pigs and marine carnivores each possess a single Ly49 and KIR gene, but it is not clear if these are functional.[348] Finally, several species have no readily identifiable Ly49 or KIR genes[332] (eg, teleost fish instead possess a large number of novel immunetype receptors with sequence homology to mammalian LRC-encoded receptors[349]). Perhaps these species have had alternative convergent evolutionary stratetgies to preserve inhibitory MHC-I-specific receptors.

Additional studies of the Ly49-like and KIR-like molecules as well as potential new orthologues in other species will be of interest to evolutionary biologists for several reasons including prior description of NK-like cells in lower vertebrates and MHC genes that are coevolving.[332,350] Moreover, in primitive chordates, NK-like, missing-self-like recognition

affects histocompatiblity reactions[351] but the molecular determinants of histocompatibility involves molecules unrelated to mammalian Ly49, KIR, or even MHC itself.[352,353,354] Thus, evolutionary studies of NK-cell receptors and their ligands may provide unique insight into missingself and other histocompatiblity reactions.

While we have focused thus far on mouse Ly49 and human KIR as the major MHC-I-specific receptors, there are other well-described NK-cell receptors belonging to

either the lectin-like receptor or Ig-like receptor superfamilies. These receptors also have specificities for MHC-I molecules.

Human and Mouse CD94/NKG2

The analysis of CD94 (Klrd1) and NKG2 (Klrc, excluding NKG2D [Klrk1]) family of molecules was especially challenging and required insightful investigations. Identified by subtractive hybridization, the human NKG2 molecules are type II integral membrane proteins with external C-type lectin domains[355] encoded in the NKC[356] (see Fig. 17.3). Initial attempts to express NKG2 molecules on the cell surface were thwarted. Meanwhile, mAb reactivity suggested that CD94 was variably expressed on human NK cells as a disulfidelinked dimer (70 kDa NR, 43 kDa R),[357] and both activation and inhibition functions for CD94 were described.[358,359,360,361] Surprisingly, cDNA cloning revealed that CD94 has a short seven amino acid cytoplasmic domain, suggesting that it cannot signal on its own.[360] Furthermore, anti-CD94 immunoprecipitates were not detectable from radiolabeled CD94 transfectants, despite easily detectable expression on FACS analysis with the same mAbs.[362,363] These apparent discrepancies were resolved when it became clear that CD94 heterodimerizes with NKG2 molecules[362]; NKG2A is the 43 kDa molecule previously identified as Kp43 with anti-CD94 mAbs.[364,365] While CD94 may be expressed as a homodimer, the NKG2 partner provides the signaling motif, whether activation or inhibition.[364,366] (NKG2B is an alternatively spliced form of NKG2A. The rest of the NKG2 family is discussed in the following.)

The ligand specificity for CD94/NKG2 receptors was also initially thought to be promiscuous as interactions with many classical (class Ia) and nonclassical (class Ib) HLA molecules had been described.[359,362,364,367,368,369,370] However, human CD94/NKG2 receptors directly recognize HLA-E, a MHC-Ib molecule homologous to mouse Qa-1.[371,372,373] HLA-E (and Qa-1) is widely expressed with limited polymorphism.[374,375,376] While HLA-E heavy chain is expressed with β2m and a peptide occupying its peptide-binding cleft, its peptide repertoire is largely derived from the leader sequences of MHC-Ia molecules, as previously noted for mouse Qa-1.[377,378] HLA-E (or Qa-1) expression thus requires normal production of HLA-E (or Qa-1) and synthesis of certain MHC-Ia molecules. Mouse CD94/NKG2 recognizes Qa-1 that shares many features with HLA-E.[379,380] These findings need to be considered in the context of the prevailing view at the time that mouse and human NK cells use structurally different receptors to recognize MHC-I molecules.[381] Clearly, the CD94/NKG2 receptors and their ligands are conserved in humans and mice.

The crystal structure of human CD94/NKG2A bound to HLA-E was resolved to 2.5Å and 4.4Å resolution.[382,383] Remarkably, CD94/NKG2A interfaces with HLA-E in a manner analogous to TCR recognition of peptide-loaded MHC-I,[384] including TCR binding to HLA-E itself.[385] Both innate and adaptive receptors for HLA-E lay across the peptide-binding cleft, though peptide itself plays a relatively minor role in binding CD94/NKG2A.[382,383] Strikingly, this binding is distinct from that of Ly49 receptors to their classical MHC-I ligands (see previous discussion). On the other hand, this binding interface is similar to binding of another NKC-encoded, lectin-like receptor, the NKG2D activation receptor, to its MHC-like ligands (see following discussion). Thus, NKC-encoded, lectin-like receptors surprisingly use different strategies to contact their ligands, even though these ligands have structurally related MHC-I folds.

Despite its conservation between mice and humans, the role of CD94/NKG2 receptors in NK-cell function is still incompletely understood. For example, viruses encode peptides that bind and enhance expression of HLA-E, providing a CD94/NKG2A-dependent mechanism to avoid NK-cell attack.[386,387] By contrast, human NK cells expressing CD94/NKG2C (an activation receptor) expand in response to cytomegalovirus (CMV)-infected targets.[388] When a large number of human NK-cell clones were obtained from two normal individuals, CD94/NKG2 seemed to account for the majority of self-MHC-specific receptors on clones from one individual whereas KIRs dominated the self-specific receptors on clones from the other individual, suggesting that some individuals may depend on CD94/NKG2 for self-tolerance.[389] Qa-1 and HLA-E can present peptides derived from other molecules, including the signal sequence of heat shock protein 60 (Hsp60) that is induced by a number of stimuli,[390,391] a multidrug resistance transporter,[392] or blastocyst MHC expressed in embryonic tissues.[393] This may result in loss or gain of recognition by the inhibitory CD94/NKG2A receptor, suggesting intrinsic mechanisms to perturb inhibition by CD94/NKG2A in certain circumstances.

Yet, CD94 appears to be dispensable in certain strains of mice, such as DBA/2J, that do not appear to have any untoward NK-cell phenotype.[394] This finding has been recapitulated in studies of a CD94 knockout mouse on the 129 strain background.[395] Interestingly, CD94 knockout mice are more susceptible to ectromelia virus,[396] as detailed below.

CD94/NKG2 molecules may be important in T-cell function. CD94/NKG2A is rapidly induced on antigenspecific CD8+ T cells during polyoma virus and other infections,[397,398,399] and CD8+ T cells expressing CD94/NKG2A preferentially proliferate during persistent infection, suggesting that CD94/NKG2 receptors may play a role in memory T-cell responses,[400] and that TCR specificity is correlated with CD94/NKG2A expression by human CTL.[401] Indeed, CD94/NKG2A inhibits antigen-specific cytotoxicity in polyoma virus responses, although this effect is pathogen-dependent. CD94/NKG2A has been studied with other viral infections, including herpes simplex virus,[402] murine CMV,[403] gHV68, and influenza,[404] for example. Although not all studies revealed functional consequences, the recurring theme is the appearance of CD94/NKG2A on previously activated CD8+ T cells. Thus, CD94/NKG2 receptors may regulate T-cell responses.

Other Human Immunoglobulin-like Receptors Specific for Major Histocompatibility Complex-I Molecules

The human LILR family is encoded in the LRC (see Fig. 17.3), just centromeric to the *KIR* genes. There are two general forms of these receptors, subfamily A that appears to be activation receptors, and subfamily B that has the ITIMs

characteristic of inhibitory receptors. The best characterized members, LILRB1 (also known as CD85j, Ig-like transcript 2 [ILT2], or leukocyte IG-like receptor 1 [LILR1]) is broadly expressed whereas LILRB2 (CD85d, ILT4, or LIR2) is not expressed on NK cells but is expressed by myelomonocytic cells, including DCs and monocytes. Both recognize HLA class I molecules[405,406] with LILRB1 exclusively binding folded HLA class I molecules with β2m, whereas LILRB2 can bind both folded and free HLA class I heavy chains.[407] Interestingly, a human CMV protein, UL18, binds LILRB1 with 1000-fold higher affinity than HLA molecules, implicating a role for LILRB1 in host defense.[408] The ligands and functions of other LILRBs (LILRB3 [CD85a, ILT5, LIR3], LILRB4 [CD85k, ILT3, LIR5], LILRB5 [CD85c, LIR8], and LILRB6 [CD85b]) are as yet unknown but they may not be able to bind HLA due to structural constraints.[409]

LILRB1 has four Ig-like domains and binds a conserved region in the α3 domain of most, if not all, classical and nonclassical HLA class I molecules (HLA-A, -B, -C, -E, -F, and -G).[408] Interestingly, the crystal structure of LILRB1 bound to HLA-A2 (3.4Å resolution) reveals that it binds MHC molecules under the peptide-binding domain where it contacts α3 and β2m, more akin to Ly49 engagement of MHC than KIR[409] (see Figs. 17.4 and 17.5). Even though LILRB1 and LILRB2 have differing capacities to bind free HLA molecules, LILRB2 has an HLA class I binding site that overlaps with but is distinct from that for LILRB1.[410] LILRB1 binds UL18 in a manner structurally similar to HLA class I binding.[411]

Interestingly, LILR genes demonstrate allelic polymorphisms,[412] though less so than the adjacent KIR cluster.[413] Nonetheless, polymorphisms in LILRB1 may affect receptor expression.[414] Moreover, polymorphisms in LILR genes are associated with certain autoimmune diseases, such as rheumatoid arthritis.[415]

Major Histocompatibility Complex-Independent Natural Killer-Cell Inhibitory Receptors

As already mentioned, NK cells also express inhibitory receptors for non-MHC ligands, such as mouse gp49b, which binds the αvβ3 integrin,[323] and there is a growing list of other such molecules.[416] Some of these receptors will be discussed in a more appropriate context in the following sections. Most of these receptors contain cytoplasmic ITIMs so their inhibitory function can be predicted even if not directly tested, though some caution is required because the motifs may be involved in other signaling processes.

Human and mouse NK cells express the ITIM-bearing leukocyte-associated Ig-like receptor 1 (LAIR-1, CD305), which is an Ig-like molecule broadly expressed by most leukocytes and encoded in the LRC.[417,418] Initial reports indicating that LAIR-1 binds epithelial cellular

adhesion molecule were irreproducible.[419,420] Instead, LAIR-1 binds multiple forms of collagen,[421] which has been validated in crystallographic and biochemical studies.[422] Interestingly, LAIR-1 mediates inhibition that is independent of Src homology 2 (SH2)-domain-containing phosphatases, and instead recruits C-terminal Src kinase (Csk),[423] suggesting that Csk may be involved in inhibitory signaling. Although the in vivo context for functional interaction awaits further characterization, it is reminiscent of the broader reactivity of the Siglecs.

The CD33-related sialic acid binding Ig-like lectins (CD33rSiglecs) are type I receptors with varying numbers of Ig-like domains expressed on a broad array of cells and encoded in the "extended" LRC[312,424,425] (see Fig. 17.3). Despite having sialic acid recognition in common, the Siglecs appear to show differences in carbohydrate recognition, depending on the specific glycan context.[424] Human NK cells express Siglec-7 (p75, adhesion inhibitory receptor 1 [AIRM1]) and Siglec-10, whereas some mouse NK cells express a related Siglec-E.[425] Siglec-7 has been most extensively studied. As expected, its cytoplasmic ITIM can recruit SHP-1 and inhibit NK-cell functions.[426,427] Moreover, expression of its ligand on targets inhibits NK cells in a Siglec-dependent manner.[428] However, the effects appear to be modulated by *cis* interactions between the Siglec receptor and its carbohydrate ligands on the NK cell itself,[424,428,429] reminiscent of *cis* interactions between Ly49 and MHC ligands, as previously discussed.

The Ig-like receptors, termed paired Ig-like receptor (PILR)α and β, are not encoded in the LRC, rather on human chromosome 7 (mouse chromosome 5).[430,431] Mouse PILRα is an ITIM-containing inhibitory receptor, whereas PILRβ is an activation receptor that couples to DAP12.[430,432] Both receptors are expressed on NK (and other immune) cells and recognize CD99. Interestingly, sialylated O-linked glycans on CD99 are involved in recognition by PILRs.[433]

Thus, NK cells (and other leukocytes) express multiple inhibitory receptors that are capable of MHC-independent recognition. How they participate in NK-cell responses and contribute to MHC-dependent effects are beginning to be elucidated, and some appear to play a specific role in the context of activation receptors, as discussed in the following.

Natural Killer-Cell Activation Receptors

NK cells clearly kill MHC-I-deficient targets more efficiently than MHC-I-sufficient targets. However, this enhanced killing does not occur simply because a nonspecific default pathway is unleashed when MHC-I is absent. Instead, it is clear that susceptible targets express ligands for NK-cell activation receptors. In general, these receptors and their ligands were defined following description of the inhibitory receptors.

Approaches to Identification of Activation Receptors

Initial progress in elucidating NK-cell activation receptors was difficult. The approaches that yielded the molecular definition of the TCR, such as subtractive hybridization, mutagenesis of T-cell tumors, and anticlonotypic mAbs,[434,435,436] were of limited success.[437,438] Unlike the working paradigm of MHC restriction that guided the molecular identification of the TCR,

the principles guiding NK-cell activation by targets were unclear. Breakthroughs in identifying NK-cell activation receptors thus required other approaches.

Some activation receptors were recognized because they were first identified on other cells, such as FcγRIII. Other

activation receptors were identified by genetic means, such as cDNA clones for molecules resembling the inhibitory receptors but lacking cytoplasmic ITIMs. Others were identified by a genetic positional cloning approach. Specific stimulation of NK cells through mAbs proved useful for the initial identification of candidate activation receptors and to validate the activation function of receptors identified by other means.

NK cells can be stimulated to mediate antibody-dependent cellular cytotoxicity (ADCC) through the FcγRIII (CD16) receptor that binds the Fc portion of the IgG coating a target. In a related way, anti-FcγRIII can also trigger through CD16 in a process termed “redirected lysis” or “reverse ADCC” because the antibody binds in the opposite orientation to ADCC. A few mAbs against other NK-cell surface molecules also can activate in the redirected lysis assay, highlighting a relatively unique functional property of the recognized molecules (and mAbs), because activation does not occur when most NK-cell surface molecules are cross-linked. First, popularized for analysis of anti-TCR antibodies,[439] redirected lysis occurs when IgG reacts specifically with the NK-cell receptor, and its Fc portion binds a target cell Fc receptor (FcγR) that apparently provides bridging and cross-linking effects.[439] Target lysis does not occur if FcγR binding on the target is prevented with FcγR-deficient targets, $F(ab')_2$ fragments of the anti-NK-cell receptor antibody, or anti-target cell FcγR Ab blockade. In the latter case, Fc regions must be removed to prevent inadvertent triggering of conventional ADCC via CD16 on the NK cell. Thus, the redirected lysis assay is a helpful experimental tool.

Gene transfer studies have been helpful adjuncts to study NK-cell receptors. NK cells are difficult to transfect, and there are few useful tumors with the notable exception of RNK-16, a rat NK tumor line.[440] Viral vectors, such as vaccinia virus, have been useful for gene transfer with the caveat that functional experiments have to be performed within a small time frame before untoward effects occur.[441] Recent use of lentiviral vectors also show promise for gene transfer into primary NK cells.[442]

Recent studies have exploited reporter cell assay systems similar to those used to identify TCR ligands.[443] ITAMmediated signaling leads to inducible, nuclear factor of activated T cells (NFAT)-dependent expression of a reporter molecule, such as β-galactosidase or GFP. Even an inhibitory receptor can be used to activate the reporter cell by fusion of its extracellular domain to a suitable transmembrane and cytoplasmic domain containing ITAMs. Such reporter cells can then be used to detect ligands.[444,445,446]

In the following sections, we will describe NK-cell activation receptors with an emphasis on those with known ligands.

Activation Receptors Related to Major Histocompatibility Complex-Specific Inhibitory Receptors

Despite initial characterization as inhibitory receptors for MHC-I, the Ly49 family contains

other members (ie, Ly49D and Ly49H in C57BL/6 mice) without cytoplasmic ITIMs. Instead, they are activation receptors containing charged transmembrane residues for association with DAP12 that facilitates expression and provides signal transduction capacity.[447,448,449,450] Although Ly49H will be considered below in the context of viral infection, Ly49D has no known role in viral defense. A positional cloning approach indicated that Ly49D is the product of the *Chok* locus, which controls NKcell specificity for killing of a xenogeneic target, Chinese hamster ovary cells,[159,451] due to recognition of a Chinese hamster MHC-I molecule.[452] Interestingly, when Ly49D was transfected into RNK-16 cells, Ly49D can recognize $H2D^d$,[440] but $H2D^d$ tetramers do not bind Ly49D for unclear reasons, although potentially reflecting lower avidity.[213,262] Several other Ly49 receptors have been identified in non-C57BL/6 mouse strains that have properties of activation receptors (charged transmembrane residues, no ITIMs) but they have been less well characterized,[257,258] except for Ly49P in MA/My mice, which is involved in controlling viral infection that is related to MHC-I recognition[453] (see subsequent details). Thus, some members of the Ly49 family are activation receptors with apparent specificity for MHC-I, potentially with less avidity.

Molecular cloning of the KIR family also led to the identification of two domain receptors (also known as p50) or three domain Ig-like receptors with short cytoplasmic domains lacking the ITIM.[454,455] These molecules are now known as the KIR2DS or KIR3DS, respectively, with numbers for specific molecules (ie, KIR2DS1 [CD158h, p50.1], KIR2DS2 [CD185j, NKAT5, p50.2, clone 49], KIR2DS3 [NKAT7], KIR2DS4 [CD158i, NKAT8, clone 39], KIR2DS5 [CD158g, NKAT9], and KIR3DS1 [CD158e2]). Expression of these molecules may be difficult to determine because mAbs for KIR2DL molecules cross-react with KIR2DS molecules.[456] KIR2DS molecules can associate with DAP12 and activate NK cells in the redirected lysis assay.[454,457] KIR2DS and KIR3DS molecules can recognize HLA class I molecules with specificities similar to corresponding inhibitory KIRs, apparently with lower avidity.[458,459,460,461] However, KIR2DS4 and HLA-C alleles and KIR3DS1 and HLA-B alleles influence their respective interactions.[462,463] Thus, further analysis is needed to support the hypothesis that activating forms of KIRs bind HLA alleles less well than the inhibitory receptors as a potential explanation for dominance of inhibition over activation (see Fig. 17.2D).

It remains possible that the activating forms of the Ly49s and KIRs have other ligands and perhaps their MHC specificities are instead somehow related to their physiologically relevant ligand. Indeed, this has been demonstrated for Ly49H, an activation receptor that recognizes a virusencoded ligand with an MHC-I-like fold.[444,446,464] Moreover, KIR2DS4 may recognize a non-MHC ligand.[465] Thus, further analysis is required for understanding the role of Ly49 and KIR activation receptors in MHC-I recognition and with respect to their inhibitory counterparts.

In addition to NKG2A, the NKG2 family also contains NKG2C, NKG2E, and NKG2F, which are products of different genes.[355,466] (NKG2B is an alternatively spliced isoform of NKG2A, whereas NKG2H is an alternatively spliced isoform of NKG2E.) NKG2C and NKG2E lack cytoplasmic ITIMs and contain charged transmembrane residues for association with

DAP12.[467] While the role of NKG2F is unknown

because it lacks an external domain and remains inside the cell, associated with DAP12 but not with CD94,[468] NKG2C and NKG2E form functional heterodimers with CD94.[364] Like CD94/NKG2A receptors, these heterodimers recognize HLA-E or Qa-1, but unlike CD94/NKG2A receptors, they activate NK cells.[469,470] Interestingly, the inhibitory form binds with higher affinity to HLA-E than the activating form.[382,383,471,472] There also appears to be some peptide preference between the different functional forms[382,383,473] that may be relevant in certain physiologic situations. Thus, the CD94/NKG2 receptors may discriminate between subtle differences in their MHC-Ib ligands.

FcγRIII (CD16)

Frequently overlooked but perhaps the first molecularly defined activation receptor on NK cells is FcγRIII (CD16), through which NK cells mediate ADCC against IgG-coated targets.[474,475] Unlike other Fcγ receptor-bearing effector cells, NK cells are generally thought to express only one of the known Fcγ receptors that binds IgG with low affinity,[476] although others suggest that human NK cells may express FcγRII isoforms.[477] There are two human FcγRIII isoforms with identical extracellular domains.[476] Human NK cells express only FcγRIIIA., which is a transmembrane molecule, whereas FcγRIIIB has a glycosylphosphatidyl-inositol (GPI) linkage and is expressed by neutrophils. In mice, only the transmembrane isoform (FcγRIII) is present[478] and displays 95% sequence conservation with muFcγRII. The recently described FcγRIV is a newly recognized orthologue of human CD16A but is not expressed on mouse NK cells.[479,480] There are species differences in CD16 binding to mouse IgG isotypes; mouse IgG3 mAbs bind human CD16 the most efficiently (3 > 2a > 2b >> 1), whereas they bind mouse CD16 with the lowest affinity (2b > 2a > 1 >> 3).[476] In the laboratory, a rabbit antimouse Ig polyclonal Ab, whose Fc portion binds strongly to both human and mouse CD16, could be added to facilitate Fc receptor binding.

The transmembrane FcγRIII molecules are physically associated with FcεRIγ and less commonly with CD3ζ.[481] FcγRIII can also associate with γζ heterodimers. The associated chains are required for optimal cell surface expression of FcγRIII and for signal transduction. After cross-linking, FcγRIII activates biochemical events that are reminiscent of T-cell activation, leading to granule exocytosis and cytokine production.[161,482,483,484,485] In vivo, ADCC may be useful in host defense against pathogens or infected cells if Abs are bound to their surface, triggering not only killing but also cytokine production and other NK-cell responses. Although NK cells are generally thought to participate early in a primary immune response (see subsequent discussion), the delay required for isotype switching to IgG production suggests that CD16 cross-linking on NK cells plays a role in secondary immune responses in vivo.

Regardless, ADCC is remarkably similar to natural killing and was important for the initial establishment of the concept of NK-cell activation receptors.[161] Yet, CD16 is not required for NK-cell target recognition because human CD16-CD3- lymphocytes can still mediate natural killing.[486] Moreover, CD3ζ is phosphorylated upon CD16 ligation but not when NK cells are

exposed to NK-sensitive targets. Deficiency of γ chain abrogated ADCC but not natural killing.[474] Thus, CD16 is not involved in natural killing.

CD16-related artifacts must be considered when studying NK cells. Flow cytometry experiments may be flawed if CD16 binding is not taken into account. To eliminate this possibility, $F(ab')_2$ fragments should be used. Alternatively, blockade of FcγRIII binding may be sufficient with protein A or G (that bind Fc region on Ig) or anti-FcγRIII mAbs, such as unlabeled mAb 2.4G2 (ATCC HB 197) that reacts with both mouse FcγRII and FcγRIII.[478] Similarly, as discussed previously, antibody blockade experiments should be done with caution if the antibody specifically reacts with the target because ADCC may be stimulated.

NKG2D

NKG2D (KLRK1) was first cloned from human NK cells as a cDNA related to NKG2A and C.[355] However, NKG2D is distinct from other NKG2 molecules for several reasons. There is only limited sequence homology between NKG2D and other NKG2 molecules (28% amino acid identity for the lectin-like domain) whereas other NKG2 molecules are closely related to each other (70% identity). Rather than heterodimerizing with CD94, NKG2D is expressed as a disulfide-linked homodimer on all NK cells in humans and mice. In humans, NKG2D is also expressed on all γδTCR+ and CD8+ T cells, whereas in mice, NKG2D is expressed on most NKT and γδTCR+ T cells but not on resting CD8+ T cells.[81,82,83] However, essentially all activated mouse CD8+ T cells express NKG2D. In both humans and mice, CD4+ T cells do not express NKG2D, but it is found on a subset of CD4+ T cells in patients with rheumatoid arthritis.[84] Finally, NKG2D has functional properties and ligand specificities that distinguish it from the other NKG2 molecules, indicating that NKG2D should not be considered as a member of the NKG2 family.

NKG2D does not have any known cytoplasmic motif and was first shown in humans to preferentially associate with a signaling chain termed DAP10, encoded by a gene localized 130 bp away from the gene for DAP12.[487] DAP10 does not have any ITAMs; instead, it contains a YxxM motif for recruitment of PI3K.[487] This motif is similar to that found in CD28, and functional studies indicate that NKG2D can act as a costimulatory molecule on T cells.[488,489,490] Moreover, DAP10 has a site for recruitment of Grb2.[491] Thus, NKG2D may provide qualitatively different signals, resulting in different cytokine production, for example,[490] than activation receptors associated with ITAM-signaling chains.

Other studies have suggested that NKG2D functions as a primary activation (triggers alone) rather than costimulatory receptor (does not stimulate unless it synergizes with another receptor) on NK cells.[80,492] Such studies need to be reconsidered in light of several factors. 1) Many studies of NKG2D function use targets that are poorly killed by NK cells. When these targets are transfected with NKG2D ligands, killing is enhanced in an NKG2D-dependent manner. However, such studies do not distinguish whether NKG2D functions as a primary activation receptor or as a costimulatory receptor (analogous to CD28 requirement for

full activation of T cells) as the same experimental outcome is anticipated in either case. 2) When cross-linking is done with immobilized mAbs alone and CD16 coengagement on NK

cells is avoided, NKG2D functions as a costimulatory receptor on mouse IL-2-activated NK cells.[80] 3) In mice but not humans, there are two alternatively spliced isoforms of NKG2D.[34,493] A long form (NKG2D-L) contains a 13 amino acid extension at the amino terminus (cytoplasmic domain) as compared to the short form (NKG2D-S). Resting NK cells predominantly express NKG2D-L that preferentially associates with DAP10. However, activation of NK cells with cytokines causes a transient increase in NKG2D-S that associates with ITAM-containing DAP12 as well as DAP10. However, others have found that NKG2D-L can associate with DAP12, albeit to a lesser degree, and that both isoforms are present in resting NK cells.[494] Regardless, in the absence of DAP10, mouse NKG2D can associate with DAP12,[35] allowing it to signal akin to a primary activation receptor. Thus, mouse NKG2D is an unusual example of a receptor with the same extracellular domain but with potentially different functional outcomes (primary activation versus costimulation), depending on its associated partner chain.

There is remarkable plasticity for NKG2D in that it can bind many apparently disparate ligands that are only superficially related to each other by sequence alignment, and human NKG2D can bind mouse ligands and vice versa. Based on soluble MICA binding, the first human NKG2D ligands were found to be MICA and MICB (MHC-I chain-related, A and B) encoded on chromosome 6p21.3, centromeric to HLA-B locus.[81] Subsequently binding studies of UL16 from human CMV (HCMV) identified the ULBP (UL16 binding protein) family that in turn binds NKG2D.[495] The UL16-binding proteins (ULBPs) are encoded by genes in the retinoic acid expressed transcript (*RAET1*) gene family (official HUGO nomenclature) encoded on chromosome 6q24.2-q25.3 and discovered by genomic mining. Whereas *RAET1F*, *RAET1J*, *RAET1K*, and *RAET1M* are pseudogenes, other *RAET1* genes give rise to ULBP1 (RAET1I), ULBP2 (RAET1H), ULBP3 (RAET1N), ULBP4 (RAET1E), ULBP5 (RAET1G), and ULBP6 (RAET1L), some of which have been extensively studied as ligands for NKG2D.[495,496,497,498] MICA, MICB, ULBP4, and ULBP5 are considered to be transmembrane proteins whereas the other RAET1 proteins are GPI-linked.[499]

Mouse NKG2D ligands were discovered with soluble NKG2D that was used for expression cloning.[82,83] Two types of ligands were originally defined: the minor histocompatiblity antigen H60 and members of the retinoic acid early inducible gene-1 (RAE-1) family. It is now clear that the mouse NKG2D ligands are the H-60 family, consisting of H60a, b, and c, the RAE-1 family, consisting of RAE-1α, β, γ, δ, and ε (also known as Raet1a-e), and murine ULBP-like transcript (MULT1).[82,83,500,501,502] There are strain-specific differences in ligand expression. For example, BALB/c mice express H60a, RAE-1α, β, and γ, whereas C57BL/6 mice do not express these molecules and express RAE-1δ and ε.[503] In addition, there are allelic forms of NKG2D ligands (eg, 80 different alleles of MICA and 33 alleles of MICB [hla.alleles.org/classo.html]), b ut these have not been fully characterized in humans (or mice).

Where studied, all NKG2D ligands have distant amino acid similarity to MHC-I, although they share only about ˜25% amino acid identity with each other. Within a family, however, they may be much more closely related (up to 90% identity). None of the NKG2D ligands associates with β2m or binds peptides.[504,505,506,507] Many contain only the α1/α2 platforms and

many are GPI-linked to the plasma membrane. The ligands display binding to NKG2D in two ways based on affinity.[501,502,504,508,509] For example, RAE1α, β, γ, and δ, and H60b and c demonstrate low-affinity interactions with mouse NKG2D, similar to MICA to human NKG2D (K_D = ~300 to 8700 nM). In contrast, RAE1ε (also described as RAE1B6),[509] H60a and MULT1 show a much higher affinity interaction (K_D = 6 to 30 nM). Thus, closely related molecules within a family may display wide disparity in affinities whereas distantly related molecules can share high affinity with NKG2D.

Structural studies at 2.6 to 3.5 Å resolution indicate that the NKG2D ligands have MHC-I-like folds, though the "peptide-binding cleft" is closed.[504,505,510] NKG2D binds its ligands more analogous to TCR docking on MHC and unlike Ly49 recognition (see Figs. 17.4 and 17.5), despite the relationship of NKG2D and Ly49 receptors as NKCencoded, lectin-like homodimers that bind MHC-related molecules.[504,510,511] Indeed, NKG2D interactions with its ligands are much more aligned with CD94/NKG2A recognition of HLA-E, as described previously. Moreover, NKG2D uses largely nonoverlapping patches to engage a similar orthogonal footprint on its disparate ligands. Interestingly, the putative immunoevasion molecule, UL16, binds MICB in essentially the same manner as NKG2D is predicted to bind, even though UL16 has a different three-stranded β-sheet structure.[512] Additional structures of NKG2D complexed with other ligands should yield additional insight as to how NKG2D can bind a panoply of distantly related ligands with varying affinities.

NKG2D function has been described in the "inducedself" model (see Fig. 17.2E) because expression of its ligands can be inducible and can override inhibitory influences of MHC-I.[513,514,515] In many cases, low basal transcriptional levels are markedly upregulated in pathologic conditions. For example, MICA and MICB expression is markedly enhanced on epithelial tissues in inflammatory bowel disease.[516] Whereas this notion was initially thought to be related to heat shock elements in MICA promoter, recent detailed studies indicate that NKG2D ligand transcription in some cells is not affected by heat shock or hypoxia in vitro.[517] Instead, transcription of NKG2D ligands can be induced by several other stimuli. For example, DNA damage from ionizing radiation or chemotherapy agents results in upregulation of human and mouse NKG2D ligand transcripts and concomitant surface protein expression.[517] This process was dependent on activation of the ataxia telangiectasia, mutated (ATM), and ATM- and Rad3 (ATR)-related pathways. Interestingly, several micro-ribonucleic acids (miRNAs) can regulate MICA and MICB expression, and they are decreased following heat shock, allowing upregulation of MICA and MICB.[518] On the other hand, Dicer knockdown also results in a DNA damage response that results

in enhanced MICA and MICB expression.[519] Regardless, NKG2D ligand expression due to genotoxic responses may be relevant to chemotherapy effects in cancer, such as multiple myeloma.[520]

Other external stimuli, such as phorbol ester, retinoic acid, cytokines, and TLR stimulation, can induce NKG2D ligand expression on mouse and human cells.[500,521,522] The phorbol ester effect is regulated by the transcription factor JunB[523] and retinoic acid stimulation was

the impetus for original identification of the RAE-1 family.[524] Cytokines can also regulate NKG2D ligands. For example, IFNγ can downregulate transcripts for H60a expression on tumor cells and alter NK-cell susceptibility.[525] For MICA, the IFNγ effect is mediated through miRNAs.[526] Interestingly, TLRinduced primarily MICA and not MICB, through pathways dependent on ATM, ATR, and miRNAs.[522] Viral infection can also induce NKG2D ligands,[527] perhaps not surprisingly because viruses target NKG2D and its ligands (described in the following). For example, murine CMV (MCMV) infection induced RAE-1 mRNA and surface expression within 18 hours. This effect was independent of the DNA damage response but required PI3K activation.[527] However, PI3K activation alone was insufficient to induce ligand expression, suggesting that additional signals are required for NKG2D ligand expression by viral infections and perhaps other stimuli.

For other NKG2D ligands, transcripts are constitutively expressed in a wide variety of tissues[495,501]; posttranslational modifications alter surface protein expression levels. For example, mRNA for MULT1 is widely expressed in normal tissues[501] and MULT1 surface expression is regulated by ubiquitination.[528] MULT1 has a long cytoplasmic domain, unlike most other NKG2D ligands, which are GPI-linked. Under normal circumstances, MULT1 is ubiquitinated on its cytoplasmic Lys residues and is targeted for degradation. However, cellular stress, such as heat shock or ultraviolet irradiation, reduced its ubiquitination and allowed surface expression. In particular, MULT1 expression is regulated by the E3 ubiquitin ligases, membrane-associated RING-CH (MARCH) 4 and membrane-associated MARCH 9.[529] A human virus, Kaposi sarcoma-associated herpesvirus (KSHV), exploits this pathway to avoid NK-cell attack (detailed in the following).

Despite the nearly universal acceptance of the inducedself model for NKG2D function, it is not clear if this hypothesis is applicable to all of its ligands.[530,531] It remains possible that constitutive expression or affinity of some NKG2D ligands may be too low to permit NKG2D activation to override MHC-I-dependent and - independent inhibitory receptors. Continued analysis at the protein level is anticipated, as well as study of NKG2D ligands in specific tissues, exemplied by analysis of H60c in the skin where it is selectively expressed and can also costimulate dendritic epidermal T cells.[532]

On the other hand, chronic exposure to membranebound or soluble NKG2D ligands results in downregulation of NKG2D expression and lower functional responsiveness.[85,533,534,535] Patients with tumors expressing MIC frequently contain soluble MIC in their peripheral blood, presumably as a result of proteolytic cleavage of membrane-expressed ligands,[533,536] though the enzyme required is unclear, and the process apparently requires palmitoylation of MICA.[537] Mice Tg for NKG2D ligands show impotent NKG2D responses,[534,538] a topic better discussed subsequently in the context of NK cell tolerance and education. On the other hand, acute upregulation of an NKG2D ligand alone can rapidly induce immune responses[539] (albeit effects not examined for NK cells). Taken together, these findings may explain why tumors frequently express NKG2D ligands that would otherwise enhance their susceptibility to NK-cell attack, supporting a role for NKG2D in tumor surveillance and also the general concept that NKG2D-mediated activation is balanced between acute, induced-

self, and chronic expression of its ligands.

Additional studies support a role for NKG2D in tumor surveillance. For example, mice are more sensitive to developing methylcholanthrene-induced fibrosacromas when NKG2D is neutralized by chronic anti-NKG2D mAb administration[86] or targeted deletion.[540] Moreover, mice lacking γδT cells are more susceptible to carcinogenesis apparently due to an NKG2D-dependent effect.[500] IFNγ is a known host mediator that shapes the tumor phenotypes in a broader process known as "immunoediting,"[541,542] and IFNγ also mediates downregulation of H60 expression on tumors.[525] Thus, NKG2D and its ligands are important in the host response (or lack thereof) to tumors.

A role for NKG2D in antiviral responses is indicated by studies that show that viruses use different strategies to interfere with ligand recognition by NKG2D. This was first noted when the HCMV protein UL16 was found to bind ULBPs.[495] In infected cells, UL16 retains some (MICB, ULBP1, and ULBP2) but not all NKG2D ligands in the endoplasmic reticulum and cis-Golgi, preventing their expression on the cell surface and protecting from NK cell lysis.[543,544,545] HCMV also encodes UL142, which retains certain alleles of MICA in the cis-Golgi.[546] In mice, MCMV encodes four molecules that downregulate expression of all NKG2D ligands. gp40 from the *m152* open reading frame (ORF) downregulates all five RAE-1 ligands but has no effect on H60 or MULT1.[503,547] H60 is downregulated by the product of the *m155* ORF at a post-Golgi level, perhaps by targeting H60 for proteasomal degradation[548,549] and MULT1 expression is affected by *m145*.[550] The herpes virus Fc receptor (fcr-1), the product of the *m138* ORF, targets RAE-1ε, H60, and MULT1.[551,552] Interestingly, KSHV encodes an E3 ligase, termed K5, that can downregulate MICA and MICB expression.[553] This effect was due to ubiquitinated internalization of MICA, but not degradation, and protected cells from NK-cell cytotoxicity, suggesting that KSHV targets a normal pathway regulating NKG2D ligand expression. HCMV and other herpes viruses (KSHV, Epstein-Barr virus) encode miRNAs that affect MICA and/or MICB expression.[554,555] Non-herpes viruses also target the NKG2D pathway; adenovirus E3/19K sequesters MICA and MICB in the endoplastic reticulum,[556] whereas the orthopoxviruses, cowpox, and monkeypox viruses encode a secreted, high-affinity NKG2D ligand that antagonizes NKG2D recognition and activation.[557] Thus, the multitude of viral strategies that affect NKG2D recognition

strongly suggests that NKG2D plays an important role in the host response to viral infections.

Surprisingly, an NKG2D knockout mouse displayed enhanced resistance to MCMV infections.[87] This mouse also displayed modest changes in NK-cell development with faster NK-cell maturation that were not demonstrated in another NKG2D knockout,[540] even though both were generated directly in C57BL/6-derived embryonic stem cells. A subsequent retargeting of the *Klrk1* locus recapitulated the enhanced resistance to MCMV,[558] which for the moment is at odds with viral neutralization of NKG2D.

Finally, NKG2D may play a role in autoimmune disorders. In autoimmune type I diabetes mellitus (TIDM), MICA polymorphisms are reportedly associated with increased risk,[559] but

MICA is closely linked with *HLA*, which clearly imparts significant risk so additional analysis of large patient cohorts is needed to segregate the *MICA* effect from that of *HLA* alleles in TIDM or any other HLA-associated autoimmune disease.[560] Nonetheless, NKG2D ligands are expressed in the prediabetic NOD mouse pancreas and anti-NKG2D blockade prevents TIDM.[561] In human patients with inflammatory syndromes, such as rheumatoid arthritis, Wegener granulomatosis, and unstable angina, there is an unusual population of CD4+ CD28- NKG2D+ T cells that is expanded.[562,563,564] NKG2D can provide a costimulatory signal for T cells, at least for CD4+ CD28- T cells in rheumatoid arthritis and rheumatoid arthritis synovium expresses NKG2D ligands.[84,489] IL-15 induces NKG2D expression on intestinal epithelial T-lymphocytes that then display a LAK cell-like promiscuous killing capacity against enterocytes which upregulate NKG2D ligands from gliadin exposure, suggesting that NKG2D may play a pathogenic role in celiac sprue.[36,565,566] On the other hand, others have postulated that CD4+ NKG2D+ T cells may be normally immunosuppressive as they are inversely correlated with disease activity in patients with systemic lupus erythematosus.[567] Thus, NKG2D may play a pathogenic role, albeit somewhat unclear, in several autoimmune disorders in humans and mice.

Natural Killer Gene Complex-encoded Lectin-like Receptors Recognize Natural Killer Gene Complex-encoded Lectin-like Ligands

First identified by functional studies in the rat, Nkrp1 (Klrb1) molecules belong to a family of lectin-like, disulfidelinked homodimers with type II orientation encoded in the mouse and rat NKC[71,255,330,568,569,570,571] (see Fig. 17.3). Expression is relatively selective for NK cells, although Nkrp1 molecules are also expressed by NKT cells in rats and mice.[572,573] There is only a single gene (*NKRP1A*, CD161) in humans that is expressed on a subpopulation of NK cells.[574] The continuing allure of the Nkrp1 family stems from observations that NK1.1 (the most widely known specific serologic marker of NK cells) is encoded by *Nkpr1c* (*Klrb1c*) in C57BL/6 mice,[71] Nkrp1 receptors are conserved, and they have interesting genetics with respect to their ligands.[575]

Initial functional studies indicated that rodent Nkrp1 molecules can activate NK cells through redirected lysis,[32,571,576,577,578] which can be prevented by inhibitory Ly49 receptor engagement.[140] Mouse Nkrp1c (NK1.1) is functionally associated with FcεRIγ, although its deficiency curiously does not affect NK1.1 expression.[579] An Nkrp1a loss mutant of rat RNK-16 cells failed to kill certain targets; transfection restored killing capacity, suggesting that rat Nkrp1a is an activation receptor specific for target determinants.[580] Thus, Nkrp1 molecules were among the first described NKcell-specific activation receptors though inhibitory forms were later described.

Inasmuch as Nkrp1 molecules are homologous to C-type lectins, the ligands for Nkrp1 molecules were initially presumed to be carbohydrates but Nkpr1 molecules lack residues for coordinate binding of calcium that is required for authentic C-type lectin recognition of carbohydrates.[222] While the ligands for Nkrp1c have not yet been identified, Nkrp1f recognizes C-type lectin related g (Clrg, also known as Clec2i, Dcl1).[445,581,582,583] Nkrp1f

is presumed to be an activation receptor because it has a charged transmembrane residue and no cytoplasmic signaling motifs. The inhibitory receptor, Nkrp1d, is expressed on all NK cells in C57BL/6 mice and is specific for Clrb (Clec2d; osteoclast inhibitory lectin, Ocil). Thus, the Nkrp1 family is an MHC-independent system that is presumably involved in self-tolerance and is the first example of a lectin-like receptor recognizing a lectin-like ligand unlike MHC-like ligands for other NKC-encoded receptors.

Genome sequence analysis indicates that *Nkrp1d* in C57BL/6 mice is represented by *Nkrp1b* in other strains.[75,76,569,584] The Nkrp1b molecule from SJL and SW mice was discovered to be reactive with the anti-NK1.1 mAb, highlighting the close similarities of these molecules and serologic cross-reactivity. Whereas the older literature suggested that there are also strain differences in transcript expression with markedly lower expression in BALB/c NK cells,[585] more recent data demonstrate abundant expression of Nkrp1 transcripts.[584] Moreover, the BALB/c allele of Nkpr1b also reacts with Clrb, indicating conserved specificity and function.

The Clr molecules belong to an NKC-encoded family with type II orientation and C-type lectin homology.[581] They are most closely related to the CD69 molecule encoded by an adjacent gene. In C57BL/6 mice, seven Clr genes have been identified at the genomic level. RT-PCR analysis indicates that *Clrb* is broadly expressed, whereas *Clrg* and *Clrf* genes are present in restricted and nonoverlapping tissues, including NK cells, and *Clra* and *Clrc* transcripts have not yet been identified. *Clre*, a probable pseudogene, has numerous stop codons in its expected open reading frame. Genomic analysis indicates the existence of a rat *Clr* family,[570] whereas in humans, three genes, *LLT1*,[586] *AICL*,[587] and *DCAL-1*[588] are localized next to CD69 and are related to the Clr family of genes.

Human NKRP1A binds LLT1, a functional homolog of mouse Clr.[589,590] Moreover, activation-induced C-type lectin (AICL CLEC2B) is the ligand for the NK-cell receptor activation receptor, NKp80 (KLRF1), which is also encoded in the NKC but is absent in rodents.[591,592,593] Finally, CLEC2A (keratinocyte-associated C-type lectin, KACL) is primarily expressed in the skin and is recognized by another NK-cell activation receptor, termed NKp65 (KLRF2).[594] All of these

receptors and their ligands are lectin-like molecules encoded in the human NKC.

The genetics of the *Nkrp1* and *Clr* loci is especially interesting from several viewpoints. 1) These loci are co-mingled in the NKC, from rodents to humans[445,570,575,584,589,590] (see Fig. 17.3). 2) In mice, there is limited allelic polymorphism, with conservation of gene order and content, despite genetic proximity to the highly polymorphic *Ly49* cluster.[445,584,595] For example, compare the conservation of the Nkrp1 gene cluster with polymorphism of the Ly49 cluster in C57BL/6 and 129 strain mice.[227,257,260,445,595] 3) At the individual gene level, *Nkpr1* alleles appear to be much less divergent than the corresponding *Ly49* alleles in the same inbred mouse strains.[257,445,584,595] 4) The *Nkpr1-Clr* interval of the NKC appears to be genetically protected with suppression of recombination.[596,597] Genetic linkage of Nkrp1 and its ligands thus resembles the tight genetic linkage of receptor and ligand genes and recombinational suppression of the self-incompatibility loci in plants to prevent self-

fertilization and related mating loci in other species.[598,599] Furthermore, the coevolution of such linked genes for receptors and ligands also represents an interesting issue in evolutionary biology because reciprocal mutations in both receptor and ligand genes are simultaneously needed to generate new specificities.[598] Nevertheless, the genetic pressure to conserve the *Nkrp1-Clr* gene order and coding sequences may therefore reflect a critical role for Nkrp1 and Clr molecules in innate immune cell interactions and functions.[575]

While the in vivo role of Nkrp1 and Clr molecules is incompletely understood, the best evidence for their functional importance comes from studies in rats. Rat CMV encodes RCTL (rat CMV C type lectin-like), which closely resembles rat Clrb and regulates its expression on infected cells.[600] RCTL interacts with the Nkrp1b inhibitory receptor and inhibits NK cell killing of infected cells. An RCTL loss mutant rat CMV is attenuated in vivo in an NK-cell-dependent manner. These studies, indicating that viruses encode decoy ligands for Nkrp1 receptors, support the importance of Nkpr1-Clr interactions in immune responses.

2B4, CD2, and Signaling Lymphocytic Activation Molecule Family of Receptors

The 2B4 (CD244, SLAMF4) molecule was originally identified on mouse NK cells with a mAb that perturbed mouse NK-cell function.[601] 2B4 is a type I integral membrane protein that belongs to the family of Ig-like molecules, including signaling lymphocytic activation molecule (SLAM) (SLAMF4, CD150), NK, T, and B cell antigen (NTBA, also known as SLAMF6 or Ly108), Ly9 (SLAMF3, CD229), CD84 (SLAMF5), and CD2-like receptor activating cytotoxic cells (CRACCs; SLAMF7, CD319).[602] Although these receptors may be broadly expressed, 2B4, NTBA, Ly9, CD84, and CRACC are expressed on NK cells. NTBA, Ly9, CD84, and CRACC are involved in homophilic interactions whereas 2B4 recognizes CD48, a GPI-linked molecule expressed on hematopoietic cells.[603,604] CD48 itself is also recognized by CD2, albeit at a ninefold lower affinity than by 2B4 (K_d = ~16 μM). Anti-CD2 mAbs can stimulate NK cells in the redirected lysis assay[605] and granule exocytosis,[606] but CD2-NK cells can still mediate natural killing.[9] The cytoplasmic domains of SLAM, 2B4, NTBA, Ly9, CD84, and CRACC contain a motif with sequence similarly to the ITIM, termed the immunoreceptor tyrosine-based switch motif (ITSM) consisting of TxYxxV/I consensus sequence.[607] The ITSMs allow interactions with a signaling adapter, SLAMassociated protein (SAP, also known as SH2D1A). The importance of SAP and its associated receptors is highlighted by the X-linked lymphoproliferative (XLP) syndrome, a human immunodeficiency involving abnormal proliferation of T and B cells during Epstein-Barr virus infections due to mutations in SAP.[608] SAP is related to Ewing sarcoma-associated transcript (EAT2, also known as SH2D1B1) and EAT2-related transducer (ERT, also known as SH2D1B2), which is present in rodents and only expressed in NK cells.[604] SAP and the SAP-related molecules contain a single SH2 domain for interaction with the ITSMs of presumably all SLAM family members except CRACC.[609,610,611,612,613] Instead, CRACC recruits EAT2, which functionally substitutes for SAP.[612] Subsequently, the SAP-related proteins can recruit a wide variety of downstream signaling molecules including Fyn, a Src-family tyrosine kinase, and tyrosine phosphatases, inositol phosphatases, and adaptor molecules.[614]

The complexities of this receptor-ligand signaling pathway are evident from the previous description. Receptors have overlapping ligand specificities; they recruit different adaptors that in turn can recruit downstream signaling molecules, even those with opposing functions. In this regard, functional studies of SLAM family molecules on NK cells have often been ambiguous, often depending on the experimental approach.[602] For example, 2B4 cross-linking with mAb can both stimulate as well as inhibit mouse NK cells,[601] whereas a 2B4-deficient mouse primarily displays effects consistent with 2B4 being primarily an inhibitory receptor.[615] However, the inhibitory effect of 2B4 is more apparent in mice than humans.[604] Some of these outcomes may depend on spatial distribution, 2B4 isoforms, or differential recruitment of SAP or its related molecules.[602] Further analysis should enlighten NK-cell function and signaling because 2B4 and related receptors demonstrate MHCindependent regulation of NK cells, and mediate inhibition and activation in a functionally distinct manner from the MHC-specific inhibitory receptors and ITAM-signaling chain associated receptors, respectively.

Natural Cytotoxicity Receptors

A series of mAbs that redirected lysis of human NK cell clones lacking KIRs led to the identification of the "natural cytotoxicity receptors" (NCRs), NKp46 (NCR1, CD335), NKp44 (NCR2, CD336), and NKp30 (NCR3, CD337).[616,617,618,619,620] These molecules are selectively expressed on NK cells, though NKp44 is expressed only upon activation. Whereas NKp46 is encoded in the LRC (see Fig. 17.3), NKp44 and NKp30 are encoded in the class III region of the MHC on human chromosome 6.[621,622] cDNA cloning revealed that they are type I integral proteins with one (NKp30, NKp44) or two (NKp46) Ig-like extracellular domains.

They contain charged transmembrane residues for association with ITAM-signaling chains (ie, ζγ heterodimers (NKp46, NKp30) or DAP12 (NKp44). In the mouse, only the gene for NKp46 is present in the syntenic region of chromosome 7 with the genes for other NCRs being absent (NKp44) or a pseudogene (NKp30).[623] The NCRs appear to play a role in cytotoxicity against tumors of varying origins because anti-NCR antibodies block target killing.[624] A mouse NKp46-Ig fusion protein binds RMA-S targets and deficiency of NKp46 leads to impaired in vivo clearance of RMA-S cells.[93] Interestingly, human NCRs apparently recognize mouse tumors and vice versa, suggesting conservation of these receptor-ligand pairs across species but identity of their target ligands were elusive,[624] until recently for NKp30 and NKp46.

In functional and structural studies, NKp30 clearly recognizes B7-H6, a member of the CD28 family that also includes CTLA-4 and PD-1.[625,626] B7-H6 is not expressed normally, is found on tumor cells, and sensitizes targets to NKp30-dependent cytotoxicity by NK cells. In a 2.0 Å structure of NKp30 complexed to B7-H6, NKp30 engages its ligand in an antibody-like manner distinct from the way other receptors bind B7 family molecules. Other potential NKp30 ligands include pp65 of HCMV, though it is a tegument protein and not expressed on the plasma membrane of infected cells.[627] HLA-B-associated transcript 3 (BAT3) was also proposed, but it is a nuclear protein that is released with DNA damage or endoplasmic reticulum stress.[628] Finally, NKp30 reportedly binds poxviral hemagglutinin independent of

B7-H6 and BAT3.[629] Nonetheless, at least one ligand is now well characterized for NKp30.

Human NKp46 appears to recognize influenza hemagglutinin on infected cells.[629,630] The interaction is dependent on sialic acid residues on oligosaccharides on NKp46 itself,[630] but this specificity is difficult to explain due to the ubiquitous expression of sialylated saccharides. NKp46 and NKp30 may recognize heparan sulfate proteoglycans on their cellular targets, though this is also controversial.[631,632] Nevertheless, NKp46-knockin (GFP)/knockout mice are susceptible to influenza, consistent with a role for NKp46 in defense against influenza,[93] albeit possibly in an indirect manner.[633] These studies may provide important clues to understanding of a receptor (NKp46) conserved in humans and mice.

NKp46 Tg mice have been proposed to be useful for NKcell analysis.[95] These mice are Tg for a construct consisting of 400 bp from the human NKp46 promoter driving expression of enhanced GFP and the human diptheria toxin receptor. However, NKp46+ cells in the gut may be derived from a non-NK-cell lineage.

Human NK-22 cells were identified in the gut as being CD3- CD56+ NKp44+ cells that produce IL-22 but not IL-17 upon stimulation with IL-23.[88] In the mouse, a similar functional population producing IL-22 was identified among NKp46+ cells and to a lesser degree, among NK1.1+ cells.[89,90,91,634] Immature human NK cells in secondary lymphoid tissue and the uterus may produce IL-22.[635,636] However, other reports indicate that NK-22 cells are more closely related to lymphoid tissue inducer (LTi) cells.[634,637,638,639] Thus, there may be heterogeneity among IL-22-producing NKp46+ cells.

Other Activation Receptors

Several other NK-cell-expressed molecules can activate cytolysis. For example, mAbs against mouse CD69 and Ly-6 and rat gp42 can trigger killing.[32,33] CD69 is encoded in the NKC and is structurally related to other NKC-encoded receptors. Interestingly, CD69 expression is upregulated upon stimulation,[322] and its expression is not confined to NK cells.[640] CD69 is functionally active on a large variety of hematopoietic cells when cross-linked by anti-CD69 mAbs. Its ligand is unknown, but it regulates the function of the sphingosine 1-phosphate receptor-1 through a membrane interaction.[641] Ly-6 belongs to a large family of small (15 to 18 kDa) GPI-anchored molecules that can activate lymphocytes when cross-linked.[642,643] Rat gp42 is a GPI-anchored protein with two Ig-like domains that was originally identified on IL-2-activated NK cells and the rat RNK-16 NK cell line.[33] Anti-gp42 can activate RNK-16 but not IL-2-activated NK cells. However, CD69, Ly-6, and gp42 are not expressed on freshly isolated NK cells and are expressed only after activation through other pathways; they are therefore not involved in triggering natural killing by freshly isolated NK cells. Although their physiological role is unknown, their activation potential and enhanced killing by IL-2-activated NK cells suggest that these molecules may contribute to this phenotype.

Receptors Involved in Recognition of Epithelial Tissues

NK cells possess receptors that are specific for ligands expressed at cell-cell junctions in epithelial tissues. Interestingly, ligands, such as cadherins, carcinoembryonic antigen (CEA)-

related adhesion molecules (CEACAMs), nectins, and nectin-like proteins (necls), are involved in forming adherens junctions and are engaged in homotypic or heterotypic interactions, and thus, are not normally exposed.[644] KLRG1 (also known as mast cell-associated function antigen, MAFA) is a lectin-like receptor with a single cytoplasmic ITIM.[645,646,647] Unlike human *KLRG1*, mouse *Klrg1* resides relatively distant and centromeric from the rest of the NKC, consistent with gene duplication and chromosomal inversion events. First discovered on rat mast cells, it has a broader distribution in human and mouse, including NK and T cells but not mast cells. Expression of Klrg1 on NK cells is downregulated in MHC-I-deficient mice, unlike the Ly49s that are modestly upregulated, but no MHC binding has been observed for Klrg1.[648] Instead, mouse Klrg1 binds three of the seven "classical" cadherins, E-, N-, and R-cadherin, leading to inhibition of NK lysis.[649,650] Biophysical studies show the K_D = 120 mM for mouse KLRG1-mouse E-caherin.[651] The structure of KLRG1 at 1.8 Å resolution revealed a typical lectin-like domain for KLRG1, which binds E-cadherin at a site distinct from where the integrin $\alpha_E\beta_7$ (CD103) binds E-cadherin. A KLRG1-deficient mouse demonstrates that it is dispensable for NK- and T-cell differentiation and antiviral responses, but it has not been

exhaustively studied, especially for epithelial responses.[652] Human CEACAM1 (CD66a) contains a cytoplasmic ITIM and can directly bind CEA, thereby potentially regulating NK-cell activities in human MHC-I-deficient patients and during pregnancy.[653,654,655] Mouse NK cells also express CEACAM1.[656] Inasmuch as CEACAM1 binds homophilic and heterophilic ligands expressed on epithelial and other cells,[657] NK cells thus express several inhibitory receptors for ligands normally expressed on epithelial cells.

NK cells also express cell-cell adhesion Ig-like receptors for molecules located at the adherens junction (ie, nectins and necls).[658,659] Specifically, they express CD226 (DNAM-1, DNAX accessory molecule-1) that recognizes necl-5 (CD155, poliovirus receptor, PVR) and nectin-2 (CD112, PVRL2).[660] NK cells also express CD96 (Tactile, T-cell activation, increased late expression) that binds necl-5 but not nectin-2, and class I-restricted T-cell-associated molecule (CRTAM), a receptor that recognizes necl-2.[661,662,663] DNAM-1 associates with lymphocyte function-associated antigen (LFA-1) and regulates its capacity to bind its ligand, ICAM-1.[660,664] In addition, DNAM-1 can recruit actin-binding proteins to form an adhesive complex with other cells. DNAM-1-deficient mice have defective NK and T cells, and fail to control tumors, both transferred and de novo carcinogeninduced.[665,666] Although these receptors can activate Src and other downstream pathways,[659] they are thought to function on NK cells as adhesion receptors that enhance cytotoxicity, rather than as primary activation receptors. Conversely, NK cells also express T-cell immunoglobulin and ITIM domain (TIGIT), which recognizes PVR and PVRL2 but not PVRL3, and inhibits NK-cell killing.[667,668]

These studies suggest that these receptors may affect different NK-cell functions as related to epithelial tissues.[644,649] For example, the inhibitory receptors may regulate NK-cell transmigration across an epithelial barrier or prevent NKcell attack against normal

tissues.[649,669] While the activation receptors could also affect NK-cell transmigration,[649,669,670] they also could be poised to attack cells that have disordered cell-cell junctions, such as tumors that typically lose cadherin expression and expose nectins and necls, potentially making them more susceptible to NK attack, consistent with an "exposed-self" model for NK-cell activation (see Fig. 17.2F, G). On the other hand, tumors may become resistant to NK cells by altering expression of these molecules. Current evidence provides some support to these complex scenarios that will require further investigation.[644]

Accessory Molecules

The role of accessory molecules in NK-cell activation has been difficult to address without knowledge of the "NK-cell (activation) receptor." Nevertheless, NK-cell cytotoxicity is critically dependent on classical accessory and adhesion molecules, such as LFA-1.[671,672] Insect cells expressing ICAM-1, a ligand for LFA-1, can be killed by human NK cells through an LFA-1-dependent process, suggesting that LFA-1 alone is sufficient to trigger killing.[673] LFA-1 cross-linking does not lead to granule polarization, suggesting that it may be insufficient for triggering the killing process by itself.[143] This issue is further complicated by the capacity of receptors like DNAM-1 to modulate LFA-1 association and function on NK cells.[660] Moreover, NK cells express multiple receptors capable of binding target ligands, with each receptor potentially affecting different downstream signaling pathways. When pairs of these receptors (eg, CD16, NKp46, NKG2D, 2B4, DNAM-1, or CD2) are cross-linked, synergistic NK-cell activation in terms of cytokine production and target killing can be seen for some but not all pairs.[674] However, this approach has not been used for the panoply of NK-cell receptors. Thus, how "accessory" molecules or other receptors contribute to each activation receptor function on NK cells remains to be systematically determined.

Ligands Recognized by Both Activation and Inhibitory Receptors

Evident from the previous discussion is the general concept that NK cells usually express both activation and inhibitory receptors simultaneously. Moreover, some of these receptors with opposing functions bind essentially identical ligands. For example, both activation and inhibitory receptors in the Ly49 and KIR families reportedly bind MHC-I molecules, and CD94/NKG2A and CD94/NKG2C bind HLA-E/Qa1. In general, where studied, the inhibitory receptors tend to bind ligands with higher affinities than their corresponding activation receptor counterpart, perhaps accounting for the common observation that inhibition tends to dominate over activation. However, the overall relevance of paired activation and inhibitory receptors to NK-cell immune responses remains to be elaborated.

SIGNAL TRANSDUCTION IN NATURAL KILLER CELLS

NK cells receive two basic types of external stimuli from cytokines and chemokines, and from target cell recognition. In general, their cytokine and chemokine responses are related to those found in other cells responding to the same pathways. However, as can be appreciated from the previous description of individual target recognition receptors, the pathways leading to target killing are complicated because some receptors are coupled to ITAM-containing signaling chains (CD3ζ, FcεRIγ, or DAP12). Indeed, some receptors use more than one of

these signaling chains, which are generally thought to be equivalent but not dissected in detail. Other receptors, such as NKG2D (through DAP10), have Tyr motifs for recruitment of PI3K and Grb2. Still others (2B4 and related receptors) have ITSMs. Moreover, integrin signaling also affects NK-cell activation by targets, and it was reported that NKG2D signaling through DAP10 can affect IL15 responses and vice versa,[675] which highlights the possible cross-talk of signaling pathways more broadly in immune cells.[676] Finally, because individual NK cells can express (and use) multiple different receptors simultaneously, and some but not all work synergistically,[674] the outcomes of these activation pathways may reflect profound complexity, even without consideration of inhibitory receptor signaling events.[677]

The study of NK-cell signal transduction also comes with some caveats. Most studies have been performed on bulk populations of NK cells, NK cell clones, or in vitro adapted cell lines that may not be representative of pathways triggered in individual NK cells which may express only some but not all signaling molecules detected in the entire NKcell population. When NK cells are triggered by target cells, there may be unknown stimulation through other receptors because unknown target ligands may inadvertently trigger or modulate functions of other NK-cell receptors. Finally, there may be species (human versus mouse) differences in signaling. Despite these complexities, themes have emerged in understanding of NK-cell signal transduction.

For the signal transduction pathways stimulated by NK-cell activation receptors coupled to ITAM-containing signaling chains, downstream events resemble those found in TCR and BCR signaling.[678] Activation receptor crosslinking leads to ITAM phosphorylation by Src family tyrosine kinases, recruitment and activation of Syk family tyrosine kinases, and subsequent downstream activation events. Inasmuch as TCR and BCR signaling is covered in detail elsewhere, we will highlight here notable differences with TCR and BCR signaling. 1) Individual NK cells may simultaneously express multiple activation receptors, each of which may associate with different ITAM-signaling chains that could be phosphorylated by different Src family tyrosine kinases and/or lead to different downstream signaling events. 2) NK cells express multiple Src kinases, including Lck, Fyn, Src, Yes, Lyn, and Fgr,[679] with redundancies in their contributions to ITAM phosphorylation. For example, Fyn is activated following Ly49D (DAP12) cross-linking but NK cells deficient in Fyn, Lck, or both still kill in a Ly49D-dependent manner.[680] 3) NK cells express both Syk family tyrosine kinases, ZAP-70, and Syk itself, whereas T and B cells express either, respectively, but not both. Deficiency of either ZAP-70, Syk, or both has only minimal effects on NK cell killing,[681] suggesting other pathways for transmitting NK activation signals. 4) NK cells express many adapter molecules found in T and B cells, but their contributions to NK signal transduction are less well defined. For example, SLP-76 and linker for activation of T cells are dispensable for NK-cell signaling, although they are both required for T-cell signaling.[682,683] 5) Different isoforms of signal transduction molecules are responsible for NK-cell activation. For example, mouse NK cells utilize phospholipase C-γ2 (PLCγ2) as a critical signaling mediator[684] more like B cells than T cells.[685] 6) In contrast to T and B cells, NK-cell signaling components are generally not required for normal NK-cell development. For example, NK cells are not deficient in number or maturation state in PLCγ2-deficient mice, unlike B cells, which require PLCγ2 for

development.[684,685] Taken together, these findings highlight differences between NK-cell and T- and B-cell signaling.

Illustrating some of the aforementioned issues are studies on the Vav family of guanine nucleotide exchange factors, Vav1, Vav2, and Vav3, which are all expressed in mouse NK cells.[686] Vav2 and Vav3 are required for FcRγ and DAP12 signaling, whereas Vav1 is required for DAP10 signal transduction. Additionally, NK-cell number and differentiation are not apparently affected by Vav deficiencies even when they are required for NK-cell activation. In contrast, deficiencies in Vav family members lead to T- and B-cell development defects.[687] These observations also indicate the redundancies in NK-cell receptor signaling.

On the other hand, Vav1 appears to be central to human NK-cell activation by targets[688,689] even though the role of other Vav isoforms in human NK cells is less clear. Vav1 is also involved in macromolecular complexes with c-Cbl that are formed during NK-cell activation.[690] Interestingly, c-Cbl provides an inhibitory influence on NK-cell activation.[689] During NKG2D and 2B4 synergistic signaling, strong Vav1 signals override the c-Cbl effect to allow NK-cell activation, again placing Vav1 as a central player in human NK-cell activation.

Recruitment and activation of PI3K appears to be critical to NK-cell activation for target killing.[691,692] How PI3K is activated depends on the receptor and its proximal signal transduction events.[677] In the case of NKG2D, the YxxM motif in DAP10 is phosphorylated and recruits PI3K directly,[693] which appears to be sufficient to activate NK-cell killing in the absence of DAP12 or Syk family tyrosine kinases.[694] The pathway may be more complex in human NK cells where evidence suggests that DAP10 recruits a Grb2-Vav1 intermediate for activation.[491] For other activation receptors, Syk activation is upstream of PI3K[695] and may directly recruit PI3K.[696] PI3K in turn activates a mitogen activated protein kinase (MEK) for stimulation of extracellular signal-regulated kinase (ERK).[691] Ultimately, actin polymerization occurs, granules become polarized toward the target, and exocytosis occurs, resulting in target apoptosis, as discussed previously. Interestingly, in human NK cells, engagement of LFA-1 by ICAM-1 on insect cells was sufficient to induce granule polarization but not degranulation,[143,674] suggesting additional complexity regarding the signals required for polarization versus degranulation.

High-resolution microscopy has enabled visualization of events following NK-cell activation. Like CTLs, NK cells form discrete protein clusters at the site of contact with their targets, termed the immunological synapse,[697,698] though obviously the TCR is not involved. Following target contact, the NK immunological synapse (NKIS) is formed at the NK-target interface in discrete stages whereby receptor signaling, filamentous (F)-actin rearrangement, and polarization of granules occur.[699,700] CD2, F-actin, LFA-1, and Mac-1 accumulate in the peripheral supramolecular activation complex (pSMAC), whereas granules (perforin) and the activation receptor accumulate centrally (cSMAC).[701] Other peripheral supramolecular activation complex and centrally supramolecular activation complex components and patterns are found depending on whether or not the contacts lead to cytolysis.[698,702] With this basic outline of microscopic events, molecules required for NKIS formation and granule polarization are being dissected.[125,692,703,704,705]

Mechanism of Inhibition by Natural Killer-Cell Receptors

The now widely accepted view is that the NK-cell inhibitory receptor mechanism consists of ligand binding and receptor cross-linking followed by ITIM phosphorylation, and preferential recruitment of SHP-1, and that this mechanism

operates with both structural types of inhibitory receptors. A typical human KIR molecule has two ITIMs separated by ~24 residues. In contrast, Ly49A has only one ITIM per chain, but Ly49 molecules are normally expressed as homodimers. CD94 has a minimal cytoplasmic tail, but NKG2A has two ITIMs. Each ITIM can be phosphorylated upon receptor cross-linking (though difficult to visualize) or tyrosine phosphatase inhibition,[212,706,707,708,709,710] presumably by a Src family tyrosine kinase as in B cells,[711] although redundant expression and function of these kinases have precluded identification of a single kinase required for ITIM phosphorylation in NK cells. ITIM phosphorylation results in recruitment and activation of the intracellular tyrosine phosphatase, SH2-containing protein tyrosine phosphatase (SHP)-1 (also known as hematopoietic cell phosphatase (HCP), protein tyrosine phosphatase 1C (PTPIC), and protein-tyrosine phosphatase, nonreceptor-type, 6(PTPN6)).[212,706,707,708,712] Two ITIMs are required for sequential binding of the two SH2 domains in SHP-1.[710,713] The NK-cell MHC-specific inhibitory receptors preferentially recruit SHP-1 rather than SH2-containing inositol polyphosphate 5-phosphatase (SHIP), though they may occasionally bind SHP-2.[706,714,715] Inhibitory receptor engagement results in early KIR and SHP-1 recruitment to areas surrounded by LFA-1.[716] Moreover, early events in NK-cell activation are blocked by inhibitory receptors, such as formation of the NKIS.[716,717,718] On the other hand, KIR phosphorylation occurs within clusters at the NKIS, which may serve to focus inhibition on downstream targets,[719] such as Vav1, which is recruited into the mature synapse during NKG2D/DAP10 signaling.[704] Indeed, the downstream target of the ITIM-recruited tyrosine phosphatase appears to be Vav1 in human NK cells activated by targets.[688] Thus, the general consensus has long been that the inhibitory receptors recruit tyrosine phosphatases that dephosphorylate molecules in the activation receptor cascade, such as Vav1.

On the other hand, related ITIM-containing inhibitory receptors bind other effector molecules, such as Csk by LAIR-1 and LILRB1,[423,720] suppressor of cytokine signaling 3 (SOCS3) by Siglecs,[721] and SHIP by KLRG1[722] and FcγRIIB.[723] Even a KIR ITIM may recruit other molecules such as β-arrestin[724] and PI3K.[725] Morever, a SHIP-deficient mouse demonstrates abnormalities in NK-cell function and Ly49 receptor expression,[726] even though Ly49 receptors recruit SHP-1. The functional significance of these signaling effector molecules in NK-cell inhibition and the specificity for ITIM recruitment of selective molecules are poorly understood and is potentially related to the complexity of inhibitory receptor signaling.

Emerging data suggest that inhibitory receptor signaling may not be as simple as phosphatase recruitment to dephosphorylate proximal molecules in the activation pathway that then prevents all downstream signaling events. For example, inhibitory receptors

efficiently blocked granule polarization but inefficiently prevented degranulation.[727] During ongoing NK-cell activation, KIR2DL2 engagement by photoactivated HLA-C ligand disrupted the NKIS but had little effect on ongoing calcium flux.[728] Thus, some but not all of the signaling events downstream of NK-cell activation receptors may be effectively regulated by the inhibitory receptors, directing future studies to selected aspects of NK-cell signal transduction.

Inhibitory signaling also induces other events. Normal human NK-cell activation by susceptible targets led to Tyr phosphorylation of Vav1 and its association with c-Cbl, which was also Tyr phosphorylated.[690] In turn, c-Cbl was associated with a signaling complex consisting of an adaptor protein (Crk, either CrkII or CrkL, depending on the cell), a scaffold protein (p130CAS,[130] kDa Crk-associated substrate), and C3G (Crk SH3 domain-binding guanine-nucleotide exchange factor). These c-Cbl complexes have the potential to signal a wide variety of cellular pathways including Rap1 GTPase activation, actin reorganization, cell adhesion, and mitogen-activated protein kinase activation,[729] which appear to be critical for NK killing. By contrast, ligand engagement of either KIR or CD94/NKG2A blocked the formation of Cbl-Crk-p130CAS-C3G complexes.[690] Moreover, ligand engagement of either KIR or CD94/NKG2A induced the association of the tyrosine kinase c-Abl with Crk, and Crk phosphorylation that was shown to be required for active dissociation of Crk from Cbl and for inhibition. Thus, these studies showed that inhibitory signaling ironically involved Tyr phosphorylation and disruption of macromolecular signaling complexes, which in turn, suggest that NK-cell activation (and inhibition) may be subject to more qualitative controls than previously recognized.

Another possible explanation for inhibitory signaling is related to the inhibitory influence that c-Cbl has on NK-cell activation[689] and other immune cells, such as T and B cells.[730] Although Cbl family molecules exhibit E3 ubiquitin ligase activity, and may exert their negative effects on lymphocyte signaling by enhancing degradation of signaling components,[731] there are as yet little data supporting this mechanistic role for Cbl in NK-cell activation.[689,690] Nonetheless, current information suggests additional aspects of NK-cell inhibitory receptor signaling are yet to be discovered.

Finally, Ly49 receptors on NK cells can acquire their cognate MHC-I ligands from surrounding cells, resulting in display of both molecules on the NK cells.[732,733] Broadly speaking, this effect is probably related to trogocytosis, a poorly understood phenomenon of intercellular transfer of surface molecules.[734] How much this contributes to *cis* effects on inhibitory receptor function and its physiological relevance require further evaluation.

NATURAL KILLER-CELL TOLERANCE

NK cells display potent effector functions that must be controlled to prevent inadvertent damage to normal tissues (ie, NK cells must demonstrate tolerance to self). Although the missing-self hypothesis provides a rationale and starting point for dissection of NK-cell tolerance, it has a number of caveats that need to be considered before delving into current understanding of this aspect of NK-cell biology.

Influence of Host Major Histocompatibility Complex-I Environment

The missing-self hypothesis implies that there should be overt NK-cell autoreactivity in MHC-I-deficient hosts, but this was not observed in humans or mice.[179,180,181,735,736,737,738] Instead,

NK cells from MHC-I-deficient mice demonstrate poor killing of MHC-I-deficient targets or rejection of MHC-I-deficient BM, even though they appear normal in number, tissue distribution, and expression of activation receptors. Another very difficult issue is related to hybrid resistance whereby host NK cells in an F_1 hybrid animal can reject BM grafts from either inbred parent.[739,740] It was difficult to understand how NK cells discriminate between cells expressing the full complement of self-MHC alleles versus those otherwise normal cells expressing only some self-MHC molecules. NK-cell-mediated rejection of MHC-I-sufficient BM grafts also depends on which host MHC-I allele is present.[741,742] Thus, NK cells are regulated by host MHC environment, not just by the target cell in effector responses.

The MHC-specific inhibitory receptors were likely to be involved in self-tolerance because they explain the influence of MHC expression on NK-cell effector functions against target cells. However, how these receptors are related to self-tolerance in vivo was a challenging issue. Several hypotheses were proposed. An individual NK cell can simultaneously express multiple inhibitory receptors but some may not recognize self-MHC. The “at least one receptor” model suggests tolerance is achieved as long as each NK cell expresses at least one receptor with self-MHC specificity.[389,743] There are changes in the repertoire of MHC-I-specific inhibitory receptors, depending on the MHC haplotype, but these differences are modest, regardless of whether the receptor is self-specific or not.[210,248,389,743,744] As determined by antibody reactivity, the expression level of an NK receptor on an individual NK cell decreases when the host expresses the MHC ligand for that receptor.[208,209,745] Functional analyses of NK cells with “downregulated” receptor expression suggest that such NK cells are more sensitive to small changes in MHC ligand expression on the target, as explained by the “receptor calibration” model.[744,746] However, these studies involved in vitro conditions that could alter their intrinsic functional capacities. Thus, several hypotheses based on the MHC-specific inhibitory receptors were proposed to account for NK-cell self-tolerance.

Also unexplained was the observation that NK cells were found in wild-type mice expressing none of the known self-MHC-specific inhibitory receptors. These cells were functionally “hyporesponsive,” showing defective antiactivation receptor cross-linking and killing of NK-sensitive targets,[747] but it was possible that other, yet to be defined receptors were playing a role. Another issue was the appropriate pairing of polymorphic inhibitory receptors with their highly polymorphic cognate MHC ligands.[260,317] The genes for the receptors and their ligands are located on different chromosomes (ie, the receptor and ligand genes segregate independently). Thus, there must be mechanisms to provide NK cells with the appropriate inhibitory receptors with specificity for self-MHC because the appropriate pairs are not inherited together, unlike the closely linked *Nkpr1-Clr* gene pairs.[575]

The Licensing Hypothesis

Studies with target cell-free stimulation and single cell assays of NK-cell responsiveness

revealed insight into NKcell tolerance.[168,747,748] Freshly explanted, resting murine NK cells from MHC-I-deficient mice were functionally defective in triggering by immobilized antiactivation receptor antibodies.[168] Conversely, in wild-type mice, functional competence correlated with expression of a Ly49 inhibitory receptor for self-MHC-I.[168] CD94/NKG2 receptors appeared not to be relevant,[168] as confirmed by studies of a CD94-deficient mouse.[395] Particularly informative were studies with a single chain trimer MHC-I molecule, consisting of antigenic peptide-linker-β2m-linker-$H2K^b$ as a single polypeptide that binds only Ly49C.[168] In Tg mice expressing only this MHC-I molecule, only Ly49C+ NK cells were functionally competent. Although crystallographic studies revealed two potential sites on MHC-I that could be recognized by Ly49 receptors, studies of Tg mice bearing mutant MHC molecules indicate that the Ly49 receptors recognize the same site on their MHC ligands (site 2) for both education and effector inhibition.[749] Thus, NK cells use their MHCspecific receptors interacting with self-MHC-I to become competent to be triggered through their activation receptors by (Fig. 17.6), an education process termed “licensing.”

Despite initial confusion over the term licensing,[750] most investigators now concur that licensing or education by self-MHC-specific receptors results in fuctionally competent NK cells.[751] Moreover, human NK cells are also subjected to a similar process involving KIR and self-HLA ligands[752,753] that may also explain clinical studies relating KIR and HLA alleles and disease and even human immunodeficiency virus (HIV) control.[754,755] Such KIR-HLA relationships frequently involve pairs with high affinities and resolution of chronic infections[756] that are difficult to explain when only considering effector inhibitory function of the KIRs. Thus, licensing may be clinically relevant and may be applicable to other clinical uses of NK cells (see following discussion) because it is a second function of the NK-cell receptors for MHC.

Licensing leads to appropriate pairing of inhibitory receptors with self-MHC and strongly suggests that there are two types of self-tolerant NK cells (see Fig. 17.6).[750,757] Regardless of the MHC-I environment, licensed NK cells are tolerant because they have inhibitory receptors for self-MHC, the same receptors involved in licensing. Unlicensed NK cells are also tolerant because they are not functionally competent and have no need for inhibition by self-MHC under steady-state conditions. In hosts heterozygous for MHC alleles, each MHC allele could potentially license different NK-cell populations. This aspect of licensing is relevant to hybrid resistance because an (A × B)F_1 hybrid animal should have NK cells that are separately licensed on different MHC alleles.[750] F_1 hybrid NK cells that were licensed by MHC alleles from parent A should be inhibited by A alleles but not B alleles, and thus reject BM from parent B. The converse should also be true. In the F_1 animal itself, NK cells are licensed by either parental allele so all NK cells should be inhibited by normal tissues that codominantly express both MHC alleles. Licensing potentially explains how NK cells distinguish cells expressing the full complement of MHC-I from those expressing only some alleles.

Although initial studies on licensing were focused on only a few receptors and MHC alleles to demonstrate convincing effects, subsequent studies have demonstrated that

the licensing status of an individual NK cell is dependent on the Ly49 receptor, MHC allele, and the number of expressed self-MHC-specific Ly49 receptors.[219,758] For example, different MHC alleles appear to be more potent in licensing Ly49A+ NK cells, in a hierarchical manner.[219] The same hierarchy of MHC alleles was seen with Ly49A downregulation and inhibition of Ly49A+ NK cells in effector responses. An MHC allele was more potent at inhibition as compared to licensing, providing a margin of safety against NK-cell autoreactivity.[219,759] Interestingly, MHC heterozygosity was comparable to homozygosity with capacity of an MHC allele to license.[219] Studies of mice bearing one, two, or more MHC alleles also show similar effects.[758] These results have prompted a refinement of the licensing hypothesis (ie, the "tuning" or "rheostat" model) whereby the strength of inhibitory receptor engagement by self-MHC determines the degree to which an NK cell is capable of being activated.[750,760]

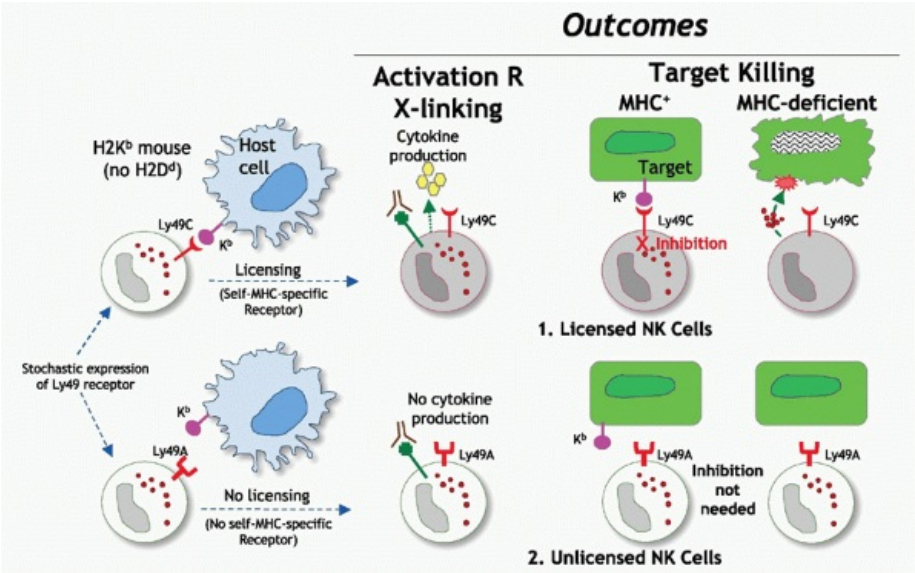

FIG. 17.6. Licensing of Natural Killer (NK) Cells by Host Major Histocompatibility Complex (MHC)-I. Depicted is the situation in a mouse expressing only $H2K^b$ that is a ligand for Ly49C but not Ly49A. Cells expressing Ly49C therefore have a self-specific receptor, whereas those expressing Ly49A do not. Ly49C engagement by self-MHC-I results in a licensed NK cell that has functional competence to be triggered through its activation receptors. These cells can be inhibited by self-MHC through the same receptor that conferred licensing. Ly49A+ NK cells remain self-tolerant because they are unlicensed. For clarity, only one MHC allele and cells expressing one Ly49 receptor are shown. Activation receptors are also not shown for the target killing depiction. Normally, the host has multiple MHC alleles, each of which could license different NK cells, and individual NK cells express multiple Ly49s simultaneously. Each NK cell is likely to be licensed separately, potentially by different MHC alleles, and through different Ly49s. Modified from Elliott and Yokoyama.[750]

Where and with whom licensing occurs is currently unclear. While original studies suggested that licensing occurs during development in the BM,[168] adoptive transfer of otherwise unlicensed NK cells from an MHC-deficient host into an MHC-sufficient environment results in licensed donor NK cells.[761,762] The converse was also observed (ie, loss of function when wild-type NK cells were transferred into an MHC-deficient environment). These studies add to the discussion of whether an NK cell interacts with self-MHC in *trans* (on another cell) on in *cis* (on the same NK cell).[763] What is difficult to exclude is the possibility that NK cells may take up MHC-I from other cells via their MHC-specific receptors,[732,733] but the transfer studies indicate that the NK cell itself does not need to synthesize MHC-I. Thus, licensing may be a dynamic process in which NK cells constantly test the same site on their MHC-I ligands to simultaneously maintain functional competency and effector inhibition.

Although licensing is a positive outcome (ie, the acquisition of functional competence), it requires the ITIM of the self-specific Ly49 receptor to deliver signals that ultimately result in a licensed NK cell[168] (see Fig. 17.6). The nature of such signals is not yet known, and at least two qualitatively different models are being considered. The MHC-specific receptor could confer licensing in a positive way by delivery of signals that directly induce a differentiation process and

license NK cells, akin to a stimulatory receptor and also known as the “arming” hypothesis[764] In the second model, also known as the “disarming” hypothesis,[764] the MHCspecific receptors decrease the effect of a putative, as yet uncharacterized, self-specific activation receptor. If unimpeded by self-MHC-I, NK cells become hyporesponsive due to overstimulation through the activation receptor. This model is somewhat akin to T-cell anergy and places the self-MHC-specific receptor in a familiar light as an inhibitory receptor. Both models are similar to those previously proposed,[765] but engagement of the MHC-specific receptor with self-MHC is now known to be a required key step[168] and is common to both models. Also, the models are not mutually exclusive and either could be affected by coreceptors or adhesion molecules. Regardless, licensing may be explained by either the arming or disarming hypothesis.[750]

For the arming hypothesis, it is difficult to reconcile the involvement of the ITIM in the self-MHC specific receptor in licensing,[168] though recent analysis shows that inhibitory receptor signaling is more complex than previously recognized.[689,690] Recent studies also suggest that there are few differences in genes expressed by licensed verus unlicensed NK cells.[766] Instead, in licensed NK cells, the activation receptors appeared to be localized in nanodomains in the plasma membrane, whereas in unlicensed cells, the activation receptors were apparently confined to the actin meshwork.[766] Future studies will be needed to validate this correlation and how the self-MHC-specific receptors mediate these changes.

For the disarming model, studies on mice constitutively expressing activation receptor ligands by transgensis or retroviral transduction of hematopoietic stem cells have been informative.[534,538,767,768] In support of the disarming hypothesis, continuous engagement of NKG2D or Ly49H resulted in hypofunctional NK cells, akin to anergy. Indeed, m157 Tg mice could not resist MCMV infections normally, and the Ly49H+ NK-cell subset was

selectively hyporesponsive. However, the anergic phenotype was unaffected by expression of a self-MHC-specific receptor.[767] Although it remains possible that receptor-ligand interactions that normally govern NK-cell self-tolerance were not well represented in these Tg mice, the current data nonetheless do not support the disarming hypothesis as an explanation for licensing and suggest that "anergy" may be a distinct tolerance mechanism for NK cells, perhaps analogous to separable tolerance mechanisms for T and B cells.[769]

In addition to bone marrow rejection, licensed NK cells may provide primary protection in viral infections and may enhance CD8+ T-cell responses.[770,771,772] On the other hand, unlicensed NK cells may gain functional competence by exposure to cytokines.[168] During MCMV infection, unlicensed NK cells (ie, cells without self-MHC-specific receptors) appear to control viral replication in both MHC-deficient and -sufficient mice.[773,774,775] Thus, the role of self-tolerant NK cells in immune responses requires additional study.

NATURAL KILLER-CELL DEVELOPMENT

Early evidence indicated that the complete phenotypic and functional maturation of NK cells occurs in the BM and requires an intact microenvironment because BM ablation or congenital BM defects lead to abnormal NK cells.[776,777,778,779,780] Indeed, certain aspects of NK-cell development are regulated by direct interactions between developing NK cells and stromal elements, such as interactions between membrane lymphotoxin-α (LTα)-expressing NK-cell precursors (NKPs) and LTα-responsive stromal cells that are necessary for normal development.[154,781] In vitro, NK cells can be generated from early hematopoietic cells in a cytokine cocktail consisting of stem cell factor (c-kit ligand), IL-7, flt-3 ligand, and IL-15.[782,783,784,785,786,787,788,789] Direct contact with stromal cells appears to be required for acquisition of Ly49 receptors by developing NK cells. Moreover, the Tyro3 family of receptors (Tyro3, Mer, Axl) on NK cells and their ligands (Gas6, protein S) on stromal cells are apparently necessary for expression of NKcell receptors and functional differentiation in vitro and in vivo.[790,791] Thus, NK-cell development requires certain cytokines and direct stromal cell contact.

Although the general topic of NK-cell development is currently an active area of investigation, and is thus subject to future modifications, several major themes have emerged that will be summarized here. The earliest step involves the commitment of hematopoietic stem cells in the BM to the common lymphoid progenitor that can give rise to NK, T, and B cells, but not to myeloid cell lineages.[792,793] Mice deficient in various transcription factors, including Ikaros and PU.1, display severe defects in the development of all lymphoid cells including NK cells, while myeloid and erythroid lineages are less affected.[794,795,796,797,798] Thus, NK-cell development appears to share a common pathway with other lymphocytes, providing evidence that NK cells belong to the lymphocyte lineage.

Commitment to the NK-cell lineage from the common lymphoid progenitor (CLP) appears to involve an intermediary cell with T- and NK-cell potential (T/NK progenitor), perhaps reflecting the close resemblance of T- and NK-cell effector functions. Consistent with this bipotentiality, CD3ε and FcεRIγTg mice exhibit selective defects in both NK- and T-cell development.[799,800] Moreover, deficiencies in several genes, including transcription factors

and IL-15,[54,801] affect development of NK-cell and certain T-cell subpopulations, particularly NKT cells and memory T cells. T/NK progenitor populations, including immature thymocytes, can give rise to T and/or NK cells but not to other lineages, depending on culture conditions, such as Notch signaling.[802,803,804,805,806,807,808] Interestingly, the transcription factor Bcl11b is required to maintain T-cell fate by apparently repressing NK-cell fate. Specifically, Bcl11b is required for T-cell specification,[809,810,811,812] and its deletion, in committed T-cell precursors or even mature T cells, results in loss of T-cell phenotype and instead acquisition of NK cell-like phenotype,[809] highlighting the developmental pathways shared by these cell lineages.

NK cells also have a developmental relationship to Lymphoid Tissue inducer (LTi) cells. In addition to phenotypic similarities as previously discussed for NK-22 cells, LTi and NK cells also share a relatively unique feature in expressing surface LTα, which influences development of lymphoid tissues and NK cells, respectively.[154,781] Moreover, deficiencies of either Ikaros or Id2 result in defects in LTi and NK cells, though other cells are also affected.[813,814] Interestingly,

mice lacking the thymocyte selection-associated high mobility group box protein DNA-binding protein lack both LTi and CD122+ NK cells.[815] The NK-cell defect is NK cell-intrinsic, and Id2 overexpression could not compensate for thymocyte selection-associated high mobility group box protein (TOX)-deficiency.

Until recently, the acquisition of IL-2/15Rβ subunit (CD122) was considered to mark the earliest identifiable committed NKP.[805,816] However, an earlier progenitor population (pre-NKP) has been identified that has not yet expressed CD122.[817] Upon adoptive transfer, these lineagenegative (lin-) cKit- Flk2- CD27+ CD244+ IL-7Rα+ CD122- cells from the BM could give rise to NK cells in the BM, blood, and spleen but no other cell lineages. Thus, IL-15 is not required for commitment to the NK cell lineage, even though it is required for subsequent NK-cell developmental stages as illustrated by the persistent expression of CD122.[44,53,54,55,56,57]

CD122 expression is regulated by the combined action of the T-box transcription factors, T-bet (Tbx21) and Eomesodermin (Eomes) that have redundant function in NK-cell development.[801,818] Specifically, *Tbx21-/- Eomes*+/- mice have marked decreases in CD122 expression and NK cells, whereas *Tbx21-/- Eomes*+/+ mice manifest no defect in CD122 expression and more modest defects in NK-cell number. Moreover, Eomes targets the promoter of *Cd122*. IL-15 appears to regulate the basic leucine zipper (bZip) transcription factor E4BP4 (E4 binding protein 4,[819] also known as nuclear factor IL-3[820]) in NK-cell development. *E4bp4*-/- mice display profound NK-cell deficiency.[821,822,823] Gene transduction of *E4bp4*-/- hematopoietic stem cells with *E4bp4* rescued NK-cell development in vitro even in the absence of IL-15, suggesting that E4BP4 acts downstream of IL-15 signaling. *E4bp4*-/- mice show no alterations in other hematopoietic cells except for a defect in CD8a+ cell development. [824] This latter finding may be relevant to phenotypic overlap between NK cells and DCs.[115,116,117,118,119] Regardless, Eomes affects NK-cell development by promoting CD122 expression, whereas E4BP4 affects commitment to the

NK-cell lineage by apparently acting downstream of IL-15.

Committed NKPs next differentiate into mature NK cells in a series of putative developmental intermediate stages that occur in the BM.[98,816] Originally defined by correlating phenotypic markers, including NK-cell receptors, integrins, and other molecules with apparently distinct developmental stages,[825,826] these stages have been confirmed by studies following serial acquisition of markers during NK-cell differentiation in vitro.[789] Regardless, these stages of committed NKPs are undergoing constant refinement as new rate-limiting steps are being uncovered, such as in studies of mice lacking specific transcription factors or as new markers and tools are developed.[827] Nonetheless, a few highlights should be noted.

NK-cell receptors involved in target recognition are expressed at immature stages, with NK1.1 and CD94/NKG2 being among the first, followed by NKp46, and NKG2D then the Ly49s.[827] Following Ly49 acquisition, developing NK cells undergo spontaneous proliferation at an immature stage.[98] Thereafter, as NK cells acquire high-level expression of Mac-1 (αMβ1) and CD43, proliferation markedly decreases unless challenged by pathogens such as viruses that can stimulate mature NK-cell proliferation.[98,166] NK cells then gain functional activities associated with splenic NK cells, indicating that Mac-1 expression correlates with a late maturation stage. A selective NK-cell deficiency in a Tg mouse is manifested by a failure to become mature, functional Mac-1^{hi} cells,[828,829] consistent with this differentiation step. Finally, while CD27 is expressed from the very earliest stages of NK-cell development,[817] its diminished expression within the Mac-1+ subset is associated with a more responsive capacity.[830] Thus, Mac-1 and CD27 expression are now commonly used to ascertain NKcell maturation in the mouse.

In addition to the transcription factors mentioned previously, several other transcription factors, including Ets-1, Id2, IRF-1, MEF, and GATA-3, have been implicated in NK-cell development and function.[813,831,832,833,834,835,836] The need for Id2 in NK-cell development can be overcome by deletion of the gene for the E protein, E2A.[814] IRF-1-deficient mice lack NK cells, and this defect can be overcome by the addition of IL-15, suggesting that stromal cells produce IL-15 in an IRF-1-dependent manner.[813] Expression of Bcl2 restored the CD8+ T-cell deficiency but not the NK-cell deficiency in IRF-1-deficient mice.[837] IRF-2-deficient mice manifest a late defect in NK-cell maturation with normal constitutive proliferation but increased apoptosis thereafter.[838,839] In contrast to the other transcription factors, GATA-3 does not affect NK cell number; rather, it controls their IFNγ production and their homing to the liver.[836] Similarly, CCAAT/enhancer binding protein (C/EBP) γ-deficient NK cells display defective effector functions.[840] The relationships of the transcription factors to each other are just beginning to be elaborated in terms of regulating NK-cell development and function.

As for mouse NK cells, human NK-cell developmental stages have been identified by correlating markers on in vivo subsets.[841,842,843,844] In general, these stages have been recapitulated by in vitro development of functional human NK cells from hemapoietic stem cells from umbilical cord blood or differentiated embryonic stem cells.[845,846] As in the

mouse, a combination of cytokines and stromal cells is necessary for in vitro differentiation.

These studies suggest that human NK cells differentiate in secondary lymphoid tissues as revealed by studies of $CD56^{bright}$ and $CD56^{dim}$ NK cells.[110,847] $CD56^{bright}$ NK cells preferentially express CD94/NKG2 receptors (versus KIRs), are CD16-, and are better cytokine producers and less efficient killers than the $CD56^{dim}$ subset that tend to be KIR+ and CD16+.[109] A CD34+ CD45RA+ hematopoietic precursor cell (HPC) was identified that expressed the integrin $\alpha_4\beta_7$ at high levels.[847] This population was found at low levels (< 1% of HPCs) in the BM but was markedly enriched in lymph node (LN; > 95% of HPCs), and could be differentiated into $CD56^{bright}$ NK cells in vitro. On the other hand, in nonreactive LNs, NK cells tend to be $CD56^{bright}$ whereas in reactive LNs, they tend to be $CD56^{dim}$, the predominant population in peripheral blood.[110] $CD56^{bright}$ cells acquire the $CD56^{dim}$ phenotype when stimulated in vitro with proinflammatory

cytokines, such as IL-12, or with IL-15 in *trans* in a humanized mouse model.[848] Taken together, these data suggest that human NK cells differentiate in secondary lymphoid tissues in response to inflammation by first becoming $CD56^{bright}$ then completing maturation to the $CD56^{dim}$ phenotype.

Although the maturation of mouse NK cells in secondary lymphoid tissues has not been studied carefully, there is an abundance of NK cells with an immature phenotype in organs, such as the liver.[98] On the other hand, recent studies also provide evidence for thymic maturation of a subpopulation of mouse NK cells, termed “thymic” NK cells[111] These cells are characteristically CD127+ $CD69^{high}$ $Ly49^{low}$ $CD11b^{low}$ in contrast to conventional resting splenic NK cells that are CD127- CD69- $Ly49^{hi}$ $CD11b^{hi}$. Thymic NK cells were enriched in LNs and are absent in GATA-3-deficient and in athymic nude mice, indicating that these cells require GATA-3 and an intact thymus for their development. Indeed, thymic NK cells can develop in vivo and in vitro from double negative (CD4- CD8-) 1 (DNI) subsets of immature thymocytes.[789] Interestingly, mouse thymic NK cells bear some phenotypic markers that tend to be found on human $CD56^{bright}$ NK cells.[111] The contribution of secondary lymphoid tissues to NK-cell development, the role of thymic NK cells in immune responses, and the relationship of these mouse and human NK-cell subsets remain to be clarified.

ROLE OF NATURAL KILLER CELLS IN IMMUNE RESPONSES

Mature NK cells in the periphery are involved in rapid innate defense. However, they constitute only a small population of cells (about 2.5% of splenic leukocytes in C57BL/6 mice). How can this small population quickly respond with enough of a critical mass to effect significant innate defense? One mechanism involves the expression of multiple activation receptors by individual NK cells.[449] By contrast to clonally distributed TCRs endowing the individual T cell with the ability to respond only to one antigen, an individual NK cell appears capable of responding to multiple activation receptor ligands. Furthermore, the naïve T-cell population contains only rare cells with a TCR for the relevant antigen, whereas large percentages of the NK-cell population express any given activation receptor in an

overlapping fashion. This multiple activation receptor expression on sizeable subpopulations would allow a substantial number of NK cells to quickly respond to a given specific insult. Another mechanism is related to their constitutive expression of cytokine receptors that permit many NK cells to be stimulated by proinflammatory cytokines produced early in the course of an immune response. Finally, NK cells appear poised to respond rapidly. They constitutively express mRNA for effector molecules, such as granzymes and cytokines, but no protein due to translational control, and can rapidly produce these molecules upon stimulation.[29] Thus, large numbers of NK cells can rapidly respond to a particular stimulus through their activation or cytokine receptors.

Where do NK cells respond? In the mouse, mature conventional NK cells are found primarily in the spleen, blood, and liver. Interestingly, NK cells are localized to the red pulp of the spleen.[849,850] In the liver, they are in the sinusoidal regions rather than the parenchyma, and few NK cells are present in other solid organs. In viral infections, NK cells infiltrate the liver parenchyma in the vicinity of infected foci.[849,851] Several chemokines, including MIP1α, have been implicated in NK-cell localization to liver parenchyma during immune responses,[852] for example, but the NK cell "chemokine code" needs to be clarified.[853] Surprisingly, there are relatively few NK cells in naïve lymph nodes,[849,854] and the thymic NK-cell phenotype is overrepresented among the few resident NK cells,[111] although NK cells can be recruited to draining LNs.[855,856] However, human NK cells are relatively abundant in LNs where they appear to mature, as discussed previously. Study of human NK-cell responses in solid tissues has been limited for obvious reasons. Nonetheless, NK cells seem best suited for surveying the blood for transformed or infected cells and pathogens during acute immune responses but can be recruited to pathologic sites as needed.

As early innate immune responders, NK cells have the capacity to shape the adaptive immune response. For example, early NK-cell control of viral infection essentially limits antigen load and presentation by DCs thereby limiting CD4+ T-cell responses.[857] By contrast, early control also reduces activation of plasmacytoid DCs, thereby lessening the detrimental effects of type I IFNs, preserves the conventional DC compartment, and accelerates CD8+ T-cell responses.[858] Early IFNγ production by NK cells can prime and polarize T-helper responses.[855,859,860,861] In leishmania infections, later production of IL-10 by NK cells has an inhibitory effect on T cells.[862] In addition, NK-cell lysis of targets also enhances T-cell responses.[863] Thus, NK cells have the capacity to enhance, suppress, and polarize adaptive immune responses.

Natural Killer Cells and Tumor Surveillance

An abundant early literature supported a role for NK cells in resisting tumor growth and metastasis.[3] Most prior work utilized experimental protocols involving adoptive transfer of tumor cells into mice where NK cells may eliminate > 90% of tumor cells within the first 24 hours.[864] Several long-term assays of in vivo tumor clearance are available, such as survival or lesion size, but T-cell responses need to be excluded even in syngeneic hosts due to the possibility of tumor-specific peptides. Clearance of intravenously administered radiolabeled tumor cells can be measured with radioactivity of the lung as an index of tumor burden.

Because this lung clearance assay can be performed as early as 4 hours after tumor inoculation, it is relatively confined to innate NK-cell responses in the unimmunized host.[15] In these assays, NK-deficient mice are unable to clear adoptively transferred tumors.[828]

On the other hand, few studies are available on control of primary tumor formation by NK cells (ie, tumor surveillance).[865] Probably the most systematic studies in a single experimental model involve fibrosarcoma development after subcutaneous methylcholanthrene challenge.[866,867,868] In brief, NK cells collaborate with NKT cells in preventing

fibrosarcomas through mechanisms involving perforin, TRAIL, and IFNγ. There is also evidence for involvement of NKG2D[86] and its ligands with respect to the immunoediting of tumors by NK cells.[525,542]

In humans, epidemiological data indicates a strong correlation between high cytotoxic activity of peripheral blood lymphocytes and reduced cancer risk.[869] In addition, ongoing studies of BM transplantation for leukemia demonstrate a relationship between KIR, HLA alleles, and reduced risk of relapse from leukemia in some circumstances.[870,871] Thus, current data support the initial concept that NK cells are involved in tumor immunosurveillance.

Natural Killer Cells in Host Defense Against Pathogens

While NK cells reportedly respond to a wide variety of microorganisms including viruses, bacteria, parasites, and fungi,[872,873] the role of NK cells in infections is probably best illustrated by human patients with selective NK-cell deficiencies.[874,875] Although the molecular basis for most human NK-cell deficiencies is unknown, several points can be gleaned. 1) NK-cell deficiency is associated with a propensity for severe or recurrent virus infections, particularly herpes viruses. 2) Difficulty with tumors is not a common feature, except for virus-related lesions. 3) The disorder is rare, perhaps because patients succumb to overwhelming infection before the syndrome is recognized. 4) Defective NK cells can be found in other genetic and acquired immunodeficiency disorders that affect other immune components. For example, NK cell activity is significantly diminished in AIDS.[876,877] NK-cell infection with herpesvirus 6 induces de novo expression of CD4 rendering susceptibility to HIV-1 infection,[878] perhaps accounting, in part, for increased susceptibility of patients with acquired immunodeficiency syndrome to opportunistic infections, such as severe CMV.[879] Immature NK-cell number and function in the developing fetus may be clinically relevant to the classic “TORCH” syndrome, birth defects associated with maternal toxoplasma, rubella, CMV, and herpes virus infections.[880] Thus, NK cells appear to be especially important in controlling infections, especially from herpes viruses.

In mouse models, detailed evaluation of NK-cell responses against *Listeria* and viral infections have been especially revealing.[881,882] In vivo antibody depletion of NK cells results in marked viral replication in internal organs (spleen, liver), and lethality with MCMV, vaccinia virus, or mouse hepatitis virus.[883,884,885] A similar phenotype was observed in Tg mice lacking NK cells.[886,887] Interestingly, if depleting antibody was given to wild-type mice

later in the infection, there was no untoward effect.[884] Thus, NK cells are significant in early, innate immunity to infections.

Natural Killer-Cell Cytokine Responses and Production during Infection

During infection, NK cells can respond to several different cytokines resulting in production of other cytokines. In listeriosis, the classic model for T-cell-dependent resistance, *scid* mice achieve acute control of infection despite absence of T cells,[888] due to early NK-cell production of IFNγ.[889] However, NK cells do not appear to respond directly to *Listeria*. Rather, macrophages produce IL-12 that then stimulate NK-cell secretion of IFNγ and infection control.[164,890] Furthermore, TNFα can synergize with IL-12 to induce NK-cell production of IFNγ, whereas IL-10 is antagonistic.[164] The increased susceptibility of mice lacking IL-12 receptor, IFNγ, or the IFNγ receptor signaling pathway[891,892,893,894] are consistent with macrophage production of IL-12 that stimulates NK cells to secrete IFNγ in listeriosis.

While a similar IL-12-IFNγ pathway is also operational in MCMV infections,[886,895,896] IL-18 also contributes somewhat to NK cell control of MCMV.[897] However, IL-12 appears to be more critical than IL-18 because uniform lethality was observed in IL-12p35-/-mice challenged with MCMV while all IL-18-/- mice survive.[897] On the other hand, neutralization of IL-18 is a common feature of orthopox-viruses.[898] For example, ectromelia virus (mousepox) contains an ORF for an IL-18 binding protein (IL18BP) that effectively neutralizes the effects of IL-18 on NK cells.[899] In addition to augmented IFNγ production, IL-18 enhances perforin-dependent cytotoxicity.[900,901,902]

Importantly, not all viral infections are controlled by NK cells. For example, NK-cell depletion has little effect on lymphocytic choriomeningitis virus (LCMV) infections.[883,896,903] Yet, during infections, even with LCMV, cytotoxicity of NK cells is enhanced and proliferation ensues. These events constitute systemic effects directly or indirectly mediated by cytokines, such as IL-12, IL-18, and IFNα/β.[904] However, IFNγ production is not seen in LCMV infections.[895,905] This apparent paradox is due to an inhibitory effect of IFNα/β on IL-12-dependent IFNγ production.[905] Inhibition by IFNα/β is mediated through the STAT1 signaling pathway. In the absence of STAT1, IL-12 responsiveness is restored and IFNα/β induces IFNγ production. These studies indicate that the NK-cell cytokine response to infection varies with the pathogen even though many responses may appear to be similar.

A challenging issue is the role of IL-15 in NK cell responses in vivo[906] because IL-15 and IL-15Rα-deficient mice lack NK cells.[53,54] Nevertheless, NK cells can be stimulated during infection by IL-15 and control viral replication during in vitro cultures.[906,907,908,909,910] Moreover, IL-15 can provide protection to herpes simplex viral infections.[910] IFNα/β can stimulate IL-15 production that can drive NK-cell proliferation.[911] Interestingly, however, NK-cell proliferation can occur in an IFNα/β- or IL-15-independent manner.[912,913]

NK-cell responses to cytokines are also regulated by other innate lymphocytes. For example,

in TCRδ-/- mice, *Listeria* infection is enhanced compared to TCRβ-/- mice and is associated with diminished production of IFNγ by NK cells, suggesting that γδT cells regulate NK-cell responses.[914] Similarly, NKT cells can regulate NK cells because administration of α-galactosylceramide, a potent ligand for the TCR on NKT cells, results in nearly concomitant activation of NK cells[79] that may be exploited as a potential cancer immunotherapy. [915] The mechanism behind the NK and NKT cell cross-talk involves IFNγ, apparently produced initially by an activated macrophage.[916] Inasmuch as NKT cells can

recognize glycolipid antigens in mycobacteria,[917,918] these studies indicate a potential physiologically important mechanism and therapeutic intervention for NK-cell activation in innate control of these organisms.[919]

Natural Killer-Cell Activation Receptors in Infection

There are several observations from studies of viral evasion indicating the importance of NK-cell activation receptors in infection. Because viruses have evolved numerous strategies to downregulate MHC-I molecules on infected cells to avoid MHC-I-restricted cytotoxic T-lymphocytes,[186] virally infected cells should have enhanced susceptibility to NK-cell lysis. However, viruses also encode proteins that evade NK cells.[920] In many cases, viral interference of NK cells is related to enhanced function of inhibitory MHCI-specific NK-cell receptors. For example, murine and rat CMV contain ORFs *m144* and *r144*, respectively, that encode molecules with sequence and structural homology to MHC-I and enhance in vivo virulence presumably by interacting with as yet unidentified NK-cell inhibitory receptors.[921,922,923,924,925] MCMV also encodes m157 that can bind the inhibitory receptor Ly49I in 129 strain mice (see following discussion), as well as other MHC-I-like molecules of unknown function.[444,446,464,926] HCMV encodes an MHC-I-like molecule (UL18) that binds LIR1 (ILT2), an Ig-like inhibitory receptor on NK cells,[405,411,927] though its functional significance is somewhat unclear.[928] HCMV also encodes a peptide that binds and enhances expression of HLA-E that in turn binds CD94/NKG2A, a lectin-like NK-cell inhibitory receptor.[386,929,930,931] Another example is the selective downregulation of MHC-I by HIV-1.[932,933] In this case, the virus downregulates HLA-A and B but not HLA-C or E; the former HLA molecules tend to be restricting elements for MHC-I-restricted CTLs, whereas the latter are selectively recognized by human KIRs and CD94/NKG2A. Therefore, viruses have evolved mechanisms to selectively engage inhibitory receptors that presumably prevent the action of NK-cell activation receptors.

Viruses can also directly block triggering of NK-cell activation receptors. For example, both HCMV and MCMV encode multiple proteins that block NKG2D ligand expression by intracellular retention with functional consequences in vitro and in vivo,[920] as previously detailed. HIV-1 Nef also blocks NKG2D ligand expression.[934] Cowpox and monkeypox viruses use a different strategy; they encode a highaffinity, soluble antagonist that binds NKG2D and blocks its ligand recognition.[557] HCMV, Epstein-Barr virus, and KSHV use yet another strategy by encoding miRNAs that target MICB mRNA.[554,555] More generally, KSHV also avoids NK-cell activation through K5 that downregulates expression of ICAM-1 and B7-

2, ligands for NK cell coreceptors involved in target-induced stimulation.[935] Thus, viruses use multiple strategies to specifically thwart NK-cell responses through their activation receptors.

The viral evasion strategies implicate NK-cell activation receptors that specifically recognize infected cells; several have been identified. Human NKp46 binds hemagglutinin of influenza virus and hemagglutinin-neuraminidase of parainfluenza virus, suggesting it may be involved in resistance to these viruses.[630] However, this interaction is dependent on sialic acid residues that are widely expressed, and the in vivo significance of these findings is difficult to assess in humans. Nevertheless, susceptibility of NKp46-deficient mice to influenza infections corroborates these findings.[93] The autosomal dominant *Cmv1* gene in the NKC is responsible for resistance of certain mouse strains to MCMV[596,597,936,937]; MCMV-resistant C57BL/6 mice are susceptible when depleted of NK cells.[938] Extensive genetic and immunological evidence established that *Ly49h* is responsible for genetic resistance to MCMV.[449,938,939,940,941,942] A DAP12-signaling mutant mouse could not resist MCMV,[943] consistent with in vitro signaling studies showing that Ly49H signals through DAP12.[448,939] Thus, Ly49H is an NK-cell activation receptor responsible for genetic resistance to MCMV.

The ligand for Ly49H is encoded by the *m157* ORF in MCMV.[444,446] m157 and 11 other putative MCMV molecules have predicted MHC-I folds, now validated by crystallography.[464,926] Interestingly, in mice lacking adaptive immunity, m157 mutant MCMV clones emerge during MCMV infection, indicating selection pressure from Ly49H+ NK cells result in escape mutant viruses.[944] The reasons for maintenance of *m157* in the MCMV genome are still under investigation, but several observations suggest *m157* may be advantageous to the virus under certain circumstances. 1) m157 binds to the Ly49I inhibitory receptor in 129 mice.[446] 2) *m157*-deletion viruses cause a modest decrease in viral titers in mice lacking both Ly49I and Ly49H, suggesting yet another immune evasion role.[945] 3) A unique aspect of herpes virus biology is the capacity to become latent. If the virus kills the host during the acute viral replicative phase during which Ly49H mediates its control, then there will be no latent phase. 4) Host-virus coevolution often results in attenuated viruses,[946] and other MCMV proteins have positive effects on host responses.[947] Indeed, as one aspect of this coevolution, natural variants of m157 show differential binding activities to a broader range of inhibitory receptors in different mouse strains, including inhibitory Ly49C from B6 mice.[948,949] Thus, studies of m157 reflect the coevolution of the host and virus.

Interestingly, other Ly49 activation receptors also recognize MCMV-encoded proteins. In MA/My mice, the Ly49P activation receptor is responsible for resistance in the context of $H2^k$.[453,950,951,952] This receptor-ligand interaction is more complex than Ly49H-m157 because Ly49P appears to recognize the cell surface combination of $H2D^k$ in association with m04/gp34 encoded by MCMV. However, there appears to be another molecule required for Ly49P recognition as m04 expression on $H2D^k$-expressing cells was insufficient for recognition; infection with Δ*m04* MCMV was required.[453] Recent studies demonstrate that

other Ly49 activation receptors from different mouse strains (BALB/c, NOD/LtJ, PWK/Pas) can also recognize MCMV-infected cells in an m04-H2 allele-dependent manner, providing in vivo control.[953] Taken together, these remarkable studies indicate NK cells recognize MCMV in an "MHC-restricted" manner that is fundamentally different than MHC-restriction as defined for T-cell biology.

Loci for resistance to other pathogens, such as ectromelia virus and herpes simplex virus, have also been genetically mapped to the NKC.[954,955] These loci are termed *Rmp1* and *Rhs1*, respectively, and C57BL/6 mice are resistant. *Rmp1* was initially mapped using DBA/2 mice that lack a functional *Cd94* gene.[394,954] Recent studies of a CD94-deficient mouse show ectromelia virus susceptibility, suggesting that *Rmp1* is encoded by *Cd94*.[396] CD94/NKG2E appears to recognize ectromelia virus-infected cells via Qa-1 and synergizing with NKG2D. Thus, NKC-encoded NK-cell activation receptors mediate NK-cell-dependent resistance to viruses.

In addition to target killing, NK-cell activation receptors also trigger cytokine production in vitro. For example, Ly49H+ NK cells can be selectively activated to produce IFNγ and chemokines within 6 to 8 hours after coculture in vitro with MCMV-infected macrophages or m157 transfectants,[444,956] and m157 itself is expressed soon after infection.[957] However, during early MCMV infection in vivo, IFNγ production was not confined to the Ly49H+ NK-cell subset in C57BL/6 mice, indicating early relative "nonspecific" stimulation of NK cells.[166] Moreover, infection stimulates NK-cell proliferation[958,959] but early (days 1 to 2 postinfection) in vivo NK-cell proliferation was nonselective with respect to Ly49H expression. This proliferation resembled the cytokine-driven "bystander proliferation" observed in T cells in response to viral infections or stimulation with IFNα/β,[960] suggesting that the initial phase of viral-induced NK-cell proliferation represents a nonspecific response to proinflammatory cytokines (IL-12, IFNα/β) and proliferative cytokines such as IL-15.[912] The nonselective proliferation phase was followed by a period of preferential proliferation of Ly49H+ NK cells peaking at days 4 to 6 of MCMV infection.[166] The selective phase of NK-cell proliferation reflected the augmentation of pro-proliferative cytokine stimulation by Ly49H signaling mediated via DAP12.[59] Other activation receptors also trigger specific proliferation in MCMV infection, such as Ly49L+ NK cells in BALB/c mice.[953] However, in infection with vaccinia virus, which lacks a ligand for Ly49H, the initial phase of nonspecific NK-cell proliferation was found but the later specific proliferation of Ly49H+ NK cells was absent.[166] Thus, initial virus-specific NK-cell responses may be masked by generic cytokine responses and only later become detectable.

In humans, how NK cells participate in viral infections has been challenging to understand. However, an unprecedented opportunity to study human NK-cell responses during an epidemic of *Puumala hantavirus* revealed rapid and sustained expansion of NK cells.[961] Most cells expressed CD94/NKG2C and a self-HLA-specific KIR, consistent with expansion of licensed NK cells. Interestingly, expansion of CD94/NKG2C+ NK cells occurs in HCMV+ individuals but not with Epstein-Barr virus or herpes simplex virus infections,[962] though this could not explain the finding in the hantavirus-infected individuals. Regardless, children

infected with HCMV show a similar expansion of CD94/NKG2C+ NK cells; in one case of a T-cell-deficient infant, the expanded NK-cell population was associated with resolution of infection, suggesting that human NK cells can control HCMV.[963,964] Moreover, expansion of CD94/NKG2C+ NK cells also occurs in the setting of acute Chikungunya virus infection.[965] In vitro studies revealed that human NK cells can respond to HCMV-infected fibroblasts by producing cytokines and degranulating. These responses were enhanced by IL-12 and type I IFNs, and there was evidence for stimulation through NKp46 and DNAM-1. However, there was no apparent involvement of the CD94/NKG2C activation receptor,[966] despite expansion of CD94/NKG2C+ NK cells with prolonged culture.[388] Thus, the factors driving human NK-cell expansion and control of viral infection are not completely understood.

MEMORY-LIKE NATURAL KILLER RESPONSES

Although innate immunity is typified by the absence of memory responses, several recent studies suggest that NK cells have memory-like responses, more typical of adaptive immunity, apparently blurring the distinction between innate and adaptive immune responses.[751] In classic contact hypersensitivity (CHS) assays in vivo, NK cells appear to mediate hapten-specific responses in a T- and B-cell-independent manner.[967,968] Adoptive transfer of Ly49C/I+ liver NK cells from sensitized C57BL/6 mice transferred CHS. In addition, hapten-specificity was long lived, as NKdependent responses lasted at least 4 weeks. Subsequent studies indicated that exposure to virus and viral particles, specifically influenza virus, vesicular stomatitis virus, HIV-1, and MCMV, can also induce virus-specific memory-like NK cells.[969,970] Upon adoptive transfer, NK cells can then protect against lethal challenge with the sensitizing virus. While MCMV protection apparently occurred with sensitized splenic NK cells, protection from other viral challenges required liver NK cells expressing CXCR6. Thus, emerging studies suggest that NK cells can display memory-like responses.

The role and basis for NK-cell memory-like responses will require detailed investigation. It is not yet clear if this aspect of NK-cell function is relevant to “vaccination” and how much it contributes to immune protection when immune T and B cells are present. It is unclear how NK cells can demonstrate “antigen” specificity in the absence of the somatic rearrangement mechanism underlying T- and B-cell antigen receptor gene recombination because NK memory-like responses were seen in *Rag2*-/- mice.[967] Moreover, cytokine stimulation alone, without “antigen” stimulation, can induce NK cells to have more robust responses later.[971] Finally, there appear to be significant differences in the inflammatory characteristics and histological features of CHS related to NK-cell responses,[972] suggesting that there may be aspects to be considered that differ from conventional concepts of T-cell-mediated CHS.[968] Thus, although mechanistic details should be forthcoming, this topic has generated intense interest as indicated by review articles which now outnumber the primary literature by about three to one, because the concept of NK-cell memory breaks traditional views on innate and adaptive immunity, and potentially opens the door for examination of related processes in other innate immune components.

NATURAL KILLER CELL AND DENDRITIC CELL INTERACTIONS

Given that both NK cells and DCs, when separately studied, are critical early responders in host immune defense, it was not surprising that these cells could communicate in a bidirectional manner.[973] Since the initial description of this “cross-talk,” innumerable studies have been published indicating that NK cells can respond to signals derived from the various DC subsets and vice versa, in a variety of different immune responses in mice and humans.

Data support both cell contact-independent and -dependent pathways. The contact-independent pathways are perhaps better understood. For example, a variety of stimuli, such as certain TLR ligands,[26,974,975] can activate DCs to produce cytokines. Indeed, activated DCs can produce cytokines, including IFNα/β, IL-12, IL-15, IL-18, and apparently IL-2,[26,975,976,977,978,979] that can stimulate NK-cell production of other cytokines, such as IFNγ. Moreover, these cytokines enhance NK-cell cytotoxicity by increasing protein expression of perforin and granzymes[29] as well as perforin-independent cytotoxic pathways. The cytokines can also enhance responses mediated by ITAM-signaling chain-associated receptors.[59] The in vivo relevance of TLR-induced, DC-produced cytokines is evident in studies showing that TLR9-dependent activation of plasmacytoid DCs in MCMV infections is critical for appropriate Ly49H-dependent NK-cell control of infection.[974]

Direct NK-DC cell-cell contact can also enhance NKcell activation.[973] Several molecules have been implicated in this process, including cytokine-induced DC expression of ligands for human or mouse NKG2D.[980,981] Human DCs can also activate resting NK cells via the NKp30 receptor.[982] Other studies indicate that mouse NK cells can be activated by DCs in a TREM-2-dependent manner through the DAP12 signaling pathway.[983] DCs can also present IL-15 in *trans* that promotes NK-cell development and primes NK cells to respond to bacterial and viral pathogens.[31,984] This process may also be relevant to human NK-cell differentiation.[848]

On the other hand, NK-DC interactions can induce DC maturation.[985] For example, MHC-I-deficient targets can activate NK cells that then induce DC maturation.[986] NK-DC interactions also enhance TH1 polarization apparently through NK-cell production of IFNγ .[855] During MCMV infections, recognition of virus-infected cells by NK cells is critical for maintenance of DC subsets in the spleen.[987] While NK-DC cell contact is also subject to inhibitory effects and even killing of DCs by NK cells,[988,989] the capacity of NK-DC interactions to induce T-cell responses[855,981,986,990] has led to interest in exploiting these interactions for therapeutic vaccines.[991]

A hallmark of DC maturation is migration to a draining LN. Interestingly, however, deliberate introduction of DCs into the lymphatics leads to robust recruitment of activated NK cells.[855] Real-time imaging indicates that NK cells contact DCs in the superficial regions of the LNs where they are less motile and their interactions with DCs are more extensive than T-cell motility and contacts with DCs.[992] *Leishmania* infection led to NK-cell secretion of IFNγ and migration to the paracortex where CD4 T-cell activation occurred, indicating dynamic interactions in the LN not previously appreciated. In humans, DCs in LNs may be involved in differentiation of $CD56^{bright}$ NK cells into $CD56^{dim}$ NK cells.[110]

NATURAL KILLER CELLS AND MATERNAL-FETAL INTERACTIONS

One enigmatic area of continuing interest concerns NK cells in maternal-fetal interactions.[993,994,995] Several observations are related: 1) Initially described as granulated metrial gland cells, maternal uterine NK (uNK) cells accumulate in the uterus, near the fetal trophoblast layer, in all mammalian species examined thus far. 2) At the time of implantation, uNK cells are the most abundant leukocyte present. 3) In humans, uNK cells closely resemble $CD56^{bright}$ subpopulation, but there are phenotypic differences, including expression of activation markers, and different repertoire of MHC-specific receptors. 4) In some mice lacking NK cells, reproductive defects have been described.[996,997] 5) Trophoblasts can stimulate mouse uNK cells.[998,999] 6) There are significant differences in the anatomy of the maternalfetal interface that may limit extrapolation of experimental results from one species to another,[994] although recent studies suggest that rodent uNK cells may interact with trophoblast tissues in a manner similar to human uNK cells.[1000,1001] Thus, uNK cells may provide important clues to understanding maternal-fetal interactions.

Interestingly, counterintuitive insight has come from epidemiological data regarding KIR and HLA genotype associations with reproductive failure.[1002,1003] The role for HLA-G in these disorders is unclear, though early studies suggested that human trophoblasts express the nonclassical MHC-I molecule, HLA-G,[1004] but not other MHC-I or -II molecules; HLA-G may protect the fetus from uNK cell attack.[1005] However, HLA-G is relatively nonpolymorphic, so this may not be able to explain alloantigenicity of the fetus. By contrast, recent studies, using newly available staining reagents, indicate that trophoblast cells predominantly express HLAC.[1003] Furthermore, protection from reproductive failure is associated with maternal KIR haplotypes encoding the KIR2DS1 activation receptor that is specific for HLA-C2, whereas unopposed inhibitory receptors are associated with increased risk. In addition, protection increased when the fetus carried HLA-C2. The implication of this work is that uNK cells sense fetal tissues via their activation and inhibitory receptors to guide the dynamic process of placental remodeling,[1006] and suggest a mechanism for selection of KIR and HLA genotypes in different populations.

Indeed, uNK cells appear to regulate the placental vasculature. Mice lacking NK cells show defects in placental blood vascular remodeling that appears to be partially IFNγ-dependent.[1007] In addition, human uNK cells produce angiogenic factors, particularly early in pregnancy.[1008] Recent studies in mice and rats recapitulate some of the findings observed in humans,[1000,1001,1003] providing new experimental approaches to better understand the role of uNK cells in maternal-fetal tolerance.

NATURAL KILLER CELLS IN HUMAN DISEASE

Throughout this chapter, we have used human disorders involving NK cells to help illustrate their biology. Whereas NK-cell dysfunction has been associated with a large number of other diseases, it is not yet clear if they are clearly involved in a pathogenic manner. However, KIR and HLA genotypes have been linked with an increasing number of human ailments,[754]

providing strong evidence implicating a pathogenetic role for NK cells in these diseases. For example, hepatitis C virus can cause a chronic, persistent infection, although some patients resolve the infection. Interestingly, patients who are homozygous for a KIR gene (KIR2DL3) are more likely to clear hepatitis C virus if they are also homozygous for the HLA-C alleles recognized by KIR2DL3.[756] In papillomavirus infections that can go on to produce cervical carcinomas, resistance to developing neoplasia is similarly associated with genotypes encoding certain KIR-HLA receptor-ligand pairs.[1009] In HIV-1 infections, certain KIR and HLA alleles are associated with reduced risk of infection and slower progression.[1010,1011,1012,1013] These associations are even more compelling given a recent report indicating that the KIR genotypes are associated with amino acid polymorphisms in HIV-1 itself, suggesting that NK cells through their KIRs selected specific HIV-1 genotypes.[1014] These sequences enhance binding of inhibitory KIRs to HIV-1-infected CD4+ T cells and reduce the antiviral activity of NK cells, providing a putative mechanism to explain the association of specific KIR and HLA genotypes with HIV-1 progression. Thus, while the means by which other KIR-HLA combinations modify disease progression is a topic under current investigation, the emerging data nonetheless demonstrate the importance of NK cells and KIR specificities in human disorders and treatments.

Studies also suggest that KIR specificities may be clinically useful to guide treatment. For example, in BM transplantation for leukemia, donor NK cells may help provide as in anti-leukemia effect against residual malignant cells in the recipient if there is a mismatch between the donor and recipient HLA alleles.[870] While this observation was not uniformly observed in other transplant centers,[871,1015,1016] improvements in determing KIR polymorphisms have guided donor selection strategies, leading to superior outcomes in BM transplant therapy for leukemia and neuroblastoma.[1017,1018] Thus, KIR genotyping is clinically useful.

Dysfunctional NK cells are found in patients with FHL who typically demonstrate HLH, as described previously. NK-cell dysfunction is also found in systemic onset juvenile idiopathic arthritis and macrophage activation syndrome associated with that disease.[1019] However, it is not yet clear if NK dysfunction is a cause or effect of systemic illness.

Early studies used LAK cells for adoptive immunotherapy of cancers refractory to conventional therapy.[1020] Several cases of complete remission were reported, but the treatment required intravenous administration of high doses of IL-2 that has significant toxicity. Improved understanding of NK-cell biology and their receptors and specificities has renewed interest in using NK cells for adoptive immunotherapy.[1021,1022] In addition, clinical use of IL-15 may allow for more specific NK-cell activation while sparing the toxicity seen with IL-2.[1023] However, these approaches are still in their infancy and will require controlled studies.

Finally, NK-cell proliferative disorders are associated with both chronic viral infections (Epstein-Barr virus) and autoimmune phenomenon.[8,1024,1025] NK-cell malignancies are particularly aggressive and can appear as lethal midline granuloma due to the propensity of NK lymphomas to present in the sinus and nasopharyngeal passages where they are especially destructive.[1026] NK cells are also associated with hydroa vacciniforme and

hypersensitivity to mosquito bites.[1027]

CONCLUSION

Detailed studies have moved NK cells from the fringes of immunology into the mainstream. Along the way, there have been innumerable challenges, some from "mistaken notions" based on existing paradigms for other immune cells, because NK cells have novel mechanisms of participating in immune defense and tolerance.[1028] Nonetheless, as immunologists and physicians gain more appreciation for the molecular basis for NK-cell biology, the future holds promise for insight into a number of enigmatic and unusual human diseases as well as common disorders, such as hepatitis C virus and HIV infections, and exploitation of NK cells for immunotherapy.

Finally, the elucidation of KIR genotypes and their role in infection and pregnancy support a broader view. The net outcome of selection for certain KIR and HLA genotypes may reflect a short-term survival advantage in terms of infection and a longer-term survival advantage as determined by reproductive influences. Similar processes must also be ongoing in other mammalian species and support the basis for convergent evolution of the NK-cell inhibitory receptors for MHC-I. Thus, "NK cells are centrally involved in both immunity and reproduction."[1029]

ACKNOWLEDGMENTS

I thank members of my laboratory and our collaborators for their continued interest in dissecting the molecular basis for NK-cell activities and tolerance. I thank Megan Cooper, Tony French, and Dorothy K.Sojka for their review of the manuscript. Investigations in the author's laboratory are supported by the National Institutes fo Health, the Barnes-Jewish Hospital Research Foundation, and the Howard Hughes Medical Institute.

Chapter 18

CD1d-Restricted Natural Killer T Cells

Albert Bendelac

INTRODUCTION AND DEFINITION

Natural killer T (NKT) cells are cluster of differentiation (CD)1d-restricted T cells that use semi-invariant αβ T-cell receptors (TCRs) and reside as long-lived effector cells in lymphoid tissues and in the microvasculature of organs such as the lung and the liver. They promptly release a broad range of cytokines and chemokines in response to microbial and self-lipid antigens presented by CD1d glycoproteins, exerting a protective or pathogenic role in infection, inflammation, allergy, and cancer. The NKT lineage is best defined by expression of *Zbtb16*, which encodes promyelocytic leukemia zinc factor (PLZF), a master transcription factor that directs acquisition of innate-like effector properties during thymic development.

The NKT lineage is a member of the larger family of so-called innate-like lymphocytes, which includes B1 B cells, marginal zone B cells, intraepithelial γδ T-cell sublineages, the CD8αα TCRαβ population of intestinal lymphocytes, and the MR1-restricted mucosal associated invariant T cells.[1] Like NKT cells, these lineages express semi-invariant TCRs or B-cell receptors encoding specificity for conserved microbial and self-ligands. Their “canonical” antigen receptors are sufficient to instruct lineage differentiation during development in the thymus or bone marrow, in a process matching antigen specificity with specialized effector functions and homing to dedicated tissue environments. These stereotypical properties, which are reminiscent of truly innate lymphoid cells, such as natural killer (NK) cells, represent a distinct host defense strategy, perhaps corresponding to an early phase of evolution of adaptive T- and B-cell immunity.

CANONICAL NATURAL KILLER T T-CELL RECEPTORS

In mice, the vast majority of CD1d-restricted NKT cells express the semi-invariant Vα14-Jα18 TCRα chain paired with β chains made of Vβ8, Vβ7, or Vβ2 joined to variable DβJβ segments, whereas the homologous Vα24-Jα18 chain associated with Vβ11 is used in humans[2] (Table 18.1). The “canonical” sequence of the TCR alpha chain is entirely encoded in the genome, although alterations due to nucleotide trimming and N additions can be tolerated if they preserve the antigenic specificity of the TCR. These canonical rearrangements arise randomly and at very low frequency in both fetal and adult life, but massive thymic expansion post-TCR expression ensures a high frequency of NKT cells among recent thymic emigrants.[3]

Other semi-invariant TCRs have been identified among mouse CD1d-restricted NKT cells, including Vα10-Jα50/Vβ8,[4] Vα3.2-Jα9/Vβ8, and Vα8/Vβ8,[5] but their combined frequency is modest compared to the dominant Vα14-Jα18 TCR. Nevertheless, these cells appear to adopt a similar NKT effector phenotype, likely because they follow the same thymic developmental pathway.

ANTIGENIC LIGANDS OF NATURAL KILLER T CELLS

Cluster of Differentiation 1d

CD1d is one of five members of the mammalian family of lipid-presenting, β2-microglobulin-associated, major histocompatibility complex (MHC)-like CD1 molecules, and the only one conserved in mouse.[6,7] The mouse CD1 locus contains *cd1d1* encoding a functional surface glycoprotein and a duplicated gene *cd1d2*, which is generally poorly expressed and, in the C57 background, is inactivated by a frameshift mutation preventing surface expression.[8] CD1d is found constitutively on the cell surface of most antigen-presenting cells, including dendritic cells (DCs), macrophages, and B cells, with particularly high levels on marginal zone B cells.[9] Of relevance to NKT-cell development, CD1d is also prominently but transiently displayed on cortical thymocytes. It is also expressed by endothelial cells and hepatocytes.

CD1d is assembled in the endoplasmic reticulum by association with β2-microglobulin before reaching the cell surface and undergoing extensive rounds of internalization and recycling between the late endosome/lysosome and the plasma membrane[10,11,12] (Fig. 18.1). The rapid rate of internalization depends upon a tyrosine motif encoded in its cytoplasmic tail, which binds adaptor protein (AP)-2 and AP-3 in mouse, and AP-2 in human. This intense recycling accounts for the steady state accumulation of CD1d in the late endosome/lysosome for mouse or late endosome for human. While a diversity of exogenous and endogenous lipids can load CD1d in various compartments,[13,14,15] the late endosome/lysosome environment is optimized for lipid antigen acquisition due to the presence of efficient glycolipid processing enzymes and lipid transfer proteins such as saposins,[16,17,18] Gm2 activator,[16] Niemann-Pick type C2 protein,[19] and, in humans, CD1e.[20] In this acidic compartment, short or polyunsaturated lipids loaded at the cell surface are quickly removed and replaced by long and saturated lipids that bind more stably to CD1d but require lysosomal transfer proteins for loading.[21] Unlike MHC class II, CD1d expression and its presentation of lipid antigens at the cell surface are

independent of toll-like receptor (TLR) signaling and DC maturation.[22] Thus, immature DCs can readily present purified lipid antigens to NKT cells and become activated upon CD40 engagement by NKT cells.

Lipid Ligands of Natural Killer T cells

bial α-glycosylated Lipid Ligands

The first universal NKT ligand emerged from studies of marine sponge extracts that prolonged survival of mice bearing B16 melanoma.[23] The active principle of the sponge *Agelas mauritianus* was an alpha-branched galactosylceramide, which after slight modification led to the synthesis of an extremely potent variant named KRN7000, commonly referred to as αGalCer[24,25] (Fig. 18.2). Over 95% of mouse and human NKT cells recognize αGalCer, irrespective of their variable CDR3 β sequence.[26,27] Furthermore, the mouse CD1d-αGalCer tetramers stain the NKT cells of both human and nonhuman primates,[28,29] attesting to the high degree of conservation of this recognition system.

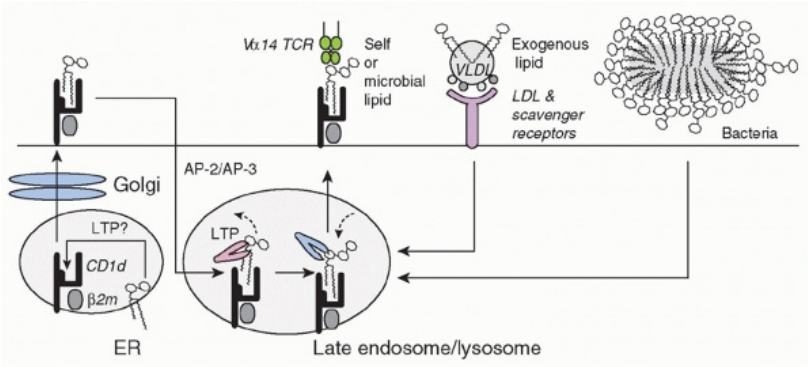

FIG. 18.1. Presentation of Lipid Antigens by Cluster of Differentiation (CD)1d. CD1d acquires lipid antigens after biosynthesis in the endoplastic reticulum and Golgi prior to reaching the cell surface. Multiple rounds of AP-2/AP-3 clathrinmediated internalization to the late endosome/lysosome and recycling to the plasma membrane allow lipid exchange. Lysosomal degradation pathways provide lipid antigens for exchange in a process assisted by lysosomal lipid transfer proteins such as saposins, Gm2 activator, NPC-2, and CD1e. Exogenous lipids bound to lipoproteins enter the cell through scavenger receptors and low-density lipoprotein receptor. Microbial organisms access the lysosome after phagocytosis.

The marine sponge lipid turned out to be closely related to microbial lipids found in some gram-negative lipopolysaccharide (LPS)-negative bacteria. Notably, *Sphingomonas*, a member of the class of α-proteobacteria and a ubiquitous bacterium found in terrestrial and marine environments (including as a bacterial symbiont of sponges), uses alphabranched glycuronylceramides as a substitute for LPS in the outer membrane of its cell wall.[30] It can

infect dendritic cells and macrophages to activate NKT cells.[31,32] Other structurally related α-glycosylated lipids, such as α-galactosyldiacylglycerol, found in *Borrelia burgdorferi*, the agent of Lyme disease,[33] and α-glucosyldiacylglycerol, found in *Streptococcus pneumoniae*,[34] also activate mouse and human NKT cells. Such α-branched glycolipids have not been reported in vertebrates, suggesting that they represent a pathogen signature that the canonical NKT TCR may have evolved to recognize.

Endogenous β-glycosylated Lipid Ligands

Vα14 NKT cells are spontaneously autoreactive to CD1dexpressing cells.[35] For example, NKT hybridomas or clones

can be activated to secrete modest amounts of cytokines when cultured in the presence of fresh thymocytes, DCs, and various tumor cell lines.[8,35,36,37,38] This autoreactivity and the agonist ligands involved appear to be central not only for NKT-cell thymic development,[36] but also for their response to various microbial infections, especially when the pathogens themselves do not express NKT ligands.[31,39] The identification of self-ligands is therefore of major relevance to key aspects of the biology of NKT cells.

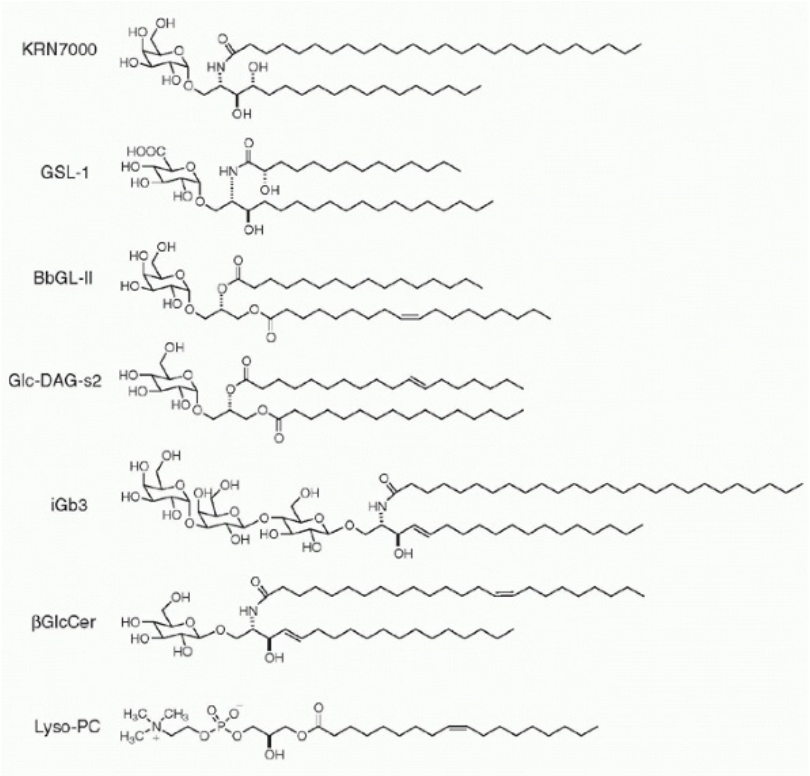

FIG. 18.2. Self- and Foreign-Lipid Antigens Recognized by Natural Killer T Cells. From top to bottom, KRN7000, or reference α-GalCer, synthetic version of the original marine sponge antigen; *Sphingomonas* GSL-1; *Borrelia burgdorferi* BbGL-II, α-galactosyldiacylglycerol; *Streptococcus pneumoniae*, α-glucosyldiacylglycerol; isoglobotrihexosylceramide iGb3; β-glucosylceramide; and lyso-phophatidylcholine.

In the mouse system, recognition of self-ligands by Vα14 NKT cells is largely dependent upon CD1d endosomal trafficking,[40,41] suggesting the recognition of endosomal/lysosomal lipid antigens. This may not be the case for their human counterpart, Vα24 NKT cells.[42] The

search for a lysosomally-loaded self-ligand recognized by NKT cells led to the identification of a trihexosylceramide, iGb3, which is synthesized in the Golgi as an intermediate in the biosynthetic pathway of iGb4 and is also generated in the lysosome after degradation of iGb4 by β-hexosaminidase AB.[43] iGb3 is further degraded into LacCer by α-galactosidase A (Fig. 18.3). Mice lacking β-hexosaminidase B lacked 95% of their NKT cells, a defect associated with the impaired ability of their thymocytes to stimulate autoreactive NKT hybridomas. Conversely, unlike αGalCer, iGb3 is recognized with a Vβ7 > Vβ8 > Vβ2 hierarchy of affinities that mirrors the relative selection of NKT thymic precursors.[44] Furthermore, DCs lacking α-galactosidase A exhibited greater spontaneous stimulation of NKT cells,[45] consistent with the demonstrated accumulation of iGb3.[46,47,48]

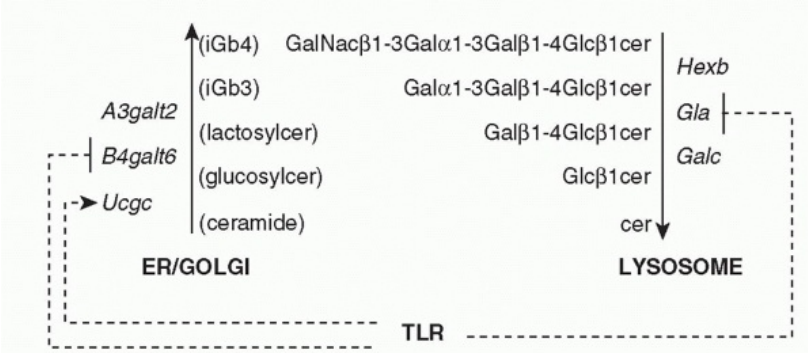

FIG. 18.3. Toll-Like Receptor (TLR)-Mediated Regulation of the Synthesis and Degradation of Natural Killer T Cell Glycosphingolipid Antigens. TLR signaling downregulates *B4galt6* encoding lactosylceramide synthase and *Gla* encoding α-galactosidase A, but upregulates Ucgc encoding β-glucosylceramide synthase. These changes result in the net accumulation of β-glucosylceramide and iGb3.

Among several genes encoding Galα1-3Gal transferases, *a3galt2* is considered more specialized for iGb3 synthesis. As *a3galt2* null mutant mice did not show NKT cell defects[49] and the human homologous gene appeared dysfunctional,[50] iGb3 may not be the sole endogenous glycosylceramide recognized by mouse and human NKT cells. Other reports have suggested that β-galactosylsylceramide[51] and β-glucosylceramide[52] might also function as natural ligands of NKT cells, but these claims have not yet been widely replicated. While the respective importance of all these candidate ligands remains to be further studied in physiological and pathological conditions, it is possible that NKT cells might recognize multiple endogenous β-glycosylceramides as weak agonists.

Importantly, several enzymes involved in the synthesis and degradation of β-glycosylceramides appear to be coordinately regulated in conditions associated with NKT-cell activation[45,52,53] (see Fig. 18.3). For example, TLR signaling was shown to specifically downregulate α-galactosidase A in the degradation pathway,[45] leading to increased iGb3.[46] In the biosynthetic pathway, TLR signaling upregulated β-glucosylceramide synthase while downregulating lactosylceramide synthase, thus increasing β-glucosylceramide.[52] Collectively, these findings suggest that microbial organisms lacking NKT ligands can nevertheless activate NKT cells through TLR-mediated accumulation of endogenous glycosphingolipid ligands.

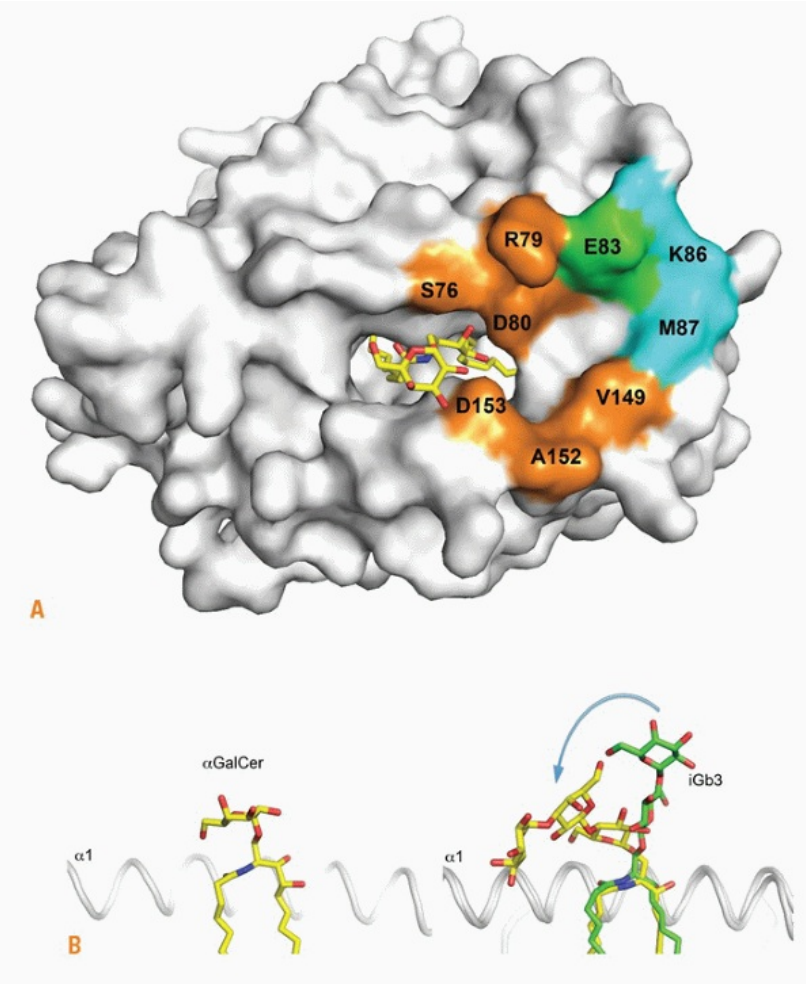

FIG. 18.4. Natural Killer T (NKT) T-Cell Receptor (TCR) Recognition of αGalCer and iGb3. A: Conserved footprint of the mouse NKT TCR on the surface of cluster of differentiation (CD)1d-αGalCer and CD1d-iGb3 (the lipid shown is αGalCer): *orange*, CDR3α; *cyan*, CDR2β; *green*, CDR3α and CDR2β. **B:** Binding mode of αGalCer and iGb3 to CD1d and TCR. *Left*, αGalCer (same structure before and after TCR binding); *right*, iGb3 before (*green sticks*) and after (*yellow sticks*) TCR binding. Note that the distal sugar is not represented before TCR binding. Courtesy of Dirk Zajonc (La Jolla Institute of Allergy and Immunology, San Diego, CA).

Lysophosphatidylcholine was also reported to stimulate a fraction of human but not mouse NKT cells,[54,55] suggesting that upregulation of this ligand in multiple myeloma and other inflammatory conditions might also contribute to NKT-cell activation.

Structural Basis of Lipid Recognition by Natural Killer T cells

The lipid-binding pocket of CD1d is particularly well adapted to bind self- and microbial glycosphingolipids, with the acyl chain in the A' hydrophobic pocket and the sphingosine chain in the F' hydrophobic channel.[56,57,58] The hydroxyl groups of the sphingosine emerge from the groove to establish hydrogen bonds with the α1 helix Arg79 and Asp80, while the galactose is stabilized though hydrogen bonds between its 2- and 3-hydroxyl groups and Asp153 of the α2 helix. Thus, the protruding sugar is solidly anchored in a position parallel to the plane of the α-helices, explaining the exquisite stimulatory properties of several carbohydrate hydroxyl groups. In contrast, the trisaccharide chain of iGb3 protrudes in orthogonal orientation to the plane of the α-helices, with the proximal glucose forming

hydrogen bonds with the α2 helix, in particular Asp153 and Thr156, whereas the position of the ceramide backbone is similar to αGalCer (Fig. 18.4).

How could such highly dissimilar structures be recognized by the same TCR? In the ternary structure of the human TCR-CD1d-αGalCer complex, the TCR docked parallel to and at the extreme end (F' pocket) of the CD1d binding groove, enabling a lock-and-key type of interaction with the solidly anchored, rigid αGalCer antigen. The docking was parallel to the long axis of the binding groove, contrasting with the diagonal footprints observed for MHC-restricted TCRs.[59] The CDR3α loop encoded by the conserved germline Jα18 segment provided a majority of contacts, straddling the antigen binding cleft and engaging electrostatic interactions with α-GalCer, the α1 and the α2 helices of CD1d. CDR1α interacted solely with αGalCer, and CDR2β formed a stretch of interactions with the α1 helix. Consistent with the great diversity of CDR3β usage, this loop contact was limited to a single van der Waals contact with Gln150 of the α2 helix.

The ternary structure of the TCR-CD1d-iGb3 complex was recently elucidated. Unsurprisingly, given the conservation of Jα18 and CD1d in both structures, the overall footprint of the TCR on the CD1d-glycolipid surface was unchanged compared with CD1d-αGalCer. Strikingly, however, the TCR appeared to simply “squash” the trisaccharide headgroup of iGb3 over the α2 helix of CD1d, with the proximal β-linked glucose molded into an orientation similar to the α-linked galactose of αGal-Cer (see Fig. 18.4). Each of the three sugars made stabilizing polar and van der Waals interactions with CD1d residues. The proximal and second sugars also contacted the TCR CDR2α loop, which is not involved in CD1d-αGalCer recognition. The importance of the distal sugar is reflected by the lack of detectable stimulation by lactosylceramide where the third sugar is absent. These conformational changes imply a highly dynamic interaction process during the association phase. The energy penalty incurred for binding self-ligands could be overcome in specific conditions that strengthen the immune synapse. For example, this may occur during TLR-induced inflammation, which upregulates lymphocyte function-associated antigen (LFA-1) and intercellular adhesion molecule (ICAM-1) integrin interactions, or during thymic development, which involves homophilic engagement of signaling lymphocytic activation molecule (SLAM) family receptors.

Additional crystallographic studies further illustrated the difference between self- and foreign-antigen recognition. The α-glycosyldiacylglycerol antigens of *Borrelia burgdorferi*[33,60,61] and *Streptococcus pneumoniae*[34] adopted configurations relatively similar to αGalCer, although some induced fit was observed for both CD1d and the glycolipid upon TCR binding. In the case of *Streptococcus pneumoniae*, an unusual sn2 alkyl chain, vaccenic acid (with an unsaturation at C7), was important for favorable positioning of the glucose. After insertion of a stretch of hydrophobic aminoacids in the CDR3β loop in order to enhance binding to CD1d, other self-lipids such as β-GalCer, Galα1-4GlcCer (lactosylceramide), and phosphatidylinositol could be recognized.[62] Although somewhat contrived, this system revealed a similar bending of the β-linkage between the proximal sugar and the ceramide backbone as seen for iGb3, raising the possibility that several β-linked self glycolipids might serve as autoantigens.

DEVELOPMENT AND HOMEOSTASIS OF NATURAL KILLER T CELLS

Development

The major determinant of NKT cell development is the semi-invariant TCR, which, upon binding to CD1d ligands expressed by cortical thymocytes, provides the signals required for induction of the lineage-specific transcription factor PLZF. Therefore, insights into the peculiar nature and context of TCR engagement and its downstream signaling have

considerably advanced our understanding of the molecular mechanisms of NKT-cell development.

T-Cell Receptor Expression and Positive Selection

The use of CD1d-αGalCer tetramers specific for the canonical mVα14-Jα18/hVα24-Jα18 TCRs has revealed a sequence of selection, expansion, and differentiation events preceding the terminally differentiated NK1.1+ stage.[3,63,64] As illustrated in Figure 18.5, NKT cells originate from mainstream thymocyte precursors that transit through the pre-TCRα+TCR+ stage to reach the CD4+CD8+ double positive (DP) stage, where stochastic Vα-Jα rearrangements lead to expression of canonical Vα14-Jα18/Vβ8, Vβ7 or Vβ2 TCRs. These rearrangements involve distal gene segments that require prolonged cell survival mediated by Bcl-xL, whose expression depends on HEB-induced RORγt.[65,66,67] All Vβ families can pair with the Vα14-Jα18 chain, but only the biased set of Vβs confers specificity for the endogenous ligands. Although Vβ8 predominates among mature NKT cells, the most enriched Vβ family relative to preselection frequency is Vβ7, followed by Vβ8 and Vβ2.[44] This is consistent with the observation that endogenous ligands displayed on the surface of thymocytes activate the Vα14-Jα18 TCRs with a Vβ7 > Vβ8 > Vβ2 hierarchy of affinity, and that in mice expressing very low levels of CD1d, NKT cells showed increased representation of Vβ7.[44,68,69,70,71] Notably, this hierarchy of affinity parallels that of iGb3 but is different from αGalCer, which favors Vβ8. Thus, the naturally selected Vβ repertoire seems to precisely reflect the affinities of the preselected repertoire for endogenous ligands, suggesting that negative selection plays little role in shaping the Vβ repertoire. However, this does not imply that NKT cells are impervious to negative selection because transgenic overexpression of CD1d decreased the relative frequency of the high affinity Vβ7+ cells and exposure to αGalCer-induced deletion of NKT thymocytes.[69]

Developmental Stages

The earliest signaled NKT precursors are rare CD4+CD8+ DP cells that express the semi-invariant TCR. These cells become CD4+ single positive (SP) cells expressing high levels of CD24, a marker of immature cortical thymocytes, as well as CD69, a marker of positive selection.[64] This is the socalled stage 0 of NKT development. As $CD24^{high}$CD4+ cells mature into the next $CD24^{low}$CD4+ stage 1, they undergo several rounds of cell division.[3] Cell cycle may be initiated as early as stage 0, as suggested from the analysis of cyclin D2-or c-Myc-deficient mice.[72,73] The lineage expansion following positive selection ensures the high frequency that is critical for innate immunity. During this phase, a fraction of CD4+

cells downregulates CD4 to become CD4-CD8- double negative (DN) T cells,[64] acquiring a more restricted Th1 cytokine and chemokine profile and an enhanced ability to reject tumors.[74,75,76] Dividing cells first activate their interleukin (IL)-4 locus (stage 1) then interferon (IFN)-γ (independently of both stat6 and stat4) as they upregulate CD44 and downregulate CD62L (stage 2).[3,63,77] Thus, unlike other αβT cells, postselection NKT lineage cells undergo a sequence of events that is reminiscent of the antigen-driven activation, expansion, and effector differentiation of mature T cells.[78]

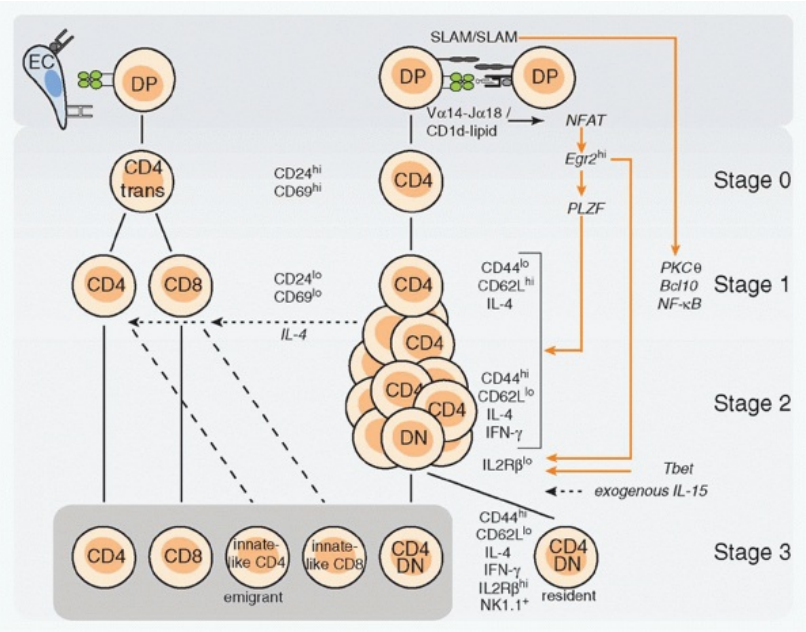

FIG. 18.5. Development of Natural Killer T (NKT) Cells. Thymic stages of NKT-cell development are aligned with corresponding stages of cluster of differentiation (CD)4 and CD8 T-cell development. Stage 0 NKT cells correspond to the transitional CD4 cells. Note the cross-talk between NKT cells and CD4 and CD8 T cells, which is mediated by interleukin-4, and results in the differentiation of “innate-like” CD4 and CD8 T cells in Balb/C mice. DP, CD4+CD8+ double positive; DN, CD4-CD8- double negative; EC, epithelial cell.

NKT lineage cells emigrate from the thymus after upregulation of the S1P1 receptor,[79] as dividing effector-type cells. They represent up to 5% of recent thymic emigrants in the mouse spleen.[3,80] Within a couple of days after emigration, they express NK lineage receptors, including the activating NK1.1 and NKG2D receptors and the inhibitory CD94/NKG2A, Ly49A, C/I, and G2 receptors. Acquisition of this terminal differentiation program is associated with cessation of division and with upregulation of IL2Rβ, which is necessary for IL-15 signaling. Intriguingly, a fraction of NKT thymocytes downregulate the S1P1R and remain as permanent residents in the thymic medulla, where they undergo the same terminal maturation program.[79] These thymic residents appear to be absent in humans.[81]

Recent thymic NKT emigrants and their immediate precursors, stage 2 NKT thymocytes, express neuropilin 1 (Nrp-1), a transmembrane receptor for vascular endothelium growth factor and semaphorin family members.[82] Nrp-1 represents a convenient marker of recent thymic NKT emigrants, as it remains expressed for a few days and is downregulated after terminal maturation to stage 3.

Homotypic Thymocyte-Thymocyte Interactions

The thymic cell types involved in presenting NKT ligands have been thoroughly investigated. Unlike MHC class I or class II, CD1d is prominently expressed on cortical thymocytes, which is consistent with the ability of cortical thymocytes to stimulate NKT hybridomas.[36] Bone marrow chimera experiments demonstrated that NKT-cell development required CD1d expression by cortical thymocytes but not radioresistant stromal cells.[83,84,85] This is radically different from conventional T-cell development that is driven by MHC expression on thymic epithelial cells. Transgenic experiments using promoters for Lck, MHC class I, or MHC

class II to redirect CD1d to various cell compartments in CD1d-deficient hosts suggested that expression on cortical thymocytes was necessary and sufficient for lineage development.[70,86,87,88] This conclusion was recently confirmed after

conditional deletion of CD1d using Cd4-Cre.[89] Mixed chimera experiments using CD1d knockout pLck-CD1d transgenic TCR Cα knockout bone marrow (where thymocyte development is arrested at the DP stage) as the sole source of CD1d expression demonstrated that expression of CD1d solely on cortical thymocytes was sufficient for the full differentiation of NKT cells.[87] Intriguingly, however, the transition to the NK1.1 positive stage was partially impaired after emigration to peripheral tissues, although it was preserved for the cells remaining as residents in the thymus. Terminal differentiation was fully restored if CD1d was re-expressed on MHC class II expressing cells or if the cells were transferred into wild-type recipients.[80,87]

Homophilic Signaling Lymphocytic Activation Molecule-f Family Interactions

A major pathway that is selectively recruited by the thymocyte-thymocyte interactions involves homophilic binding of SLAM family receptors, mainly Slamf1 (SLAM) and Slamf6 (Ly108), which are expressed by cortical thymocytes, but not by thymic epithelial cells.[90] These partially redundant receptors signal through the adaptor SLAM-associated protein (SAP) and the kinase Fyn, explaining earlier reports of developmental arrest in SAP- or Fyn-deficient NKT precursors.[91,92,93,94,95] SAP- and Fyn-deficient NKT thymocytes were blocked at stage 0 and could not be rescued by expression of Bcl-2 or Bcl-xL. They showed lower induction of CD69,[90] suggesting defective signaling by the TCR, perhaps due to a role of Slamf-SAP-Fyn signaling in stabilizing the immune synapse.[96] Individual ablation of Slamf1 or Slamf6 resulted in a modest twofold defect in the expansion of the NKT lineage between stages 1 and 2. However, in "pseudo-double mutant" mixed chimeras where Slamf1/CD1d double deficient NKT precursors were forced to see their ligands on Slamf6-deficient thymocytes, a > 10-fold reduction of NKT cells was observed, demonstrating a requirement of Slamf receptors at the time of TCR engagement by CD1d ligands.[90] Notably, the Slamf locus exhibits considerable polymorphism, which may underlie some of the reported variations in NKT-cell frequencies in different mouse strains and in humans. Genetic studies have provided support for this hypothesis by identifying the lack of expression of Slamf1 by cortical thymocytes in the nonobese diabetic (NOD) strain, which is spontaneously NKT deficient.[97]

Signaling in the Natural Killer T-Cell Microenvironment

Engagement of the semi-invariant TCR activates the same Ras/MAP kinase and calcineurin pathways as reported for MHC-restricted TCRs during positive selection.[98,99] Notably, NKT thymocytes show elevated and sustained expression of the early growth response (Egr) factors 1 and 2 compared with the weak and transient expression observed in MHCrestricted thymocytes.[100] Egr1 is thought to be downstream of the Ras/MAP kinase pathway, whereas Egr2 is mainly induced by the calcineurin/nuclear factor of activated T cells (NFAT) pathway. Egr1 and Egr2 mediate the survival of MHC-restricted T-cell precursors after positive selection through induction of Bcl2 and Bcl-xL.[101,102,103] In the case of NKT cells, however, sustained Egr elevation has specific lineage-determining consequences. Egr2 directly binds to the promoters of NKT lineage-specific genes such as *Zbtb16*, encoding PLZF, and *Il2rb*, encoding the β chain of the IL-15 receptor, and it is required for their induction. This suggests a direct connection between the peculiar signaling emanating from the TCR synapse and these NKT lineage checkpoints.[100] The sustained elevated Egr levels

likely result from the TCR recognition of agonist ligands[36,43] or from the Slamf-SAP-mediated stabilization of the immune synapse.[96] As some *Zbtb16* messenger ribonucleic acid induction was detected in SAP-deficient NKT precursors, SAP may not be absolutely required for PLZF induction.[104]

TCR and Slamf-SAP-Fyn signaling both involve the canonical NF-κB pathway through PKCθ and Bcl-10.[105,106] Mice lacking these downstream signaling components showed partial defects in NKT-cell development,[107,108] as further detailed in the following.

Thus, NKT-cell development is tightly dependent on the signaling elicited through the TCR and Slamf-SAP-Fyn pathways, the specific contributions of which remain to be dissected. Notably, redirecting the expression of MHC class II proteins on cortical thymocytes through ectopic expression of the transcription factor CIITA led to the differentiation of "innate-like" CD4+ thymocytes in a SAP-dependent manner. These cells resembled stage 2 NKT cells and expressed PLZF, reinforcing the notion that homotypic thymocyte-thymocyte interactions, Slamf-SAP-Fyn signaling, and PLZF define a dedicated thymic pathway for the production of innate-like effector T cells.[109,110,111,112] In that context, the reciprocal expression patterns of CD1 and Slamf receptors by thymocytes and of MHC proteins by epithelial cells may well serve the primary purpose of creating different niches for different thymic lineages.[90]

Cluster of Differentiation 4 and Cluster of Differentiation 8 Coreceptor Expression

NKT cells originate from the same pool of DP precursors as MHC-restricted T cells and emerge from thymic selection as CD4 SP cells expressing the CD4 lineage factor ThPOK/c-Krox in a Gata-3-dependent manner.[113,114] A fraction goes on to downregulate CD4 and acquire the DN phenotype, but they still stably express ThPOK, which is essential to downregulate CD8. In humans, some NKT cells can express CD8αα homodimers. ThPOK-deficient NKT cells did not express CD4, and some of them also failed to repress CD8, but otherwise they appeared to develop normally.[113] Their functional properties, however, have not been fully assessed. CD8α-deficient mice showed a modest but significant bias toward the selection of high-affinity Vβ7 TCRs compared with littermate controls.[83] A similar bias was observed after anti-CD8 antibody treatment, suggesting a minor role of CD8 as a coreceptor for CD1d. Transgenic expression of CD8α resulted in the disappearance of NKT thymocytes, suggesting a role in negative selection,[83] a conclusion subsequently challenged when the transgenic model was found to have impaired Vα-Jα rearrangements.[114]

Thus, while NKT-cell development does not appear to rely on CD4 or CD8 coreceptors, the induction of ThPOK and CD4 in this lineage may simply reflect the path of high

affinity TCRs whose signaling is coreceptor independent.[115] However, the subsequent CD4 downregulation in up to 50% to 70% of NKT cells, despite persistent ThPOK expression, remains to be explained.

Cluster of Differentiation 28-B7 Interactions

A modest decrease in the thymic expansion of NKT cells was reported in mice lacking CD28 or B7,[116,117] but the nature of the B7-expressing cell type (epithelial cells or DCs) has not been determined.

Transcriptional Control of Natural Killer T-Cell Development: The Central Role of Promyelocytic Leukemia Zinc Factor

The transcription factor PLZF encoded by *Zbtb16* was identified as the signature master

transcription factor of the NKTcell lineage.[104,118] PLZF is a member of the BTB-ZF family of transcription factors, which also includes Bcl6 and ThPOK. It is composed of a bric-a-brac, tramtrack, and broad (BTB) homodimerizing domain and nine Kruppel-type Cys2His2 zinc fingers. The BTB domain binds a corepressor complex made of histone deacetylases, N-Cor, and SMRT, whereas deoxyribonucleic acid binding is mediated by the zinc fingers. PLZF is induced in NKT precursors just after TCR signaling, with high amounts detected on nearly half of stage 0 and all of stage 1 and 2 cells, and lower levels found in stage 3 cells.

Mice lacking PLZF through either the *luxoid* mutation, which induces a frameshift leading to a truncated BTB protein without zinc fingers, or deletion of exon 2 encoding the BTB domain, exhibited a block in NKT-cell development,[104,118] as well as defects in spermatogonial cell maintenance and osteoblast differentiation.[119,120] PLZF-deficient NKT precursors identified by CD1d-αGalCer tetramers were blocked at stage 1, unable to acquire effector characteristics. Instead, they maintained a naïve phenotype and function, recirculating between blood, lymph node, and spleen, rather than homing to liver and lung, and producing IL-2 instead of IL-4 and IFNγ upon stimulation. Intriguingly, however, they incorporated BrdU at the same high rate as wild type, but without showing expansion, suggesting aborted division or increased cell death.

Ectopic expression of PLZF under the CD4 or Lck promoter induced a typical stage 2 NKT program in CD4 T cells, with downregulation of CD62L, upregulation of CD44 and LFA-1, dual secretion of IL-4 and IFNγ, and homing to liver and lung.[104,121,122,123] Notably, the full effector conversion depended on expression of PLZF at high levels comparable to stage 1 and 2 NKT thymocytes, which was only achieved in the CD4 promoter transgenic model.[124] In these mice, nearly 100% of CD4 cells acquired the effector phenotype at the CD4 SP stage. This effector conversion was also observed in MHC class II-restricted TCR/RAG knockout transgenic models. Thus, while the induction of PLZF requires the signaling environment of NKT cells, the NKT effector program can be transferred by PLZF alone. The molecular basis of the extensive gene reprogramming induced by PLZF, in particular the direct target genes and the biochemical mechanisms of gene activation or repression, are currently being studied.

Other Transcription Factors

The induction of Tbet represents an essential step at the transition between stage 2 and stage 3,[125,126,127] coinciding with the relative decrease in PLZF expression. Both Tbet and Egr2 contribute to *Il2rb* induction,[100] allowing responsiveness to IL-15. While the pathways leading to Tbet induction independently of Stat1 or Stat4 remain unclear, a role for Ets1 or MEF has been suggested.[127,128]

Mice lacking Gata-3 exhibited severe but complex NKTcell defects[129] consisting of a considerable reduction of most of their thymic and peripheral NKT cells, with the strange exception of their stage 3 thymocytes which accumulated normally. Gata-3 is required for ThPOK induction, explaining the loss of CD4 by residual NKT cells.[113]

Mice lacking TGFβRII had severe NKT-cell developmental defects, particularly in a competitive chimera setting.[130] Mutant NKT cells had defective expression of the IL-7 receptor and increased apoptosis at stage 1, but a normal rate of cell division at stage 2. Tbet and IL2Rβ were expressed by a larger than normal fraction of stage 2 cells. These effects were mediated by different branches of TGFβ signaling, including Tif-1γ, Smad4, and the Smad4/Tif-1-independent pathway.

Complex and somewhat conflicting results have been reported regarding the role of different NF-κB factors. Mice lacking IKKβ or expressing a degradation resistant form of I-κBα

generally exhibited severe cell-intrinsic defects at stage 1 and 2, due in part to apoptosis. These effects appeared to be mediated by the partly redundant functions of NF-κB1, RelA, and c-Rel.[131,132,133,134] The upstream activator of NF-κB may include signaling through TCR, SLAM/SAP/Fyn, or CD28/B7. In contrast, ablation of RelB in the alternate pathway impaired early NKT cells development nonspecifically by disrupting the thymic stroma.

While early reports suggested some cell-intrinsic role for lymphotoxin signaling in NKT-cell development,[135] more recent analysis indicated that the major attrition in lymphotoxin-deficient animals occurred during the transition from the thymus to the periphery, possibly related to a defect in NKT thymocyte emigration in the absence of interaction between LTβR on thymic stromal cells and lymphotoxin on bone marrow-derived cells.[136]

cMyc is induced as early as stage 0, when NKT cells enter S phase. Its conditional ablation resulted in developmental arrest at stage 0,[72] similar to cyclin D2-deficient mice (unpublished data), suggesting that entry into cell cycle occurred at stage 0, one stage earlier than previously thought.[64]

Micro-Ribonucleic Acids

Conditional ablation of *Dicer* in thymocytes led to a massive loss of NKT thymocytes but the micro-ribonucleic acids involved have eluded identification.[137,138,139,140]

Other Promyelocytic Leukemia Zinc Factor-Positive Lineages

γδT cells expressing the semi-invariant Vγ1Vδ6 receptor were previously shown to express the NK1.1 marker, home to the liver, and produce IL-4, like Vα14-Jα18 NKT cells.[141]

These cells were not only dependent on SAP for their differentiation, but also expressed PLZF.[142,143,144] In OP-9 supported thymocyte cultures, PLZF could be induced after crosslinking with Vγ-specific TCR antibodies. Likewise, TCR αβ thymocytes upregulated *Zbtb16* messenger ribonucleic acid after injection of anti-TCRβ antibodies in vivo.[100] These findings support the notion that agonist signaling induces PLZF to generate innate-like αβ and γδ lineages. MR-1-specific Mucosal-associated invariant T cells were also reported to express PLZF[104] and home to liver and gut.[145] Together with experiments showing that CD4 T cells selected by MHC class II expressed on thymocytes also acquired PLZF in a SAP-dependent manner,[109,110,111,112] these observations reveal an authentic cellular and molecular pathway dedicated to the generation of innate-like lymphocytes.

Deficiencies or mutations affecting certain genes associated with TCR signaling produced a phenotype characterized by a cell-intrinsic expansion of the PLZF-expressing thymic lineages, including Vγ1Vδ6 T cells and Vα14-Jα18 NKT cells. This expansion was associated with a bystander conversion of MHC-restricted thymocytes, mainly CD8 T cells, into innate-like CD62L^{lo} CD44^{hi} CD122^{hi} eomesodermin^{hi} effectors, caused by IL-4 secreted by the PLZF-expressing cells. This complex phenotype was observed in mice lacking the Tec kinases Itk or Rlk,[146,147,148] or bearing the Y145F mutation in the scaffold protein SLP76, which impairs binding of these kinases after TCR signaling.[143] Mice lacking the inhibitor of E proteins Id3, which can be induced downstream of the TCR-activated MAP kinases, showed a strikingly similar phenotype,[143,149,150] as did mice after conditional ablation of CREB binding protein,[151] a general transcriptional coactivator, and KLF2, a transcription factor that controls CD62L and S1P1 receptor upregulation after positive selection.[148,152]

The convergent impact of these different genes suggests the existence of a negative regulatory pathway that physiologically contains the expansion and function of innatelike T

cells. Notably, wild-type BALB/c mice spontaneously exhibited a similar, albeit milder, phenotype as mutant C57BL/6 mice, including a relative expansion of PLZFexpressing NKT thymocytes and a bystander induction of CD44, CD122, eomesodermin, and the rapid production of cytokines by CD8 SP thymocytes.[148] This phenotype was dependent on *klf13*.[153] Thus, there is a natural crosstalk between innate-like and conventional T cells during thymic development, whose variations may have a profound impact on the immune system.

Homeostasis

NKT cells are produced at a similar rate from fetal to adult life, and they persist indefinitely after adult thymectomy. The mechanisms ensuring their long life in peripheral tissues are detailed in the following.

Interleukin-15

Like NK cells and CD8 memory cells, mature NKT cells critically depend on IL-15 for their terminal maturation as well as their survival and homeostatic renewal.[154,155,156] Cell-type-specific ablation of IL-15Rα, which is essential to present IL-15 at the surface of IL-15-producing cells, revealed that the sole source of IL-15 for development was a nonhemopoietic radiation-insensitive stromal cell type, most likely a medullary epithelial cell.[157] In contrast, both radiation-resistant and hemopoietic cells served as partly redundant sources of IL-15 for peripheral NKT cells.

CXCL16

CXCR6 signaling, in response to CXCL16 produced by endothelial cells, is critical for the survival of liver NKT cells in basal conditions, but not for their specific accumulation or their crawling behavior in the liver sinusoids.[158]

Cluster of Differentiation 1d Ligands

In mice lacking CD1d in peripheral tissues, the full terminal maturation of NKT cells after thymic export is partially altered but the overall frequency, tissue distribution, survival, and functional properties of NKT cells are not significantly impaired.[80,87] Thus, peripheral NKT cells do not require contact with self-antigens for homeostasis.

Microbiota

NKT cells did not exhibit major disturbances in their development or function in germ-free mice.[78,159,160] However, mice lacking NKT cells were reported to harbor changes in the composition of their microbiota.[160]

TISSUE DISTRIBUTION AND RECIRCULATION

In C57BL/6 mice, NKT cells represent ˜0.2% of the T-cell population in blood and peripheral lymph nodes; ˜2.5% of T cells in spleen, mesenteric, and pancreatic lymph nodes; 5% in the lung; and up to 40% in the liver. Furthermore, parabiotic experiments have shown that, unlike most lymphocytes, NKT cells do not recirculate and are lifelong residents of lymphoid tissues, lung, and liver.[161]

Tissue and Intravascular Residents

This tissue residency is particularly remarkable in the liver and lung where NKT cells are mainly found within the capillary microvasculature.[158,161] Intravital imaging using confocal microscopy of the liver of $CXCR6^{GFP}$ mice, where a majority of brightly fluorescent liver

lymphocytes are Vα14 NKT cells, demonstrated their presence inside the sinusoid capillaries, adhering to the luminal side of endothelial cells and crawling, without directional bias, at a speed of ˜10μm/min (Fig. 18.6). While other effector T cells and monocytes can adopt a similar crawling behavior transiently, before they extravasate to enter inflamed tissues, NKT cells are constitutively and permanently crawling in steady-state conditions.

The expression of high amount of CXCR6 by NKT cells matches the production of the corresponding chemokine ligand CXCL16 by endothelial cells lining the sinusoids. CXCR6 appeared to be important for the survival of liver NKT cells[158] as well as NK cells,[162] but it was not required for liver accumulation. Furthermore, the adhesion and crawling processes were unaltered by pertussis toxin treatment, suggesting independence from $G\alpha_i$ protein signaling.[163]

Thus, the constitutive activation of LFA-1 was neither a consequence of TCR signaling, as NKT cells normally accumulated in the liver of mice lacking CD1d outside of the thymus,[80,87] nor of chemokine-induced $G\alpha_i$ protein signaling. Notably, transgenic expression of PLZF in MHC class II-restricted CD4 T cells was sufficient to induce their liver retention, indicating that the adhesion and crawling behavior are an integral component of the PLZF-induced functional program.[161]

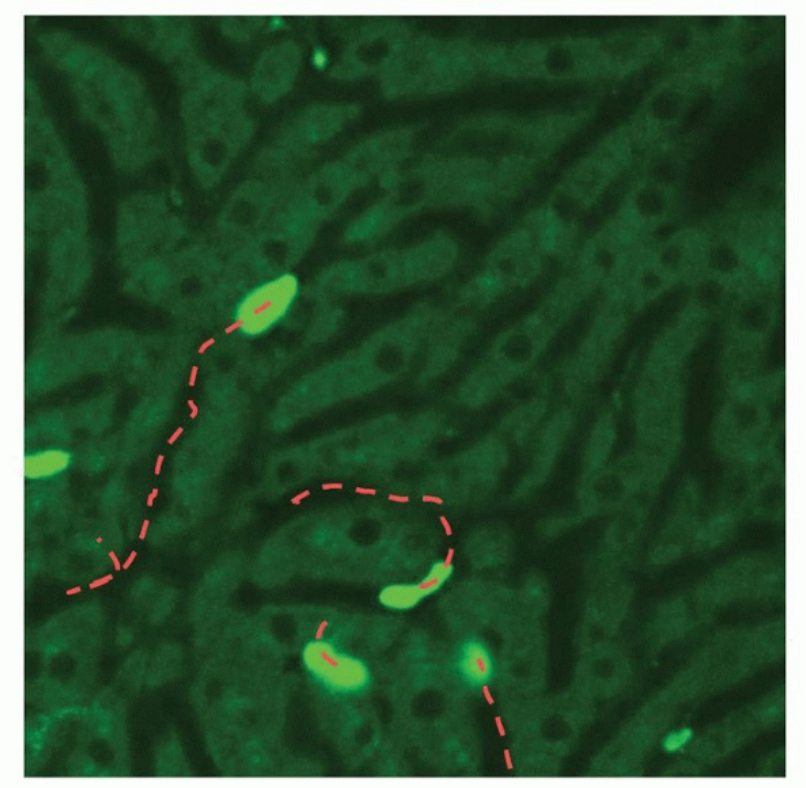

FIG. 18.6. Intravascular Patrolling by Liver Natural Killer T (NKT) Cells. Fluorescent NKT cells in CXCR6-GFP "knock-in" mice are crawling on the luminal side of sinusoid endothelial cells. *Dashed lines* show their path over a period of 10 mn in a live imaging study. (Courtesy of Frederic Geissmann, King's College, London, UK, and Dan Littman, New York University, New York, NY, USA)

Organ-specific Natural Killer T-Cell Sublineages

DN NKT cells expressing Rorγt and producing IL-17 and IL-22 but not IL-4 or IFN-γ selectively resided in skin and draining axillary and inguinal lymph nodes.[164,165] While they shared the usual CD44^{hi}CD62L^{lo} effector phenotype of other NKT cells, they did not express the stage 3 markers Tbet, IL2Rβ, CD69, or NK receptors and instead displayed a CD103^{hi} CCR6+ CD121a+ phenotype. The identification of a minor cell population in the thymus with a similar phenotype suggested that they constituted a separate developmental sublineage.[166] Intriguingly, their expression of Nrp-1, a marker of recent thymic emigrants and their rapid disappearance after adult thymectomy, suggested that, unlike most NKT cells, they represented a short-lived population.[82]

A subset of NKT cells expressing the IL-25 receptor and biased toward production of IL-4, IL-3, and IL-9 was found in the thymus, spleen, and lung, but was poorly represented in the liver and bone marrow.[167] Whether these cells constitute a tissue-specific sublineage that differentiates in the thymus or in the periphery remains to be determined.

NATURAL KILLER T-CELL FUNCTIONS

Functional Properties

DC activation and the explosive release of cytokines and chemokines by NKT cells have well-documented functional consequences in a variety of pathological or therapeutic conditions involving lymphoid tissues and body organs. Important factors biasing the Th1, Th2, or Th17 outcome of NKT-cell activation in vivo have recently emerged. They include the structure of the lipid antigen, the antigen-presenting cell type, the tissue, and the coexposure to TLR ligands. These will be discussed in two separate contexts: the administration of synthetic NKT ligands, which function as potent vaccine adjuvants, and the activation of NKT cells in the context of microbial infection.

Vaccine Adjuvant Properties

Dendritic Cell-based Network of Activation

Several studies have characterized a cascade of activation events following the exogenous administration of NKT ligands such as αGalCer (Fig. 18.7). The central feature was a cross-activation between NKT cells and DCs initiated upon the presentation of αGalCer by resting DCs to NKT cells. Activated NKT cells upregulated CD40L, Th1 and Th2 cytokines, and chemokines; CD40 crosslinking induced DCs to upregulate CD40, B7.1, and B7.2 and IL-12p40, which in turn enhanced NKT-cell activation and cytokine production.[168,169] DCs upregulated MHC class I- and class II-mediated antigen presentation, particularly cross-priming, and secreted CCL17,[170] a chemoattractant for naïve CCR4+ CD8 T cells. IL-12 released by DCs promoted prolonged IFN-γ production by NK cells and activated their cytolytic properties.[171,172] Thus, αGalCer promotes robust CD4 and CD8 T-cell-mediated adaptive immune responses against coadministered nonreplicating protein antigens.[173,174,175] Furthermore, although TLR signaling is not involved in the innate response to αGalCer, the combination of TLR and NKT ligands was synergistic.[176]

Th1 and Th2 Variants

Different synthetic agonists showed biased Th1 versus Th2 outcomes mainly due to their differential ability to induce IL-12 from DCs and to transactivate NK cells. Variants of the original αGalCer (KRN7000) with short or unsaturated lipid chains induced similar Th2 but decreased Th1 cytokines.[177,178,179] While early reports pointed to the lower TCR affinity of a variant with truncated phytosphingosine chain (psC9:0, called “OCH”),[180] several other

Th2 variants, including acylC8:0 or acylC20:2, demonstrated identical interactions based on affinity measurements and crystal structures.[56,181,182] All these Th2 variants had increased solubility in water and could be rapidly loaded onto CD1d molecules at the cell surface. In contrast, αGalCer was almost exclusively loaded in the lysosome due to a requirement for lipid transfer proteins. Whereas αGalCer remained stably associated with CD1d, the short or unsaturated variants were rapidly ejected upon recycling to the acidic endosome.[21] Interestingly, αGalCer was found associated with surface CD1d molecules on lipid rafts, whereas the short or unsaturated variants were loaded to CD1d molecules outside of these rafts, perhaps as a consequence of their different loading compartments.[182] However,

this is unlikely to explain the Th2 bias, as the variants induced the same balance of cytokines as αGalCer when tested in vitro with purified antigen-presenting cells. A more likely explanation for the Th2 bias was suggested by in vivo studies with mice carrying a floxed CD1d allele. Indeed, while αGalCer presentation was mostly limited to lysosomally active DCs and macrophages, which produced IL-12, the Th2 variants were broadly presented by all CD1d-expressing cell types, most of which did not produce IL-12.[89] Thus, structural differences in lipids resulted in the involvement of different antigen-presenting cell types, altering the cellular network and the outcome of NKT-cell activation (Fig. 18.8).

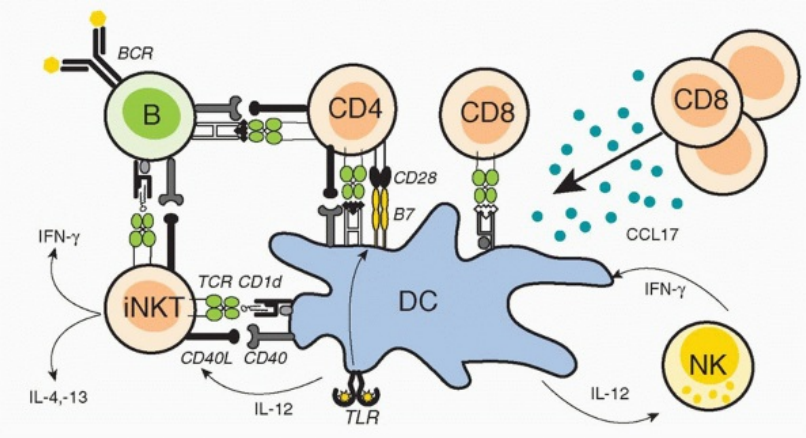

FIG. 18.7. Cellular and Molecular Network Activated by the Natural Killer T (NKT) Ligand αGalCer. Cross-activation between NKT cells and dendritic cells (DCs) lead to cluster of differentiation (CD)40L-CD40 interactions, activating the DC to present peptide antigens to CD4 and also to CD8 cells (cross-priming). NKT cells promptly release Th1 and Th2 cytokines. Naïve CD8 T cells are chemoattracted through CCL17 secreted by DCs. NK cells are "transactivated" by DCs and interleukin-12 to release interferon-γ in a prolonged manner. B cells seeing antigens can receive cognate help from NKT cells and/or from CD4 cells.

Anergy

A limitation to the adjuvant properties of NKT ligands is the rapid NKT TCR downregulation and apoptosis, followed by a long-lasting depletion and a state of anergy.[183,184,185] Anergy could be partially avoided by CD28 costimulation or PD1 blockade,[186,187] or by the administration of αGalCer-pulsed DCs, or αGalCer conjugated to nanoparticles.[188,189,190] The mechanism of NKT-cell anergy remains obscure.

Natural Killer T-Cell Help to B Cells

NKT-cell activation by agonist ligands promoted antibody production, affinity maturation, and switching against associated antigens. Help could be indirect, through CD40L-CD40 mediated activation of the DCs presenting peptide antigen to CD4 T cells, which in turn provided MHC II-restricted help to B cells recognizing a linked antigen. Alternatively, direct NKT-B cell cognate interactions have been demonstrated in vitro and in vivo.[191,192,193,194,195,196,197] The relevance of this direct cognate help was illustrated by infection with *Sphingomonas*, which carries abundant glycosphingolipid ligands in its cell wall.[198] The production of immunoglobulin (Ig)G antibodies against the bacterial membrane appended enzyme pyruvate dehydrogenase complex-E2 depended on CD1d expression by B cells, as evidenced in mixed bone marrow chimeras where CD1d expression was limited to one Ig allotype-marked, B-cell compartment. NKT cells engaged in cognate and prolonged interactions with B cells, after acquiring a stereotypical Bcl-6 dependent follicular helper program with induction of CXCR5, PD1, and IL-21, and migration to the germinal center.[196,197] Intriguingly, immunization with αGalCer-nitrophenol (NP) induced faster but less sustained germinal center formation with fewer long-lived plasma cells and inferior memory compared with keyhole limpet hemocyanin-NP or ovalbumin-loaded (OVA)-NP,[196,197] suggesting that NKT cell help to B cells was intrinsically inferior to conventional T-cell help. However, other variables might have contributed to these differences, including the monovalency of NP in the case of αGalCer, differences in bioavailability, cellular targeting, half-life, and processing of the different immunogen preparations. It is also possible that the rapid induction of NKT-cell anergy after exposure to αGalCer might limit the interactions required for effective B-cell help.

Splenic marginal zone B cells constitutively express approximately eight times more CD1d on their surface than other B-cell subsets.[9] They responded to antigen in an accelerated manner with increased sensitivity conferred by the complement receptor CD21, which lowers the B-cell receptor signaling threshold to complement-coated antigen.[199] These characteristics have long suggested a special function in CD1d-mediated B-cell responses. In support of such

NKT-MZB interactions in vivo, depletion of marginal zone B cells impaired the IgM anti-NP antibody response after systemic administration of αGalCer-NP.[200]

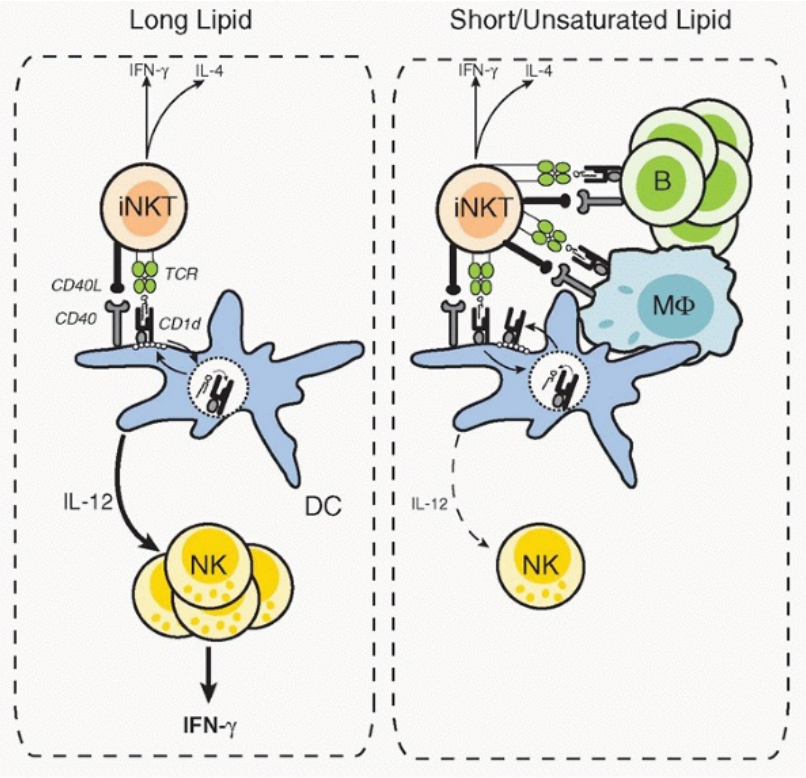

FIG. 18.8. Th1 and Th2 Agonist Ligands of Natural Killer T (NKT) Cells. *Left*, long and saturated αGal-Cer variants (including KRN7000) load cluster of differentiation (CD)1d in the lysosomal compartment due to their requirement for lipid transfer proteins. The main antigen-presenting cell is a dendritic cell (DC), which produces lots of interleukin (IL)-12 and transactivates NK cells. *Right*, short or polyunsaturated lipids load CD1d directly at the cell surface, but are rapidly ejected upon recycling to the lysosome due to displacement by longer, hydrophobic peptides at acidic pH. These short or polyunsaturated lipids are promiscuously presented by all CD1d expressing cells, limiting DC interactions, interleukin-12 production, and natural killer transactivation. CD1d complexed with long and saturated variants sit in lipid rafts, whereas CD1d complexed with short or polyunsaturated variants are excluded from lipid rafts.

Natural Killer T-Cell Help to Macrophages and Myeloid Suppressor Cells

Subcapsular CD169+ macrophages efficiently captured and presented αGalCer to NKT cells in lymph nodes after footpad injection of 200 nm silica beads coated with the lipid antigen.[201] This selective capture further emphasizes the importance of the formulation of αGalCer in targeting different antigenpresenting cell types. Notably, agonist-mediated NKT-cell interaction with myeloid suppressor cells could reverse their suppressive properties. Furthermore, natural interactions between NKT cells and myeloid suppressor cells have been suggested in transplanted cancers and influenza infection.[202,203,204]

Microbial Infections

The recognition of either microbial α-linked glycolipid antigens or self-β-linked antigens induced by TLR signaling ensures the recruitment of NKT cells in most microbial infections (Fig. 18.9). Which of these modes of activation predominates for individual microorganisms is somewhat controversial, as TLR signaling induces IL-12, which is a potent amplifier of IFN-γ secretion, and NKT cells upregulate their IL-12 receptor upon TCR signaling.

Direct Microbial Lipid Recognition

Glycosphingolipids closely related to αGalCer were found in the cell wall of *Sphingomonas*,[30,205] a prominent gram-negative LPS-negative member of α-proteobacteria, an abundant class of bacteria. These glycosphingolipids included the dominant α-branched glucuronyl and galacturonyl ceramides (GSL-1) and the less abundant di- (GSL-2), tri- (GSL-3), and tetraglycosylated (GSL-4) species. Although they form structures that are reminiscent of LPS, their synthesis pathway and their role in the microbial cell wall are not well understood. GSL-1 activates large proportions of mouse and human NKT cells,[31,32,206,207] but it is unclear at present whether the more complex GSL-2, -3, and -4 can be recognized by NKT cells or even whether they can be efficiently processed into GSL-1 by host antigen-presenting cells. During infection, *Sphingomonas* was phagocytosed by macrophages and DCs, and elicited an activation cascade similar to exogenous αGal-Cer. NKT-deficient mice had 15- to 1000-fold more residual bacteria than their wild-type littermates in the first few days after infection.[31,32] High doses of *Sphingomonas* induced a lethal toxic shock in wild-type but not NKT-deficient littermates. These observations have led to the hypothesis that NKT cells and their canonical TCR specificity might have evolved to meet the challenges of these gram-negative LPSnegative bacteria. While *Sphingomonas* can cause severe infection, particularly in immunocompromised hosts, other more deadly members of the class of α-proteobacteria may have provided stronger evolutionary pressures on the NKTcell system. Particularly interesting is the case of *Ehrlichia*, a tick-borne pathogen and member of the *Rickettsiales*, which is of widespread significance for mammals, including wild and domesticated ruminants, dogs, and humans in some regions of the world such as Africa and east Asia. *Ehrlichia muris*

activated NKT cells independently of MyD88, and its clearance was profoundly impaired in CD1d- or Jα18-deficient animals.[31] However, the cell wall composition of *Ehrlichia*, a gram-negative, LPS-negative obligate intracellular bacterium, has not been elucidated.

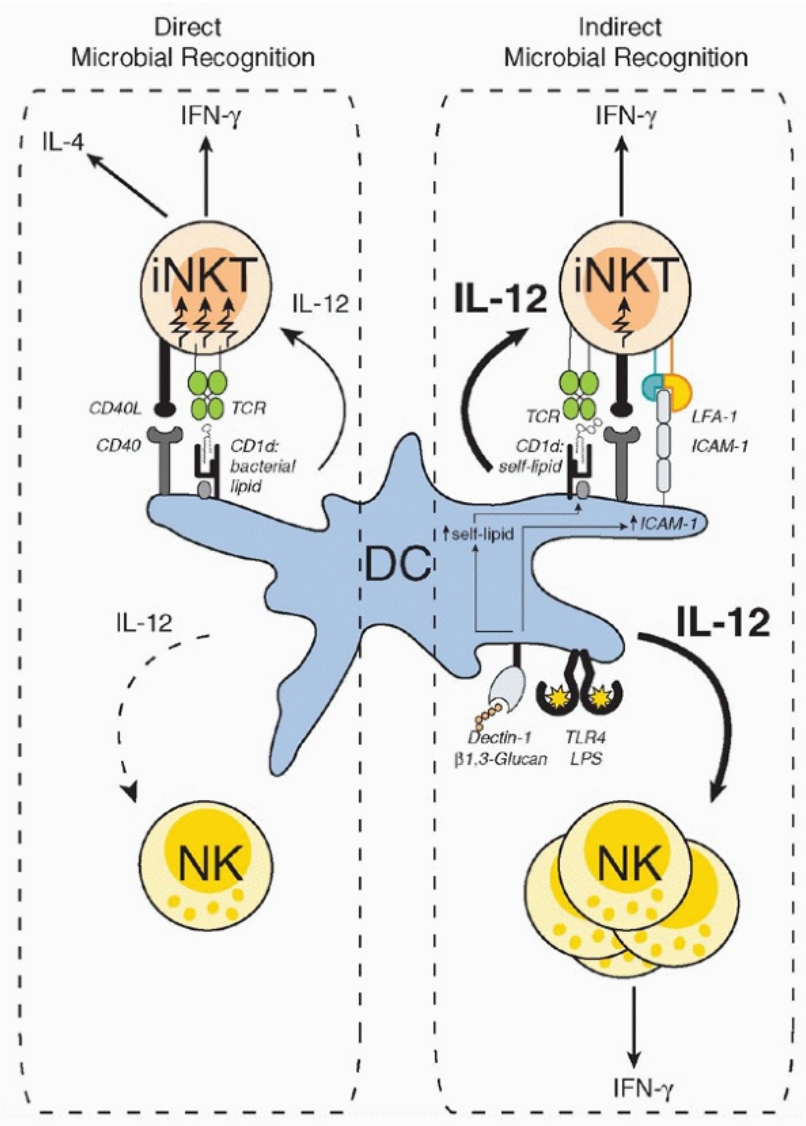

FIG. 18.9. Dual Recognition of Self- and Microbial Ligands in Microbial Infections. *Left*, microbial organisms expressing agonist ligands can elicit direct activation of natural killer T (NKT) cells. *Right*, microbial organisms lacking NKT ligands activate NKT cells through the enhanced recognition of self NKT ligands. These self ligands are upregulated by toll-like receptor- or dectin-1-mediated signals, and their recognition is enhanced by upregulation of intercellular adhesion molecule at the immune synapse. Interleukin-12 secreted by dendritic cells amplifies interferon-γ produced by NKT cells and by natural killer cells.

Other bacteria such as *Streptococcus*[34,208] and *Borrelia*[33] expressed α-linked diacyglycerol lipids that bound CD1d and could directly engage the mouse and human NKT TCR, resulting in accelerated microbial clearance. *Borrelia* was normally cleared by NKT-deficient mice, except at later time points in the joints.[163,209] Intravital microscopy of the liver response to an intravenous inoculation of *Borrelia burgdorferi* showed rapid microbial uptake by stationary Kupffer cells followed by the attraction and arrest of NKT cells in the sinusoids. Stable, CD1d-mediated contacts between Kupffer cells and NKT cells depended on the secretion of CXCL9 by Kupffer cells and the pertussis toxin-sensitive response of CXCR3-expressing NKT cells.

Self-Lipid Recognition

Many bacteria that do not harbor NKT ligands nevertheless induce massive amounts of IFN-γ in a NKT- and CD1d-dependent manner.[31,39] This secretion of IFN-γ is considerably amplified through TLR-induced IL-12 released by DCs and macrophages and the transactivation of NK cells (see Fig. 18.9). TLR signaling regulates several glycosphingolipid enzymes, leading to the accumulation of stimulatory glycosphingolipids (see Fig. 18.3), and activation of LFA-1/ICAM-1 interactions further facilitate NKT-cell recognition of these low-affinity ligands. However, contrary to an early report,[210] NKT cells do not usually constitute the predominant cell-type producing IFN-γ in response to IL-12

in vivo,[39,211] which explains why they generally do not appear to play an essential role in many bacterial infections. Nevertheless, bacterial clearance and neutrophils were reportedly decreased in the lungs of CD1d-deficient mice after infection with *Pseudomonas aeruginosa*.[212] This may not be the case at other sites of infection.[213] Different conclusions were also reported regarding the importance of NKT cells versus NK cells in lethal LPS-induced toxic shock.[214,215]

Fungal and Parasitic Infections

The production of IgG antibodies to the malaria circumsporozoite antigen, a key component of protective immune responses in humans, was suggested to depend on NKTcell recognition of malarial glycosylphosphatidylinositol antigens in a mouse model.[216] However, additional experiments failed to detect a CD1d-dependent component to this antibody response and glycosylphosphatidylinositols have not been identified as NKT-cell antigens in other reports.[217,218] In the context of helminth infection, DCs pulsed with *Schistosoma mansoni* eggs activated NKT cells to secrete Th1 and Th2 cytokines in vitro in a β-hexosaminidase B-dependent but MyD88-independent manner, suggesting recognition of the self-ligand iGb3 in the absence of TLR signaling.[219]

Intratracheal infection by the fungal pathogen *Aspergillus fumigatus* indirectly stimulated NKT-cell production of IFN-γ through activation of the dectin-1/MyD88 pathway by the major cell wall polysaccharides, β-1,3 glucans. Clearance of the pathogen was impaired in NKT-deficient mice.

Viral Infections

Viruses can activate TLR signaling through the adaptors MyD88 and TRIF, which in turn activate autoreactive NKT cells. Relatively modest defects in viral clearance have been reported in CD1d-deficient mice infected with encephalomyocarditis virus[220] or coxsackie B3,[221] but these defects were not observed in Jα18-deficient mice, ruling out a specific role of Vα14 NKT cells. Influenza virus clearance was normal or modestly impaired in mice lacking NKT cells.[222,223] Infections with lymphocytic choriomeningitis virus, mouse cytomegalovirus, vaccinia virus, and coronavirus were unaffected. In humans, a profibrotic role of Vα24 NKT cells was suggested in hepatitis C[224] and non-Vα24 CD1d-restricted T cells were found in the liver.[225] Although a specific role of Vα14 NKT cells in herpes simplex virus infection is controversial,[226,227] studies have suggested that viral invasion may be associated with countermeasures against CD1d or NKT cells. For example, herpes simplex virus-1 drastically and specifically impaired CD1d recycling from lysosome to plasma membrane, an essential pathway for glycolipid antigen presentation to NKT cells.[228] Kaposi sarcoma-associated herpes virus encodes two modulators of immune recognition MIR1 and MIR2 that downregulated CD1d along with other immunologically relevant molecules such as

MHC class I, CD86, and ICAM-1 through ubiquitination of lysine residues in their cytoplasmic tail.[229] The lethal outcome of infections with Epstein-Barr virus in patients with X-linked lymphoproliferative immunodeficiency syndrome due to SAP mutations was hypothesized to result from the absence of NKT cells.[93] Which of these effects or associations reflect specific viral evasion/immune defense strategies and the nature of the putative NKT ligands involved in these infectious conditions remain to be determined.

Autoimmunity, Inflammation, and Allergy

Asthma

Studies in the OVA/Alum model of asthma in mouse and a report that humans with asthma harbored high percentages of Vα24 NKT cells in their bronchoalveolar lavage suggested a broad role of NKT cells in various forms of airway allergic inflammation. However, these studies have not been widely confirmed.[230]

Other studies have focused on the presence of airborne NKT ligands in natural environments, for example in house dust or in air samples where *Sphingomonas* is one of the predominant microbial species identified.[231,232] Airway exposure to these NKT ligands resulted in the rapid CCL17-induced recruitment of resident intravascular NKT cells into the lung with formation of eosinophilic granulomas. Notably, a single airway exposure to protein antigen associated with NKT ligands led to massive recall allergic airway inflammation upon airborne challenge with protein alone. Likewise, coadministration of house dust extracts containing unidentified NKT ligands promoted allergic sensitization to airborne OVA in an NKT-dependent manner.

Thus, emerging studies indicate that natural exposure to airborne NKT ligands in the environment may constitute a previously unappreciated cause of allergic sensitization.

Diabetes and Autoimmune Diseases

Many reports have suggested a role of NKT cells, usually of regulatory nature, in autoimmune diseases such as type I diabetes, arthritis, and lupus, and in atherosclerosis and inflammatory bowel disease.[233] These reports mostly relied on comparisons between wild-type versus Jα18- or CD1ddeficient mice but did not offer precise mechanistic insights into the putative function of NKT cells and their mode of recruitment. Some of these studies did not use littermates as wild-type controls and have not been widely reproduced. Furthermore, the recent discovery that NKT thymocytes impact the function of MHC-restricted T cells in a bystander manner, through the secretion of IL-4,[148] suggests that alternative, indirect mechanisms might contribute to these observations.

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is an enigmatic disease characterized by the presence of antimitochondrial antibodies, liver lymphocytic infiltrates, and the chronic destruction of the biliary epithelium leading to cirrhosis.[234] The autoantibodies recognize an epitope of the mitochondrial pyruvate dehydrogenase complex-E2 enzyme that is particularly well conserved in *Novosphingobium aromaticivorans*, a strain of *Sphingomonas*. Further, patients with PBC, including those

lacking antimitochondrial antibodies, were specifically seropositive against *Sphingomonas*, which was detected by polymerase chain reaction in stool samples of 25% of diseased or healthy individuals, suggesting that PBC may be induced by aberrant host reactivity to this bacterium.[235] Patients with PBC also showed an enrichment of Vα24 NKT cells in liver biopsies and a depletion in blood.[236] In light of the recent finding that *Sphingomonas* cell

wall glycolipids specifically activate NKT cells, these studies suggested that NKT cells might play a key role in the pathogenesis of PBC by promoting aberrant responses to *Sphingomonas*. An experimental model of infection induced a chronic liver disease with PBClike granulomas and antimicrobial autoantibodies, which could be transferred by lymphocytes. These provocative findings support the hypothesis that PBC might be the consequence of cryptic episodes of bacterial infections, perhaps triggered by commensals containing NKT ligands, leading to NKT cell-assisted breakdown of tolerance to shared microchondrial/bacterial antigens.

Cancer

A role of Jα18 and non-Jα18 CD1d-restricted NKT cells in cancer surveillance has been inferred from reports that CD1d- and Jα18-deficient mice seemed to differ from wildtype mice in their susceptibility to a variety of spontaneous and transplanted cancers.[237] Vα14 NKT cells were suggested to exert protection against spontaneous sarcomas. These included fibrosarcomas in mice injected intramuscularly with methylcholantrene,[238] osteosarcomas and hemopoietic tumors in p53+/- mice,[239] and carcinomas in transgenic adenocarcinoma of the mouse prostate mice.[240] Some transplanted cancers seemed aggravated in their progression by the presence of non-Vα14 NKT cells, apparently because of their secretion of IL-13 and interaction with myeloid suppressor cells.[202,203] These cancer studies have commonly concluded that endogenous ligands might be induced and presented by the tumor themselves or by antigen-presenting cells. The crosstalk between myeloid-derived cells and NKT cells resulted in suppression, or on the contrary, to exacerbation of immune responses against cancer. In most cases, however, the nature of these putative ligands has escaped precise identification. One exception lies with the proposed role of lysophosphatidylcholine as a tumor antigen in myeloma patients.[54]

A serious challenge to the interpretation of these studies is their near exclusive reliance on comparisons between wild-type and NKT-deficient mice and the lack of direct evidence of NKT cell involvement in the antitumor response. Moreover, some studies did not use proper littermate controls, or could not be independently reproduced. For example, the longstanding but isolated report that methylcholantrene-induced sarcomas were naturally controlled by Vα14 NKT cells[238] could not be confirmed in recent double-blind studies comparing large groups of CD1d- or Jα18-deficient mice and their littermate controls.[241] In addition, some of the reported results may be explained by an indirect rather than a direct function of NKT cells, for example due to their cross-talk with conventional T cells.[148]

CONCLUSION

Recent Advances

In the past 4 years, pivotal discoveries have advanced our understanding of the biology of NKT cells, particularly regarding their dual recognition of self- and foreign-lipid antigens; their role in infectious and allergic diseases; their specialized effector functions within microenvironments; their expression of a lineage-specific master transcription factor, PLZF; and their cross-talk with MHC-restricted T cells.

Remaining Challenges

The nature and the hierarchy of self- and foreign antigens recognized by NKT cells and their proposed role in a variety of diseases remain a work in progress. Are there other, perhaps more broadly relevant NKT ligands and what controls their expression?

Which class of microorganisms might explain the evolution of this elaborate lineage? Might NKT cells protect against diseases that have recently disappeared, at least in Western societies? In that regard, typhus-like disease after infection by tick-borne *Ehrlichia* may be

comparable to malarial disease in its devastating impact in endemic regions.

What are the signaling events underlying NKT-cell differentiation, particularly the signals inducing PLZF, the molecular mechanisms of PLZF function, and the acquisition of NK receptors? Are there master transcription factors, similar to PLZF, that control other innate-like lineages such as CD8αα TCRαβ IELs and B1 B cells?

Finally, will NKT agonists demonstrate efficiency and safety as vaccine adjuvants to combat infections and cancer in humans?

Other Cluster of Differentiation 1-restricted T Cells?

Although there is strong evidence that the majority of CD1drestricted αβ T cells in mice belong to the NKT lineage,[5] little is known about the human populations of αβT cells restricted by CD1d or other CD1 isotypes such as CD1a, b, and c.

Convergent studies reviewed in this chapter suggested that thymic selection by ligands predominantly expressed on cortical thymocytes or other hemopoietic cells was a key determinant of innate-like lineage decision. As CD1a, b, c, and d are all predominantly expressed on cortical thymocytes, they might mainly select PLZF-expressing T cells. This hypothesis remains to be directly tested in fresh human T-cell populations. Notably, humanized mice expressing a CD1b-restricted human TCR together with human CD1b under its own regulatory elements developed effector-like T cells that expressed PLZF.[242] Other insights have come from studies of a small subpopulation of human αGalCer-specific T cells that did not express Vα24, but used the remaining conserved elements of the NKT TCR, Jα18 and Vβ11. These cells expressed intermediate amounts of PLZF and kept a naïve $CD62L^{hi}$ $CD45RO^{hi}$ phenotype.[124] This natural example suggests that PLZF expression may be a reliable marker of T cells selected by CD1 molecules, but that different levels of expression may be imparted depending on as yet unknown factors such as perhaps, the intensity of TCR

P.447

signaling. Other studies based on the large scale cloning of fresh T cells have suggested that 3% to 10% of the cord blood T-cell population may be CD1-restricted and naïvelike, with a larger proportion of memory-type cells appearing in adults.[243] These important studies could not, however, determine whether the CD1-restricted T cells were selected by CD1 molecules or were merely cross-reactive cells primarily selected by MHC.

Most fresh CD1-restricted T cells identified so far in mice and humans have shown a CD4+ or CD4-CD8β- DN phenotype, with occasional expression of CD8α but rarely CD8β.[124,243] This coreceptor expression pattern parallels the one found in mouse and human CD1d-restricted NKT cells where it is associated with expression of ThPOK/cKrox, suggesting that most CD1-restricted T cells might also express this transcription factor.

These observations provide a background for studies of fresh, unimmunized CD1-restricted T cells in humans, which are now possible through the use of tetramers. Together with studies of “humanized” mice expressing human CD1-restricted TCRs and CD1 molecules, a more definitive characterization of the different populations of CD1-restricted T cells should emerge. Will they demonstrate the heavy contribution of germline TCR segments and the basal autoreactivity that is a hallmark of NKT cells? Will they display adaptive or innate-like features? Forthcoming answers to these fundamental questions will not only be crucial for clinical applications, but will also shed light on the evolutionary logics of lipid antigen recognition.

ACKNOWLEDGMENTS

I thank members of my laboratory and my colleagues Luc Teyton and Paul B. Savage for their insights, contributions, and comments on this chapter; Dirk Zajonc for discussions and for providing Figure 18.4; Frederic Geissmann and Dan Littman for providing Figure 18.6; and

Seth Scanlon for help with the figures. Albert Bendelac is supported by the Howard Hughes Medical Institute and by grants from the National Institutes of Health.

Chapter 19

Macrophages and Phagocytosis

Siamon Gordon

INTRODUCTION

Macrophages (Mø) represent a family of mononuclear leukocytes that are widely distributed throughout the body within and outside of lymphohemopoietic organs. They vary considerably in lifespan and phenotype, depending on their origin and local microenvironment. Mature Mø are highly phagocytic, relatively long-lived cells that are adaptable in their biosynthetic responses to antigens and microbial stimuli. The functions of Mø within tissues are homeostatic, regulating the local and systemic milieu through diverse plasma membrane receptors and varied secretory products. They react to, and themselves generate, signals that influence growth, differentiation, and death of other cells, recognizing and engulfing senescent and abnormal cells. These activities contribute substantially to recognition and defense functions against invading microorganisms, foreign particulates, and other immunogens. Innate immune functions of Mø complement their contributions to acquired humoral and cellular immunity, in which they regulate activation of T-and B-lymphocytes; this is achieved in part through their specialized derivatives, dendritic cells (DCs) of myeloid origin. Mø, with or without DCs, process and present antigen; produce chemokines and cytokines such as interleukin (IL)-1, IL-6, IL-12, IL-18, IL-23, tumor necrosis factor (TNF)-α, IL-10, and TGFβ; and phagocytose apoptotic and necrotic cells. Acting directly or under the influence of other immune cells, Mø capture extra- and intracellular pathogens, eliminate invaders, and deliver them to appropriate subcompartments of lymphoid organs. As key regulators of the specific as well as the natural immune response, Mø boost as well as limit induction and effector mechanisms of the specific immune response by positive and negative feedback.

The properties and roles of DCs, especially in antigen presentation, are described in detail elsewhere in this volume. Here, we focus on other members of the Mø lineage, consider their interrelationship, and outline specialized properties that underlie their roles in the execution and regulation of immune responses. A number of texts and presentations deal with the history and broad aspects of Mø immunobiology.[1,2,3,4,5,6,7,8]

SOME LANDMARKS IN THE STUDY OF MACROPHAGES

Our understanding of Mø developed in parallel with the growth of immunology as an experimental science. Metchnikoff, a comparative developmental zoologist, is widely credited for his recognition of phagocytosis and leukocyte recruitment as a fundamental host defense mechanisms of primitive, as well as highly developed multicellular organisms.[3,4,7] The Nobel awards of 2011 to Bruce Beutler,[9] Jules Hoffman,[10] and Ralph Steinman[11] reflect the paradigm shift of immune recognition from lymphocytes to innate antigen-presenting cells (APCs). Metchnikoff already clearly stated the link between capture of infectious microorganisms by the spleen and subsequent appearance of reactive substances (antibodies) in the blood, although mistakenly ascribing their production to the phagocytes themselves. The importance of systemic clearance of particles by Mø, especially Kupffer cells in liver and other endothelial cells, was enshrined in the term reticuloendothelial system. Although it was rejected by influential investigators in the field in favor of the term mononuclear phagocyte system, the appreciation that sinuslining Mø in liver and elsewhere

share common properties with selected endothelial cells is worth preserving. 3 Earlier studies by Florey and his students, including Gowans, established that circulating monocytes give rise to tissue Mø. Van Furth and his colleagues investigated the life history of Mø by kinetic labeling methods; subsequently, the development of membrane antigen markers facilitated a more precise definition of specialized Mø subpopulations in tissues such as brain. The appearance and potential importance of Mø during development also became evident as a result of sensitive immunocytochemical methods. Morphologic and functional studies by Humphrey and many others drew attention to striking diversity among Mø-like cells in secondary lymphoid organs, especially within the marginal zone of the spleen, where complex particulates and polysaccharides are captured from the circulation.

The era of modern cell biology impinged on Mø studies following the studies of Cohn,[12] Hirsch, and their colleagues. Their work touched on many aspects of cell structure and function, including phagocytosis (the zipper mechanism of Silverstein), fluid- and receptor-mediated endocytosis, secretion, and antimicrobial resistance. Isolation and in vitro culture systems became available for cells from mice and humans, especially after the identification of specific growth and differentiation factors such as colony-stimulating factor-1 (CSF-1). It is perhaps fitting that the earliest known natural knockout (ko) affecting Mø, a natural mutation in the op gene in the osteopetrotic mouse, should involve CSF-1.[13] Cell lines retaining some but not all features of

mature Mø have been useful for many biochemical and cellular studies. Macrophages and dendritic cells can be derived from embryonic stem cells and induced pluripotent cells by growth in appropriate culture conditions and transfection of selected transcription factors.

The role of Mø as antigen-processing cells able to initiate adaptive immune responses had false trails (“immunogenic ribonucleic acid [RNA]” was thought to be involved at one time) and encompassed early genetic strategies (Mø of mice selected for high antisheep erythrocyte antibody responses by Biozzi and colleagues displayed enhanced degradative properties; adherent cells from defined guinea pig strains were shown to play an important role in major histocompatibility complex [MHC] Ia-restricted antiinsulin responses). For many years, the APC functions of adherent cells were highly controversial as promoted by Unanue, who concentrated on intracellular processing by Mø, and Steinman, who discovered the specialized role of “DCs” in antigen presentation to naive T-lymphocytes. The importance of Mø as effector cells in immunity to intracellular pathogens such as *Mycobacterium tuberculosis* was recognized early by Lurie and Dannenberg. Mackaness used *Listeria monocytogenes* and bacille Calmette-Guérin (BCG) infection in experimental models and developed the concept of Mø activation as an antigen-dependent but immunologically nonspecific enhancement of antimicrobial resistance. The subsequent delineation of T-lymphocyte subsets and characterization of interferon (IFN)-*γ* as the major cytokine involved in macrophage activation, including MHC II induction, merged with increasing knowledge of the role of reactive oxygen and, later, nitrogen metabolites as cytotoxic agents. The role of virus-infected Mø as MHC I-restricted targets for antigen-specific CD8+ killer cells was part of the initial characterization of this phenomenon by Zinkernagel and Doherty. D'Arcy Hart was an early investigator of the intracellular interactions between Mø and invaders of the vacuolar system, especially mycobacteria, which survive within Mø by inhibiting acidification and phagosomelysosome fusion, thus evading host resistance mechanisms. Mouse breeding studies by several groups defined a common genetic locus involved in resistance to BCG, *Leishmania*, and *Salmonella* organisms. The host phenotype was shown to depend on expression in Mø and, many years later, the gene (termed N-ramp for natural resistance-associated membrane protein) was identified by positional cloning by Skamene, Gros, and their colleagues. Positional cloning by Beutler and associates led to the identification of the gene responsible for lipopolysaccharide (LPS) resistance in particular mouse strains. Together with studies by Hoffmann and his colleagues on the toll pathway in *Drosophila*, this work resulted in an explosion of interest in the identification of mammalian tolllike receptors (TLRs) and their role in innate immunity to infection. At the same time, it became apparent that some malignant tumors contain macrophage populations that may favor their growth.

This brief survey concludes with the identification of Mø as key target cells for infection, dissemination, and persistence of human immunodeficiency virus (HIV), tropic for Mø by virtue of their expression of cluster of differentiation (CD)4, chemokine coreceptors, and DCSIGN, a C-type lectin also expressed by DCs. Although Mø had been implicated by earlier workers such as Mims as important in antiviral resistance generally, their role in this regard was neglected before the emergence of HIV as a major pathogen.

Many molecules have been identified as important in Mø functions in immunity and serve as valuable markers to study their properties in mice and humans. These include Fc and complement receptors, which are important in opsonic phagocytosis, killing, and immunoregulation; scavenger receptors originally implicated in foam cell formation and atherogenesis by Brown and Goldstein; nonopsonic lectin receptors, such as the mannose receptor (MR) and *β*-glucan receptor (dectin-1) and secretory products such as lysozyme, neutral proteinases, TNFα, chemokines, and many other cytokines. A range of membrane antigens expressed by human and rodent mononuclear phagocytes has been characterized and reagents made available for further study of Mø in normal and diseased states. Recently, the role of deoxyribonucleic acid (DNA)-binding transcription factors including members of the NF-*κ*B and ETS (Pu-1) families has received increased attention in the study of differential gene expression by Mø. Gene inactivation has confirmed the important role of many of these molecules within the intact host, and use has been made of cell-specific or conditional ko to uncover the role of Mø in immunologic processes. Naturally occurring inborn errors in humans such as the leukocyte adhesion deficiency syndrome and chronic granulomatous disease have contributed to the analysis of important leukocyte functions, including those of Mø, in host resistance to infection. Mutations in a monocyte-expressed gene (nucleotide oligomerization domain [NOD]-2), involved in cytosolic sensing of microbial products and NF-*κ*B activation, have been implicated in a subset of individuals with an enhanced susceptibility to Crohn disease. The validity of murine ko models for human genetic deficiencies has been confirmed for key molecules involved in Mø activation, such as IFNγ and IL-12. *N*-ethyl *N*-nitrosourea mutagenesis has begun to reveal new macrophage innate immune functions, as has increasing application of system biology tools for microarray, proteomic, epigenetic, and microRNA analysis.

PROPERTIES OF MACROPHAGES AND THEIR RELATION TO IMMUNE FUNCTIONS

Introduction

Mø participate in the production, mobilization, activation, and regulation of all immune effector cells. They interact reciprocally with other cells while their own properties are modified to perform specialized immunologic functions. As a result of cell surface and auto- and paracrine interactions, Mø display marked heterogeneity in phenotype,[14,15] a source of interest and considerable confusion to the investigator. Increasing knowledge of cellular and molecular properties of Mø bears strongly on our understanding of their role in the immune response. These will be reviewed

briefly, with emphasis on functional significance, and attention will be drawn to unresolved and controversial issues.

Growth and Differentiation: Life History and Turnover

In contrast to T- and B-lymphocytes, monocytes from blood give rise to terminally differentiated Mø that cannot recirculate or reinitiate DNA replication except in a limited way. Unlike other myeloid granulocytic cells, Mø can be long lived and retain the ability to synthesize RNA and protein to a marked extent, even when in a relatively quiescent state as “resident” cells. These are distributed throughout the tissues of the body and constitute a possible alarm-response system, but they also mediate homeostatic and poorly understood trophic functions. Following inflammatory and immune stimuli, many more monocytes can be recruited to local sites and give rise to “elicited” or “immunologically activated” Mø with

altered surface, secretory, and cytotoxic properties. The origins of Mø from precursors are well known: from yolk sac (and possibly earlier paraaortic progenitors), migrating to fetal liver, then spleen and bone marrow, before and after birth.[16] Yolk sac precursor cells may contribute to the establishment of selected tissue macrophages such as Langerhans cells in the adult.[17] In the fetus, mature Mø proliferate actively during tissue remodeling in developing organs. In the normal adult, tissue Mø do not self-renew extensively except in specialized microenvironments such as epidermis,[18] nervous system, or lung; after TH2-type parasitic infection, there can be considerable further replication at local sites of inflammation.[19] Growth and differentiation are tightly regulated by specific growth factors and their receptors (eg, IL-3, CSF-1, granulocyte-macrophage [GM]-CSF/IL-34, IL-4, IL-13) and inhibitors (eg, IFNα/β, transforming growth factor [TGF]-β, leukemia inhibitory factor), which vary considerably in their potency and selectivity. These processes are modulated by interactions with adjacent stromal and other cells (eg, through c-kit/ligand and Flt-3/ligand interactions). The growth-response of the target cell to an extrinsic stimulus decreases progressively and markedly (from 10^8 or more to 10^0) during differentiation from stem cell to committed precursor to monoblast, monocyte, and Mø, yet even the most terminally differentiated Mø such as microglial cells can be "reactivated" to a limited extent by local stimuli. Elicited/activated Mø respond more vigorously than resident Mø to growth stimuli in vivo and in vitro, but the molecular basis for their enhanced proliferation is unknown.

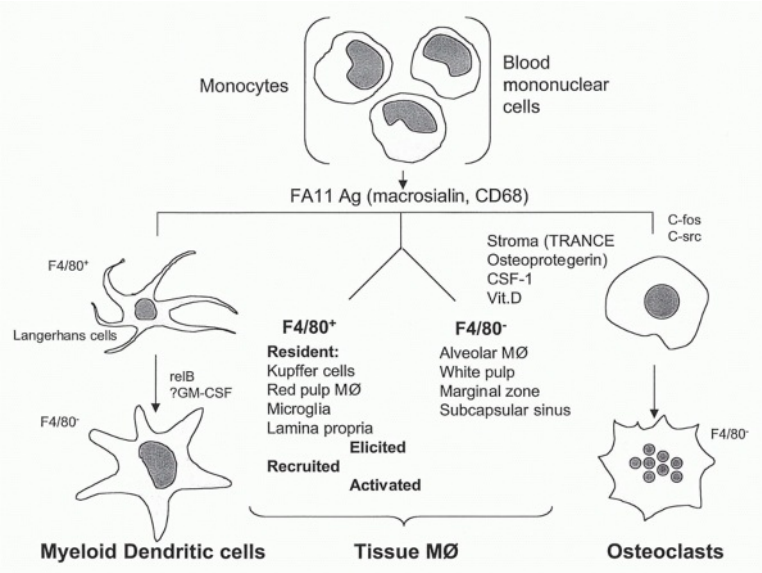

FIG. 19.1. Differentiation of mononuclear phagocytes based on antigen markers FA-11 (macrosialin, murine CD68) and F4/80. See text for detailed discussion.

Although this general picture of blood monocyte-totissue Mø differentiation has been accepted for some time as a result of parabiosis, adoptive transfer, and irradiation-reconstitution experiments, recent studies in mouse and man have demonstrated monocyte heterogeneity and distinct properties,[20,21,22,23] with a subpopulation remaining within the vasculature, to perform a patrolling function. Our understanding of DCs and osteoclast differentiation is still compatible with a relatively simple model (Fig. 19.1) in which major Mø populations in mouse tissues can be characterized by selected antigen markers such as F4/80 (Emrl,

a member of a family of EGF-TM7 molecules) and macrosialin (CD68), a pan-Mø endosomal glycoprotein related to the lysosome-associated membrane protein (LAMP) family. The DCs of myeloid origin (see elsewhere in this volume) share many properties with

monocyte/macrophages,[24] but are specialized to capture, process, and present antigens to naïve lymphocytes. Circulating precursors of DCs and and macrophages are normally present in the mononuclear fraction of blood in small numbers[25]; studies in the mouse may not reflect the origin and differentiation of precursor cells in humans.[26] Monocytes that have crossed the endothelium may be induced to "reverse migrate" into the circulation by selected stimuli in tissues.[27] Finally, the mouse spleen has been shown to serve as a reservoir of monocyte/Mø for recruitment to sites of inflammation.[28]

Circulating mononuclear precursors for osteoclasts are less defined and differentiate into mononucleate cells, recruited in response to sphingosine-1-phosphate to bone, for example,[29] where they fuse to form multinucleate bone-resorbing osteoclasts.[30] Local stromal cells, growth factors such as CSF-1, steroids (vitamin D metabolites), and hormones (eg, calcitonin, for which osteoclasts express receptors) all contribute to local maturation. Osteoprotegerin, a naturally occurring secreted protein with homology to members of the TNF-receptor family, interacts with TRANCE, a TNF-related protein, to regulate osteoclast differentiation and activation in vitro and in vivo.

Use of antigen markers such as CD34 on progenitors, CD14 and CD16 on monocytes, and chemokine receptors and multichannel fluorescein-activated cell sorter analysis have made it possible to isolate leukocyte subpopulations and study their progeny and differential responses in different mouse tissues and models of disease.[31] The mononuclear fraction of blood may contain precursors of other tissue cells, including mesenchymal stem cells able to synthesize matrix proteins such as collagen, and some endothelial cells. Perhaps the mysterious follicular dendritic cells (FDCs) with mixed hemopoietic and mesenchymal properties fall in this category.

The large-scale production of immature and mature DClike cells from bulk monocytes in cytokine-supplemented culture systems (IL-4, GM-CSF, TNFα) has revolutionized the study of these specialized APCs. Individually, the same cytokines give rise to Mø-like cells, and early during in vitro differentiation, the cellular phenotype is reversible. Later, when mature DCs with high MHC II, APC function, and other characteristic markers are formed, differentiation is irreversible. This process is independent of cell division, although earlier progenitors in bone marrow and GM-CSF-mobilized blood mononuclear cells can be stimulated to multiply, as well as differentiate, in vitro. These examples of terminal differentiation observed with DCs and osteoclasts may extend to other specialized, more obvious Mø-like cells. Mature Mø can be derived by growth and differentiation in steroid-supplemented media in Dexter-type long-term bone marrow cultures that contain stromal fibroblasts and hemopoietic elements. These Mø express adhesion molecules responsible for divalent cation-dependent cluster formation with erythroblasts (EbR). This receptor, possibly related to V-CAM, cannot be induced on terminally differentiated peritoneal Mø if these are placed in the same culture system. This contrasts sharply with the ready adaptation of many tissue Mø to conventional cell culture conditions, when the cells often adopt a common, standard phenotype. Irreversible stages of Mø differentiation may therefore occur in specialized microenvironments in vitro or in vivo.

Little is known about determinants of Mø longevity and turnover. Growth factors such as CSF-1 enhance Mø survival and prevent induction of an apoptotic program. The expression of Fas-L and Fas on Mø has been less studied than on lymphocytes; they and other members of the TNF and its receptor family may play a major role in determining Mø survival, especially in induced populations, where cell turnover is markedly enhanced. Tissue Mø vary greatly in their lifespan, from days to months. Apart from inflammatory and microbial stimuli, local and systemic environmental factors such as salt loading and hormones, including estrogen, are known to influence Mø turnover.

Tissue Distribution and Phenotypic Heterogeneity of Resident Macrophages in Lymphoid and Nonlymphoid Organs

The use of the F4/80 plasma membrane antigen made it possible to detect mature Mø in

developing and adult murine tissues and define their anatomic relationship to other cells in endothelium, epithelium, and connective tissue, as well as the nervous system.[32,33] Subsequently, other membrane antigens,[34] macrosialin, sialoadhesin, and others were identified as useful markers for Mø in situ (Table 19.1). Mø subpopulations in different tissues display considerable heterogeneity in expressing these and selected receptor antigens (eg, complement receptor [CR]3 and class A scavenger receptor [SR-A]), drawing attention to unknown mechanisms of homing, emigration, and local adaptation to particular microenvironments. From the viewpoint of immune responses, a few aspects deserve comment.

Fetal Liver and Bone Marrow

Mature Mø form an integral part of the hemopoietic microenvironment and play a key role in the production, differentiation, and destruction of all hemopoietic cells. The fetal liver is a major site of definitive erythropoiesis from midgestation.[16] The bone marrow becomes active in the production of hemopoietic cells from shortly before birth, and Mø are a prominent component of the hemopoietic stroma throughout adult life. Mature "stromal" Mø in fetal liver and adult bone marrow express nonphagocytic adhesion molecules such as sialoadhesin (Sn), an immunoglobulin (Ig)-superfamily sialic acid-binding lectin (Table 19.1), and the EbR referred to previously, which is also involved in adhesion of developing myeloid and possibly lymphoid cells (Fig. 19.2). VLA-4 has been implicated as a ligand for EbR. Ligands for Sn include CD43 on developing granulocytes and on lymphocyte subpopulations. Sn clusters at sites of contact between stromal Mø and myeloid but not erythroid cells. Chemokines are able to induce polarized expression of adhesion molecules such as intercellular adhesion molecules and CD43 in leukocytes, but the significance

of altered ligand distribution for interactions between Mø and bound hemopoietic cells is unknown. Adhesion of immature cells to stromal Mø may play a role in regulating their intermediate stages of development before release into the bloodstream, whereas fibroblasts in the stroma associate with earlier progenitors, as well as with Mø. Discarded nuclei of mammalian erythroid cells are rapidly engulfed by stromal Mø, but the receptors involved in their binding and phagocytosis are unknown. Mø also phagocytose apoptotic hemopoietic cells generated in bone marrow, including large numbers of myeloid and B cells. We know little about the plasma membrane molecules and cytokine signals operating within this complex milieu, but it is clear that stromal Mø constitute a neglected constituent within the hemopoietic microenvironment.

TABLE 19.1 Selected Differentiation Antigens Used to Study Murine Macrophage Heterogeneity

Ab	Ag	Structure	Ligands	Cellular Expression	Function	Comment
F4/80	F4/80 (EMR1)	EGF-TM7	?	Mature Mø, absent T areas	Peripheral tolerance	Useful marker development, CNS
FA-11	Macrosialin (CD68)	Mucin-LAMP	OX-LDL	Pan-Mø, DC	Late endosomal	Glycoforms regulated by inflammation and phagocytosis
5C6	CR3	β2-integrin	iC3b, ICAM	Monocytes,	Phagocytosis,	Important in

	(CD11b, CD18)			microglia, PMN, NK cells	adhesion	inflammatory recruitment, PMN apoptosis
2F8	SR-A (I, II)	Collagenous, type II glycoprotein	Polyanions, LTA, LPS, bacterial proteins		Adhesion, endocytosis	Protects host against LPS-induced shock
		Isoforms differ, cysteine-rich domain	Modified proteins β-amyloid apolipoprotein A, E			
				Mø, sinusoidal endothelium	Phagocytosis of apoptotic cells and bacteria	Promotes atherosclerosis
SER-4	Sn (Siglec-1)	Ig superfamily	Sialyl glycoconjugates (eg, CD43)	Subsets tissue Mø	Lectin	Strongly expressed
3D6						Marginal zone metallophils in spleen and subcapsular sinus of lymph nodes

CNS, central nervous system; DC, dendritic cell; ICAM, intercellular adhesion molecule; Ig, immunoglobulin; LAMP, lysosome-associated membrane protein; LPS, lipopolysaccharide; LTA, lipoteichoic acid; Mø, macrophages; NK, natural killer; OX-LDL, oxidised low density lipoprotein; PMN, polymorphonuclear neutrophil; Sn, sialoadhesin; SR-A, type A scavenger receptor.

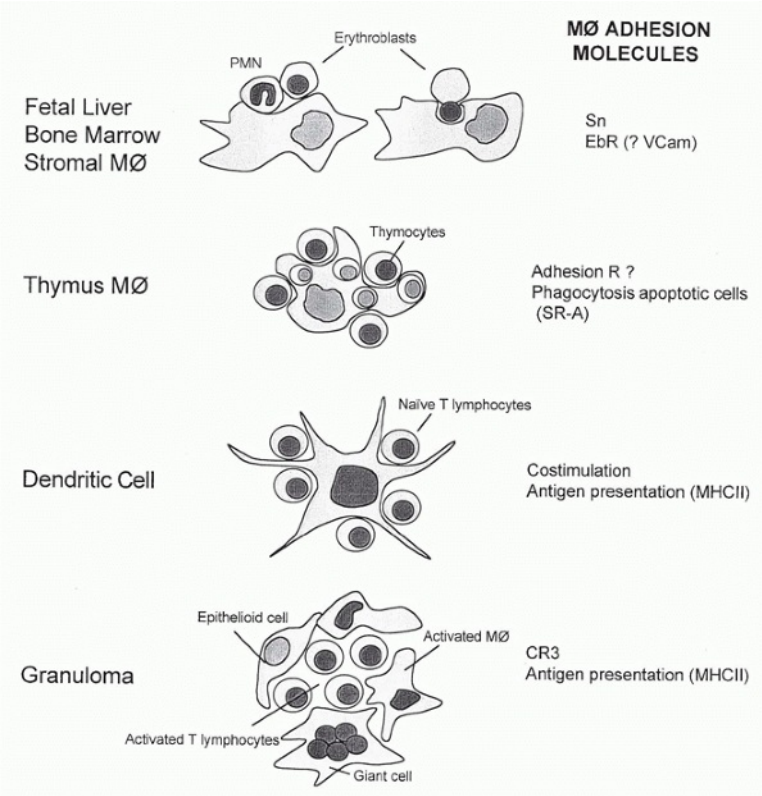

FIG. 19.2. Associations of tissue macrophages with other hemopoietic cells to illustrate variations on a common theme. See text for details.

Thymus

Apart from their remarkable capacity to remove apoptotic thymocytes, the possible role of Mø in positive and negative selection of thymocytes has been almost totally overlooked; more attention has been given to local DCs and their specialized properties. Mature Mø with unusual features are also present in cortex and medulla. Clusters of viable thymocytes and Mø can be isolated from the thymus of young animals by collagenase digestion and adherence to a substratum (see Fig. 19.2). The nonphagocytic adhesion receptors responsible for cluster formation are more highly expressed by thymic than other Mø, but their nature is unknown (N. Platt, unpublished observations). These Mø also express MHC class II antigens and other receptors such as the SR-A (see subsequent discussion), which contributes to phagocytosis of apoptotic thymocytes in vitro, but is redundant in vivo; other markers, such as the F4/80 antigen, are poorly expressed in situ but can be readily detected after cell isolation. A striking difference between thymic and several other tissue Mø subpopulations is their independence of CSF-1; the CSF-1-deficient *op/op* mouse lacks osteoclasts and some Mø populations, including monocytes, peritoneal cells, and Kupffer cells, but contains normal numbers of thymic Mø, as well as DCs and selected Mø in other sites. A second ligand for the CSF-1 receptor Fms, IL-34, may account for CSF-1 independence.[35] Factors involved in constitutive recruitment of thymic Mø are unknown; following death of thymocytes induced by ionizing radiation or glucocorticoids, intensely phagocytic Mø appear in large numbers; it is not known what proportion arises locally and by recruitment.

Spleen

From the viewpoint of the Mø, the spleen is perhaps the most complex organ in the body.[36,37] It contributes to hemopoiesis, which persists postnatally in some species or can be induced by increased demand, can serve as a reservoir as noted previously, and

contributes to the turnover of all blood elements at the end of their natural lifespan. The spleen filters a substantial proportion of total cardiac output, captures particulate and other antigenic materials from the bloodstream, and plays an important role in natural and acquired humoral and cellular immunity. The organ is rich in subpopulations of Mø that differ in microanatomic localization, phenotype, life history, and functions (Fig. 19.3). Mø are central to antigen capture, degradation, transport, and presentation to T- and B-lymphocytes, and contribute substantially to antimicrobial resistance. Recent work has unveiled an unexpected role in facilitating activation of other lymphocyte subsets, such as invariant natural killer T cells[37]; CD 169+ macrophages also activate CD8 T cells in response to dead cell-associated antigens in lymph nodes and by transferring antigen to DCs in the spleen. Because other hemopoietic and secondary lymphoid organs can replace many of these functions after maturation of the immune system, the unique properties of the spleen have been mainly recognized in the immature host and in immune responses to complex polysaccharides. Splenectomy in the adult renders the host susceptible to infection by pathogenic bacteria such as pneumococci that contain saccharide-rich capsular antigens; the marginal zone of the spleen in particular may play an essential role in this aspect of host resistance.

The properties of Mø in the unstimulated mature mouse spleen are different according to their localization in red or white pulp and the marginal zone. Mø are intimately associated with the specialized vasculature. Species differences in splenic anatomy and phenotype are well recognized, although Mø display broadly common features in humans and rodents. Subpopulations of Mø, DCs, and cells with mixed phenotypes have been characterized by in situ analysis by antigen markers, liposome or diphtheria toxin-depletion studies, various immunization and infection protocols, and cytokine and receptor gene ko models in the mouse. The results raise questions about the dynamics and molecular basis of cell production, recruitment, differentiation, emigration, and death within each distinct splenic compartment. Cell isolation methods are still primitive in correlating in vitro properties with those of Mø subpopulations in vivo and remain an important challenge. Detailed aspects of splenic architecture, DC origin and function, and T- and B-lymphocyte induction and differentiation are described elsewhere in this volume. Here, some features of Mø in the normal and immunoreactive organ are highlighted.

Marginal Zone Macrophages

The marginal zone of spleen consists of a complex mixture of resident cells (reticular and other fibroblasts, endothelium), Mø, DCs, and lymphoid cells, including subpopulations of B-lymphocytes. It constitutes an important interface with the circulation that delivers cells, particulates, or soluble molecules directly into the marginal sinus or via the red pulp. Resident Mø are present as specialized metallophilic cells in the inner marginal zone, and other Mø are found in the outer zone; the latter may be more phagocytic. Sn is strongly expressed by the marginal metallophils, compared with only weak expression in red pulp and virtual absence in the white pulp. Sn+ cells appear in this zone 2 to 4 weeks postnatally in the mouse as the white pulp forms. Liposomes containing clodronate, a cytotoxic drug, can be delivered systemically and deplete Sn+ cells and other Mø; regeneration of different Mø subpopulations in spleen occurs at different times, and this procedure has been used to correlate their reappearance with distinct immunologic functions. Marginal

zone Mø lack F4/80 but may express an undefined ligand for F4/80 on circulating activated DCs, which mediates peripheral tolerance to anterior chamber or gut-derived antigens.[38] Marginal zone Mø express phagocytic receptors, such as SR-A, which is more widely present on tissue Mø, as well as MARCO, a distinct collagenous scavenger receptor, which is almost exclusively present on these Mø in the normal mouse. The structures and possible role of these pattern recognition receptors in uptake of microbes are discussed subsequently. In vivo studies have shown that an Mø lectin, the MR, may be involved in transfer of mannosylated ligands to the site of an immune response in the white pulp.[39] The MR contains a highly conserved cysteine-rich domain, not involved in mannosyl recognition, that reacts strongly with ligands on a subset of marginal metallophilic Mø, sulfated glycoforms of Sn, and CD45,

among others; this has been demonstrated with a chimeric probe of the cysteine-rich domain of the MR and human Fc (CR-Fc) and by immunochemical analysis of tissue sections and affinity chromatography of spleen ligands. After immunization, this probe additionally labels undefined cells in the FDC network of germinal centers, as well as tingible body Mø. It is possible that marginal zone Mø can be induced to migrate into white pulp as described after LPS injection; alternatively, they may shed complexes of soluble MR-glycoprotein ligand for transfer to other CR-Fc+ cells, which may be resident or newly recruited mononuclear cells. Finally, the marginal metallophilic Mø population depends on CSF-1 for its appearance and on members of the TNF receptor family, as shown with *op/op* and experimentally produced ko mice.

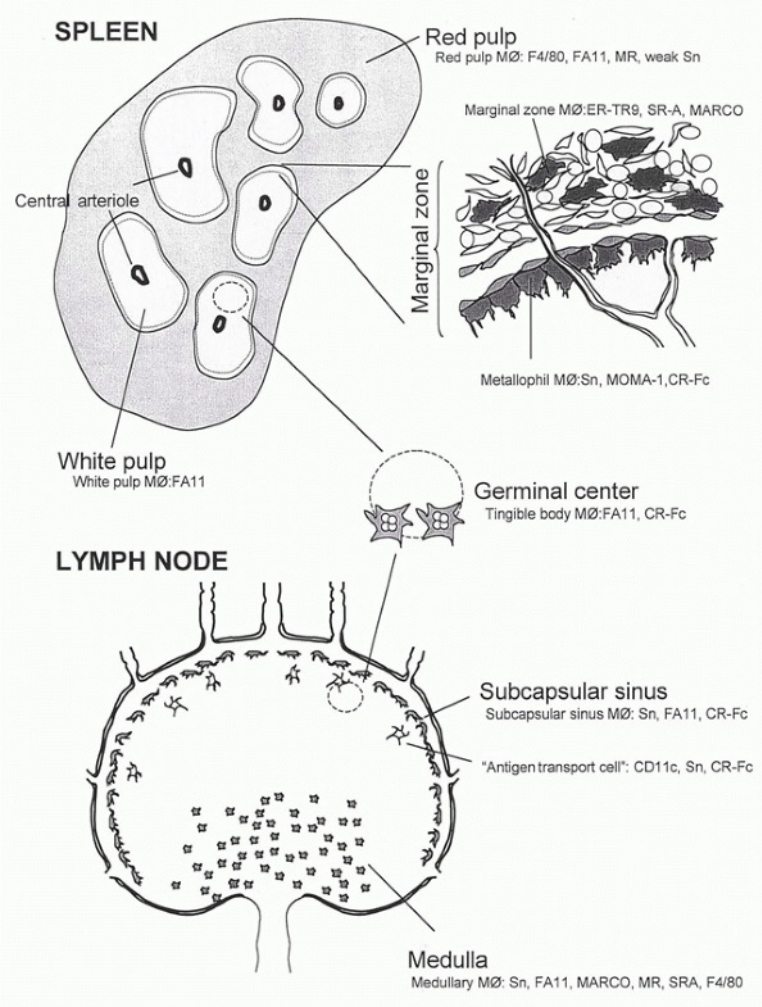

FIG. 19.3. Microheterogeneity of macrophages in spleen, resting, and antigen-stimulated lymph nodes. See text for markers and details.

White Pulp Macrophages

The F4/80 antigen is strikingly absent on murine white pulp Mø, which do express FA-11 (macrosialin), the murine homolog of CD68. Actively phagocytic Mø express this intracellular glycoprotein in abundance compared with DCs. After uptake of a foreign particle (eg, sheep erythrocytes or an infectious agent, such as BCG or *Plasmodium yoellii*), white pulp Mø become more prominent, although it is not known whether there is migration of cells into the white pulp or transfer of phagocytosed material and reactivation of previous resident Mø. Tingible body Mø appear to be involved in uptake and digestion of apoptotic B-lymphocytes.

Red Pulp Macrophages

These express F4/80 antigen and MR strongly and in the mouse include stromal-type Mø involved in hemopoiesis. Extensive phagocytosis of senescent erythrocytes results in accumulation of bile pigments and ferritin, and play an important role in iron turnover[40] and tolerance.[41] The role of various phagocytic receptors in clearance of host cells and pathogens by red pulp Mø requires further study.

There is no evidence that Mø, other than interdigitating DCs, associate directly with CD4+ T-lymphocytes in the normal spleen. Following infection by BCG, for example, or by other microorganisms such as *Salmonella*, there is massive recruitment and local production of Mø, many of which associate with T-lymphocytes. Newly formed granulomata often appear first in the marginal zone (focal accumulations of activated Mø and activated T cells). As infections spread into the white and red pulp, the granulomata become confluent and less localized, obscuring and/or disrupting the underlying architecture of the spleen. The possible role of activated Mø in T-cell apoptosis and clearance in spleen has not been defined.

Lymph Nodes

F4/80 antigen is relatively poorly expressed in lymph node (see Fig. 19.3), but many macrosialin (CD68)+ cells are present. The subcapsular sinus is analogous to the marginal zone and contains strongly Sn+ cells; this is the site where afferent lymph enters, containing antigen and migrating DCs derived from skin and mucosal surfaces. The medulla contains Sn+, CD68+ Mø, which also express high levels of SR-A. As in the spleen marginal zone, subcapsular sinus Mø are strongly labeled by the CR-Fc probe. Following primary or secondary immunization, the staining pattern moves deeper into the cortex and eventually becomes concentrated in germinal centers. The kinetics of this process strongly suggests a transport process by Mø-related cells resembling antigen transport cells described previously. CR-Fc+ cells can be isolated by digestion of lymph nodes and form clusters with CR-Fc- lymphocytes. Adoptive transfer has shown that fluorescein-activated cell sorter-isolated CR-Fc+ cells resemble DCs in their ability to home to T-cell areas and to present antigen to naive T and B cells. Overall, there is considerable heterogeneity in the population of migratory APCs involved in antigen capture, transport, and delivery to T and B cells, and it may turn out that specialized tissue Mø as well as myeloid-type DCs can migrate in response to immunologic stimuli, especially TLR ligands.[42]

Peyer Patch

Although less studied, the Mø in Peyer patch resemble the CD68+, F4/80- cells described in spleen and white pulp and in other T-cell-rich areas. They are well placed to interact with gut-derived antigens and pathogens taken up via specialized epithelial M cells in the dome, and deliver antigens to afferent lymphatics, as myeloid DCs. These cells are distinct from abundant F4/80+ cells in the lamina propria found all the way down the gastrointestinal tract and may play a role in the induction of mucosal immunity. Recent studies have described heterogeneous populations of resident and recruited macrophages and DC in the mouse intestine.[43] The role of the microbiome[44] has received a great deal of attention in regard to innate cell phenotype and epithelial integrity in the gut.

Nonlymphoid Organs

Regional F4/80+ and CD68+ Mø are well described in liver (Kupffer cells), dermis, neuroendocrine and reproductive organs, and serosal cavities, where they are able to react to systemic and local stimuli. In the lung, alveolar Mø are strongly CD68+ but only weakly F4/80+ and are distinct from interstitial Mø and intraepithelial DCs. In the lamina propria of the intestine, Mø display a downregulated phenotype, ascribed to TGFβ of local origin.[45] In addition, resident Mø are found throughout connective tissue and within the interstitium of organs, including heart, kidney, and pancreas. These cells vary greatly depending on their local microenvironment; for example, in the central nervous system, microglia within the

neuropil differ strikingly from Mø in the meninges or choroid plexus.[46] Perivascular Mø in the brain can be distinguished from resident microglia by their expression of endocytic receptors (eg, the SR-A and MR, and of MHC I and II antigens). Microglia are highly ramified, terminally differentiated cells of monocytic origin; many Mø markers are downregulated. Their phenotype is influenced by the blood-brain barrier, normally absent in circumventricular organs, and disrupted by inflammatory stimuli. Microglia can be reactivated by local LPS and neurocytotoxins; they are then difficult to distinguish from newly recruited monocytes, which acquire microglial features once they enter the parenchyma of the brain. Resting microglia are unusual among many tissue Mø in that they constitutively express high levels of CR3 and respond to CR3 ligands, such as mAb, by induced DNA synthesis and apoptosis. In other sites, such as lung and liver, CR3 expression is a feature of recent myeloid recruitment, including monocytes. Resident Kupffer cells lack constitutive CR3 but express a novel CR implicated in clearance function.

Resident tissue macrophages in human tissues express CD68 antigen, but their phenotypic diversity and microheterogeneity in different organs remain poorly defined. Access to skin biopsies, bronchoalveolar lavage, and placenta, for example, provides material for further analysis.

Enhanced Recruitment of Monocytes by Inflammatory and Immune Stimuli: Activation in Vivo

In response to local tissue and vascular changes, partly induced by resident Mø during (re)activation by inflammatory, infectious, and immunologic stimuli, monocytes are recruited from marrow pools and blood in increased numbers; they diapedese and differentiate into Mø with altered effector functions as they enter the tissues.[47] These Mø are classified as "elicited" when cells are generated in the absence of IFNγ and as "immunologically activated" after exposure to IFNγ. Enhanced recruitment can also involve that of other myeloid or lymphoid cells; selectivity of the cellular response depends on the nature of the evoking stimulus (immunogenic or not), the chemokines produced,

and the receptors expressed by different leukocytes. Mø and other cells produce a range of different chemokines and express multiple seven-transmembrane, G protein-coupled chemokine receptors. The chemokines can also act in the marrow compartment, especially if anchored to matrix and glycosaminoglycans, may display other growth regulatory functions, and can control egress. Locally bound or soluble chemokines induce the surface expression and activity of adhesion molecules on circulating white cells, as well as directing their migration through and beyond endothelium. Feedback mechanisms from periphery to central stores and within the marrow stroma may depend on cytokines and growth factors such as macrophage inflammatory protein-1α and GM-CSF, which inhibit or enhance monocyte production, respectively. The adhesion molecules involved in recruitment of monocytes, originally defined by studies in humans with inborn errors and by use of inhibitory antibodies in experimental animal models,[48] overlap with those of polymorphonuclear neutrophils and lymphocytes and include L-selectin, β2-integrins, especially CR3, CD31, an Ig-superfamily molecule, and CD99; additional monocyte adhesion molecules for activated endothelium include CD44, vascular cell adhesion molecules, β_1-integrins, and newly described receptors such as EMR2 and CD97, members of the EGF-TM7 family.[33] The mechanisms of constitutive entry of monocytes into developing and adult tissues, in the absence of an inflammatory stimulus, are unknown.

By contrast with the uncertain precursors of resident Mø and DC populations, distinct monocyte subsets have been implicated in the enhanced mobilization and turnover in response to inflammatory, infectious, and metabolic stimuli, as noted previously (Fig. 19.4). Differential expression of the fractalkine receptor, CCR2, and other chemokine receptors, together with antigen markers (Gr-1 in mouse and CD14 in human), have made it possible to define monocyte heterogeneity. Although such subsets seem to be conserved across several species, their properties may reflect stages of cell activation along a continuous spectrum

rather than true differentiation.

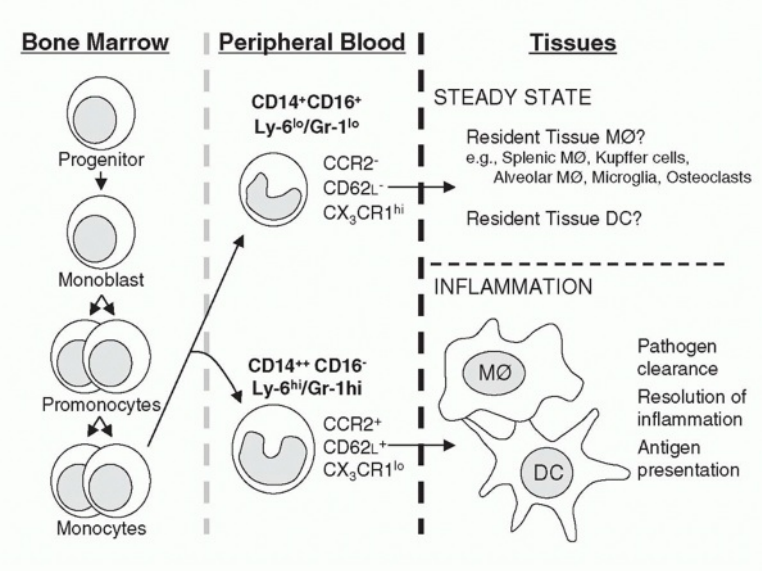

FIG. 19.4. Distinct monocyte subsets give rise to inflammatory and resident macrophages and dendritic cells. The origin of different resident subpopulations is not clear. See text for further details.

The migration and differentiation of newly recruited monocytes once they have left the circulation are poorly understood. They are able to enter all tissues, undergoing alterations in membrane molecules and secretory potential under the influence of cytokines and surface interactions with endothelial cells, leukocytes, and other local cells. Phenotypic changes mentioned in the following section have been characterized by a range of in vitro and in vivo studies. Well-studied examples include murine peritoneal Mø—resident, elicited by thioglycollate broth or biogel polyacrylamide beads, and immunologically activated by BCG infection. The latter provides a useful model of granuloma formation in solid organs but does not fully mimic the human counterpart associated with *M. tuberculosis* infection. Granuloma Mø vary in their turnover and immune effector functions and display considerable heterogeneity; lesions contain recently recruited monocytes, mature, epithelioid Mø (described as secretory cells), and Langhans giant cells. Interactions with T-lymphocytes, other myeloid cells, DCs, fibroblasts, and microorganisms yield a dynamic assembly of cells as the granuloma evolves, heals, and resolves (see Fig. 19.2). Apoptosis and necrosis of Mø and other cells contribute to the balance of continued recruitment and local proliferation. The emigration of Mø rather than DCs from sites of inflammation is less evident, although it has become clear that elicited Mø within the peritoneal cavity, for example, migrate actively to draining lymph nodes.[49]

Gene ko models have confirmed the role of molecules previously implicated in recruitment, activation, and granuloma formation. These include the adhesion molecules listed previously, their ligands, such as intercellular adhesion molecule-1, and key cytokines such as IFN*γ*, IL-12, IL-23, and TNF*α*, as well as their receptors. Antimicrobial resistance and Mø cytotoxicity resulting from production of reactive oxygen and nitrogen metabolites are now accessible to study

in knockouts of the phagocyte oxidase and inducible nitric oxide synthase. kos of membrane molecules of immunologic interest expressed by Mø and other cells include MHC class II and I, CD4, and CD40L, other accessory molecules such as B7-1 and B7-2, and the Mø-restricted intracellular molecule N-ramp.

The study of inborn errors in humans[50,51] and of disease models in genetically modified

mice has brought insight into essential, nonredundant contributions of molecules that regulate Mø activation in vivo, including immunopathology syndromes such as septic shock and autoimmunity. Examples include myeloid antigens such as TREM-1/2,[52] associated with DAP-12, receptor-ligand pairs such as CD200/CD200 receptor,[53] and suppressors of cytokine signaling proteins.[54,55] TNFα is essential for host resistance to infection[56] and also contributes to immunopathology. Highly effective anti-TNF*α* therapy for chronic inflammatory diseases such as rheumatoid arthritis can result in reactivation of latent tuberculosis.

The potential for innate,Th1- and Th2-type regulation of Mø demonstrated in vitro, and discussed subsequently, can result in highly complex, often coexistent, heterogeneity of Mø phenotype in situ (see Fig. 19.4). Although almost all granuloma Mø express lysozyme,[57] only subpopulations express cytokines such as IL-1*β*, IL-6, and TNF*α*. Pro- and anti-inflammatory cytokines, IL-12, IL-18, IL-10, and TGF*β*, produced by Mø themselves and other cells, modulate the phenotype of Mø in vivo.

Intravital imaging has provided insights into the dynamics of interactions of myeloid and lymphoid cells in granuloma formation.[58] Studies of human granulomatous, chronic inflammation provide opportunities to dissect genetic and acquired influences (eg, in NOD-2 deficiency in Blau syndrome[59] and Crohn disease[60]). The mouse resistance protein Irgm1 (LRG-47)[61] has also been implicated in pathogen defense.[62]

Apart from the local interactions outlined, Mø regulate systemic host reactions to immune and infectious stimuli by producing circulating cytokines such as IL-6 and arachidonate- and other lipid-derived metabolites, including resolvins, that contribute to the resolution of acute inflammation.[49] These mediators also act on neural and endocrine centers, crossing the blood-brain barrier, or are generated locally by reactive microglia and Mø. MicroRNAs have been identified that play a role in resolution.[63] Glucocorticosteroids are powerful immunomodulators[64] and form part of a network that regulates monocyte recruitment and Mø functions through circulating mediators such as migration inhibition factor. Mø contain potent enzymes involved in steroid biosynthesis and catabolism.[65]

Although the immunologic relevance of Mø-induced responses may seem evident, many aspects remain unclear. For example, what is the role and phenotype of monocyte/macrophages in the immune reconstitution inflammatory syndrome, associated with dual acquired immunodeficiency syndrome/tuberculosis infection, recipitated by antiretroviral treatment[66]? Do Mø actively suppress or destroy activated T-lymphocytes, thus contributing to regulation of immune responses and peripheral tolerance, or are Mø only passive removers of dying cells? Do Mø contribute to recruitment, differentiation, and death of DCs at sites of inflammation before their migration to secondary lymphoid organs? Do adjuvant-stimulated Mø interact with B-lymphocytes, directing their migration into germinal centers? Are interactions of activated Mø with antibody and complement, through different Fc and complement receptors, implicated in fine-tuning humoral responses? Are activated Mø themselves cytocidal for infected host cells, and to what extent do they in turn interact with and provide targets for attack by natural killer cells and cytotoxic T-lymphocytes? Study of a range of experimental models and disease processes in vivo should yield new insights, as well as extend and confirm mechanisms already defined in vitro.

Phagocytic Recognition and Intracellular Infection

The initiation and localization of an immune response depends on recognition by Mø and other cells of particulate agents or soluble proteins that are foreign or modified-self.[67] Phagocytic and endocytic recognition by Mø and DCs depends, in turn, on opsonic (mainly antibody, complement) and nonopsonic pattern recognition receptors that interact with a range of related ligands (Fig. 19.5). Innate and acquired responses are thus interlinked. Different FcR are involved in uptake and destruction of targets as well as in negative

regulation of effector functions.[68] CRs[69] are also heterogeneous; CR3 interacts with C3-derived ligands formed by activation of the classical, alternate, or lectin pathways and mediate phagocytosis, cell migration, and cell activation. Other ligands include intercellular adhesion molecules. CR3 functions are modulated by fibronectin, via integrins, other adhesion molecules, and inflammatory stimuli. FcR ligation and cross-linking activates tyrosine kinases such as syk that are essential for phagocytosis; CR3 signaling is less defined and may not trigger a respiratory burst or arachidonate release, unlike FcR, thus favoring pathogen entry. Antibodymediated uptake targets an organism or soluble antigen to a different, degradative compartment[70] (Fig. 19.6A, 19.6B) and usually results in its neutralization and destruction, although enhancement of infection can also occur in Mø.[71] Flavivirus infection in the presence of specific antibody can result in the dengue hemorrhagic shock syndrome. Immune complexes, with or without complement, localize antigens to FDCs and other FcR+ CR+ cells. Mø themselves are able to produce all components of the complement cascade in significant amounts at local sites, which may be less accessible to circulating proteins made by hepatocytes.

Nonopsonic receptors reacting directly with ligands on microorganisms[72] include CR3, lectins, especially the MR and *β*-glucan receptor, the scavenger receptors SR-A and MARCO, and the family of TLRs. MRs are present on Mø, DCs, and sinusoidal endothelium.[39] They mediate phagocytosis and endocytosis, including macropinocytosis, and structurally resemble another multilectin, Dec 205, present on DCs as well as tissue Mø and epithelial cells in thymus; carbohydrate recognition by the latter has not been demonstrated. The MR has eight C-type lectin domains, homologous to the mannose-binding protein, a circulating

hepatocyte-derived, acute-phase reactant. Mannose-binding protein, also known as mannan-binding lectin, contains a single lectin domain per polypeptide, which oligomerizes like other collectins to achieve multivalent interactions and activate complement via associated serine proteases. MR expression on Mø is selectively down- and upregulated by IFNγ and IL-4/13, respectively. A possible role of the cysteine-rich domain in transport of immunogenic glycopeptides within secondary lymphoid organs has been proposed.[73]

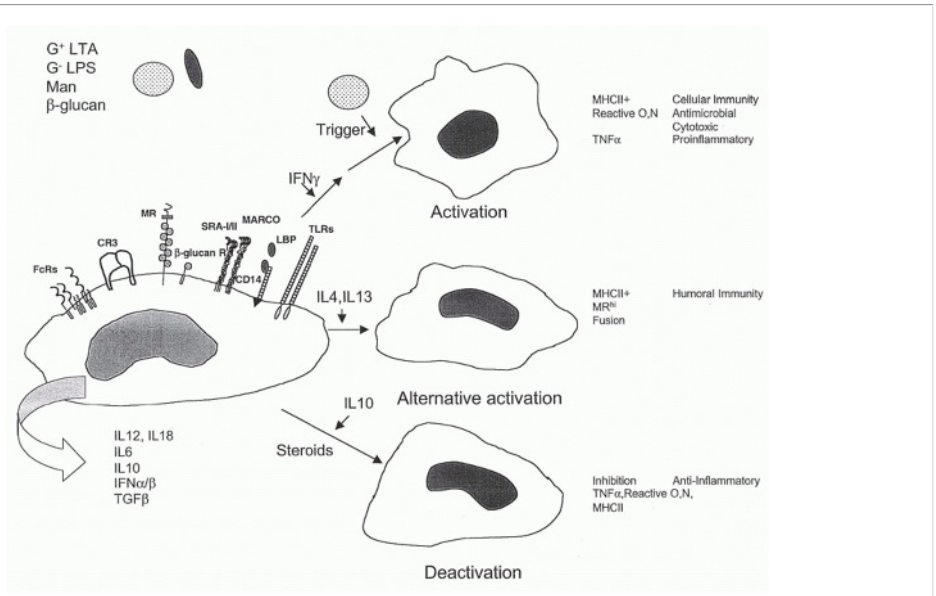

FIG. 19.5. Macrophage activation and the role of microbial stimuli and cytokines. See text for details.

The *β*-glucan receptor, previously reported as dectin-1, is related to C-type lectins and is

responsible for phagocytic recognition of unopsonized zymosan and for Mø activation (Figs. 19.7 and 19.8).[74] It contains an immunoreceptor tyrosine-based activation motif-like motif in its cytoplasmic domain that is essential for phagocytosis and induced secretory responses (eg, TNF*α*). It cooperates with TLR2 and synergizes with other TLRs in cell activation, utilizing syk and CARD9,[75] and can promote TH17 differentiation.[76] It is essential for resistance to a range of fungal particles in vivo, as shown by studies with ko mice and in human primary innate immunodeficiency.[77] Dectin-2, a distinct mannan-binding lectin, has also been implicated in TH17 differentiation.[45,78]

SR-A mediates endocytosis of modified proteins (eg, acetylated lipoproteins) and selected polyanions, such as apolipoprotein A1 and E,[79] LPS, and lipoteichoic acid.[72] In addition, it can serve as an adhesion molecule and contributes to phagocytic clearance of apoptotic thymocytes and gram-negative as well as gram-positive bacteria. MARCO, a related collagenous receptor,[72] mediates cell adhesion and phagocytosis of bacteria but is independently regulated, as discussed subsequently. MARCO[80] and Mincle,[81] a lectin-like receptor, contribute to macrophage responses to trehalose dimycolate, a virulence factor of pathogenic *M. tuberculosis*. An initial report of a phosphatidylserine receptor implicated in the recognition of novel lipid ligands expressed on the surface of apoptotic cells was not confirmed. CD36 (thrombospondin receptor), vitronectin receptors, CD91, and CD44 have all been implicated in the uptake of senescent polymorphonuclear neutrophils by Mø.[82] Other opsonins for apoptotic cell clearance include milk fat globule protein (lactadherin). A role for Mø SR-A in immune induction has not been demonstrated, but studies in SR-A ko mice have revealed an important inhibitory role in limiting TNFα production by immunologically activated Mø. Wild-type, BCGprimed mice produce granulomata rich in SR-A+ Mø; SR-A ko mice restrict growth of this organism and form normal granulomata containing activated, MHC II+ Mø; on additional challenge with LPS, the ko mice die more readily than wild-type animals. TNF*α* levels in the circulation rise markedly because of unopposed triggering via CD14, a receptor for the LPS-binding protein, and contribute to septic shock, because blocking anti-TNF mAb protects these mice.

The family of TLRs consists of homo- or heterodimeric transmembrane molecules related to the IL-1 receptor, which are involved in innate immunity to microbial constituents and activation of Mø responses, and are discussed elsewhere in this volume.[83] Downstream signaling depends on association with other soluble and membrane molecules, as well as with intracellular proteins. MyD88, for example,

has been implicated in many but not all TLR-induced signaling resulting in transcription factor regulation, cell activation, or apoptosis.

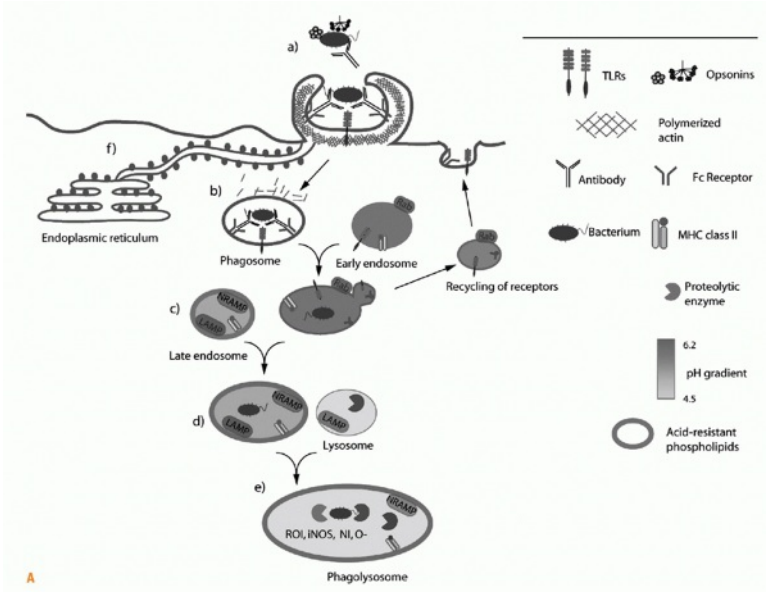

FIG. 19.6. Phagocytic Pathway in Macrophages. A: Heterophagy. Fc receptor-mediated phagocytosis. **a:** Microbes are coated with a variety of opsonins, including complement, pentraxin 3, and antibodies. A number of receptors are involved in initial recognition of microbes and induction of proinflammatory signaling (eg, the toll-like receptors [TLRs], and especially TLRs 2, 4, and 5), but these receptors are not phagocytic. Receptors involved in phagocytosis include the complement receptors, Fc receptors, and others. **b:** Fc receptor ligation initiates a signaling cascade that results in actin polymerization and extension of the plasma membrane. Phagocytosis mediated by this method occurs via the "zipper" mechanism (ie, sequential binding between the Fc receptors and their ligands along the length of the microbe). **c:** Fusion with the early endosome results in a slight drop in pH that results in the uncoupling of receptors with their ligands. Receptor recycling is facilitated by the Rab proteins, which also confer the ability to undergo subsequent fusion. The developing phagosome now contains major histocompatibility complex (MHC) class II and TLRs, including those that signal from within the developing endosome (eg, TLR9). **d:** Fusion with the late endosome results in the addition of the lysosome-associated membrane proteins, the accumulation of acid-resistant phospholipids, and a subsequent drop in pH. **e:** On fusion with lysosomes, the low pH results in the activation of a number of proteolytic enzymes. These are necessary for both direct antimicrobial activity and the creation of peptides for presentation via MHC class II. The phagolysosome is a highly oxidative environment, exposing the pathogen to destructive reactive oxygen and reactive nitrogen intermediates. **f:** Under certain circumstances, the phagosome may contain markers specific for the endoplasmic reticulum (ER). The ER may contribute directly to the creation of the phagocytic membrane in some circumstances (eg, phagocytosis of latex beads), or ER-derived vacuoles may contribute MHC class I and other molecules to the endosomes or the developing phagolysosome. *(continued)*

Naturally occurring microbial ligands for these nonopsonic receptors are still poorly defined; individual receptors mediate microbial binding and uptake of microorganisms, although each contributes only part of total binding (see Fig. 19.6A).[72,84] Particle uptake involves multiple membrane receptors, the cytoskeleton, bulk membrane flow, and remodeling, including formation of a phagocytic synapse and signaling pathways[85,86] (see Fig. 19.8[87]). Phagosome formation and maturation resemble endocytic uptake, initiating Mø vesicle trafficking and recirculation, fusion with lysosomes, acidification, ion fluxes, and digestion. Table 19.2 lists immunologic and other markers

used to identify intracellular compartments.[88] Guanosine triphosphate-binding proteins and complex signaling cascades play an important role in these dynamic events.[62] A key issue that needs to be resolved is how cell and receptor functions are modulated so that microbial phagocytosis or invasion induces inflammatory responses, unlike the uptake of apoptotic cells. The MHC II biosynthesis and subcellular localization and proteolytic processing of peptide antigens in vacuolar and cytosolic compartments of APCs are discussed elsewhere in this volume. Cytokines, especially IL-4/13, IL-10, and IFNγ, influence endocytosis via MR-dependent and -independent pathways and selectively alter vesicle dynamics.

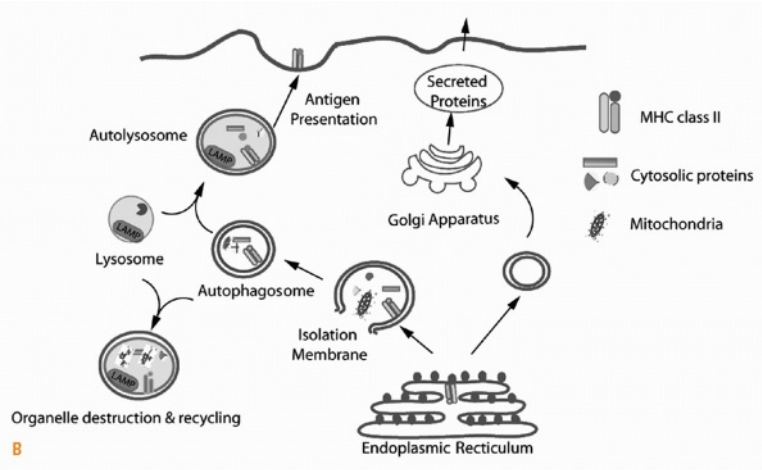

FIG. 19.6. *(continued)* **B:** The autophagy pathway. Autophagy is a homeostatic process that can be further enhanced in macrophages in the presence of interferons or by starvation. Cytosolic proteins and organelles are found in ER-derived cytoplasmic vesicles. These vesicles fuse with lysosomes, and the proteins and organelles are degraded and recycled. Conventional wisdom states that endogenous and cytoplasmic proteins are presented by MHC class I molecules, whereas exogenous peptides are presented by MHC class II molecules; however, it has become clear that peptide presentation is altered considerably on induction of autophagy. The presentation of peptides from intracellular and lysosomal source proteins is increased on MHC-II.

Pathogens vary in using Mø plasma membrane molecules for entry and evasion of host defenses, and modify the composition of the resultant phagosome membrane (Fig. 19.9A, 19.9B).[89] Mycobacteria, for example, employ a range of mechanisms to evade killing by Mø, including delayed maturation of phagosomes and inhibition of fusion with lysosomes and acidification (Fig. 19.9A, 19.9B and 19.10).[90,91] *Listeria monocytogenes* escapes into the cytosol by disruption of the phagosome membrane,[92,93] whereas *Leishmania* multiplies in phagolysosomes.[94] Humoral (antibody, complement) and cellular (IFNγ) mechanisms overcome parasitization of Mø by diversion to lysosomes or induce killing via oxygen/nitrogen (O/N)- dependent and other mechanisms.

Entry of microbial constituents such as muramyldipeptide from vacuolar compartments to the cytosol can result in sensing by NOD-like receptors, inflammasome assembly, activation of caspase-1, and processing and release of IL-1 β.[95,96,97] Nucleic acid recognition results in cytoplasmic and mitochondrial-associated protein signaling responsible for type 1 interferon gene expression (see Fig. 19.9A, 19.9B).[98] A novel ligand, c-di-AMP, secreted by cytosolic *Listeria monocytogenes*, activates a host type I IFN response[92] and may serve as a sensing mechanism for many intracellular pathogens (see Fig. 19.10).[99] STING is a direct innate immune sensor of cyclic di-GMP, another cytosolic metabolite of intracellular microbial infection.[100] It has recently become clear that induction of autophagy and apoptosis by

intracellular pathogens, including *Mycobacterium tuberculosis*, provides important host-protective responses[101] (see Figs. 19.6B and 19.9A, B). For a review on autophagy in immunity and inflammation, see Levine et al.[102,102a]

Although the "canonical" entry pathway described here and illustrated in Figure 19.6A is used and modified by many pathogens, recent evidence has shown that organisms such as *Legionella pneumophila*[102,103] (see Fig. 19.9C, D) and *Brucella abortus*[104] induce vacuoles with novel membrane components or colonize compartments derived from the Golgi apparatus and the endoplasmic reticulum. The relative contributions of plasma membrane and endoplasmic reticulum (see Fig. 19.6A) to vacuole formation varies considerably, depending on the nature of the phagocytic cargo or invading pathogen.[105] Opsonins such as antibody are able to divert the cargo to lysosomes. IFNγ can induce

P.464

guanosine triphosphate-binding proteins that associate with vacuoles inhabited by a range of intracellular pathogens (eg, *Toxoplasma gondii*), thus marking them for destruction within the macrophage.[62,106]

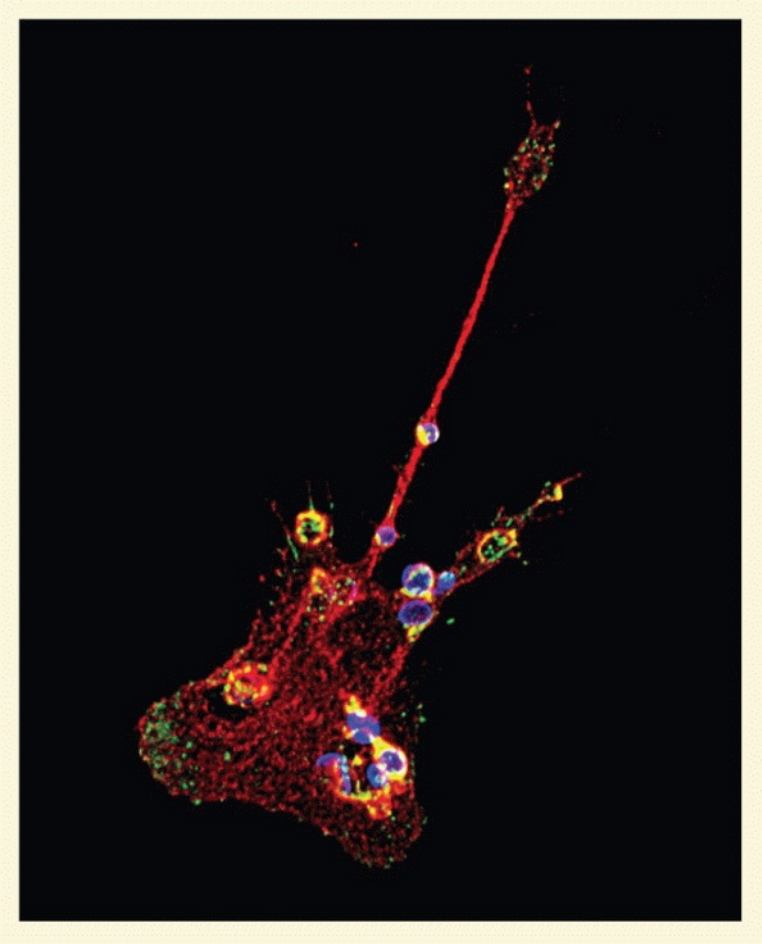

FIG. 19.7. Macrophages Rock! Macrophage engaging zymosan particles. Macrophages are adherent but motile. They use focal adhesions to anchor themselves to the extracellular matrix. Membrane ruffles and lamellipodia form at the leading edge of the cell to enable them to crawl around, and they extend pseudopodia to explore their environment and capture microbes and dead cells for phagocytosis. Consequently, their morphology is highly variable and constantly changing. © Helen Goodridge and David

TABLE 19.2 Membrane or Content Markers Used to Identify Phagosomes as Resembling a Given Endocytic Compartment or the Endoplasmic Reticulum

Compartment	Markers
Early endosome	Membrane markers: TfR, Rab5, annexins, I, II, and III Proteases: immature cathepsin D
Late endosome	Membrane markers: M6PR, Rab7, LAMP1, LAMP2, CD63, CD68 Hydrolases: acid phosphatase, aryl sulfatase, trimetaphosphatase Proteases: cathepsin B, D, H, dipeptidyl peptidase I and II Phospholipid: LBPA
Lysosome	Membrane markers: LAMP1, LAMP2, CD63 Hydrolases: acid phosphatase, aryl sulfatase, trimetaphosphatase

	Proteases: cathepsin B, D, H, dipeptidyl peptidase I and II
ER	Membrane markers: calnexin, calreticulin Enzyme: glucose-6-phosphatase

CD, cluster of differentiation; ER, endoplasmic reticulum; LAMP, lysosome-associated membrane protein; LBPA, lysobisphosphatidic acid; M6PR, mannose-6-phosphate receptor; TfR, transferrin receptor. From de Chastellier C. Electron microscopy. In: Cossart P, Boquet P, Normark, et al., eds. *Cellular Microbiology* , 2nd ed. Washington, DC: ASM Press, 2005:451, with permission.

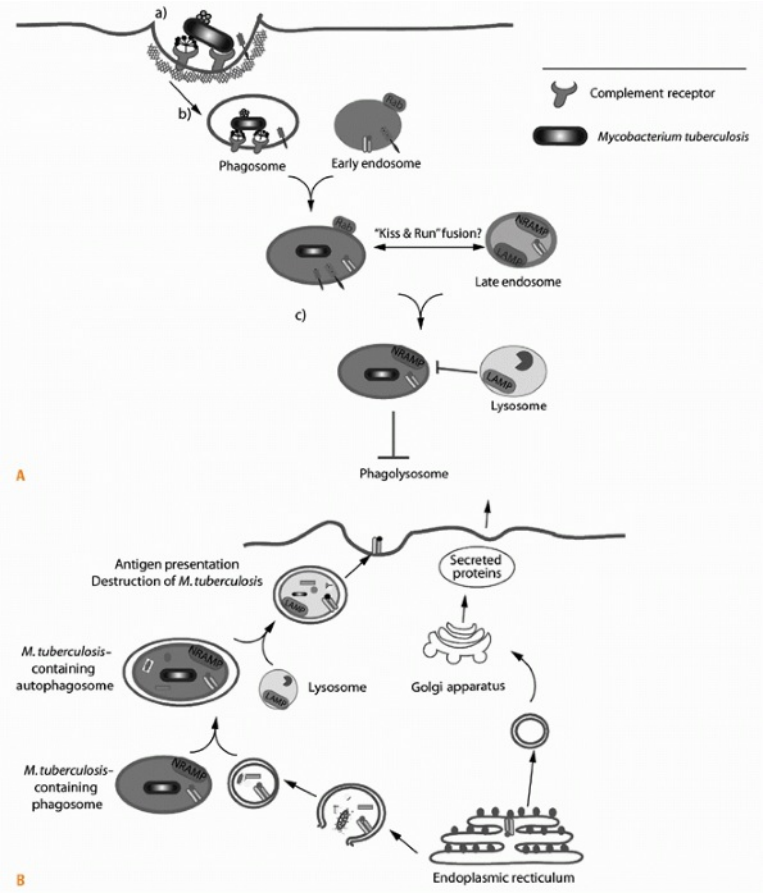

FIG. 19.9. Interactions of Selected Intracellular Pathogens with the Phagocytic Pathway. A: *Mycobacterium tuberculosis* evades destruction by subverting normal phagolysosome maturation. **a:** Phagocytosis of *M. tuberculosis* occurs via the complement pathway (although it may not require direct binding of complement to the bacterium) and is characterized by (**b**) "sinking" phagocytosis (ie, very little filopodia formation or actin polymerization). **c:** The *M. tuberculosis*-containing vacuoles contain markers of the early and late endosomes such as Rab5 and Nrampl but are devoid of most lysosomal markers, including the lysosome-associated membrane proteins, and do not undergo normal acidification. It has been proposed that the colocalization of some but not the normal allotment of endosomal markers can be explained by the concept of "kiss and run" fusion. This implies that the early and late endosomes may have transient contact with the *M. tuberculosis*-containing vacuoles, and there may be a selective transfer of markers rather than a complete fusion. The high pH of the *M. tuberculosis*-containing vacuole (pH 6.2) does not allow optimum loading of major histocompatibility complex (MHC) class II molecules, and thus they remain loaded with nonmycobacterial

peptides. Elevated pH also inhibits production of inducible nitric oxide synthase, which is required for killing. In the presence of interferon (IFN)-γ, normal acidification may be restored, resulting in destruction of the pathogen. **B:** *M. tuberculosis*-containing phagosomes are targeted to the autophagy pathway on treatment with IFNγ. IFNγ treatment can both restore the normal process of acidification and alter the expression of a number of endoplasmic reticulum proteins, the result of which is the targeting of *M. tuberculosis*-containing phagosomes to the autophagosomes. The fusion between the *M. tuberculosis*-containing phagosomes and lysosomes results in an autolysosome with low pH that destroys *M. tuberculosis* and results in *M. tuberculosis* peptides being presented via MHC class II. *(continued)*

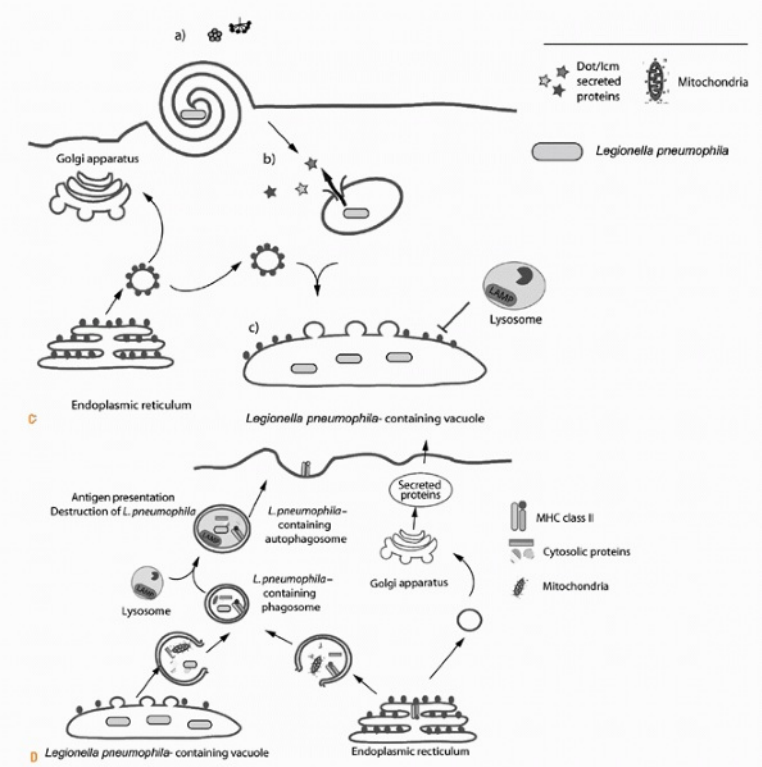

FIG. 19.9. *(continued)* **C:** *Legionella pneumophila* survives intracellularly by subverting phagosome maturation at an early stage. **a:** The recognition and uptake of *L. pneumophila* are not well characterized, but phagocysis occurs via a "spiral" mechanism. **b:** Once inside the cell, *L. pneumophila* uses a specialized secretion system (ie, Dot/Icm secretion system) to secrete proteins directly into the cytosol. These proteins alter the morphology of the vacuole in a number of ways, for example, by actively recruiting vesicles in transit from the endoplastic reticulum to the Golgi apparatus and inhibiting the fusion of lysosomes. **c:** The *L. pneumophila*-containing vacuole thus has many similarities to the Golgi apparatus and endoplastic reticulum, and is rich in peptides, the primary carbon source for *L. pneumophila.* **D:** Macrophages enhance autophagy in response to *L. pneumophila*. A consequence of residing in a vacuole that so closely resembles the endoplastic reticulum is that it is subject to autophagy. *L. pneumophila*-containing phagosomes fuse with lysosomes, resulting in destruction of the pathogen and antigen presentation. Factors secreted from *L. pneumophila* cause macrophages to increase the number of autophagosomes, although autophagosomes containing *L. pneumophila* mature more slowly, and thus it is believed that the bacteria encode factors to delay normal progression.

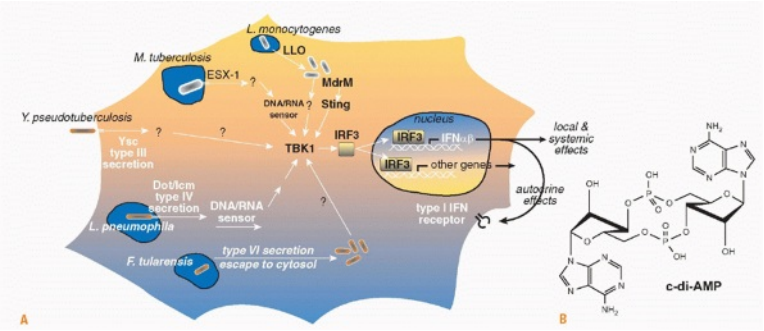

FIG. 19.10. Host Pathways Leading to the Expression of Interferon (IF) Beta and Coregulated Genes. A: Virulent, but not avirulent, intracellular pathogens activate a cytosolic surveillance pathway of innate immunity. Induction of IFN beta by all depicted bacterial species is MyD88 and TRIF-independent, indicating that toll-like receptors are not required. Sting and TBK1 are necessary for IRF3 activation.Wild-type *Listeria monocytogenes* enters the cytosol and activates the expression of IFN beta, while LLO-minus mutants that fail to enter the cytosol do not. Mutants in the multidrug efflux pump, MdrM, enter the cytosol, but induce threefold less IFN beta expression. The *L. monocytogenes* ligand is c-di-AMP **(B)**, while the receptor remains unknown. Mycobacterium tuberculosis resides in a phagosome that resembles early endosomes. Mutants in the ESX-1 auxiliary secretion system and phthiocerol dimycocerosate synthesis fail to induce IFN beta expression. Both TBK-1 and IRF3 are required. The infectious spore from *Histoplasma capsulatum* induces the expression of IFN beta, whereas the parasitic yeast form does not. *Legionella pneumophila* resides in a modified vacuolar compartment that has features of the endoplasmic reticulum. The Dot/Icm-type IV secretion system is necessary for intracellular growth and, independently, for induction of IFN beta expression. Both MDA5 and MAVS are required, suggesting that the ligand may be ribonucleic acid. *Francisella tularensis* needs to enter the cytosol to induce expression of IFN beta. The putative type VI secretion system is required for entry into the cytosol and induction of IFN beta. In each case, nucleic acids may be the ligands specifically recognized by cytosolic receptors, leading to the activation of IFN beta and co-regulated genes. Courtesy of D.A. Portnoy and R.E. Vance. For further information see Vance et al.[91] and Woodward et al.[92]

Clearance of proteinase-inhibitor complexes (eg, by CD91) and of haptoglobin-hemoglobin complexes by the Mø-receptor CD163, and protection by hemeoxygenase-1, are essential homeostatic functions of tissue Mø, limiting potentially injurious extracellular molecules.[107] Other molecules released by injured infected cells can serve as alarmins[108] and danger signals (eg, heat shock proteins[109] and S100 family members,[110] inducers of inflammatory and immune responses).

Major unsolved questions remain concerning phagocytosis, intracellular infection, and immune responses. How do sterile particulate antigens[111] and microbial agents induce T=cell responses, and what are the relative contributions to this process of Mø and DCs, abundant and sparser professional phagocytes, respectively? What is the role of Scavenger and RAGE[72,110] receptors mediating entry of diverse ligands in subsequent adaptive immunity? Does TLR engagement within vacuoles determine the kinetics of phagosome maturation as well as induce local intracellular responses? What determines the balance between total antigen degradation and loading of MHC molecules? What interactions take place between intracellular pathogens and host Mø, especially in regard to hypoxia[112] and nutritional requirements of the host and microbe? What is the role of pathogen-derived secretory products in the vacuolar milieu, in recruitment of organelles such as endoplasmic reticulum and mitochondria, and in effects on host cell biosynthesis? What are the

intracellular killing mechanisms, and how can organisms survive, or become latent, within Mø? To what extent do extracellular pathogens interact with macrophages and DCs[113]? Finally, what receptor-mediated signals induce the secretion of Mø molecules such as IL-12, IL-23, and IL-10 that direct and regulate the resultant specific immune response?

Gene Expression and Secretion

Knowledge of Mø gene expression and protein synthesis is growing rapidly from the application of gene array and proteomic technologies. After surface and endocytic stimulation, the mature Mø is able to secrete a very large range of high- and low-molecular weight products. These include enzymes involved in antimicrobial resistance (lysozyme), neutral proteinases and arachidonate metabolites that

contribute to inflammation and tissue repair, cytokines such as IL-1 and TNFα that modulate the activities of other leukocytes and endothelium, and reactive oxygen and nitrogen intermediates implicated in host defense. Proinflammatory cytokines account for part of the effects of immune adjuvants in promoting, broadening, and sustaining humoral responses. The ability to release these products depends on the prior history of the Mø, whether resident, recruited, or activated (primed), its encounters with microbial wall products, including LPS acting via TLRs, or with apoptotic cells, and exposure to cytokines and other immunomodulatory molecules in its immediate environment. Ligation of specific receptors induces various signaling pathways[114] and is able to alter gene expression in the Mø selectively. NF-κB,[115] Pu-1 and other transcription factors,[116,117,118,119] and IFN regulatory factor families[119,120] contribute to Mø-restricted or activation-dependent changes in gene expression, as does epigenetic regulation.[121] Product expression depends further on translational regulation, posttranslational modification such as proteolytic processing, intracellularly or at the cell surface, and coexpression of inhibitors such as IL-10. Messenger RNA turnover varies greatly for different products due to the presence or absence of specific 3′ instability sequences. Many Mø products are labile and act close to the cell surface; overproduction results in tissue catabolism and systemic effects associated with widespread infection or chronic inflammation, often as a result of an immunologically driven disease process.

TABLE 19.3. Modulation of Macrophage Phenotype

Category	Stimulus	Selected Marker Changes	Function
Innate activation	Microbial products (eg, LPS, other TLR ligands)	Costimulatory molecule expression, MARCO upregulation	Phagocytosis, adaptive immunity
Classic activation	Interferon γ	MHC II upregulation, proinflammatory cytokine secretion, inducible NO synthase	Cell-mediated immunity (eg, intracellular pathogens)
Alternative activation	IL-4/IL-13	Upregulation of MHC II, arginase, mannose receptor, Ym1, FIZZ1 (resistin-like), production of selected chemokines, macrophage fusion	Parasitic and allergic immunity, repair

Innate and acquired deactivation	Apoptotic cells, IL-10, glucocorticoids, TGF*β*, PGE2	Various surface and secretory markers, (eg, anti-TNF*α* actions)	Anti-inflammatory and altered immunity

IL, interleukin; LPS, lipopolysaccharide; MHC, major histocompatibility complex; NO, nitric oxide; PGE2, prostaglandin E2; TGF*β*, transforming growth factor-*β*; TLR, toll-like receptor; TNF*α*, tumor necrosis factor-*α*.

Whereas most bioactivities have been defined in vitro, there is evidence that expression of Mø secretory activities may be quite different in situ; lysozyme production is characteristic of all Mø in culture but is downregulated on most resident cells in vivo, and its expression by granuloma Mø, for example, depends on induction by immune or phagocytic stimuli. 5′ promoter sequences of human lysozyme and CD68 transgenes have been used to target tissue- and Mø activation-specific expression of reporter molecules in vivo. The promoters of these and other Mø-restricted molecules may, in due course, make it possible to direct Mø biosynthetic activities precisely, to boost or inhibit immune responses.

Modulation of Macrophage Activation in Vitro

Our understanding of Mø activation derives from studies of induction of MHC II and costimulatory antigens; of effector functions such as proteinase, TNF*α*, reactive oxygen intermediate and reactive nitrogen intermediate release; of expression of membrane receptors such as MRs; and of resistance to infectious agents, for example, *Mycobacteria*, *Listeria*, *Candida*, and HIV. Generalizations can be made, but it must be remembered that organisms vary considerably in their ability to evade or survive Mø restriction mechanisms, and they interact with Mø in individual ways. Various inhibitory cell surface molecules (eg, CD200, SIRPα,[122] and TAM receptors[123]) are known to regulate Mø activation through interactions with other activating plasma membrane receptors. Receptors including FcR*γ* use paired immunoreceptor tyrosine-based activation motif and immunoreceptor tyrosine-based inhibitory motif intracellular signaling motifs.

Figure 19.4 and Table 19.3 illustrate various pathways and markers of Mø activation that result from microbial, cellular, and cytokine interactions. Knowledge is based mainly on in vitro experiments and in vivo challenge of selected animal models. Innate activation depends on direct stimulation by microbial products, independent of cytokines, although often enhanced by concomitant stimulation (eg, by IFN*γ*). Newly discovered markers of innate activation of mouse peritoneal macrophages include upregulation of MARCO, SR-A, via a TLR pathway, and of CD200, a more widely expressed IgSF membrane glycoprotein able to inhibit TLR, NOD-like receptors, and inflammasome activation. Induction of MARCO, a phagocytic receptor for a range of bacteria, represents an adaptation of the innate immune response to microbial contact Analysis of the actions of individual cytokines (IFN*γ*, IL-10, IL-4/13) on defined Mø targets (murine peritoneal Mø and

human monocyte-derived Mø) reveals three characteristic and distinctive in vitro phenotypes across a spectrum of activation.[124,125] IFN*γ* and its production and amplification via IL-12, IL-23, or IL-18 play a central role in MHC II induction, enhanced antimicrobial resistance, and proinflammatory cytokine production, characteristic of Th1-type (M1-type) responses; conversely, IL-10 suppresses markers of activation while inducing selective expression of other Mø genes. A comparable link between Mø/APC and the induction of Th2-type responses has proved elusive to identify. IL-4/13 have closely overlapping functions and induce an alternative, M2-type activation phenotype in Mø consistent with increased APC function and humoral responses in allergy and parasitic infection as well as giant cell formation (see Table 19.3).[126] It is important to distinguish modulation of Mø immunologic properties by IL-4/13 from marked deactivation and inhibition of proinflammatory and cytotoxic

functions by IL-10 and glucocorticosteroid. Immune complexes are also able to induce an analogous, regulatory alternative activation pathway, which overlaps with, but differs from IL-4/13- and IL-10-induced phenotypes.[127] By extension, GM-CSF, glucocorticosteroids, TGF-β, and type I IFN all modulate Mø gene expression with individual signatures.

The interplay of cytokines derived from Mø themselves, from activated T- and B-lymphocytes, and from other cells (eg, natural killer cells, endothelial cells) results in reciprocal positive or negative interactions and time-dependent changes in activating and inhibitory signals. Some predictions from in vitro studies can be extended to the intact host. For example, IFNγ, IL-12, and IL-23 deficiency results in inability to restrict opportunistic organisms in murine models and in humans, and inducible nitric oxide synthase is important for resistance to a range of infectious agents.[128] IL-10 deficiency, on the other hand, results in overactive Th1-dependent inflammation, for example, in gut. IL-4 deficiency by itself has little effect on Mø phenotype in vivo because IL-13 mimics many of its actions. These cytokines share a common receptor subunit, and its targeted genetic ablation makes it possible to study Mø that lack the ability to respond to both IL-4 and IL-13.

The foregoing analysis is oversimplified. Combinations of cytokines in vitro have different effects on Mø than the sum of the parts. For example, the combination of IL-4 and GM-CSF induces differentiation of human monocytes into immature DCs, whereas each alone induces cells with distinctive Mø properties. Furthermore, a particular “Th2-type” cytokine such as IL-10 can display radically different effects on antimicrobial (inducible nitric oxide synthase dependent) killing, which is markedly suppressed, and anti-HIV activities of Mø, which are enhanced. Whereas IFNγ and IL-4 may have opposing actions on MR expression and phagocytosis of yeast, in combination they synergize to enhance uptake markedly. Other combinations of cytokines, such as IFN$\alpha\beta$ and IFNγ, can antagonize each other, presumably by competition for signaling pathways. Selected pathogens such as *Francisella tularensis* are able to modulate macrophage responses to infection from an M1- to an M2-type, thus facilitating their survival.[129] Finally, alternative activation of macrophages has recently been implicated in thermoregulation.[130] A great deal remains to be learned about Mø behavior in physiology as well as disease.

CONCLUSION AND SOME REMAINING ISSUES

Mø influence and respond to all other cells involved in immunity, during both the afferent and efferent limbs. Many of the molecules that mediate particular functions are now defined, but their role within the Mø and in intercellular interactions is often poorly understood. Mø developed during the evolution of multicellular organisms before immunologically specific, clonotypic responses of B- and T-lymphocytes emerged. A recent report of a rearranging, TCR-like receptor in macrophages needs confirmation.[131] Mø themselves diversified in parallel with T-helper lymphocytes, generating DCs as specialized APCs for naïve T-lymphocytes and yielding a range of effector cell phenotypes in response to diverse activated T cells, both CD4+ and CD8+. Mø and their derivatives cluster with differentiating hemopoietic cells in fetal liver and bone marrow, with developing thymocytes, with naïve CD4+ T lymphocytes and antigen during immune induction, and with activated T cells and microbial pathogens in granuloma formation (see Fig. 19.2). In addition, they associate with antigen-stimulated B-lymphocytes during cell expansion, diversification, and apoptosis. A major challenge will be to define the role of specific and accessory surface molecules by which Mø discriminate between live and dying cells and to uncover the intrinsic and extrinsic factors that control Mø activities within these diverse immune cell interactions.

Our understanding of the multiple roles of Mø and DCs in immunoregulation is also evolving as we better appreciate their specializations and adaptations. Central issues in the immunobiology of Mø remain interesting topics for further investigation. These include the following:

Mø display broad functions in homeostasis, beyond host defense and immunity, which may be special instances of a more general role in preserving host integrity, comparable to that of

the central nervous and endocrine systems. Their dispersion, plasticity, and responsiveness raise obvious questions for the biologist. In particular, what are their roles in development, in trophic interactions within different organs, in angiogenesis,[132] repair, and fibrosis[133]?

The Mø lie at the heart of the classic immunologic question of recognition of altered or non-self, especially of particulates. What are the actual exogenous and endogenous[134] ligands recognized by the diverse range of plasma membrane receptors capable of direct detection, and what determines whether uptake of a target is immunologically silent or productive? How can this information be harnessed for vaccine development?

The delineation of further subsets of CD4+ T lymphocytes (TH17, regulatory T cells) suggests that it will be useful to define the effects on the Mø phenotype of contact-and cytokine-dependent interactions with these cells. It is likely that further distinctive type 2 activation pathways of Mø will be discovered by microarray and protein analysis.

Once activated, Mø change their ability to recognize and destroy targets, directly or in concert with antibody, complement, and other less-defined opsonins. Can Mø directly kill virus-infected and other immunologically activated cells? If so, do they use MHC matching, even in a limited way, and do they contribute to tolerance and, by implication, autoimmunity by failure to perform such a suppressive function?

A special case in which Mø are present in large numbers at a site of “failure” to respond immunologically is the fetoplacental unit. CSF-1 is produced locally at high levels; does this deactivate Mø or make them switch to perform a trophic role? Do tumors that are rich in Mø adopt a similar strategy[135,136,137]? Catabolism of tryptophan by Mø enzymes has been put forward as another mechanism for preventing local destruction of an allogeneic fetus.[138] This is but one example of a growing interest in immunometabolism.[139]

Although Mø express a large number of genes involved in household functions and share expression of others with a limited range of cell types, they also express highly restricted molecules responsible for unique functions. Can these be harnessed for Mø-specific gene targeting at selected microanatomic sites to deliver functionally precise signals at predetermined times? Techniques are becoming available for at least part of this fantasy, and they should provide new insights into the multiple roles of the Mø in immunity.

ACKNOWLEDGMENTS

I thank my colleagues for discussions; Drs. Martinez-Pomares, Bowdish, Goodridge, Underhill, Portnoy, and Vance for providing illustrations; and Dr. Annette Pluddemann for help in preparing the manuscript. Research in the author's laboratory was supported by grants from the Medical Research Council, UK, the Wellcome Trust, the Arthritis Research Council, and the British Heart Foundation.

Chapter 20

Granulocytes and Mast Cells

Patrizia Scapini

Nicola Tamassia

Carlo Pucillo

Marco A. Cassatella

INTRODUCTION

Polymorphonuclear leukocytes or granulocytes are hematopoietically derived blood cells that typically act at the frontline of innate defense in host response to foreign microorganisms. Granulocytes contain heterogeneous cytoplasmic granules, which are storage pools for cell-specific intracellular enzymes, preformed receptors, cationic proteins, and other cell-specific molecules. According to their granular staining properties, polymorphonuclear leukocytes are classified into three different populations: neutrophils, eosinophils (Eos), and basophils (Bas). Neutrophil granules stain preferentially with neutral dyes, eosinophilic granules stain with acidic colorants such as eosin, and Ba granules stain with basic dyes.

Mast cells (MCs), similarly to polymorphonuclear leukocytes, represent another crucial effector cell type of the innate immune system that also stores elevated amounts of preformed inflammatory mediators within their cytoplasmic granules. However, while polymorphonuclear leukocytes are mainly peripheral blood-circulating cells, MCs are tissue resident cells distributed throughout the vascularized tissues or serosal cavity. Granulocytes and MCs differ in their functions and roles during the inflammatory process, MCs, Bas, and Eos being, for instance, essential components of allergic inflammation. Interestingly, recent data have revealed that granulocytes and MCs may also play key roles in orchestrating the transition from innate to adaptive immunity. These latter observations have caught the attention of immunologists who are currently reevaluating the importance of granulocytes and MCs, and very intensively working to clarify their multifaceted aspects in immunity.

NEUTROPHILS

Neutrophils are well known to function as the first line of defense against invading pathogens, principally bacteria and fungi, but also viruses.[1] These cells, together with monocytes, macrophages, and dendritic cells (DCs), feature the characteristic properties of the “professional” phagocytes and utilize several effector mechanisms to destroy pathogens, including the generation of massive amounts of reactive oxygen species (ROS) in combination with the discharge of many potent antimicrobial enzymes or factors.[1] Because of their powerful microbicidal equipment, neutrophils are often depicted as harmful cells that can

cause damage to the surrounding tissues during acute inflammation (as observed in those inflammatory diseases dominated by neutrophils).[1] Nonetheless, extensive research performed in the last 20 years has recognized neutrophils as highly versatile and sophisticated cells displaying a significant synthetic capacity as well as an important role in linking the innate and adaptive arms of the immune response.[2,3]

Neutrophil Generalities

Neutrophils are the most abundant (40% to 70%) circulating leukocyte type in human blood, normally present at 2.5 to 7.5 × 10^9 cells/L.[4] Morphologically, these cells can be identified by the peculiar shape of their nucleus, which is polymorphous and usually consists of three to five sausage-shaped masses of chromatin connected by fine threads (Fig. 20.1). Mature neutrophils are terminally differentiated, nondividing cells that develop and mature in the bone marrow from pluripotent CD (cluster of differentiation)34-positive (CD34+) stem cells, under the regulatory effects of several colony-stimulating factors (CSFs), including granulocyte-macrophage CSF (GM-CSF), granulocyte CSF (G-CSF), interleukin (IL)-3, and IL-6.[4] Neutrophils can be cytofluorimetrically identified by their characteristic morphology (high side scatter) and expression pattern of plasma membrane proteins such as CD66b, CD11b, CD15, and CD16, in conjunction with the lack of expression of CD2 and CD19. In humans, circulating polymorphonuclear leukocytes are 10 to 20 μm in diameter, display a half-life previously thought to correspond to 7 to 12 hours, but more recently reevaluated and extended to up to 90 hours,[5] and exist in a dynamic equilibrium with a "marginated" pool that is sequestered within the microvasculature of many organs.[1,4] In the resting uninfected host, the peripheral neutrophil population is maintained within a constant number by several mechanisms. One of them consists in programming neutrophils to spontaneously undergo apoptosis[1,3] to be, in turn, cleared by tissue macrophages located in the bone marrow, spleen, and liver.[6] In this latter context, a feedback loop involving an IL-23/IL-17/G-CSF axis, crucial for the regulation of neutrophil production, has been recently identified in mice.[7] According to this model, the uptake of apoptotic neutrophils by macrophages and DCs would determine a downregulation of their IL-23 production. Consequently, the Th17 subset of proinflammatory T-lymphocytes would be poorly sustained and thus much less IL-17A would be generated. As IL-17A positively regulates fibroblast- and endothelial cell-derived G-CSF, which is essential for controlling both granulopoiesis and neutrophil survival, the final outcome of this circuit—triggered by the massive neutrophil

apoptosis at peripheral sites—would consist in a decrease in the levels of neutrophils released from the bone marrow.[7] On the other hand, the number of circulating neutrophils can dramatically increase (even up to 10-fold) under acute inflammatory conditions (eg, during a bacterial infection), from accelerated neutrophil production and release from the bone marrow.[4] Moreover, even the lifespan of neutrophils is significantly extended under inflammatory conditions, as various host- and pathogen-derived mediators such as G-CSF, GM-CSF, interferon (IFN)-γ, tumor necrosis factor (TNF)-α, lipopolysaccharide, and nucleic acids inhibit neutrophil apoptosis and hence prolong their survival.[8]

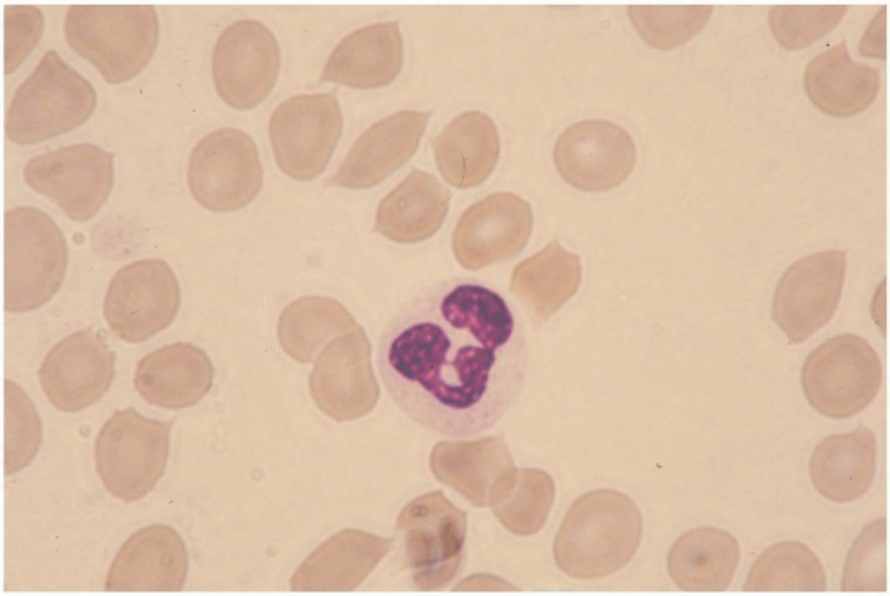

FIG. 20.1. A Polymorphonuclear Neutrophil Circulating in Peripheral Blood. From *Anderson's Atlas of Hematology* ; Anderson, Shauna C., PhD. Copyright 2003, Wolters Kluwer Health/Lippincott Williams & Wilkins.

During an acute inflammatory response, neutrophils are rapidly recruited to the site of injury by a coordinated sequence of events that begin with the elaboration of various mediators able to specifically promote their migration from the intravascular compartment. Mediators derive from numerous sources (tissue macrophages, endothelial cells, activated plasma components) and include vasoactive amines, proinflammatory lipids, small polypeptides, chemotactic factors, and cytokines such as TNFα, IL-1β, or IL-17A (the latter being one of the most abundant products of Th17 cells).[1,3] Chemotactic factors, in particular, are generated in temporally distinct waves and include C5a, leukotriene-B_4 (LTB_4), formyl-Met-Leu-Phe (fMLF), as well as neutrophil specific chemokines, such as CXCL8/IL-8, CXCL1/GROα, CXCL5/epithelial cell neutrophil-activating protein-78, etc.[1,3] Once recruited at an inflammatory site, neutrophils function as mobile arsenals that recognize, phagocytose, and ultimately destroy their targets. If the acute inflammatory response correctly subsides, then neutrophils may actively participate in its resolution (see following discussion). If not, an uncontrolled and continuous release of the proinflammatory cargo (ROS and proteases) by neutrophils recruited at the site of infection/injury may eventually lead to destruction of bystander tissue, and thus to exacerbation of the ongoing inflammation, ultimately provoking the onset of chronic inflammatory/autoimmune diseases.[9]

Neutrophil Microbicidal Mechanisms

To destroy and eliminate invading pathogens, neutrophils essentially utilize two fundamental mechanisms[10]: an oxygen-dependent process that is mediated by the generation of ROS, which include O_2^- (superoxide anion), hydrogen peroxide, singlet oxygen, and other products derived from the metabolism of hydrogen peroxide; and an oxygen-independent process consisting in the release into the phagocytic vacuole of lytic enzymes; and antimicrobial

polypeptides stored in their intracellular granules.[10] The oxygen-dependent process, also referred to as the “respiratory burst,” is defined as an increase of a mitochondrial independent oxidative metabolism that leads to the generation of O_2^-, which occurs through the activation of the phagocytic NADPH oxidase, an enzymatic system that is unique to phagocytes (neutrophils, monocytes, macrophages, DCs, and also Eos). Nicotinamide adenine dinucleotide phosphate (NADPH) oxidase is a multiprotein complex formed by a flavocytochrome-b_{558} (a heterodimer of gp91*phox* and p22*phox* chains, where *phox* stands for phagocyte oxidase), three cytoplasmic components (namely p40*phox*, p47*phox*, p67*phox*) and either Rac1 or Rac2 from the Rho family of low-molecular-weight GTPases (Fig. 20.2). Upon cell stimulation, the cytosolic components of the complex become phosphorylated and assemble together with the cytochrome and Rac1/2 on the plasma membrane, thus forming the active enzyme that produces superoxide anion radicals, by catalyzing the transfer of electrons from NADPH to molecular oxygen (see Fig. 20.2). O_2^- is converted by superoxide dismutase into hydrogen peroxide, which, in the presence of myeloperoxidase and halogens, is then metabolized into hypochlorous acid. The latter represents one of the neutrophil's

major weapons against microbes, as it also synergizes with granule proteins to kill pathogens in the neutrophil phagolysosome. O_2^- can also reacts with other cellular radicals, such as nitric oxide, to form different species of cytotoxic oxidant, such as peroxynitrite. The critical role of NADPH oxidase and its products in host defense is best illustrated by the plight of patients with chronic granulomatous disease, in which mutations in any of the NADPH oxidase complex subunits (gp91*phox*, p22*phox*, p40*phox*, p47*phox*, and p67*phox*) leads to a severe immunodeficiency characterized by defective killing of phagocytosed pathogens for the lack of ROS generation.[10] These infections typically involve microorganisms for which oxidant-mediated killing is particularly critical for effective host defense, such as *Staphylococcus aureus*, *Aspergillus* spp., *Nocardia*, and a variety of gramnegative enteric bacilli.

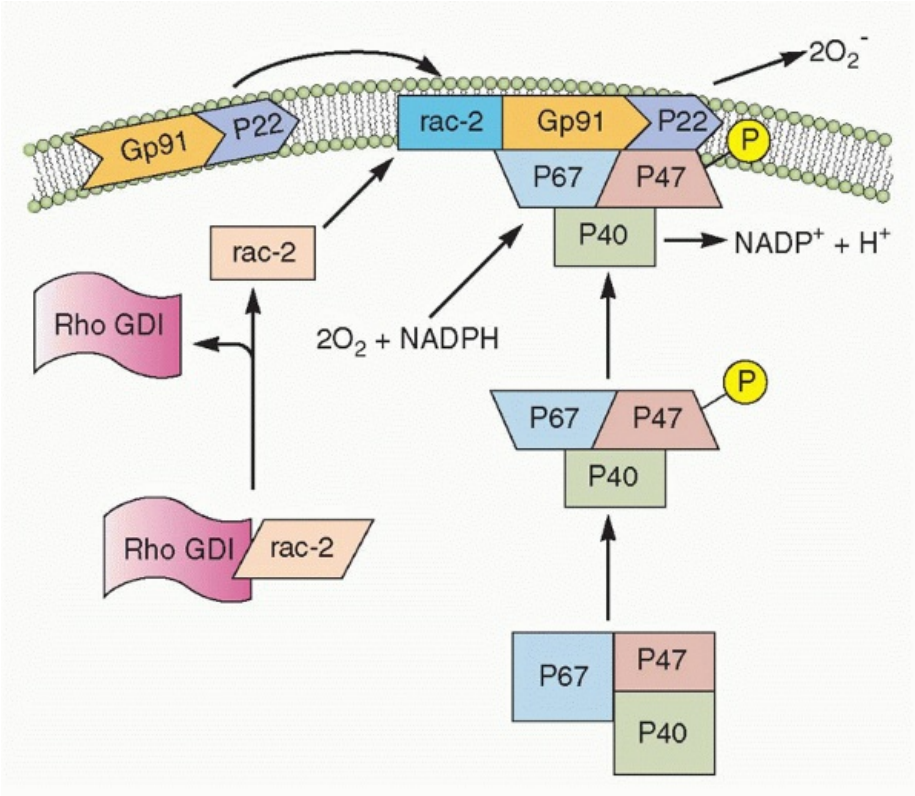

FIG. 20.2. Nicotinamide Adenine Dinucleotide Phosphate (NADPH) Oxidase Assembly. In the resting neutrophil, the cytochrome b subunits gp91-phox and p22-phox are tightly bound in the membrane. p47-phox, p67-phox, and rac-s complex are in the cytosol. Upon activation, Rho GDP-dissociation inhibitor (GDI) releases rac-2, and p47-phox becomes phosphorylated. This causes translocation of rac-2, p47-phox, and p67-phox to the membrane and complex formation with the cytochrome components, thereby completing the assembly of the active oxidase. (After Burg ND, Pillinger MH. *Clin Immunol*. 2001;1:7-17.)

The release of potent proteolytic enzymes contained in their granules represents the other crucial mechanisms utilized by neutrophils to eliminate pathogens following phagocytosis.[10] Neutrophil granules are subdivided into peroxidase-positive granules (based on the presence of myeloperoxidase, their marker), also called primary or azurophil granules (owing to their affinity for the basic dye azure A), and peroxidase-negative granules that include the specific (secondary) granules, the gelatinase (tertiary) granules, and the secretory vesicles[11] (Fig. 20.3). The different types of granules appear at progressive stage of neutrophil development,[11] with the primary granules, as suggested by the name, being the first ones to appear during hematopoiesis at the promyelocyte stage. As highlighted in Figure 20.3, granules are released in a hierarchical order and under separate control by mature neutrophils, depending on the type of stimulus.[11]

Azurophil or primary granules undergo limited exocytosis in response to stimulation and are packaged with acidic hydrolases and antimicrobial proteins that contribute primarily to the killing and degradation of engulfed microorganisms into the phagolysosome.[11,12] These granules contain myeloperoxidase, an enzyme that catalyzes the formation of hypochlorous

acid, hydrolases, lysozyme, matrix metalloproteinases, and three structurally related serprocidins (serine proteases with microbicidal activity): proteinase-3, cathepsin G, and elastase. The latter proteins can degrade a variety of extracellular matrix components, including elastin, fibronectin, laminin, type IV collagen, and vitronectin. Azurophil granules also contain antimicrobial molecules such as bactericidal/permeability-increasing protein (which is important for killing gram-negative bacteria) and α-defensins, a family of small cysteine-rich antibiotic peptides with broad antimicrobial activity against bacteria, fungi, and certain enveloped viruses.[11,12]

Specific (or secondary) granules, which are formed at the myelocytic stage, are smaller and less dense than the azurophil ones, and contain unique constituents, such as collagenase, haptoglobin, vitamin B_{12}-binding protein, as well an extensive array of membrane-associated proteins including cytochromes, signaling molecules, and receptors.[11,12] Secondary granules also contain an arsenal of antimicrobial substances, such as lactoferrin, neutrophil gelatinase-associated lipocalin, lysozyme, hCAP18 (cathelicidin human cationic antimicrobial protein of 18 kDa, the proform of LL-37), and pentraxin-3. The inhibitory effect of antimicrobial proteins include depriving ions essential for microbial survival, degrading structural components of microorganisms (eg, peptidoglycan), and disrupting the integrity of target cell membrane by punching pores in the membrane or by perturbing membrane integrity. Neutrophil-specific granules also contain an important family of soluble proteinases, known as matrix metalloproteinases (MMPs), which include neutrophil collagenase-2 (MMP-8), gelatinase-B (MMP-9), and leukolysin (MMP-25). These proteinases are generally stored as inactive proenzymes and undergo proteolytic activation following granule fusion and interaction with azurophilic granule contents. Neutrophil MMPs disrupt major structural components of bacteria and/or extracellular membranes, and are therefore crucial not only for bacterial killing, but also for neutrophil extravasation and migration.[11,12]

Tertiary granules are produced at the metamyelocyte stage of differentiation and are smaller, lighter, and more easily exocytosed than the other granule classes.[11,12] These granules are indeed important primarily as a reservoir of matrixdegrading enzymes and membrane receptors needed during polymorphonuclear leukocyte extravasation and diapedesis. The primary constituent of tertiary granules is gelatinase, a latent metalloenzyme with the capacity for tissue destruction. Finally, the secretory vesicles are smaller than the other granules, are generated by endocytosis during the late stage

of nuclear neutrophil segmentation in the bone marrow, and are the most readily mobilizable.[11,12] These vesicles are preferentially directed to the plasma membrane, as reflected in the density of vesicle-associated membrane protein (VAMP), a fusogenic protein associated with the granule membrane. Secretory vesicles do not contain toxic substances, but mainly plasma proteins like albumin and receptors (including β_2-integrins, the complement receptor [CR]1, receptors for formylated bacterial peptides [fMLF-R], CD14, the Fc portion of γ-immunoglobulins (Igs) [FcγRIII/CD16], and the metalloprotease leukolysin). Heparin-binding protein (also known as CAP37 or azurocidin), whose release is essential for the polymorphonuclear leukocyte-induced increase in vascular permeability at the initial stage of extravasation, is also stored in the secretory vesicles.

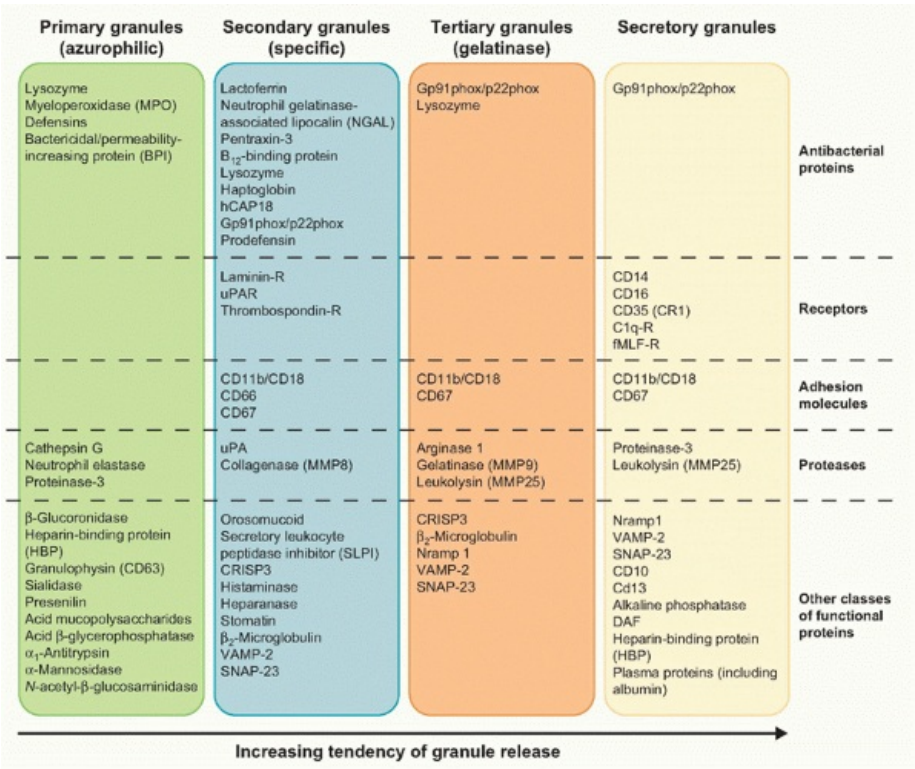

FIG. 20.3. Main Constituents of Neutrophil Granules.

An additional nonphagocytic microbicidial mechanism used by neutrophils to capture and destroy microbes in the extracellular space consists in the ability of neutrophils to form so-called neutrophil extracellular traps (NETs).[13] The latter structures consist of nuclear chromatin decorated with antimicrobial peptides and enzymes (eg, bactericidal/permeability-increasing protein, elastase, pentraxin3, cathepsin G, and many others) that lacks membranes and cytosolic markers.[13] NETtosis, a novel type of neutrophil death mechanism that occurs under settings of extreme neutrophil stimulation (different from necrosis, apoptosis, and also independent from caspase activation), underlies the generation of NETs.[14] Accordingly, the nuclear envelope, granules, and cell membranes gradually dissolve during NETtosis, allowing the nuclear contents to mix and condense in the cytoplasm before being released into the extracellular space.[14] NETs, in turn, bind to various grampositive and gram-negative bacteria (such as *Staphylococcus aureus*, *Salmonella typhimurium*, *Streptococcus pneumoniae*,

and group A streptococci), as well as to pathogenic fungi (such as *Candida albicans*). Similarly to what happens in the phagolysosome, the high local concentration of antimicrobial peptides and enzymes is responsible for the killing of the pathogens trapped by NETs.[13] The observation that neutrophils from patients with chronic granulomatous disease do not form NETs has suggested, on the one hand, that ROS-mediated signaling/cascades are involved in NET generation, and, on the other hand, that the lack of NETs might contribute to the pathogenesis of chronic granulomatous disease.[3,14] Whatever the case, it is noteworthy to remark that both the oxygen-dependent and -independent effector mechanisms in host

defense toward pathogens are also utilized by neutrophils for their cytotoxic and tumoricidal activities.

Neutrophil Receptors

Under inflammatory conditions, neutrophils sense a wide range of extracellular ligands that, through the interaction with specific receptors, subsequently trigger a number of effector functions, including adhesion, migration, phagocytosis, survival, cell activation, gene expression modulation, target cell killing, and mediator production and release.[1,3,15] For instance, agonist-stimulated neutrophils may trigger not only degranulation, but also the release of arachidonic acid and/or other eicosanoids (eg, prostaglandin [PG]E_2), via the activation and/or the upregulation of PLA_2 and COX-2, respectively. Upon appropriate stimulation, neutrophils can also generate LTA_4 through the action of 5-lipoxygenase, as well as LTB_4 by converting LTA_4 via the action of LTA_4 hydrolase.[15] A nonexhaustive list of neutrophil receptors includes 1) receptors for proinflammatory mediators (eg, the anaphylotoxin complement component C5a, LTB_4, platelet-activating factor [PAF], substance P, and fMLF); 2) receptors for cytokines, such as IFNγ, IL-1, IL-4, IL-6, IL-10, IL-13, IL-15, IL-18, TNFα, G-CSF, GM-CSF, and many others; 3) receptors for chemokines, including CXCR1 and CXCR2; 4) receptors/adhesion molecules for the endothelium; 5) receptors for tissue matrix proteins; and 6) opsonin receptors, such as FcγRs and those for the major cleavage fragments of the complement system (see following discussion). Neutrophils also express a variety of pattern recognition receptors (PRRs), including all toll-like receptors (TLRs), with the exception of TLR3, cytoplasmic ribonucleic acid helicases involved in viral ribonucleic acid recognition such as MDA5 and RIGI, and deoxyribonucleic acid binding cytoplasmic proteins (IFI16 and LRRFIP1).[3]

The Role of Neutrophils in Acute Inflammation

In order to carry out their prototypical defensive role in acute inflammation, bloodstream neutrophils must extravasate. To do so, they attach to activated endothelium, transmigrate through postcapillary venules (diapedesis), and then migrate toward a corresponding chemotactic gradient to the injury site where they recognize their target, engulf, and finally destroy it.

Neutrophil Extravasation

In general, leukocyte recruitment during inflammation, also called extravasation, is a multistep and highly complex phenomenon characterized by a number of predetermined steps occurring in the vessel lumen, known as leukocyte capture (or tethering), rolling, activation, and firm adhesion (arrest)[16] (Fig. 20.4). These latter steps are not discrete phases of inflammation; rather, they simply represent a sequence of events from the perspective of each leukocyte. Moreover, each of these steps appears to be necessary for the effective leukocyte recruitment; blocking any of them can severely reduce leukocyte accumulation in the tissue.[17] Adhesion of blood leukocytes to the endothelium during inflammation requires specific leukocyte-endothelial interactions involving different families of adhesion molecules. The latter include members of the selectin family and their cognate carbohydrate and glycoprotein ligands, which mediate the initial leukocyte deceleration along the vessel wall (a

process called “rolling”), as well as members of the integrin family and their cognate Ig superfamily ligands, which mediate the subsequent high-affinity adhesion and arrest of leukocytes to the venules[16,17] (Table 20.1).

Under noninflammatory conditions, neutrophils (as well as other leukocytes) travel primarily through the center of the blood vessel lumen, where the flow is fastest. In response to proinflammatory signals, however, both the neutrophils and the blood vessels undergo a series of changes. As a consequence of vascular dilatation, blood flow first increases and then slows, thus facilitating the interactions between leukocytes and the endothelial cells. The process of capture/tethering and rolling then ensues, in which L-selectins on neutrophils, and P- or E-selectins on endothelia, interact with sialyl-Lewisx moieties or PSGL-1 on their respective cell partners. Although these interactions are reversible and transient, they prepare neutrophils for a tighter binding, integrin-mediated step.[16,17] The most important neutrophil integrins are four, each one composed of an identical β-subunit β_2, known as CD18) noncovalently linked to different α-subunits: CD11a/CD18 ($\alpha_L\beta_2$, lymphocyte function antigen), CD11b/CD18 ($\alpha_M\beta_2$, CR3), CD11c/CD18 ($\alpha_X\beta_2$, CR4), and CD11d/CD18.[18] When neutrophils encounter their specific chemoattractants (eg, CXCL8), displayed bound to glycosaminoglycans on the vessel wall, neutrophil integrins are converted from an inactive to an active conformation[16,17] (see Fig. 20.4). Activated integrins can interact with their counterreceptors on the surface of the TNFα and/or IL-1β-activated endothelium (eg, intercellular adhesion molecule-1 [ICAM-1] and intercellular adhesion molecule-2), leading to the strong adhesion and arrest of the cells. Neutrophils then flatten and transmigrate between and through the endothelial cells of postcapillary venules into the surrounding tissue (see Fig. 20.4), also secreting a broad range of MMPs that degrade the basement membrane. Transmigration involves homophilic interaction of CD31/PECAM-1 and JAM-A on neutrophils and endothelial cells, where CD31/PECAM-1 and JAM-A act sequentially to mediate neutrophil migration through the venular walls.[17,18] Once in the interstitial compartment, neutrophils migrate along the chemotactic gradient toward the site of

injury or infection and, once arrived, begin to react with the etiopathogenic agent.

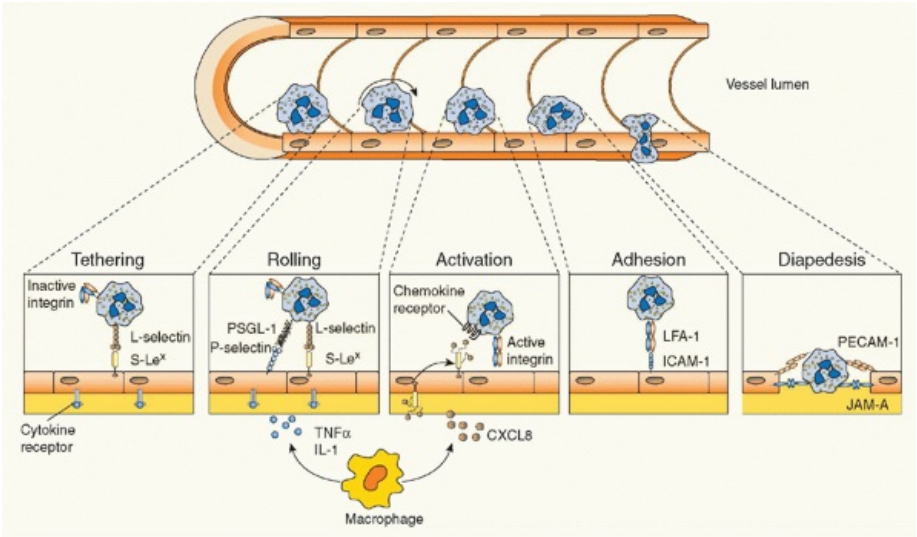

FIG. 20.4. Leukocyte Transmigration. Following an inflammatory stimulus, tissue-resident macrophages and other cells release inflammatory mediators such as tumor necrosis factor α and interleukin-1, which induce the rapid expression of preformed P-selectin (and transcription-dependent E-selectin expression) on the endothelium. The interaction between selectins and their glycoprotein ligands initiates leukocyte tethering and rolling. Activation by chemokines—and other leukocyte activators (eg, leukotriene-B_4 or platelet-activating factor)—presented on endothelial cells causes leukocyte integrin activation, thus resulting in transition from cell rolling to cell firm adhesion, in view of the strength of integrin-mediated binding with endothelial immunoglobulin superfamily members. Leukocytes can then transmigrate through the endothelial monolayer and chemotactically move toward the inflammatory stimulus. Examples of adhesion molecules involved in each step are depicted.

The fundamental importance of adhesive glycoproteins in vivo is testified by those individuals affected leukocyte adhesion deficiency (LAD) disease, who display an abnormally high susceptibility to bacterial infections.[19] Several types of LAD disease have been identified. In LAD-I, mutations of the β2 integrin typically eliminate the expression of all four integrin complexes. Because of the multiple defects in adhesion-related functions, patients with LAD-I develop recurrent bacterial and fungal infections, mostly with *Staphylococcus aureus* or gram-negative enteric microbes. Neutrophilia with paucity of neutrophils at inflamed or infected sites is characteristic of LAD-I, while typical clinical features include frequent skin and periodontal infections, delayed separation of the umbilical cord and omphalitis, and deep tissue abscesses. LAD-II is caused by mutations in the membrane transporter for fucose and thus is associated with loss of expression of fucosylated glycans on the cell surface. Fucosylated proteins such as sialyl-Lewis X (CD15s) are ligands for endothelial selectins and are important for the rolling phases of leukocyte extravasation. Patients with LAD-II also have leukocytosis and form pus poorly, although infections tend to be less severe in patients with LAD-II than in patients with LAD-I. Finally, LAD-III has been recently described. LAD-III is an autosomal recessive disorder caused by mutations in the human kindlin-3 gene, which codes for a protein essential for integrin activation. Consequently, LAD-III is characterized by impaired adhesion of leukocytes to the endothelium of inflamed tissues and by severe bleeding. Curiously, a number of LAD-III patients additionally suffer from osteopetrosis.

Neutrophil-Mediated Phagocytosis

Neutrophils play a critical role in host protection as they eliminate microorganisms through phagocytosis (the cellular process of engulfing particles larger than 0.5 μm). While many cells in our body are capable of phagocytosis, neutrophils do it to an extent sufficient to be considered “professional phagocytes” (eg, a single neutrophil can engulf up to 10 to 12 particles [eg, bacteria]).[20] Phagocytosis is triggered either through receptor (eg, mannose receptor or Dectin-1) recognition of certain polysaccharides present on the surface of some yeast cells and/or upon the binding of opsonized microorganisms through, for instance, FcγRs and CRs.[20] Neutrophils constitutively express the low-affinity

FcγRs (FcγRIIA/CD32A and FcγRIIIA/CD16A), and, when exposed to IFNγ or G-CSF, the high-affinity FcγR (FcγRI/CD64) as well.[3] CRs expressed by neutrophils are CR1 (also known as

CD35), which binds to complement components C1q, C4b, C3b, and mannan-binding lectin; CR3, which binds to iC3b, intercellular adhesion molecule-1, and some microbes; and CR4, which binds to iC3b. By expressing these latter receptors, neutrophils are able to recognize and bind, in a cooperative manner, IgG-opsonized particles and/or complement-opsonized microbes, and then activate their phagocytosis. During the phagocytic process, the foreign particle is internalized, initially through membrane recruitment to the site of particle contact, and then via membrane extensions outward to surround the particle and form a new vesicle called a cytoplasmic phagosome.[20] (Fig. 20.5). The phagosome then undergoes fusion with neutrophil granules to form a phagolysosome, a protected space in which proteolytic enzymes and other bactericidal components are discharged and pathogen degradation occurs. At the same time, NADPH oxidase assembles on the phagosomal membrane after phagocytosis and starts to generate ROS into the phagolysosome to kill bacteria by oxidizing microbial proteins and lipids. The activity of NADPH oxidase also leads to the acidification of the phagosome, which enhances the effectiveness of pH-sensitive antimicrobial compounds. Thus, neutrophil mechanisms of pathogen destruction within the phagosome are multiple and involve granule fusion, toxic oxygen radical production, activation of latent proteolytic enzymes, and the activity of antibacterial proteins (see Fig. 20.5). Remarkably, an activation of gene transcription and a selected generation of cytokines also occur during phagocytosis, a feature that neutrophils utilize for boosting a more effective innate immune response. For instance, recruited neutrophils that phagocytose

a pathogen also respond by producing chemokines, in particular CXCL8, to amplify their own recruitment, but also CCL3, CCL4, and CCL19 that serve to recruit monocytes and DCs.[21]

TABLE 20.1 Main Adhesion Molecules Involved in Leukocyte-Endothelial Cell Interaction

Adhesion Molecule	Distribution	Ligands and Counterreceptors	Function
E-selectin (CD62E)	Endothelial cells	PSGL-1, ESL-1, CD44[a], CD43[a]	Rolling
P-selectin (CD62P)	Endothelial cells, platelets	PSGL-1, PNAd	Rolling
L-selectin (CD62L)	All leukocytes except effector and memory effector T cells	PNAd, MAdCAM-1, PSGL-1, E-selectin, P-selectin	Rolling
Selectin ligands			

PSGL-1	All leukocytes	All selectins (essential for P-selectin)	Rolling
sLe^x	Myeloid cells, some memory T cells, HEVs	All selectins	Rolling
PNAd	HEV, some sites of chronic inflammation	L-selectin, P-selectin	Rolling
Integrins			
$\alpha_M\beta_2$(MAC-1; CD11b/CD18)	Granulocytes, monocytes, some activated T cells	ICAM-1, fibrinogen, C3b, JAM-C	Adhesion, transmigration
$\alpha_L\beta_2$(LFA-1; CD11a/CD18)	All leukocytes	ICAM-1, ICAM-2, JAM-A	Adhesion, transmigration
$\alpha_D\beta_2$(CD11d/CD18)	Monocytes, macrophages, eosinophils	ICAM-1, VCAM-1	Adhesion
$\alpha_x\beta_2$(p150,95; CD11c/CD18)	DCs	Fibrinogen, C3b	Adhesion
$\alpha_4\beta_1$(VLA-4)	Most leukocytes	VCAM-1, fibrinogen, JAM-B	Rolling, adhesion
$\alpha_4\beta_7$(LPAM-1)	Lymphocytes, NKCs, mast cells, monocytes	MAdCAM-1, fibronectin, VCAM-1	Rolling, adhesion
Immunoglobulin superfamily			
ICAM-1 (CD54)	Most types of cells	LFA-1 Mac-1, fibrinogen	Adhesion, transmigration
ICAM-1 (CD102)	Endothelial cells, platelets	LFA-1 Mac-1	Adhesion, transmigration
VCAM-1 (CD106)	Endothelial cells	VLA-4, $\alpha_4\beta_7\alpha_D\beta_2$	Rolling,

			adhesion
MAdCAM-1	HEVs in PP and MLN	$\alpha_4\beta_7$, L-selectin	Rolling
PECAM-1	Endothelial cells, platelets, leukocytes	PECAM-1	Transmigration
JAM-A	Endothelial cells, platelets, most leukocytes	JAM-A	Transmigration
JAM-B	Endothelial cells, HEVs	JAM-B, JAM-C	Transmigration
JAM-C	Endothelial cells, HEVs, platelets, monocytes, DC, some T cells	JAM-C, JAM-B	Transmigration

CD, cluster of differentiation; DC, dentritic cell; ESL, HEV, high endothelial venule; ICAM, intercellular adhesion molecule; JAM, LFA, MAdCAM, mucosal addressin cell adhesion molecule; NKC, PECAM, PNAd, PSGL, sLe^X, VCAM, VLA.

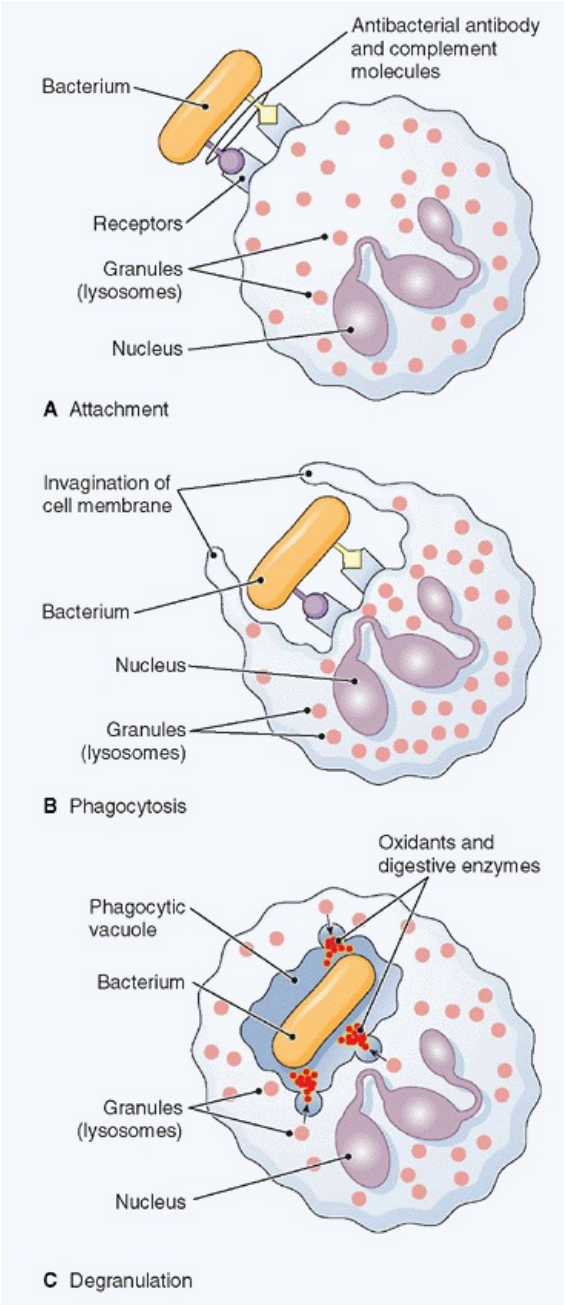

FIG. 20.5. Phagocytosis. The figure shows ingestion, digestion, and destruction of foreign particulate matter (a bacterium, in this example) by a neutrophil. **A:** Cell membrane receptors bind to antibody and complement molecules previously attached to the bacterial surface. **B:** The cell membrane creeps around the bacterium and envelopes it. **C:** The bacterium is trapped in a special space, the phagocytic vacuole, into which lysosomes discharge proteases, which together with oxidants kill it. Then, digestive enzymes dissolve it. (Thomas H. McConnell, *The Nature Of Disease Pathology for the Health Professions*, Philadelphia: Lippincott Williams & Wilkins, 2007.)

Role in the Resolution Phase of Inflammation

Locally activated neutrophils not only amplify the inflammatory process, but, surprisingly, actively participate in its resolution phase.[22] To do so, during the late, final phases of a

resolving, acute inflammatory reaction neutrophils, for instance, switch their eicosanoid biosynthesis potential from LTB_4 to lipoxins, with profound modifications of their effector functions. In fact, lipoxin A_4 (LXA_4) and LXB_4 stop neutrophil chemotaxis, adhesion, and transmigration through endothelium (by decreasing P-selectin expression), inhibit Eo recruitment, stimulate vasodilation (by inducing synthesis of PGI_2 and PGE_2), inhibit LTC_4- and LTD_4- stimulated vasoconstriction, inhibit LTB_4 inflammatory effects, and inhibit the function of natural killer (NK) cells.[22] Neutrophils also contribute to the biosynthesis of resolvins (such as resolvin E1, resolvin E2, resolvin D1, and resolvin D2) and protectin D1, which all inhibit neutrophil transendothelial migration and tissue infiltration, as well as stimulate resolution and reduce the magnitude of the inflammatory response in vivo.[22] Furthermore, neutrophils might also serve as major producers of anti-inflammatory cytokines such as transforming growth factor (TGF)β and IL-1 receptor antagonist, the latter being an endogenous inhibitor of IL-1β signaling and mediated effects.[21] Finally, neutrophils must be cleared from the inflammatory site as inflammation resolves. Indeed, neutrophils undergo apoptosis and are engulfed by tissue macrophages, which then reprogram into the M2 phenotype and start to generate antiinflammatory cytokines such as TGFβ and IL-10.[6,23]

Novel Neutrophil Effector Functions

The functions described previously for neutrophils in host defense are fundamental for combating infectious diseases. However, more recent discoveries on neutrophils as source of a variety of cytokines[21] have revealed that these cells are not only key components of the inflammatory response, but also crucial effectors of innate and adaptive immune regulatory networks.[23]

Neutrophil-Derived Cytokines and Chemokines

Numerous in vitro and in vivo studies, focusing on novel aspects of the neutrophil biology and function, have recently shed new light on the potential role that neutrophils can exert in the modulation of innate and adaptive immune responses.[23] It is now unequivocal that neutrophils are not, as for a long time thought, terminally differentiated cells “devoid of transcriptional and protein synthesis activity.”[23a] In fact, besides the several preformed or rapidly generated inflammatory mediators described previously, neutrophils display the capacity to de novo synthesize and release also several chemokines and cytokines with immunoregulatory properties.[21,23] It is, however, important to mention that, at least in vitro, neutrophils usually produce, on a per-cell

basis, fewer molecules of a given cytokine than mononuclear leukocytes.[21] However, considering that neutrophils clearly predominate over other cell types under inflammatory conditions in vivo, it becomes obvious that the contribution of neutrophil-derived cytokines can be of foremost importance. To date, a wide range of stimuli able to induce characteristic signatures of chemokine and cytokine synthesis by neutrophils have been identified. Among these, cytokines themselves, chemotactic factors (fMLF, LTB_4, PAF, C5a, and CXCL8), phagocytic particles, microorganisms (such as fungi, viruses, and bacteria), and PRR ligands can all induce the synthesis and release of chemokines and cytokines by neutrophils.[21]

Considering that neutrophils usually represent the first cell type infiltrating at the site of infections, a stimulus-specific response of neutrophils in terms of cytokine production might direct the evolution of certain types of inflammatory and immune reactions to support the transition from innate to adaptive immunity.

Table 20.2 lists all the cytokines that, to date, have been shown to be released by neutrophils in vitro, either constitutively or following appropriate stimulation, or in vivo. Numerous in vivo observations, in fact, not only have confirmed and reproduced the in vitro findings, but often have clarified their biological meaning and implications. As outlined in Table 20.2, neutrophils can produce proinflammatory, anti-inflammatory, immunoregulatory, angiogenic, and fibrogenic cytokines, chemokines, and ligands belonging to the TNF superfamily. The role of these molecules in mediating various neutrophil-dependent immunoregulatory functions is partially described in the following chapter. For instance, chemokines are particularly represented among the cytokines produced by neutrophils and include those primarily chemotactic for neutrophils themselves, monocytes, DCs, NK cells, and T helper (Th)1 and Th17 cells. It follows that a role for neutrophils in orchestrating the sequential recruitment to, and activation of, distinct leukocyte types in the inflamed tissue is plausible, as already demonstrated to occur in several experimental models.[21,23]

Neutrophils in Immunoregulation

There is now wide experimental evidence that neutrophils have the capacity to modulate the migration, maturation, and function of several leukocyte types including DCs, T cells, and B cells.[23] Regarding DCs, it is noteworthy to mention that neutrophils have been shown to produce biologically active CCL20 and CCL19, two structurally related CC-chemokines that have been suggested to play a fundamental role in trafficking of, respectively, immature and mature DCs to mucosal surfaces and lymphoid organs. Likewise, neutrophils release several antimicrobial compounds, such as lactoferrin, LL-37, and cathepsin G, that have been found to act as chemoattractants for immature DCs. In addition, neutrophils can proteolytically activate prochemerin to generate chemerin, one of the few chemokines that attracts both immature DCs and plasmacytoid DCs.[3] Neutrophils can also modulate DC maturation and function either through the release of several mediators or through direct physical interaction between Mac-1 (CD11b/CD18) and DC-specific intercellular adhesion molecule.[24] Neutrophils also act as transport vehicle for pathogens and, in turn, deliver antigens to DCs, thus playing an important role in the activation of T-cell immune responses controlled by DCs.[24]

Cytokines in **bold** refer to neutrophil studies in animal models that confirm human

findings.

[a] Messenger ribonucleic acid only.

Concerning the interactions between neutrophils and B cells, of particular interest are the findings that neutrophils produce significant amounts of BLyS/BAFF (B-lymphocyte stimulator/B-cell activating factor) and APRIL (a proliferation-inducing ligand), two related members of the TNF

family that are well known to be essential for B-lymphocyte homeostasis.[25] Therefore, it is plausible to assume a role of neutrophils not only in sustaining B and plasma cell antibody production and survival, but also in promoting B-cell-dependent autoimmune diseases and tumors, as already elegantly demonstrated in the case of B-cell lymphoma.[25]

Cross-talk between neutrophils and T cells has been repeatedly described to occur during infections or other inflammatory responses and diseases. Current evidence now indicates that neutrophils exhibit a significant chemotactic effect toward Th1 or Th17 cell subsets, through the release of CCL2, CXCL9, and CXCL10, or CCL2 and CCL20, respectively.[26] Neutrophils have also a role in directing T-cell polarization, for instance through their capacity to produce the Th1-inducing cytokine, IL-12. The latter has been clearly demonstrated in mouse models, in which strong Th1-dependent T-cell responses that result in pathogen clearance are elicited upon infection with *Candida albicans*, *Helicobacter pylori* , or *Legionella pneumophila*. Strikingly, depletion of neutrophils reverses the Th1 responses into a predominant Th2-response, therefore making the mice susceptible to infection. Besides the neutrophil's ability to modulate T-cell functions through the production of chemokines and cytokines, recent reports suggest that neutrophils travel to the lymph nodes during infections and express both major histocompatibility complex (MHC) II and costimulatory molecules.[27] However, whether neutrophils directly acquire antigen-presenting functions or transmit signals to naïve T cells remains still puzzling.

Neutrophils have also been shown to modulate the maturation, activation, and functions of NK cells, either by themselves or in cooperation with other cell types.[28] In this context, it is worth mentioning that neutrophils, by interacting with specific subsets of peripheral blood myeloid DC (eg, 6-sulpho LacNAc+ DC, also known as slanDC) can strongly potentiate IFNγ release by NK cells.[29] Importantly, the potential pathophysiologic relevance of a cell network among neutrophils, slanDC, and NK cells has been suggested by immunohistochemical studies that have revealed their colocalization in several chronic inflammatory pathologies, such as Crohn disease and psoriasis.[29] Finally, it has also been proposed that mature postmitotic neutrophils can also “transdifferentiate” into much-longer-lived cells with macrophage- or DC-like characteristics, which might constitute a further manner for neutrophils to act as regulatory cells of the adaptive immune response.[3,23]

It is important to mention that despite of all experimental observations in vivo that strongly suggest that neutrophils could potentially act as important players in the orchestration of immune responses, additional reevaluations and validations are required. Indeed, in order to

investigate the role of neutrophils in vivo, an antigranulocyte receptor-1 monoclonal antibody, RB6-8C5, has been extensively used to deplete mice of neutrophils.[30] However, RB6-8C5 not only binds to Ly6G, which is present on neutrophils, but also to Ly6C, which is expressed on neutrophils, DCs, and subpopulations of lymphocytes and monocytes. Therefore, it has recently been shown that in vivo administration of RB6-8C5 depletes not only neutrophils but also other granulocyte receptor-1+ (Ly6C+) cells. Luckily, a more specific anti-Ly6G monoclonal antibody (1A8) has been raised; it is now preferentially used to deplete neutrophils in vivo under different experimental settings.[31] Obviously, it will take some time prior to controlling and, eventually, revising all data on neutrophil depletion generated by using RB6-8C5. More importantly, the future availability of conditional knockout mice, selectively targeting, one by one, neutrophil function such as survival, migration, or activation, will help to finally clarify the specific contributions of neutrophils under different inflammatory/immune settings.

Role of Neutrophils in Angiogenesis and Tumor Growth

There is no longer doubt that, in addition to macrophages, neutrophils may positively or negatively influence the angiogenic process and tumor growth.[32] In the former case, it has been observed that neutrophils, via elastase release, may indirectly generate massive amounts of bioactive, angiostatin-like fragments, and thus inhibit fibroblast growth factor (bFGF) plus vascular endothelial growth factor (VEGF)-induced endothelial cell proliferation.[33] However, as described for macrophages, neutrophils can also favor malignant growth and progression, in relation to the type of tumor environment in which they reside, for instance via a remarkable production of proangiogenic molecules such as VEGF and CXCL8.[34] On the other hand, experimental studies of tumor cure and prevention have suggested that, at least in some models, engagement of neutrophil functions can be crucial for the establishment of an effective antitumoral immune response and immune memory reactions.[35] Indeed, neutrophils can produce several cytotoxic mediators for tumor and endothelial cell killing, including TNFα, defensins, proteases (such as elastase and cathepsin G), ROS, nitric oxide, and angiostatic chemokines (CXCL9, CXCL10, and CXCL11).[35] It has been recently found that neutrophils exposed to IFNs express and produce TNF-related apoptosis-inducing ligand,[36] another TNF superfamily member that selectively stimulates tumor cell killing. More recently, in vivo evidence proving that, similarly to M1 and M2 macrophages, neutrophils also polarize from an N1, proinflammatory and antitumoral phenotype, to an N2 anti-inflammatory and protumoral phenotype, has been provided,[37] thus supporting the notion that the tumor environment can profoundly shape the functional status of neutrophils. Furthermore, it is now well established that myelopoiesis can be profoundly modified during inflammation and cancer, releasing altered mature myelocytes and myeloid-derived suppressor cells (MDSCs) that exert immunosuppressive and protumoral activity, mainly by inhibiting T-cell functions.[38] Although mature human neutrophils do not seem to be a major component of such MDSC population, several mouse tumor models have revealed the existence of a granulocytic MDSC population with potent T-cell suppressing activity.[38] Nonetheless, lowdensity granulocytes (so called because of their abnormal behavior upon density centrifugation) able to inhibit T-cell activation and function have been found in human

patients with cancer.[39] Further research is now needed to better understand the origin, phenotype, and relationship to mature

neutrophils of all these immunosuppressive granulocytic populations. Such studies will better clarify the real role of neutrophils in cancer as well as in other inflammatory/autoimmune diseases (such as infections, psoriasis, and lupus), in which the presence of MDSC- or low-density granulocyte -like cells have been also described.[40]

Neutrophils in Diseases

Previous sections have already summarized some of the most common inherited disorders of neutrophil function that impair critical responses for host defense. Dramatic clinical consequences may also be observed as a consequence of acquired neutropenia (eg, a susceptibility to infectious diseases when neutrophil counts fall below 500 cells/μL[4]). Neutropenia can be due to depressed production (ie, hereditary neutropenias) or increased peripheral destruction.[4] Apart from the disorders associated with genetic dysfunctions or quantitative alterations of neutrophils, there are other pathologic situations in which neutrophils themselves become the predominant contributors to tissue injury, especially when the mechanisms supposed to control and inactivate their hypothetical beneficial and protective effector functions are deregulated. Examples of such pathologies, tentatively classified according to the major neutrophil-activating event,[1] are 1) diseases caused by ischemia reperfusion injury (ie, myocardial infarction); 2) bacterial infections (endotoxic shock, osteomyelitis, adult respiratory distress syndrome,); 3) cytokine-mediated diseases (rheumatoid arthritis, inflammatory bowel diseases); 4) diseases caused by crystal deposition (gout); 5) antineutrophil cytoplasmic antibody-associated vasculitis (Wegener granulomatosis, pauci-immune necrotizing crescentic glomerulonephritis); and 6) airway diseases (chronic obstructive pulmonary disease, bronchiectasis, bronchiolitis, cystic fibrosis, and even certain forms of asthma are characterized by neutrophil infiltration of the airway wall). One of the key challenges in neutrophil-dominated conditions is how to manipulate neutrophil function to abolish their destructive potential in a way that does not compromise their antibacterial and antifungal capacity. This has been difficult to achieve, as successful treatments in animal models have frequently proven ineffective or limited by side effects when used in human inflammatory diseases.

EOSINOPHILS, BASOPHILS, AND MAST CELLS

Eos, Bas, and MCs are critical effector cells not only in allergic inflammation, but also in innate and adaptive immunity. In addition, they have a crucial role in the surveillance of epithelial tissues, especially of the mucosa of the gastrointestinal, respiratory, and urogenital tracts: MCs as tissue resident sentinel cells, while Eos and Bas principally upon recruitment from the bloodstream. The microbicidal activity of these cells can be induced either after direct microorganism recognition or after activation by complement-or other leukocyte-derived products. Whereas neutrophils destroy internalized microorganisms by delivering cytotoxic intracellular compartments to them, Eos, Bas, and MCs are mainly involved in host defense against large parasites that cannot be internalized by other professional phagocytes. Eos can directly kill the parasites, whereas Bas and MCs preferentially release the contents of their granules into the external milieu upon activation, thus creating an environment hostile to

invading organisms. Furthermore, the unique property of Bas and MCs to express the high-affinity Fc receptor for IgE (FcεRI) that, after activation by antigenspecific IgE, induces rapid discharge of potent inflammatory mediators (histamine being one of them), is central to the initiation and propagation of immediate hypersensitivity reactions. Coughing, sneezing, and vomiting, all expulsive responses that typically are caused by basophil- and MCderived mediators and accompany allergic and pathologic inflammatory diseases, may actually reflect mechanisms that evolved to expel parasites. The properties and roles of Eos, Bas, and MCs in pathologic conditions such as allergy and autoimmunity are described in detail Chapter 45. Herein, we focus on the specialized properties that highlight their role in the innate and acquired immune response.

Eosinophils

Eosinophil Generalities

Eos are end-stage, multifunctional leukocytes involved in protection against parasitic helminths and bacterial and viral infections, that are also implicated in the pathogenesis of numerous Th2-type inflammatory processes and tissue injury.[41] These granulocytic, bilobed, nucleated cells were named as Eos by Paul Ehrlich in 1879, because of their intense staining with eosin, an acid aniline dye (Fig. 20.6). Eos are approximately 12 to 17 μm in diameter and represent 1% to 6 % of the total blood leukocyte population. Besides circulating and massively recruited at sites of Th2-dominated inflammation, Eos also reside in various organs, such as the gastrointestinal tract, mammary glands, and bone marrow.[41,42] Eos derive from bone marrow, CD34+ myeloid-committed progenitors, and upon maturation can be cytofluorimetrically identified by their characteristic morphology/side scatter and expression pattern of plasma membrane proteins such as CD66b, CCR3, IL-5Ra in conjunction

with the lack of expression of CD16 (to better distinguish them from neutrophils), and other lineage markers (such as CD2, CD14, and CD19).[41,42,43] Eosinophil differentiation and expansion from progenitor cells mainly occurs in response to three cytokines, namely IL-3, IL-5, and GMCSF, which provide permissive proliferative and differentiation signals through GATA-1, PU.1, C/EBPα, and C/EBPε transcription factors.[44] IL-5 is, however, the most specific factor for Eo development, differentiation, and release from the bone marrow into the peripheral circulation, especially during helminthic infection or allergic inflammation.[41,42,43] Also, allergen challenge or the experimental administration of CCL11/eotaxin-1 (acting through the CCR3 receptor) can cause bone marrow release of Eo precursors and mature Eos.[45,46] However, basal levels of Eo development can also occur in the absence of IL-5 as in antigen-induced tissue eosinophilia, as suggested by the presence of tissue Eos in asthmatic patients treated with anti-IL-5-neutralizing antibodies.[45,46] Once released from the bone marrow, Eos enter the circulation (with a half-life of 8 to 18 hours) and then traffic to tissues, at mucosal surfaces and/or sites of allergic inflammation, in response to a variety of different chemoattractants including CCL11, CCL24/eotaxin-2, CCL26/eotaxin-3, CCL5/RANTES, or LTB_4, LTD_2, PAF, and C5a. IL-4 and IL-13 play a central role in promoting Eo trafficking to mucosal tissue by upregulating eotaxins (CCL11 and CCL26) and endothelial expression of vascular cell adhesion molecule (VCAM)-1, the counterreceptor for VLA-4,

which is expressed on the surface of Eos.[45,47] In addition, GM-CSF, IL-3, and IL-5, as well as IL-33 and IFNγ, are important for promoting long-term Eo survival and activation in vitro and in tissues.[41,42,43,46]

Eosinophil Granules

Human Eos have a bilobed nucleus with highly condensed chromatin and contain up to four different populations of secretory organelles: primary granules, secondary/specific/crystalloid granules, small amorphous granules (containing arylsulfatase and acid phosphatase), and secretory vesicles.[48] These four organelles, along with vesiculotubular structures and small vesicles involved in transport and secretion by the activated cell, serve as the major subcellular sites for the eosinophil armamentarium of preformed cytotoxic and inflammatory mediators.[48] Eos also contain lipid bodies, which are non-membrane-bound lipid-rich organelles that are the major site of eicosanoid synthesis as they contain eicosanoid synthetic enzymes including 5-lipoxygenase, leukotriene C_4 synthase, and cyclooxygenase.[41,42,43,48,49] Eos contain greater numbers of lipid bodies than neutrophils, which even increase during eosinophil activation in vitro or engagement in inflammatory

reactions in vivo.[41,42,43,48,49]

Primary granules are similar to those found in other granulocyte lineages, are formed early in Eo development, and are enriched in Charcot-Leyden crystal protein (which represent less than 5% of total granules).[48,49] Charcot-Leyden crystal/galectin-10 is a hydrophobic protein of unknown function that is produced and released in high levels by activated Eos. Its characteristic hexagonal bipyramidal crystals can be detected as a hallmark of Eo involvement in host allergic and other immune responses, for instance in the stool or sputum of patients with gastrointestinal or respiratory eosinophilia.[48,49] Specific granules have a distinctive ultrastructural appearance with an electron-dense core and contain cationic proteins that give Eos their unique staining properties. The major cationic proteins in the specific granules are major basic protein (MBP, composed of two related cationic proteins, MBP-1 and MBP-2), Eo peroxidase (EPO), Eo cationic protein (the Eo's two ribonucleases RNase2 and RNase3, respectively), and Eo-derived neurotoxin (EDN). MBP is the major component of the crystalloid cores of specific granules and accounts for more than 50% of the Eo granule protein mass. MBP is highly cationic, it lacks enzymatic activity, and its toxicity is mediated by enhanced membrane permeability resulting from interactions of the cationic protein with the plasma membrane. MBP has in vitro activity toward parasites, including schistosomes and other helminths. In patients with asthma, serum and bronchoalveolar lavage fluid MBP concentration correlates with bronchial hyperresponsiveness. EDN and Eo cationic protein demonstrate in vitro toxicity to parasites and single-stranded ribonucleic acid pneumoviruses, including respiratory syncytial virus. EPO is another highly cationic protein that makes up approximately 25% of granule proteins and that catalyzes the oxidation of halides, pseudohalides, and nitric oxide to oxidant products that are toxic to microorganisms and host cells. It has been shown that, depending on the activation stimulus, Eo granule cationic proteins can be selectively secreted or released into tissues by a number of different secretory pathways, ranging from classical granule fusion and exocytosis (eg, in killing parasitic helminths), piecemeal degranulation (eg, vesicular transport from the granules in the absence of classical exocytosis), and cytolytic degranulation (release of intact membrane-bound granules directly into the tissue upon eosinophil apoptosis/cell death).[41,42,43,48,49] Studies in the past 15 to 20 years of the biochemistry, functions, and localization in tissues of the unique enzymatic and nonenzymatic cationic proteins present in Eo granules have provided compelling evidence supporting a pathologic proinflammatory and effector role for the Eo in directly inducing tissue damage.

Eosinophil Mediators

In addition to containing numerous highly basic and cytotoxic granule proteins that are released upon activation, Eos can also synthesize an arsenal of lipid mediators, ROS, and inflammatory/hematopoietic cytokines that mediate the pathophysiologic role of this granulocyte in health and disease (Table 20.3). Lipid-derived mediators generated by Eos include PGE_2, thromboxane, LTC_4, and PAF, which are all considered as responsible for many of the Eo-triggered proinflammatory activities, namely the increase in leukocyte trafficking, endothelial adhesion, smooth muscle contraction, vascular permeability, and mucus secretion.[41,42,43] Eo-derived cytokines (including TGFβ, GM-CSF, IL-3, IL-4, IL-5, CXCL8, IL-10, IL-12, IL-13, IL-16, IL-18, TNFα, CCL5, stem cell factor [SCF], NGF, and CCL11) are in part stored as preformed in granules and thus can be rapidly released upon

degranulation (similarly to MCs).[41,42,43,50,51,52]

Interestingly,GM-CSF is among the cytokines produced in greatest quantities by Eos.[53]

TABLE 20.3 Major Eosinophil-Derived Mediators

Class	Mediators	Physiologic Effects
Cationic granule proteins	MBP, ECP, EDN, EPO	Cytotoxic and bactericidal properties, smooth muscle cells contraction, mast cell activation and survival
Lipid mediators	LTD_4, LTE_4, PAF, PGE_1, PGE_2, 15-HETE	Leukocyte trafficking, endothelial adhesion, smooth muscle cells contraction, vascular permeability, inflammation
Cytokines	TNFα, IFNγ, IL-1α, IL-1β, IL-2, IL-3, IL-4, IL-5, IL-6, IL-9, IL-10, IL-11, IL-12, IL-13, IL-16, IL-17, IL-25	Inflammation, immunoregulation
Chemokines	CXCL1, CXCL5, CXCL8, CXCL9, CXCL10, CXCL11, CCL2, CCL3, CCL5, CCL7, CCL11, CCL13	Leukocyte chemoattraction and tissue infiltration of leukocytes
Growth factors	HB-EGF, LBP, NGF, GM-CSF, TGFα, TGFβ, SCF, VEGF, APRIL	Growth of various cell types

ECP, eosinophil cationic protein; EDN, eosinophil-derived neurotoxin; EPO, eosinophil peroxidase; IFN, interferon; IL, interleukin; LTD, leukotriene D; LTE, leukotriene E; MBP, major basic protein; PAF, platelet-activating factor; PGE, prostaglandin E; TNF, tumor necrosis factor.

Eos are functionally activated via an array of cell surface molecules, including Ig receptors for IgG (FcγRII/CD32) and IgA (FcαRI/CD89), receptors for complement-derived fragments (CR1/CD35, CR3, and CD88), cytokines (IL-3R, IL-5R, GM-CSF, as well as IL-1αR, IL-2R, IL-4R, IFNαR, and TNFRI), chemokines (CCR1 and CCR3), adhesion molecules (VLA4, α4β7), leukotrienes (CysLT1R and CysLT2R; LTB_4-R), prostaglandins (PGD_2 type 2R), PAF, and ligands for TLRs (TLR1, TLR4, TLR7, TLR9, and TLR10, the TLR7/8 representing an

important mechanism for host defense against viral infections).[41,42,43]

Eosinophil Effector Functions

Eos have historically been considered as end-stage effector cells, causing damage to parasitic pathogens during helminthic infections or to host tissues in allergic diseases. However, as outlined in the following, accumulating evidence suggest that Eos can perform various immune regulatory functions, pointing to a more complex role of these cells not only in regulating inflammation and bridging innate and adaptive immunity, but also in maintaining epithelial barrier functions and affecting tissue remodeling.[41,42,43]

Eosinophils in Host Defense. The earliest recognized Eo effector functions were those associated to their role in host defense against multicellular helminthic parasites, although it is now clear that Eos are also involved in host defense against viral and bacterial infections.[54] Among the several mechanisms through which Eos can exert defensive functions, the best described consist in their release of cytotoxic cationic proteins (such as MBP, Eo cationic protein, EDN, and EPO), production of ROS, antibody- and complement-mediated killing, and the expulsion of extracellular deoxyribonucleic acid traps.[43,54] Despite substantial in vitro data, there is a lack of convincing evidence of the effective role of Eos in host defense in vivo, in particular during helminthic infections. Indeed, the only human Eo-specific condition, known as hereditary EPO deficiency, has not been related to increased susceptibility to helminthic infections. Furthermore, the results from infection studies carried out in mouse models remain unclear and controversial.[55,56] Considering that many of these experiments were performed using human pathogens, which do not naturally infect rodents, and that there are several phenotypic and functional differences between human and murine Eos, the relevance of these data should be reconsidered.[55,56] It is noteworthy to mention that, as described subsequently, some of the mechanisms used by Eos in host defense against pathogens may also produce detrimental effects on the host.[42,54]

Eosinophils in Immunoregulation. Accumulating evidence suggest that Eos can perform discrete immune regulatory functions mainly through production and release of cytokines and other immunomodulatory molecules, or via antigen presentation. For instance, Eos produce cytokines that are able to act on Eos themselves, the so-called autocrine cytokines, including IL-3 and GM-CSF, which function, in part, to prevent apoptosis and prolong Eo survival, once these cells are recruited into sites of tissue inflammation, such as the lung in asthma.[41,42,43] Eos can regulate their own recruitment, as well as that of DCs and T cells, through the secretion of CCL3, CCL5, and CCL11. Eo-derived cytokines may also influence the functions of other immune cells. For instance, Eos play an important role in the regulation of MC functions, including activation, differentiation, maturation, and survival, mainly via the release of SCF.[50,51,52] Eos have also been implicated in the regulation of B-cell function, not only under homeostatic conditions, but also during immunization responses with alum.[57] Eos seem indeed able to modulate early stages of B-cell activation and IgM production.[57] The best characterized role of Eos in immune regulation is their ability to initiate Th2-type responses by modulating DC and T-cell recruitment and activation. Eo-derived EDN can recruit and activate DCs and, in turn, skew them to a Th2-promoting phenotype.[58] In several murine models of parasitic infections and airway allergen challenge, Eos have been shown

not only to precede Th2 cells arrivals in tissues, but also to be able to migrate to draining lymph nodes and polarize Th2 immune responses through the secretion of cytokines such as IL-4 and IL-25.[42,58] However, human Eos also express indoleamine 2,3-dioxygenase which, through kynurenine production, inhibits Th1 effector functions.[59]

Another important role of Eos in immune regulation is their function as antigen-presenting cells. Eos possess the capacity to internalize, process, and present antigenic peptides within the context of surface expressed MHC II, to provide costimulatory signals to T cells through surface expression of molecules such as CD80, CD86, and CD40, and to physically interact with CD4+ T cells.[60] In humans, although circulating Eos from healthy donors are generally devoid of surface MHC class II expression, they can be induced to express MHC class II and costimulatory molecules upon appropriate cytokine stimulation and after transmigration through endothelial cell monolayers.[42,60] Human Eos also constitutively express a Jagged1, a Notch ligand, suggesting a capacity of Eos to provide a polarization signal to naive CD4+ T cells.[61]

Eosinophil Homeostatic Functions. As mentioned, at baseline conditions Eos are present in tissues such as the gut, mammary gland, uterus, thymus, and bone marrow, via recruitment by the CCL11/CCR3 axis. Although their homeostatic role in all these tissues is not fully understood, Eos seem to be mainly involved in regulating the morphogenesis and maintenance of mucosal organs, as well as the immune homeostasis of the thymus and bone marrow.[41,42,43] Thymic Eos, for instance, are thought to be involved in the MHC class I-restricted negative selection of double positive thymocytes. In the bone marrow, instead, Eos colocalize with plasma cells, and by secreting a proliferation inducing ligand (APRIL) and IL-6, they play a crucial role in long-term maintenance and survival of the same plasma cells.[41,43,62]

Eosinophils in Tissue Remodeling. A growing body of evidence has proven the ability of Eos to influence tissue remodeling and fibrosis in many Eo-associated diseases, mainly due to their ability of secreting high levels of TGFβ. Human Eos also produce other profibrotic and angiogenic factors, such as osteopontin, VEGF, and MMPs.[50,51,52] Furthermore, Eos produce and release NGF and promote the extension of neurites in nerve cells.

Eosinophils in Diseases

Eos are currently thought to participate in the pathogenesis of the chronic phases of allergic diseases such as asthma, allergic rhinitis, atopic dermatitis, and hypereosinophilic syndromes.[41,42,43] Allergic diseases are associated with a mild peripheral blood eosinophilia, although in tissues and in the nasal secretions, sputum, and BAL fluid, Eos can be more significantly elevated. Studies in murine models support a role for Eos in airway remodeling, airway hyperactivity, and mucous production. Elevation of peripheral blood Eos is also observed in drug reactions, helminthic infections, as well as in specific primary immunodeficiency diseases, most notably Omenn syndrome and hyper-IgE syndrome. Eosinopenia is typically seen in acute bacterial or viral infections and with systemic corticosteroid treatment. Finally, the use of Eo-specific antibodies has demonstrated that almost all human or mouse cancers are associated with an important Eo infiltrate at some

point in tumor growth.[43]

Mast Cells and Basophils

Mast Cell Generalities

MCs were identified as granular cells in the mesentery of the frog by Dr. Von Recklinghausen in 1863 and were named “Mastzellen” by Dr Paul Ehrlich in 1878. Initial studies focused on their histologic characteristics, distribution, and abundance in health and disease. The discovery of histamine in 1910, slow-reacting substance of anaphylaxis (now leukotrienes) in 1938, and IgE in 1966 provided initial insights into the role of MCs in allergic reactions. MCs are tissue-dwelling inflammatory cells widely distributed throughout the body and are common at perivascular sites and at mucosal surfaces, particularly in those tissues that form interfaces with the external environment, such as skin, conjunctivae, and intestinal and airway mucosa.[63,64,65] Thus, MCs are strategically placed so as to function in a first line of host defense.[66,67] Morphologically, MCs in tissues appear as round, spindle-shaped, or spider-like cells, with round or oval nuclei, ranging between 7 and 20 μm in diameter, and readily identified using cationic dyes such as toluidine blue or methylene blue.[68] These dyes impart a blueto-purple change in color, known as “metachromasia,” which occurs as a result of their abundant intragranular content of sulfated proteoglycans (eg, heparin and chondroitin sulfates).[68] Of all other hematopoietic cells, only Bas share this staining feature with MCs, along with other properties (see Table 20.4

for the major similarities and differences between MCs and Bas). MCs can be cytofluorimetrically identified by their characteristic expression pattern of plasma membrane proteins serving as markers, including FcεRI (as Bas and a subpopulation of DCs), CD23, CD117, and CD203, in conjunction with the lack of expression of lineage markers (such as CD2, CD14, and CD19).[69,70] Furthermore, MCs can be identified either by biochemical reagents that detect their intracellular proteases for their enzymatic properties or by immunostaining using antibodies toward tryptase (Fig. 20.7) or chymase (the latter representing the primary method of choice for identifying human MCs in tissues).[71]

TABLE 20.4 Major Features of Mast Cells and Basophils

	Mast Cells	Basophils
Origin	Hematopoietic stem cells	Hematopoietic stem cells
Lifespan	Months	Days
Primary location	Tissues	Intravascular circulation
Site of	Connective tissues	Bone marrow

maturation		
Differentiation factors	Stem cell factor	Interleukin-3
Histamine content	1 to 15 pg/cell	1 to 2 pg/cell
Size	7 to 20 μm	5 to 10 μm
Nucleus	Oval or round	Segmented
Granules	Smaller and more numerous compared with basophils	Larger and fewer compared with mast cells
Peptidoglycans	Heparin and chondroitin sulfates	Predominantly chondroitin sulfates
Chymase content	High	Absent
Tryptase content	High	Low
Lipid mediators	PGD_2, LTB_4, LTC_4, LTD_4, LTE_4, PAF	LTC_4, LTD_4, LTE_4
Activation by Substance P	Activation	No effect
Morphine	Activation	No effect
fMLF	No effect	Activation

fMLF, formyl-Met-Leu-Phe; LTB,leukotriene B; LTC, leukotriene C; LTD, leukotriene D; LTE, leukotriene E; PAF, platelet-activating factor; PGD, prostaglandin D.

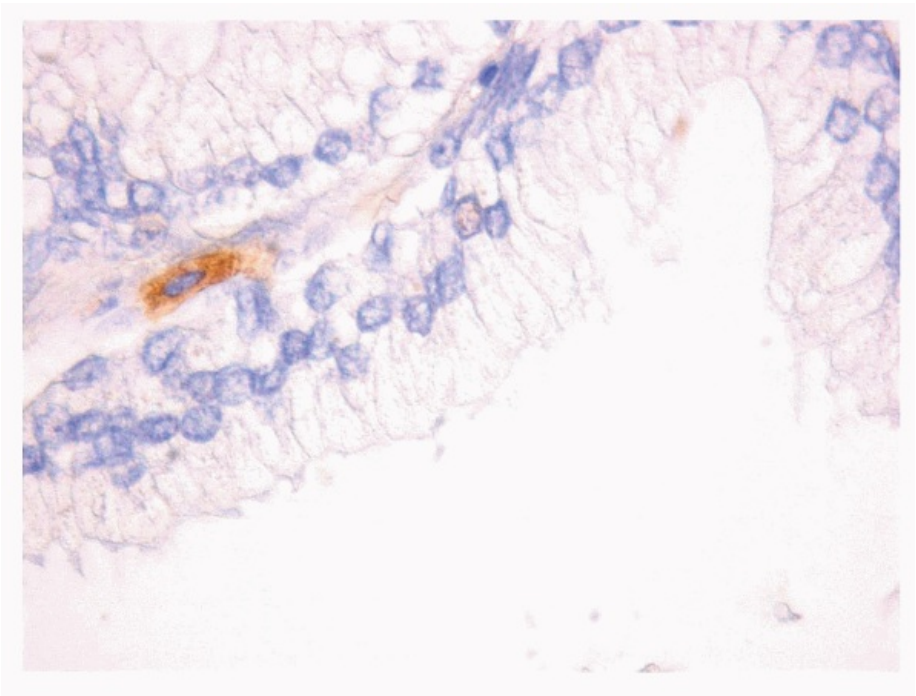

FIG. 20.7. Formalin-fixed, paraffin-embedded human prostate tissue stained with an anti-mast cell tryptase antibody.

Human MCs originate from CD34+/CD117+/CD13+ multipotent hematopoietic progenitors in bone marrow, and then migrate through blood to tissues where they mature.[72,73] Details of their differentiation and phenotypic diversification have not been definitively identified, but are likely included within the CD34+/KIT+ cell subpopulation and are clearly distinct from the basophil lineage (which is KIT/CD117- but IL-3R+).[74] In mice, a hematopoietic stem cell progresses to a multipotent progenitor, a common myeloid progenitor and a granulocyte/monocyte progenitor.[75,76] A monopotent MC progenitor is found in bone marrow and intestine, and a common basophil/MC progenitor is also found in mouse spleen, observations that await study in human. After their homing in the tissues, maturation of the MC precursors is dependent on SCF expressed on the surface of fibroblasts, stromal cells, and endothelial cells.[68,77] Accordingly, in vitro studies using mouse and human MCs confirm that soluble SCF protects MCs from apoptosis and induces their proliferation, chemotaxis, and also some degree of activation and secretion.[68] Consistently, mutant mice lacking KIT- or SCFmediated functions are often used as experimental tools to implicate a biologic role of MCs in given models.[68] While there are several studies on the mechanisms of localization of MCs to different tissues, there is little information about specific molecules that could regulate MC-progenitor trafficking to tissues, movement, and incremental recruitment upon inflammation.[63,72] Accordingly, while a range of chemokines are active on human and mouse MCs in vitro, no MC-selective chemokine has been identified yet.

MC localization to small intestine is reliant on adhesive interactions controlled by $\alpha_4\beta_7$ integrin, VCAM-1, and mucosal addressin cell adhesion molecule-1 (MAdCAM-1).[63] CXCR2 ligands also play a critical role for the constitutive localization of MC progenitors to the

intestine.[63,78] In contrast to the small intestine, MC progenitors are not abundant in normal lung. However, MCs are detected in the bronchial epithelium and airway smooth muscle, associated with pulmonary inflammation and abundant in human asthma.[79] VCAM-1 interactions with both $\alpha_4\beta_1$ and $\alpha_4\beta_7$ integrins, but not mucosal addressin cell adhesion molecule-1, are essential for the trafficking of MC progenitors to the lung during antigen-induced pulmonary inflammation.[79] It is interesting to note that in a model of *Aspergillus fumigatus* extract-induced allergic pulmonary inflammation, IgE can influence the number and function of mature MCs, but not MC progenitor recruitment.[80]

On the basis of their location, histochemical staining, content of proteases, and reactivity to selected secretagogues and antiallergic drugs, two major subtypes of MCs have been described in rodents: mucosal-type MCs, which express MC protease-1 and -2; and connective tissue-type MCs, which are positive for MC protease-4, -5, -6, and carboxypeptidase A.[81] In humans, mucosal MCs preferentially express mouse MC protease-1 and -2, whereas connective tissue MCs express MC protease-4, -5, -6, and carboxypeptidase A.[81,82] Human MCs also exhibit heterogeneity and are thus classified by their content of serine proteases as tryptase-only MC, chymase-only MC, or both tryptase- and chymase-positive MC.[81,82] Both in humans and mice, these MC phenotypes are reversible in certain microenvironmental conditions, and transdifferentiation between the phenotypes has been shown.[81,82] Each MC subtype predominates in different locations: tryptase-only MC cells are prominent within the mucosa of the respiratory (nose, lung) and gastrointestinal tracts, and increase upon mucosal inflammation, whereas tryptase- and chymase-positive MC cells are prominent within connective tissues such as the dermis, submucosa of the gastrointestinal tract, heart, conjunctivae muscularis of the uterus, and perivascular tissues.[81] In light of murine studies highlighting a “fine tuning” on the MC functions and effector properties by cytokines or matrix proteins, it seems likely that human MCs will prove to be even more heterogeneous than currently thought. Accordingly, MC phenotype, behavior, and responsiveness may be dramatically altered by cytokines, including IL-4 (which upregulates the expression of FcεRI and is particularly pivotal in regulating functional responses of MCs in mucosal inflammation), IL-5 (which promotes MC proliferation in the presence of SCF), and IFNγ (which induces the expression of the high-affinity activating FcγRI/CD64 and also decreases MC numbers).[68] Furthermore, MCs express an array of adhesion and immune receptors that may assist in the recognition of invading pathogens and in the sampling of different stimuli coming from the microenvironment.[67] This versatility is reflected in the numerous

IgE-dependent and -independent activation pathways that modulate the quality and magnitude of MC responses and cytokine release. MCs are endowed with a range of potent proinflammatory effector molecules that may be selectively released not only through FcεR1 activation, but also in response to a variety of other receptors including C3aR and C5aR, FcγRIIa/CD32a, KIT/CD117/SCF-R, IL-3R, IL-4R, IL-5R, IL-9R, IL-10R, GM-CSFR, IFNγR, CCR3, CCR5, CXCR2, CXCR4, NGFR/TRKA, the type 1 receptor for cys-LTs (CysLT1R), the adenosineA3 receptor, and many TLRs, among others.[68] Depending on the type, property, strength, and combination of the stimuli that they receive, MCs secrete a diverse and wide

range of biologically active products (Table 20.5) that can trigger, direct, or suppress the immune response.[68,83,84]

TABLE 20.5 Major Basophil and/or Mast Cell-Derived Mediators

Class	Mediators	Physiologic Effects
Preformed mediators	Histamine	Vasodilation, angiogenesis, mitogenesis, suppressor of T-cell activation
	5-HT	Leukocyte regulation, vasoconstriction, pain
	Chymase	Tissue damage, pain, angiotensin II synthesis
	Tryptase	Activation of PAR, inflammation, pain, tissue damage, degradation of antigens and peptides
	kininogenases	Synthesis of kinins, pain
	Nitric oxide synthase	Nitric oxide production
	Carboxypeptidase A	Degrades enzymes
	CRH	Inflammation, vasodilation, mast-cell VEGF release
	Endothelin	Sepsis
	Kinins	Inflammation, pain, vasodilation, mast cell trigger
	Somatostatin	Anti-inflammatory effects, mast cell trigger
	VEGF	Neovascularization, vasodilation
	Chondroitin sulfate	Connective tissue

		component, anti-inflammatory, mast cell inhibitor
	Heparin	Angiogenesis, NGF stabilization, mast cell inhibitor
Lipid mediators	LTB_4, LTC_4, PAF, PGD_2	Leukocyte chemotaxis, vasoconstriction, pain, platelet activation, vasodilation, inflammation, bronchoconstriction
Cytokines	TNFα, TGFβ, IFNα, IFNβ, IFNγ, IL-1α, IL-1β, IL-3, IL-4, IL-5, IL-6, IL-8, IL-9, IL-10, IL-11, IL-12, IL-13, IL-15, IL-16, IL-18, IL-25, SCF, MIF	Inflammation, leucocyte migration/proliferation
Chemokines	CXCL8, CCL3, CCL2, CCL7, CCL13, CCL5, CCL11, CCL19	Chemoattraction and tissue infiltration of leukocytes
Growth factors	CSF, GM-CSF, bFGF, VEGF, NGF, LIF	Growth of various cell types
Antimicrobic products	Nitric oxide, superoxide, antimicrobial peptides	Microbial killing

bFGF, fibroblast growth factor; CRH, corticotropin-releasing hormone; CSF, colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; LIF, leukemia inhibitory factor; LTB, leukotriene B; LTC, leukotriene C; MIF, migration inhibitory factor; NGF, nerve growth factor; PAF, platelet-activating factor; PAR, proteinase activated receptor; PGD, prostaglandin D; SCF; stem cell factor; TGF, transforming growth factor; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

Basophil Generalities

Bas are the rarest of the granulocytes (typically constituting 0.5% to 1.5% of peripheral blood leukocytes), are 5 to 10 μm in diameter, and exhibit a bean-shaped or bilobed condensed nucleus.[85] Compared to MCs, they have little proliferative capacity and possess fewer, but larger (up to 1.2 μm) round metachromatic granules (Fig. 20.8) enriched in histamine (stored at about 1 to 2 pg per cell).[86,87] Bas develop from CD34+ progenitors, differentiate and mature in the bone marrow in response to IL-3, and circulate in the periphery with a half-life

thought to be of a few days.[85,88] Although not predominantly tissue-dwelling cells, Bas are able to infiltrate inflamed tissues, particularly at sites of allergic inflammation within several hours after exposure to allergens, and are often accompanied by a simultaneous influx of eosinophilic granulocytes and Th2 lymphocytes.[82,85,89] Bas can be cytofluorimetrically identified by their selective pattern of plasma membrane proteins serving as markers, including FcεRI (like MCs), CD123 (the α chain of the IL-3 receptor), CD11b, and CD13, in conjunction with the absence of other lineage markers (such as CD2, CD14, CD16, CD19, and MHC class II).[89] They also express, and dynamically respond to, ligands for a variety of functional cytokine/chemokine receptors (eg, IL-5R, GM-CSFR, CCR2, and CCR3), complement receptors (CD11b, CD11c, CD35, and CD88), prostaglandin receptors (CRTH2), Ig Fc receptors (FcεRI and FcγRIIb), and TLRs. For example, following FcεRI activation (which typically triggers granule exocytosis and mediator release), a number of basophil cell surface markers, including CD13, CD63, CD107a, CD164, and CD203C, may increase.[85,89,90]

Mast Cell and Basophil Mediators

The mediators produced by MCs and Bas are schematically divided into preformed mediators, newly synthesized lipid mediators, and cytokines/chemokines (see Table 20.5).[82,86,89]

Such subdivision is not exclusive as TNFα, for instance, occurs as both preformed and as a newly synthesized molecule.[91] Preformed mediators, including histamine or MC neutral proteases (tryptase, chymase, cathepsin G, and carboxypeptidase) are stored in cytoplasmic granules and form complexes with the negatively charged, very abundantly expressed, sulfated proteoglycans.[82,92] Upon MC/Ba activation, the granules fuse with the plasma membrane and, within minutes, release their content into the extracellular environment where the various mediators dissociate from proteoglycans.[68,85] Other than being secreted upon stimulation, some molecules are also constitutively released, as in the case of MC tryptase. Consequently, tryptase levels are considered as a parameter that reflects the MC burden, and, in fact, they significantly increase in systemic mastocytosis.[82,92] Curiously, the function of tryptase in vivo is still unknown, even though, in vitro, it digests fibrinogen, fibronectin, prourokinase, proMMP-3, protease-activated receptor-2, and complement component C3; it activates fibroblasts as well. The functions of MC/Ba-derived proteoglycans and proteases are less well understood, but proteases provide some protection against snake and insect venoms.[82,92] Differently from MCs, humans Bas do not express chymase, appear to contain very low levels of heparin and tryptase (with some exceptions), but contain MBP and Charcot-Leyden crystal (which are typical eosinophil products). Activated Bas have been shown to also contain granzyme B and to directly kill target cells, at least in part by this cytotoxic serine protease.[82,90,93] More importantly, Bas, together with neutrophils, seem to be the exclusive peripheral blood source of histamine.

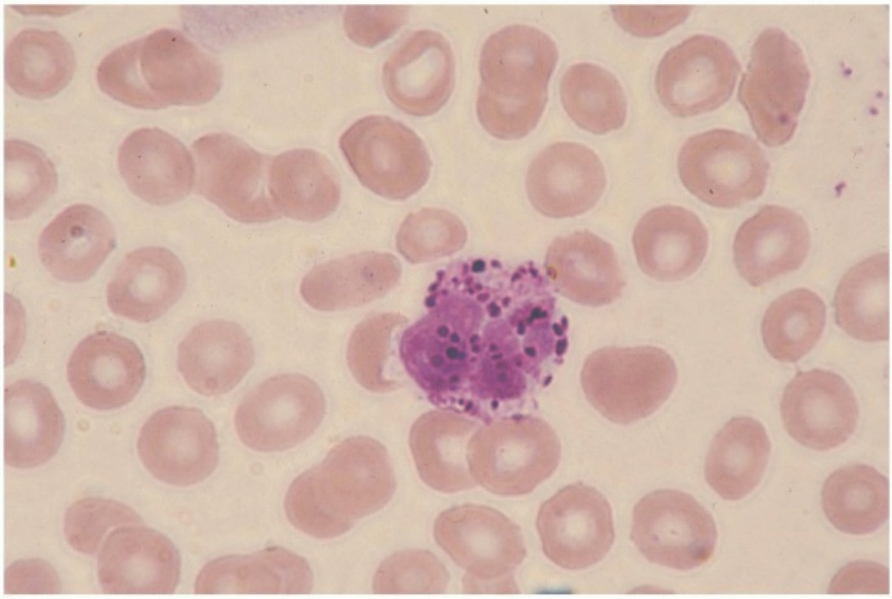

FIG. 20.8. A Polymorphonuclear Basophil Circulating in Peripheral Blood. From *Anderson's Atlas of Hematology* ; Anderson, Shauna C., PhD. Copyright 2003, Wolters Kluwer Health/Lippincott Williams & Wilkins.

Newly synthesized lipid mediators by FcεRI-activated MCs are PAF, PGD_2, and LTA_4. The latter is then converted to LTB_4 or conjugated with glutathione to form LTC_4 (the parent compound to the cysteinyl leukotrienes, which also include LTD_4 and LTE_4).[86,92] Activated Bas can produce the same lipid mediators but PGD_2 (as they lack the PGD_2 synthase).[82,86,93] PGD_2 functions as bronchoconstrictor and attracts both Eos and Bas, LTB_4 attract neutrophils and effector T-cells, while cysteinyl leukotrienes attract Eos and work as potent bronchoconstrictors, in addition to promote vascular permeability and to induce mucus production.

MCs produce several cytokines, including IL-3, IL-4, GM-CSF, IL-5, IL-6, IL-10, and IL-13, growth factors, including bFGF, SCF, VEGF, and several chemokines, including CXCL8 and CCL3.[82,86,92] In addition, MCs are considered the only cells storing very abundant levels of preformed TNFα, whose critical role in host defense against bacterial infections has been widely highlighted: in fact, specific experimental animal models lacking MC-derived TNFα result in drastically reduced neutrophil influx and significantly increased mortality.[91] Bas are a major source of GM-CSF and VEGF, and release significant amount of chemokines (CXCL8, CCL3, CCL11) in response to IgE cross-linking. Chief among the cytokines produced by Bas are IL-4 and IL-13, which are released in response to FcεRI or C5a stimulation within the range of 20 to more than 600 pg/million and < 20 to 2000 pg/million cells, respectively.[82,86,93]

Mast Cell and Basophil Effector Functions

MCs and Bas, although derived from distinct progenitors, have been recognized to express partially overlapping functions in many aspects of natural and acquired immunity.[86,87]

Traditionally, MCs and Bas, together with Eos, are considered essential components of IgE-mediated classic type 1 hypersensitivity (allergic) reactions and allergic inflammation (see Chapter 45). Nonetheless, MCs and Bas have also the ability to release and synthesize highly bioactive, proinflammatory, and cytotoxic substances, independent of signaling through FcεRI. Therefore, these cells, besides

being important modulators of allergic reaction, can also contribute to leucocyte recruitment, stromal and tissue cell activation, modulation of immune reactions, tissue remodelling, and angiogenesis.[84,89,90,94]

Mast Cells and Basophils in Allergy. Allergen-specific IgE production, with subsequent fixation of IgE to FcεRI receptors on MCs and Bas, followed by rapid degranulation and release of histamine and specific eicosanoids (eg, LTC_4), is central to the initiation and propagation of immediate hypersensitivity reactions.[65,82] It has been widely accepted that MCs contribute significantly to acute inflammatory reactions to antigens/allergens toward which the host bears antibodies of the IgE class.[95] MCs are responsible for virtually all of the increased vascular permeability and tissue swelling early in the IgE-dependent passive cutaneous anaphylactic response.[95,96] If the stimulation is of more persistent or of more severe nature, acute response may undergo transition into a late-phase reaction, which, except for the time scale ranging from a few to several hours from initial antigen challenge, is characterized by new recruitment of leukocytes (Eos, Bas, and Th2 lymphocytes) to the site of inflammation.[65] Bas play a crucial role in sustaining allergic chronic inflammation upon their entering the affected tissue, not only due to the release of stored and newly synthesized mediators, such as histamine and LTC_4, but also via the release of high amounts of the cytokines IL-4 and IL-13.[89,90,97]

Mast Cells and Basophils in Innate Immunity and Host Defense. Recent studies have demonstrated that MCs express many PRRs, including TLRs 1 to 10 and nucleotide oligomerization domain-like Receptors (NLR) (including nucleotide oligomerization domainreceptors and the NLRP3). Expression of various PRRs thus permits MCs to respond to both pathogen-associated molecular and “danger signals” resulting from cell stress or injury. Several MC functions triggered by PRR have been implicated in host defense.[84,94,98] These latter include enhancement of the recruitment or function of granulocytes, phagocytosisdependent bactericidal activities, and proteolytic degradation of endogenous mediators, which would otherwise be elevated to toxic levels, such as endothelin-1 and neurotensin. Secretion of proteases/enzymes and formation of extracellular traps that contain antimicrobial peptides, histone, deoxyribonucleic acid, and tryptase have also been proposed as potential mechanisms by which MCs exert protective functions.[94,98] In addition to their role in bacterial infections, MCs can promote host resistance to certain parasite and virus infections. However, the mechanisms involved in these functions have not been fully elucidated.[94,98] Differently from MCs, the role of Bas in host defense is less studied, especially in bacterial or viral infections. Some evidence for a role of Bas in host defense against parasitic infections and tick infestations has been reported, but the molecular mechanisms underlying the Ba-mediated protection in these processes remain to be determined.[89,99,100]

Mast Cells and Basophils in Immunoregulation. MCs and Bas manifest immunoregulatory functions in IgE-dependent and -independent inflammatory reactions, mainly by secreting soluble mediators and cytokines or by functioning as antigen-presenting cells. These cells contribute to the initiation of acquired immunity by orchestrating DC migration, maturation, and function and by interacting with T and B cells.[84,89,90,94] MCs have the potential to influence DC functions, mainly through the release of histamine, PGD_2, PGE_2, LTB_4, or cytokines such as TNF, IL-1, IL-16, IL-18, and CCL5. Generally, both in vitro and in vivo evidence indicate that MCs predominantly inhibit IL-12p70 production and induce a Th2-promoting phenotype in DCs.[94,101] MCs can also modulate B-lymphocyte functions by supporting their survival, proliferation, and IgA production, mainly through the expression of CD40L and IL-6.[94,102] Evidence of cell-contact interactions between MCs and B cells in vivo have been found to occur in secondary lymphoid organs and inflamed tissues.[94,103]

MC surface molecules and secreted products can also influence various aspects of the biology of T cells, for example, by polarizing naive T cells to Th1, Th2, Th17, and regulatory T (T_{reg}) cells or by modulating the functions of distinct T-cell subsets.[94,101] Interestingly, MCs through IL-6 secretion and via OX40/OX40L contact have recently been shown to counteract T_{reg}-mediated suppression, thus leading to the establishment of Th17-mediated inflammatory responses.[104] MCs can also induce antigen-specific T-cell proliferation and activation (of both CD8+ and CD4+ T cells) due to their expression of MHC class I and II molecules, of costimulatory molecules of the B7 family (such as ICOS-L, PD-L1, CD80, and CD86), and of members of the TNF/TNF receptor families (such as OXOL and CD40L).[84,94,101] Finally, MCs produce several mediators with anti-inflammatory activities, including TGFβ, IL-4, IL-10, and IL-9, and have been shown to play a crucial role in transplantation engraftment, for instance toward allogeneic skin graft.[94,101,105] Most likely, MCs manifest predominantly proinflammatory effects in the earlier phase of the immune response, while the anti-inflammatory effects of these cells are more pronounced at the later phase of the response to limit ongoing inflammation.[105]

Bas have the ability to regulate the acquired immune response, mainly by potentiating humoral responses and promoting Th2 polarization.[86,89] Bas can enhance B-cell survival and proliferation, and Ig production mainly through the release of IL-4, IL-6, BAFF, and APRIL.[89,106,107] The ability of Bas to polarize Th2 immune responses is dependent on their function as antigen-presenting cells and on IL-4 secretion. These Th2-promoting functions of Bas have been demonstrated in responses to protease allergens, helminthic parasites, or antigen-IgE complex in vivo.[108,109,110] Recently, the Th2-promoting functions of Bas have been linked to the development of systemic lupus erythematosus in mice deficient of the Src family protein tyrosin kinase Lyn, and in human patients.[111]

Mast Cells and Basophils in Disease

The most striking increase in MCs occurs during parasitic diseases and mastocytosis (the latter being a pathologic excess of MCs, most notably in the skin, bone marrow, gastrointestinal tract, spleen, liver, and lymph nodes, that is

usually caused by gain-of-function mutations of KIT).[68,112] The importance of MCs in IgE-allergic reactions (including rhinitis, urticaria, and asthma) is emphasized by the increased numbers of these cells seen in affected tissues in both mice and humans.[68,95] MC hyperplasia and increased MC products at sites of tissue injury have also been observed in chronic inflammatory and autoimmune diseases, such as rheumatoid arthritis and multiple sclerosis. A pathologic role of MCs in these diseases has been suggested mainly by the utilization of the K/BxN mouse model of antibodyinduced arthritis and the experimental autoimmune encephalomyelitis mouse model of multiple sclerosis.[94,112] Moreover, studies in mice indicate that activation of MCs via the NLRP3 can contribute to IL-1β overproduction and chronic urticarial rash in subjects with cryopyrin-associated periodic syndrome, a disorder associated with NLRP3 mutations.[113] There is evidence for MCs in promoting, but also in protecting against, tumor growth. The accumulation of MCs at the periphery of tumors has been observed in both rodent models and in a diverse array of tumors in humans. It is generally thought that MCs promote early angiogenesis events in tumor development through the release of mediators such as VEGF, CXCL8, angiopoietin-1, bFGF, heparin, and proteases.[114] Finally, MCs could also contribute to the pathogenesis of acute or chronic vascular events: accordingly, acute myocardial infarctions show elevations of both histamine and mature β-tryptase, suggesting that MC activation occurs concomitantly with ischemia.[94,112]

As far as Bas, it has remained obscure whether these cells actually play a crucial role or are just redundant with MCs in allergic reactions in vivo.[89,97] Human Bas have been shown to release IL-1β and TNFα upon the crosslinking of surface-bound IgD, but not IgE, suggesting a possible role of these cells in autoinflammatory disorders such as hyper-IgD syndrome.[115] Bas may also contribute to the production of autoantibodies that cause lupus nephritis.[116]

CONCLUSION

In the last few years, our perception of granulocytes and MCs has changed dramatically. In fact, there has been mounting evidence that the function of these cells is not limited to acting as first line of defense against invading pathogens, but is extended to perform additional and unexpected activities in strict collaboration with adaptive immune and other nonimmune cells. Thus, cells of innate and adaptive immunity together orchestrate complex functional programs to promote host defense, control the development of self-tolerance, and avoid autoimmunity. In this context, the gene expression pattern and phenotype of the cells discussed in this chapter must rapidly change in a coordinate, time-dependent manner in response to microenvironmental soluble and cellular signals.[117] Granulocytes and MCs, in view of their wide variety of membrane receptor are able to mediate delivery of costimulatory signals, their broad array of molecules involved in cell-extracellular-matrix adhesion and in cell-cell contacts, their extensive assortment of soluble pro- and anti-inflamatory mediators, may profoundly influence the development, intensity, and duration of adaptive immune responses that ultimately serve for host defense, allergy, and autoimmunity. A representative example of this aptitude is the plasticity that MCs manifest as a result of their reciprocal interactions with the T-cell populations exerting regulatory or activatory functions in normal and/or pathologic immune responses.[101,105] In this context, it has been demonstrated that

CD4+CD25+ T_{reg} cells establish a cell-cell contact with MCs through the OX40:OX40L axis, which regulates the MC degranulation threshold and contributes to tissue tolerance.[104,118] However, in an inflammatory environment, this MCs/CD4+CD25+ T_{reg} cell interaction induces a Th17 switch by T_{reg} cells.[104,118] On the same line, it is remarkable that, under particular settings, granulocytes and MCs display functions that in the past were ascribed only to immune adaptive cells. For instance, it has been recently demonstrated that neutrophils, among their various immunoregulatory functions,[23] can also display a B-cell-helper function that promotes Ig class switching, Ig somatic hypermutation, and antibody production by activating marginal zone B cells through BAFF, APRIL, and IL-21 secretion.[119] Similarly to neutrophils, MCs are also able to provide costimulatory signals that sustain B-cell expansion and drive the development of IgA-oriented humoral immune responses,[102] thus ascribing a B-cell-helper function that in the past was retained exclusive of T cells.

Novel activities have been described for myeloid cells also in the context of host defense, such as for instance in the case of Bas that, during primary and secondary exposure to parasites, might display different roles.[93,120] Indeed, in a murine model of primary helminthes infection,[121] Bas often accumulate in affected tissues where they produce large quantities of Th2 cytokines that not only regulate the eosinophil recruitment to the lung and the IgE production, but also favor mucosal MC infiltration.[121] However, their major defensive role occurs during the secondary infection, in which worm expulsion is more rapid (by 5 days) than in the primary one (by 10 days postinfection), as revealed by Ba depletion studies that cause an impaired worm expulsion by mice, regardless of the presence or the absence of MCs.[122]

In view of the continuously emerging findings in the field, it is predictable that in the next years there will be the discovery of additional, unsuspected biologic features that granulocytes and MCs possess.

Chapter 21

The Major Histocompatibility Complex and Its Proteins

David H. Margulies

Kannan Natarajan

Jamie Rossjohn

James McCluskey

INTRODUCTION

The extended family of glycoproteins known as major histocompatibility complex (MHC) and MHC-like molecules is now recognized to comprise a class of receptors, usually expressed at the surface of somatic cells of vertebrates, which confer a wide range of functions in the regulation of the immune response. Their cumbersome moniker, MHC, derives from the early determination that the genes that encode these molecules control one of the fundamental manifestations of an immune response, skin graft rejection, but contemporary immunologists, virologists, and tumor biologists rarely think about these molecules with allogeneic (ie, genetically distinct) skin transplantation in mind. The name MHC is a general label, and specific immunologic functions or molecular structures invoked when a particular MHC is mentioned are dependent on biologic context. In recent years, our understanding of the structure, evolution, and molecular basis of MHC-based interactions has blossomed, and our ability to exploit engineered forms of these molecules has also expanded enormously. Our blueprint for this chapter is to give an overview of MHC-regulated immunologic function and then to summarize the explosive growth in understanding of the molecular structures of MHC molecules and their ligands. Of necessity, we discuss briefly some aspects of the cell biology and cellular maturation of MHC molecules but leave the detailed description of these essential aspects of the classic MHC molecules to the chapter on antigen presentation. Basic aspects of the genetics of MHC molecules not only descriptions of the genetic loci that encode them but also discussion of what we know of the evolution of their encoding genes will be raised.

Functional glycoproteins are molecular machines and their cellular and immunologic activities depend on the shape of these macromolecules, their surface charge and ability to interact with solvent, as well as the flexibility and relationship of their structured domains and unstructured regions. To understand molecules of the MHC in a rational functional context, we consider it crucial to describe their overall structures as well as their structural interactions with bound ligands and their binding to their cognate receptors found on T cells and natural killer (NK) cells. Despite a large and ever increasing database of MHC and MHC-like structures, a number of general questions remain unanswered. We will present some of the unsolved mysteries of the evolution and function of the MHC-like molecules and their viral homologs.

The importance of MHC molecules is underscored by two general characteristics: the enormous degree of polymorphism of genes of the *Mhc* and the identification of a large number of human diseases that are profoundly influenced by either defects of MHC expression or by polymorphic variants. Every student of immunology must be acquainted with the basic biology of MHC-encoded molecules, and the student's comprehension of the regulation of the immune response, encompassing the inflammatory, NK, T-cell, and B-cell responses, will be lacking unless the function and ongoing evolution of the MHC is understood.

We stress that the evolution of the MHC is *ongoing* because for no other set of genetic markers is there such a large database cataloguing genetic polymorphism; as a result, it is apparent that not only are new alleles being identified, but that many of these new alleles have arisen recently. Dramatic examples of the ongoing evolution of MHC molecules are seen not only in new variants of the deoxyribonucleic acid (DNA) sequences observed by those that perform the necessary typing of *Mhc* genotypes for transplantation but also in surveys of the sequences of viruses, particularly the cytomegaloviruses (CMVs), which

appear to have purloined host *Mhc* genes for immunoevasion. In sequence gazing, we observe the interplay between host and pathogen, as the pathogenic viruses, exploiting their rapid generation times, develop new variations on the MHC theme for distinct purposes.

The prototypes of MHC molecules are the MHC class I (MHC-I) and class II (MHC-II) molecules, obligate cellsurface heterodimers that bind and display self- or foreign peptides at the cell surface so that T-cell receptors (TCRs) or NK cell receptors can interact with the molecular complexes in an MHC- and peptide-dependent manner.

MHC molecules are crucial for both TCR- and NK- mediated interactions. Our efforts will be to preserve some sense of the historical development of this exciting field of study and also to focus on paradigmatic genetic, structural, and functional features that unify this extensive gene/protein family. Finally, the *Mhc* provides a genetic link from immune responsiveness to autoimmune disease—those well-known strong associations of particular *Mhc* genes to particular human diseases—and we will provide an outline of the molecular basis for such associations.

Mhc Nomenclature—Dialects of Mhc

The names of the genes and proteins that are critical to understanding the *Mhc* reflect the historical discovery of their functions and differ among different species. Often confusing to students of immunology, the nomenclature of

the *Mhc* differs for different species and must deal not only with a number of distinct, but usually linked, genetic loci but also with their encoded molecules, many of which are heterodimeric glycoproteins. Because the first genes of the *Mhc* identified were those that encoded cell surface molecules that could be detected by antibodies or by transplantation responses, these are the ones that are referred to as *Mhc* genes. Now we know of more than 400 genes that map to the human or mouse *Mhc*, although technically they are all "*Mhc*" genes, the "MHC" molecules refer specifically to the MHC-I or MHC-II molecules that are related in structure and function. (Genes for several complement components and related molecules also map here and are occasionally referred to as MHC class III.) Other *Mhc*-encoded molecules with distinct structure and function are usually referred to by their specific names. Molecules that exhibit structural similarity with MHC-I molecules, whether they map to the *Mhc* or not, may be called as a group "MHC-Ib" to distinguish them from the "classical" MHC-I molecules, also referred to as "MHC-Ia." Another subset of molecules that exhibit the MHC-I fold but that are expressed by viruses may be called "MHC-Iv" molecules.[1,2]

By convention, genetic loci are indicated by designations in italics, and the encoded protein products or phenotypic descriptions are shown in a standard font. The extended genetic region is referred to as the complex; thus the general term used for all species is the *Mhc* or *MHC.* The mouse *Mhc* is referred to as *H2* (previously called *H-2)* because it was the second genetic locus involved in control of expression of erythrocyte antigens identified by Gorer.[3,4] The *Mhc* in the rat is known as *RT1*, the human locus is known as *HLA* (for human leukocyte antigen), *DLA* for the dog, *GPLA* for the guinea pig, *SLA* for the swine, and *RLA* for the rabbit. For other species, based on a suggestion by Klein,[5] the taxonomic name forms the basis for the designation, contributing the first two letters of the genus and the first two of the species to name the locus. Thus, we have *Patr* for the chimpanzee, *Pan troglodytes*; *Gogo* for the Gorilla, *Gorilla gorilla*; *Mamu* for the Rhesus macaque, *Macaca mulatta*; *Mane* for the pig-tailed macaque, *Macaca nemestrina, Mafa* for the cynomolgous monkey, *Macaca fascicularis*; and *Papa* for the Bonobo, *Pan paniscus*. A single site for curated sequences of many species of MHC molecules is the IPD-MHC Database at www.ebi.ac.uk/ipd/mhc/.[6] The most important and widely studied models are those of the human, the mouse, and the rat. For the mouse and rat *Mhc*, the search engine on the Jackson Laboratory Web site (www.informatics.jax.org/mgihome/nomen) is the most comprehensive.

The naming of new HLA genes and alleles and their quality control are governed by the World Health Organization Nomenclature Committee for Factors of the HLA System. Software conversion tools to assist in gene/protein identification are to be found at the IMGT/HLA database (www.ebi.ac.uk/imgt/hla/dictionary.html). Regular updates on HLA nomenclature featuring new alleles can be found in the journal *Tissue Antigens* and via http://hla.alleles.org/nomenclature/nomenc_updates.html. The standardization of serologically defined HLA antigens has been achieved by the exchange of typing reagents and cells in the International Histocompatibility Workshops. The *HLA Dictionary* is a summary of HLA-A,

HLA-B, HLA-C, HLA-DRB1/3/4/5, and HLA-DQB1 alleles and their association with serologically defined HLA-A, -B, -C, -DR, and -DQ antigens, respectively, available free online at the IMGT/HLA database site.[7] As defined by the Nomenclature Committee (http://hla.alleles.org/nomenclature/naming.html), each HLA allele name has a unique number corresponding to up to four sets of digits separated by colons (Table 21.1 and Fig. 21.1). The digits before the first colon describe the type, which often corresponds to the serologic antigen carried by an allotype (a genetically distinguishable form of the molecule within the same species). The next set of digits lists the subtypes, numbers being assigned in the order in which DNA sequences have been determined. Longer names are assigned only when necessary. Precise designation of human genes is by a nomenclature including a number following the locus (eg, HLA-A*01:01 and HLA-DRB1*01:01). Summaries of the hundreds of human alleles that have been identified are in Tables 21.2 and 21.3. Comprehensive databases of human *Mhc* genes are maintained at the IMGT/HLA database (see previous link)[8,9] where, at the time of this writing, more than 7000 HLA class I and class II alleles have been tabulated.

TABLE 21.1 Nomenclature of HLA Loci and Alleles

Nomenclature	Definition
HLA	The HLA region and prefix for HLA gene
HLA-DRB1	Particular HLA genetic locus
*HLA-DRB1*13*	Group of alleles encoding DR13 antigen or with sequence similarity to other DRB1*13 alleles
*HLA-DRB1*13:01*	A specific HLA allele
*HLA-DRB1*13:01:02*	An allele that differs by a synonymous mutation from DRB1*13:01:01 (ie, DNA sequence difference but no amino acid sequence difference)
*HLA-DRB1*13:01:01:02*	An allele that contains a mutation outside the coding region distinguishing it from DRB1*13:01:02
*HLA-A*24:09N*	A "null," unexpressed allele
*HLA-A*30:14L*	An allele encoding reduced or "low" cell surface expression
*HLA-A*24:02:01:02L*	An allele encoding a reduced or "low" cell surface expression, where the mutation is outside the coding region
*HLA-B*44:02:01:02S*	An allele encoding a protein that is expressed as a "secreted" molecule only
*HLA-A*32:11Q*	An allele for which a previous effect on surface expression has not been confirmed and is considered "questionable"

DNA, deoxyribonucleic acid; HLA, human leukocyte antigen.

Source: Adapted from the designations summarized by the *WHO Nomenclature Committee For Factors of the HLA System*, Stephen G.E. Marsh, http://hla.alleles.org. Also available at the IMGT website: www.ebi.ac.uk/imgt/hla/nomenclature/index.html.

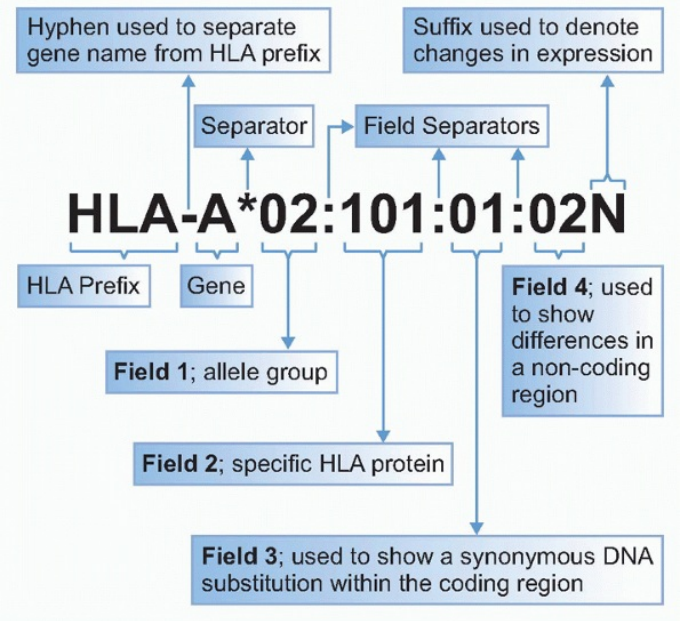

FIG. 21.1. Summary of Current HLA Gene Nomenclature. This illustration explains the nomenclature for HLA alleles as described in http://hla.alleles.org/nomenclature/naming.html.[164]

The commonly used term "haplotype" refers to the linkage of particular alleles at distinct loci that occur as a group on a parental chromosome.[10] The concept of haplotype is important in typing the *HLA* loci in the human where the linked *Mhc* genes (those genes in "linkage disequilibrium") of one chromosome of one parent will generally segregate as a group to the children. Individual haplotypes of the *Mhc* in the mouse are referred to by a lowercase letter superscript as $H2^b$, $H2^d$, or $H2^k$. Thus, the $H2^k$ haplotype refers to the full set of linked genes, *H2-K*^{k}, *H2-IA*^{k}, *H2-IE*^{k}, *H2-D*^{k}, and extends to the genes of the *Q* and *T* regions as well.[11,12] (Some haplotype designations, such as $H2^a$, refer to natural recombinants and thus have some of the linked genes from one haplotype and some from another.) A complication that demands the precise use of gene and encoded protein names is that the number of genes in a particular homologous genetic region may differ between strains or between individuals. In the mouse, although some strains have only a single gene at the *D* locus (*H2-D*^{b} for instance), other strains may have as many as five genes in homologous region (*H2-D*^{d}, *H2-D2*^{d}, *H2-D3*^{d}, *H2-D4*^{d}, and *H2-L*^{d}).[13,14]

Table 21.4 summarizes the haplotypes of common mouse strains. Included in this listing are a number of congenic inbred mouse strains, strains that contain the *Mhc* derived from one strain, and the remaining background genes from another. A regularly updated and comprehensive listing can be obtained at http://jaxmice.jax.org/literature/catalog/mhc_h2_haplotypes.pdf. An ongoing project, the "Collaborative Cross," aims to establish a panel of mouse recombinant inbred lines derived from eight diverse founder mouse strains as a resource for mammalian genetics. These lines, when their breeding is completed, will provide an opportunity for mapping a wide variety of quantitative trait loci with respect to measurable phenotypes and can be expected to play an important role in studies of immune recognition.[15]

The Immunologic Function of MHC Molecules

MHC molecules are a molecular reflection of the health status of either the cell that synthesizes them (for MHC-I molecules) or of the local environment in which the cell resides (for MHC-II). The structure of the MHC molecule depends not only on the amino acid sequence of the two polypeptide chains (α and β for MHC-II; heavy [or α] and β2m [for the light chain] for MHC-I) that form the core of the complex but also of the variable bound peptide that forms an integral part of the trimer. The MHC molecule, governed by the sequence of the encoding structural genes for the *Mhc-I* heavy chain and the *Mhc-II* α and β chains, as well as other genes involved in antigen processing and presentation, must satisfy

at least two distinct recognition functions: the binding of peptides or in some cases nonpeptidic molecules and the interaction with either T or NK cells via their respective receptors. The TCR may augment its interaction with the MHC molecule by virtue of interaction with a T cell-expressed coreceptor (cluster of differentiation [CD]8 for MHC-I and CD4 for MHC-II). Some NK receptors may also serve as coreceptors when expressed on T cells.[16] The binding of peptides by an MHC-I or MHC-II molecule is the initial selective event that permits the cell expressing the MHC molecule (the antigenpresenting cell [APC] or when this cell is to be the recipient of a cytolytic signal, the target cell) to sample fragments derived either from its own proteins (for MHC-I-restricted antigen presentation) or from those proteins ingested from the immediate extracellular environment (for the case of MHC-II). The biochemical steps involved in the production of antigen fragments from large molecules are collectively known as "antigen processing," whereas those that concern the binding of antigen fragments by MHC molecules and their display at the cell surface are known as "antigen presentation."

Specifically, MHC-I glycoproteins gather from the cell's biosynthetic pathway fragments of proteins derived from infecting viruses, intracellular parasites, or self-molecules, either expressed normally or in a dysregulated fashion as a result of tumorigenesis, and then display these molecular fragments, in complex with the mature MHC-I molecule, at the cell surface.[17,18,19,20,21] The cell-bound MHC-I/β2m/peptide complex on the APC is exposed to the extracellular milieu and is available for interaction with either T cells or NK cells. The T cell bearing an αβ receptor recognizes the particular MHC/peptide complex by virtue of a specific physical binding interaction. Each T cell is representative of a clonal population and bears a unique TCR encoded by somatically rearranged TCR genetic elements. T cells bearing αβ receptors undergo a complex selective process in the thymus. Only a small proportion of T cells that enter the thymus ultimately reach peripheral lymphoid organs, such as lymph nodes and spleen. A particular TCR can only bind a very limited selection of MHC/peptide complexes. The recognition by T cells is considered "MHC restricted" in that only a limited set of MHC molecules can bind a particular TCR and is also

termed "antigen specific" in that a particular T cell identifies a particular peptide. For any given T-cell clone, single amino acid substitutions of either the MHC or the peptide may severely diminish, obliterate, or even augment the functional interaction of the TCR with the MHC-II/peptide complex. The MHC-I system draws its spectrum of peptides from proteins in the cytosol that are degraded by the proteolytic proteasome complex to peptides that are transported from the cytosol to the endoplasmic reticulum (ER) with the aid of the intrinsic membrane peptide transporter, the transporter associated with antigen processing (TAP), are then trimmed at their amino termini[22] and are cooperatively folded as an intrinsic component of the newly synthesized MHC-I molecule.[23] Interactions with the peptide-loading complex (PLC), which includes TAP, the chaperone tapasin,[24] and Erp57,[25] are crucial to MHC-I loading. MHC-I molecules are unique among proteins in that their three-dimensional structure and thermal stability are exquisitely dependent on the heavy/light chain heterodimer being bound by an appropriate peptide.[26,27] In mutant cells that lack the necessary apparatus for generating and transporting peptides to the ER where peptide loading takes place, MHC-I molecules are expressed poorly and are inherently unstable.[28] MHC-II/peptide loading is controlled in part by the multifunctional chaperone/groove protector, Ii, as well as the important catalytic machinery of the endosomes, molecules known as HLA-DM and -DO in the human, and H2-M and H2-O in the mouse.[24] Although there remains some controversy as

to the precise site of interaction of HLA-DM with HLA-DR, evidence supports the view that this interaction catalyzes peptide interchange, leading to the selection of high-affinity antigenic peptides.[29]

[a]This summarizes HLA alleles as of January, 2012, as described by Robinson et al.8,9 and available at http://www.imgt.org or at www.ncbi.nlm.nih.gov/projects/gv/mhc/main.fcgi?cmd-init. HLA-Bw4 alleles are generally agreed to include B5, B5102, B5103, B13, B17, B27, B37, B38(16), B44(12), B47, B49(21), B51(5), B52(5), B53, B57(17), B58(17), B59, B63(15), B77(15), and A9, A23(9), A24(9), A2403, A25(10), A32(19) (http://hla.alleles.org/antigens/bw46.html). Similarly, HLA-Bw6 alleles include B7, B703, B8, B14, B18, B22, B2708, B35, B39(16), B3901, B3902, B40, B4005, B41, B42, B45(12), B46, B48, B50(21), B54(22), B55(22), B56(22), B60(40), B61(40), B62(15), B64(14), B65(14), B67, B70, B71(70), B72(70), B73, B75(15), B76(15), B78, B81, and B82.

HLA, human leukocyte antigen.

[a]This table is based on a listing of alleles maintained by the World Health Organization Nomenclature Committee for Factors of the HLA System, as of January 2012. All new and confirmatory sequences are generally submitted directly to the committee via the IMGT/HLA database using the sequence submission tool provided. The IMGT/HLA database may be accessed at www.ebi.ac.uk/imgt/hla. Serologic assignment of HLA-DR molecules is largely determined by the DRB1 gene product, whereas assignment of DQ molecules reflects serologic contributions from both DQA1 and DQB1 gene products.

HLA, human leukocyte antigen.

*Adapted from Kruisbeek561 and www.imgt.org/IMGTrepertoireMHC/Polymorphism/haplotypes/mouse/MHC/Mu_haplotypes.html#polymorphism. A dash indicates abnormal gene expression, although precise mechanism may differ in different strain. Blanks indicate insufficient data for characterization. Additional strains may be identified at http://jaxmice.jax.org/findmice/index.html.

NOD, nonobese diabetic.

MHC-II molecules, in contrast to MHC-I, are expressed on a more limited set of somatic cells —B cells, macrophages, dendritic cells, activated but not resting T cells in the human—and have a somewhat more specific function in peptide selection and presentation. In general, they bind peptides derived from the degradation of proteins ingested by the APC, and they sort their MHC-II molecules into cellular compartments where the degraded peptides are generated and catalytically transferred to the binding site of the MHC-II. The MHC-II antigen-presentation pathway is based on the initial assembly of the MHC-II αβ heterodimer with a dual function molecule, the invariant chain (Ii),

which serves as both a chaperone to direct the αβ heterodimer to an endosomal, acidic, protein processing location where it encounters antigenic peptides and also serves to protect the antigen-binding site of the MHC-II molecule so that it preferentially will be loaded with antigenic peptides in this location.[30,31,32,33] The loading of the MHC-II molecule with antigenic peptide, a process dependent on the release of the Ii derived "CLIP" peptide, in part dependent on the MHC-II-like molecule, HLA-DM in the human,[34,35] H2-M in the mouse,[36] then leads to the cell surface expression of MHC-II/peptide complexes. The MHC-II-recognizing T cells then secrete cytokines and may also be induced to proliferate or to undergo programmed cell death. Such MHC-restricted cytokine production that facilitates and augments the recruitment of additional inflammatory cells as well as APCs and antibody-producing cells is a contemporary explanation for what was historically referred to as "T-cell help." Under some physiologic circumstances, particularly during viral infection, antigens incorporated into antigen-presenting dendritic cells via an "outside in" pathway may alternatively enter the MHC-I presentation pathway. This phenomenon is known as "cross-presentation."[37,38]

MHC molecules perform a crucial role in the thymus by shaping the TCR repertoire as T-cell precursors mature into cells that eventually emigrate from the thymus and populate the spleen and other secondary lymphoid organs. In a complex, multistep process termed "thymic education,"[39] developing T cells expressing randomly rearranged TCR αβ receptors are first subjected to positive selection on MHC-I and MHC-II molecules expressed by cells of the thymic cortex in order to select for further maturation of only those cells capable of recognizing peptides in the context of self-MHC molecules. Positive selection may be viewed as setting the minimum threshold for T-cell activation. T cells surviving positive selection then migrate to the thymic medulla where those T cells with higher-than-average affinity for self-MHC-II/peptide complexes, and which therefore pose the threat of autoimmune disease should they be allowed to emigrate to secondary lymphoid organs, are deleted by negative selection. MHC-I and MHC-II molecules thus play a critical role in shaping the peripheral TCR repertoire. Indeed, mice engineered to lack MHC-I or MHC-II expression are also deficient in T cells.[36,40]

Distinct from the recognition of MHC molecules by TCRs, a number of NK-cell receptors, both activating and inhibitory, bind MHC-I molecules, and several NK receptors interact with MHC-I-like molecules encoded by CMVs.[2,41] In general, the NK/MHC-I interaction, as compared to the TCR/MHC interaction, shows considerably less peptide specificity, although the interaction is peptide dependent, and in some cases may exhibit clear-cut peptide

preferences.[42,43,44] The functional purpose of the MHC-I or MHC-I-like molecule in NK-cell recognition appears to be more subtle than that in T-cell recognition. The NK cell is tuned to a balance of inhibitory and activating signals conveyed to it via MHC interaction. In its resting state, the inhibitory signals predominate. MHC-I is a sensor of the biosynthetic and metabolic state of the cell in which it is synthesized. When the level of MHC-I is dysregulated by tumorigenesis or viral infection, this change can be detected by the NK cell. This ability of the NK cell to sense altered levels of MHC-I on target cells is the basis of the "missing self hypothesis," which explains that NK cells detect and lyse those cells defective in MHC-I expression due to the loss of the inhibitory signal that results from engagement of NK receptors by MHC-I.[45,46,47] The prototype NK receptor in the mouse is the NK inhibitory receptor, Ly49A, a C-type lectin-like molecule that signals its interaction with a normally expressed MHC-I molecule, such as H2-D^d.[48] Distinct clones of NK cells differ in the combinatorial expression of different NK receptors that have different MHC preferences. Thus, in the mouse, each distinct NK clone may express a different combination of NK inhibitory receptors such as Ly49A, Ly49C, Ly49G2, and Ly49I.[49] Because each inhibitory molecule may exhibit slight differences in its MHC-I and/or peptide preference and specificity, this kind of combinatorial expression of NK activity offers a breadth of specificity toward different potential target cells. Recently, it has been shown that developing NK cells within the thymus are also subject to an education process, known as "licensing," which prevents improper activation of their cytolytic function in peripheral tissues.[50,51,52] NK cells that develop in MHC-I-deficient humans and mice fail to kill target cells that lack MHC-I expression. Such targets are readily killed by NK cells that develop in MHC-I-sufficient thymi. Human NK cells seem to go through a similar selective/educating process, but the relevant NK receptors on human cells are generally of the killer cell immunoreceptor (KIR) inhibitory receptor family.[53]

In addition to showing preference for distinct pathways of antigen presentation, the MHC-I and MHC-II molecules also show preferential restriction to T cells of the CD8- or CD4-bearing lineages. This results from the interaction of CD8 with the nonpolymorphic α3 domain of MHC-I molecules,[54,55,56,57,58] whereas CD4 binds to membrane proximal domains of MHC-II.[59,60,61,62,63,64] The CD8 and CD4 molecules serve as "coreceptors" on the surface of T lymphocytes, providing both adhesion (increase in avidity) and specific activating signals, mediated through the kinase, lck, which modulate the avidity of the T cell in a time-dependent manner.[65,66,67,68] Additional complexities arise from the interaction of CD8 with MHC-I. CD8 is expressed as either the CD8αα homodimer or the CD8αβ heterodimer, which are expressed in a developmentally regulated fashion and seem to have distinct functions.[69] The numerous interactions of MHC molecules with other cellular components as well as with the wide variety of peptides and of various immunologic receptors reflect the robust potential of the MHC structure as a molecular sensor and as a master regulator of immune responses. These molecular interactions then read out in different cell trafficking and signaling functions.

THE MAJOR HISTOCOMPATIBILITY COMPLEX

Mhc Genetics

The *Mhc* is an extended region of the genome that spans some 4 million basepairs (Mb) on the short arm of human chromosome 6 in the region 6p21.3. The *Mhc* in the human may be considered to map from HLA-F to the gene encoding the MHC chaperone tapasin (TAP binding protein), a distance of some 2 Mb, but the "extended" human

Mhc (also known as the xMHC) covers some 7.6 Mb from the HIST1H2AA locus to SYNGAP1.[70,71,72] In the mouse, the *Mhc* encompasses almost 3.5 Mb on chromosome 17, extending from the *H2-Ke1* gene at basepair position 34056423 to the *H2-M2* gene at basepair position 37620474 (www.imgt.org/IMGTrepertoireMHC/LocusGenes/index.php?repertoire=listIG_TR&species=mouse&group=MHC). Although *Mhc* genes were among the first to be mapped here, it is now clear that a large number of genes with function unrelated to immune recognition also reside in this region. The interested reader is referred to the regularly updated maps and linkages available at various Web sites including www.ebi.ac.uk/imgt/hla, and the MHC haplotype project at www.sanger.ac.uk/HGP/Chr6/.

A schematic of the human *Mhc* is shown in Figure 21.2. For a rough guide, we also provide a

simple illustrative map comparing human, mouse, and rat *Mhc* regions (Fig. 21.3) and refer the reader to the National Center for Biotechnology Information homology Web site: www.ncbi.nlm.nih.gov/projects/homology/maps/ and National Center for Biotechnology Information Web viewer for access to detailed maps and sequences.

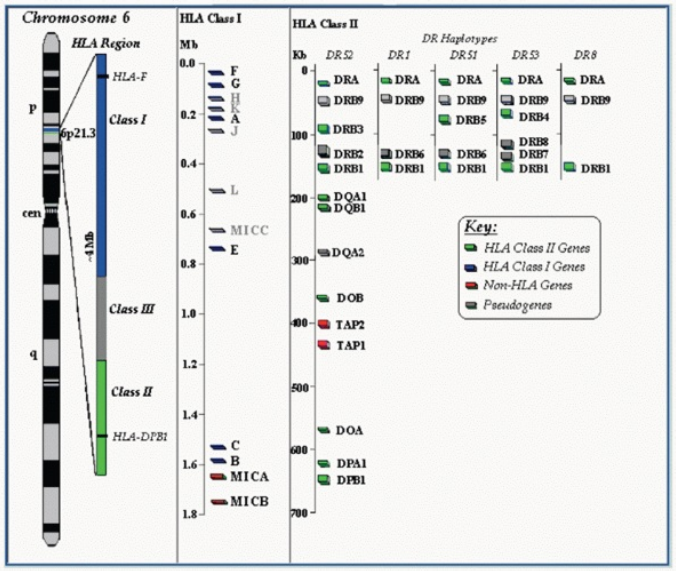

FIG. 21.2. Map of the Human MHC (HLA Region) on the Short Arm of Chromosome 6. A variety of online tools for seeking and manipulating MHC sequences can be found at www.ncbi.nlm.nih.gov/gv/mhc/main.cgi?cmd=init.

The human *Mhc* map reveals clusters of genes grouped roughly into an Mhc-II region covering about 1000 kb, an Mhc-III of about 1000 kb, and an *Mhc* class I region spanning 2000 kb (see Fig. 21.2). *HLA-DP* genes (*DPA* encoding the α chain and *DPB* encoding the β chain) are proximal to the centromere on the short arm of the chromosome and are linked to the genes encoding the related HLA-DM molecule (*DMB* and *DMA*). Between these and the *DQ* genes lie *LMP* (for low molecular weight proteins[73,74,75,76]) and *TAP*[77,78,79,80,81] genes that encode molecules that are involved in peptide generation in the cytosol and peptide transport across the ER membrane, respectively. Low molecular weight proteins

are subunits of the catalytic proteolytic proteasome complex that regulate the specificity of cleavage of proteins, and thus modulate the repertoire of peptides available for MHC-I-restricted antigen presentation.[82,83,84,85] The *TAP* genes encode a two-chain intrinsic membrane protein that resides in the ER of all cells and functions as an adenosine triphosphate-dependent transporter that pumps peptides generated in the cytosol into the lumen of the ER.[86,87] The selective transport of cytoplasmically generated peptides by different TAP proteins in the rat demonstrates that the spectrum of MHC/peptide complexes expressed at the cell surface can be significantly altered by differences in the antigen presentation pathway,[88,89,90] although there is little evidence for this phenomenon in humans.[91] Nevertheless, TAP deficiency syndromes in humans[92,93,94,95] emphasize the importance of peptide delivery in the antigen presentation pathway for normal immune function.

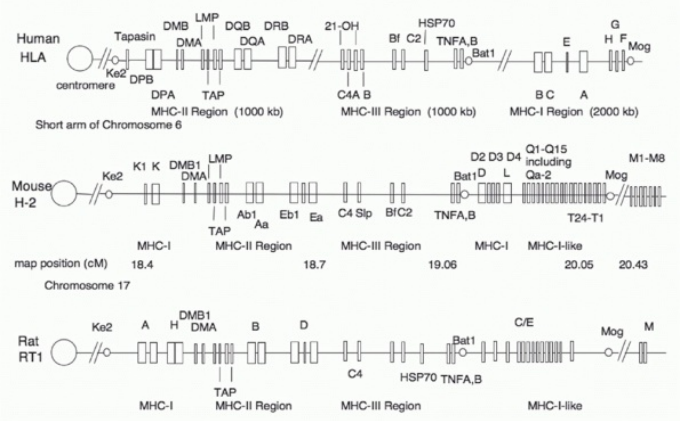

FIG. 21.3. Comparative Maps of Human, Mouse, and Rat *Mhc* Regions. This schematic map is not complete nor drawn to scale and is derived from maps available at www.ncbi.nlm.nih.gov/projects/homology/maps/.

The major *Mhc-II* genes of the human are *HLA-DRA* and *HLA-DRB* that encode the chains that form the HLA-DR molecule, a major antigen-presentation element. Genetic mapping of the human DRB region indicates that several alternative arrangements of *DRB* loci explain the varied serotypes and genotypes observed among different individuals (see Fig. 21.2). In particular, note that several HLA-DR "haplotypes," originally defined serologically as DR52, DR1, DR51, DR53, and DR8, differ not only in particular allelic genes at the *DR* locus but also in the number and precise location of several of the *DRB* genes and pseudogenes. The *Mhc-III* region is important in immunologic terms for several reasons—the structural genes for several complement components map here, as well as the structural genes for 21-hydroxylase (CYP21A2),[96,97] an enzyme critical in the biosynthesis of glucocorticoids, a deficiency of which can lead to the genetic disease congenital adrenal hyperplasia. Also located in the *Mhc-III* region are the structural genes for tumor necrosis factor (TNF) A (also known as lymphotoxin α) and B, which are cytokines made by activated T cells.[98,99,100]

The more distal region of the *Mhc* encodes other MHC molecules. In humans, the cluster of the major *Mhc-I* genes lies here, spanning two Mb, including the genes encoding HLA-B, HLA-C, HLA-E, and HLA-A, as well as HLA-H, HLA-G, and HLA-F. HLA-A, HLA-B, and HLA-C are the major MHC-I molecules of man. (A summary of these is in Table 21.2.) Serologic identification of HLA-C molecules has been difficult and imprecise. However, HLA-C molecules interact directly with NK receptors of the KIR2D family. Direct binding studies have analyzed the kinetics of the interaction of the KIR2 immunoglobulin (Ig)-like NK receptors,[101,102,103] and three-dimensional structures of KIR2DL2 in complex with HLA-Cw3 and KIR2DL1 complexed with HLA-Cw4 have been published.[104,105] Recently, the structure of a KIR3DL1 molecule in complex with HLA-B*57:01 emphasizes the unique nature of different KIR/MHC interactions.[106] The precise functions of HLA-E, HLA-F, and HLA-G are not yet clear. HLA-E and its murine analog Qa-1 bind hydrophobic leader peptides derived from some MHC-I

molecules, forming a complex recognized by the C-type lectin-like NK receptor CD94/NKG2.[107,108,109,110,111] This implies an important function for HLA-E because these molecules are expressed on placental trophoblast cells and would be expected to bind the inhibitory NK receptor, CD94/NKG2A, preventing NK-mediated rejection of the fetus.[112] HLA-E may serve as a recognition element for some T cells as well, so it also seems capable of a classical role.[113,114] Additional evidence now supports an antigen presentation function of HLA-F and HLA-G,[115,116] and the tissue restricted expression of HLA-G as well as the observation that a soluble form leads to apoptosis of CD8+ T cells suggest that this molecule may be involved in the mother's immunologic tolerance of the fetus.[117] *HLA-H* is a pseudogene mapping to this region.[118] This should not be confused with the more distantly related *HLA-HFE*, an *Mhc-Ib* gene erroneously called *HLA-H* by some authors,[118,119] which controls hereditary hemochromatosis by virtue of the interaction of its encoded protein with

the transferrin receptor.[120,121,122,123,124,125] The observations that extravillous trophoblast cells express an unusual combination of HLA-C, HLA-E, and HLA-G molecules; that uterine NK cells express NK inhibitory receptor (KIR) molecules known to interact with HLA-C allelic products; and that complex genotypes predispose to preeclampsia raise the possibility that important aspects of fetal rejection and clinical infertility may be related to MHC recognition by NK cells in the placenta.[126]

Comparison of the mouse, rat, and human *Mhc* maps (Fig. 21.3) reveals several interesting differences.[5,127,128,129] The *Mhc* genes proximal to the centromere of the mouse and rat belong to the *Mhc-I* family, rather than to the *Mhc-II* family, as they do in the human. This mapping has suggested that an intrachromosomal recombination event that occurred in some common rodent ancestor relocated some of the *Mhc-I* genes from a more distal location to the proximal site.[130] Inspection of the current human, mouse, and rat maps clearly indicates similarities in the relative locations and organization of *Mhc-II*, *Mhc-III*, and the distal *Mhc-I* genes.[128] Various genetic expansions and contractions[131] are obvious as well. In particular, the mouse *Q* and *T* regions have expanded the pool of *Mhc-I* genes, which are relatively few in the human and the rat. Early studies of congenic mouse strains mapped multiple genes to the *Q* and *T* regions,[132,133,134] and recent evidence suggests significant differences in the number of genes of this region in different strains. The mouse has some *MHC-Ib* genes that seem to be relatively unique in function. In particular, the *H2-M3* gene, which maps distal to the *Q* and *T* regions, encodes a protein that exhibits a preference for binding peptides that have N-formyl amino terminal modifications. This antigen presentation function may be geared to bacterial, protozoal, and mitochondrial antigens.[135,136,137] Rat homologues of the mouse *H2-M3* and *H2-M2* genes have also been identified.[138,139]

Mhc Polymorphism

The *Mhc's* function in immune responsiveness is also reflected in its genetic polymorphism. Polymorphism is the presence at any given time of a larger than expected number of genetic variants in a population. As populations change and evolve, we expect that genetic variants should arise but because of the selection exerted on most gene products, relatively few of these genetic variants will persist. A genetic locus that exhibits variant alleles at a frequency of more than 1% is considered "polymorphic."[5] A genetic locus that is relatively invariant is often referred to as "monomorphic," even if more than one allele is known. *HLA* genes exhibit a high degree of polymorphism; a number of different mechanisms may contribute to the generation and maintenance of polymorphism. Among these are the selective advantage of a heterozygous pool of antigen-presenting elements in a given individual that might allow the binding and presentation of antigenic peptides derived from a wide variety of environmental pathogens. Limited polymorphism would make the entire population susceptible to a chance infectious agent for which all individuals would be unable to respond, whereas widespread polymorphism would be expected to allow the APCs of at least a proportion of the population to effectively bind and present antigens derived from invading pathogens.[140] Although such a view was originally based on HLA molecules as presenting elements for pathogen-derived peptide fragments to T cells and their antigen-specific TCRs, studies suggest an additional role for *Mhc-I*-related resistance to viral infection via NK cell-mediated recognition[141,142] and altered antigen presentation pathway.[143] Additionally, the presence of a high degree of polymorphism also implies that there is little or no selective disadvantage to the expression of new variant MHC molecules.

The human *Mhc-I* and *Mhc-II* genes are clearly polymorphic, with more than 5000 alleles at the *Mhc-I* loci and some 2000 alleles at the *Mhc-II* loci known (see Tables 21.2 and 21.3) (www.ebi.ac.uk/imgt/hla/index.html).[8,9] In experimental animals, it is more difficult to demonstrate polymorphism in terms of population genetics, although typing of wild mice has confirmed the existence of natural polymorphism predicted from the analysis of inbred strains and their mutants.[144,145] The polymorphism of *Mhc-I* and *Mhc-II* genes, so evident in man and mouse, has also been documented in analyses of cichlid fishes—animals that diverged from the line leading to mammals at least several hundred million years ago.[146,147,148,149]

Genetic Mechanisms for Mhc Evolution

As both an extended genetic region and a group of genes with many belonging to the Ig supergene family,[150,151] the *Mhc* has served as a prototype for elucidating mechanisms that

contribute to the evolution of a multigene family and that add to the polymorphism that is such a dominant characteristic of the classical MHC molecules.[152] The analysis of mutations in the mouse, mostly those of *Mhc-I* genes, has led to the understanding of the mechanisms that give rise to polymorphism. Both induced and spontaneous mutations affecting skin graft acceptance or rejection have been identified, and many of these have been mapped to the *Mhc.* Gross recombinational events have been documented in the *Mhc*,[153,154] as well as more subtle mutations, many of which are multiple amino acid substitutions in a relatively small part of the protein that seem to derive from nonreciprocal recombinational events. Such recombination that occurs over short sequences

is known as "gene conversion" because of its similarity to the phenomenon that occurs in yeast.[153,154,155,156,157,158,159,160,161] Convincing evidence for interlocus gene conversion has been documented in for the *Mhc-II* genes of teleost fish[162] and by deep sequencing of *Mhc-I* genes in recently founded bird populations.[163]

Some of the polymorphisms of *Mhc* genes that have been identified clearly reflect point mutations.[164] Structural studies have shown that the profound immunologic effects of mutations of the *H2* genes $H2K^{bm1}$ and $H2K^{bm8}$ result from minimal detectable changes that may affect thermostability.[165] In addition to such mouse mutants, a number of somatic cell variants and mutants, some due to major deletions or regulatory defects, others clearly point mutants of structural genes, have been described.[166]

The Mhc and Transplantation

Although the early description of the genes of the *Mhc* was based on identification of loci involved in tumor and allograft rejection, and although these genes clearly play a role in such complex phenomena, a contemporary understanding of the function of *Mhc* genes in immunology requires little understanding of the rules of transplantation. The early history of transplantation is chronicled extensively in several books[5,167] and reflects a developing interest in tumor immunology and congenic mouse strains. The mouse has served as the model system for understanding the genetic underpinnings of skin, tumor, and organ transplantation, so a brief description of some relevant principles is in order. Comprehensive manuals and reviews are available.[168] Propagation of a mouse strain by repeated matings of brothers and sisters leads to the establishment of an inbred strain, a group of animals that is genetically identical at all loci. More complete descriptions of the process by which brother-sister mating leads to homozygosity at all loci are given elsewhere.[5,167]

"Congenic" mouse strains, also known as "congenic resistant" or "CR" strains, are those derived by first crossing two inbred strains that differ in a histocompatibility phenotype such as resistance to a transplantable tumor or ability to reject a skin graft. These are then successively backcrossed to one parental strain, and the resistance phenotype is preserved. Following at least 10 backcross generations (N10), a point at which $(1/2)^9 = 0.002$ of the genes of the selected strain should be present, the new strain is propagated by brother-sister mating. Several relevant inbred and congenic mouse strains are listed in Table 21.4 along with their *H2* designations.

The early rules of transplantation were determined by observation of the ability of either transplantable tumors or allografts (usually from skin) to survive in a particular inbred mouse strain host. The graft rejection phenomenon is an extremely sensitive and specific bioassay that permits the detection of genetic differences as small as a single amino acid in an MHC protein. It has been particularly valuable in assessing spontaneous and induced mutants (see previous discussion) and remains the absolute experimental discriminator of "histocompatibility."

In addition to the *Mhc* genes, we should not overlook the genes that encode minor histocompatibility antigens. In the mouse, these were originally identified as genetic loci responsible for graft rejection after extended periods of time. More recently, several minor histocompatibility loci have been identified as those that encode polymorphic proteins that give rise to peptides presented by MHC molecules,[169,170,171,172,173] and we now can understand the complexities of transplantation tolerance in terms not only of *Mhc* genes but also in terms of numerous proteins that may give rise to variant peptides for T-cell recognition. Not only can peptides derived from polymorphic genes throughout the genome serve as minor histocompatibility antigens but also defective translation products, or peptides

resulting from transcription of introns or noncoding strands of DNA may also produce immunologically significant peptides, which, bound by self-MHC molecules may stimulate T cells.[174,175] Whether such defective, newly synthesized proteins serve as a major source of MHC-I-bound peptides remains controversial.[176] Minor antigens that are confined to hematopoietic cells can be recognized as targets by antitumor cytolytic cells and may explain the lower incidence of relapse in hematopoietic stem cell (HSC) transplant recipients who experience graft-versus-host disease (GVHD).[177]

The Mhc and Clinical Transplantation

Processed foreign antigen complexed to HLA class I or class II molecules is recognized by a specific clonally distributed TCR for antigen on the surface of T lymphocytes. The T cell bearing an αβ receptor is capable of recognizing the unitary structure of the HLA molecule itself coordinately with the exposed parts of the peptide antigen. Corecognition of HLA and peptide antigen means that TCRs are highly specific and genetically restricted to recognizing HLA molecules of the individual from which they were derived. Thus, a killer (cytotoxic) T cell raised against an influenza virus peptide in an individual expressing HLA-A2 will not recognize influenza-infected HLA-A1. This concept is known as “MHC restriction” and was described by Shevach and Rosenthal for recognition of amino acid polymers,[178] by Zinkernagel and Doherty for recognition of viral antigens,[179,180] and by Shearer et al. for recognition of altered self-ligands.[181] Given that T cells are MHC-restricted, it is difficult to understand why they should ever recognize a foreign HLA type. However, in practice they do, data indicate that such alloreactive T cells arise with remarkably high frequency. It is estimated that between 1/10 to 1/1000 activated clonally distinct T cells are capable of responding to any random allogeneic HLA molecule.[182,183,184,185] Given the number of T cells in the human lymphoid system, this represents a striking tendency for T cells that are normally restricted to recognizing self-HLA molecules complexed to foreign peptides to cross-react on allogeneic HLA molecules. This cross-reaction can arise from direct recognition of the allogeneic HLA/peptide complex, which usually depends on the peptide antigen as well as the allogeneic HLA molecule. Alternatively, allorecognition by T cells can occur indirectly.[186,187] In such cases, peptides derived from the allogeneic HLA molecules are presented as nominal antigen after processing by the host cells bearing self-HLA molecules. In the normal course of

events, T-cell alloreactivity is an in vitro curiosity, although it is still not entirely clear why the fetal “allograft” does not stimulate the maternal immune system. However, it is the clinical transplantation of organs and hematopoietic stem cells across HLA compatibility barriers that produces graft rejection or GVHD due to T-cell alloreactivity. Fully allogeneic transplants theoretically expose the recipient immune system to up to 12 non-self-HLA allele products expressed by the allograft. Moreover, the “self-peptides” constitutively presented by allogeneic HLA molecules are likely to be quite distinct from those presented by syngeneic HLA molecules because the polymorphisms of the peptide antigen-binding cleft of the MHC-I molecule that distinguish HLA alleles alter the spectrum of selected peptides. In the presence of appropriate costimuli, allogeneic HLA/peptide complexes probably stimulate powerful T-cell responses because of the high density of unusual determinants and the diversity of new peptide ligands presented by the allogeneic HLA/peptide complexes. Because there are many MHC-linked genes encoding a host of proteins, many lacking known immunologic function, it is likely that polymorphisms in these molecules contribute significantly to the alloresponse (see previous discussion of *Mhc* genetic maps and *Mhc* alleles). Accordingly, many studies have demonstrated an incremental improvement in long-term graft survival with progressively higher levels of HLA matching at HLA-A, -B, and -DR loci. For this reason, HLA matching is essential in allogeneic HSC transplantation and highly desirable in solid-organ transplantation. The degree of HLA matching usually required for renal transplantation is shown in Figure 21.4 and for bone marrow transplantation in Table 21.5. Survival of HSC transplants varies according to the nature of the disease, disease stage, and age of the patient but can be >70% in some cases (see Centre for International Blood and Marrow Transplant Research at www.cibmtr.org/pages/index.aspx). The effect of HLA matching on solid-organ transplantation has been monitored by the Collaborative Transplant Study since 1982 (www.ctstransplant.org/).

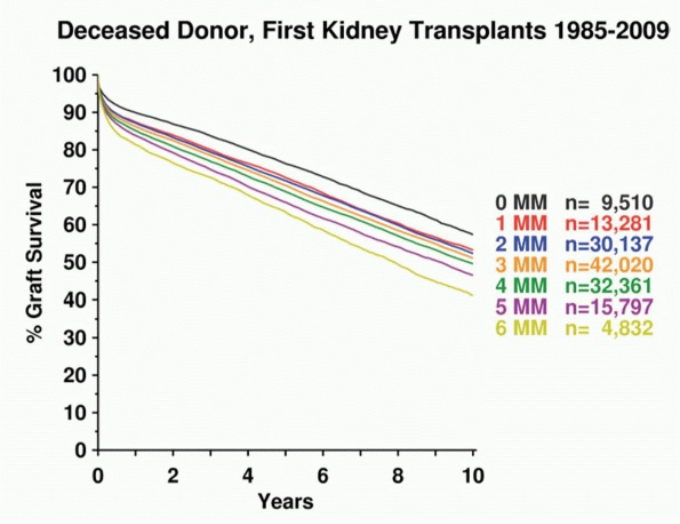

FIG. 21.4. Effect of HLA Matching on First Deceased Donor Kidnery Graft Survival. Survival of first kidney transplants based on number of HLA-A, -B, and -C mismatches as a function of time. In addition to the allogeneic cellular response, the antibody response to HLA molecules and ABO blood groups can also cause rejection of certain grafts, especially where these antibodies are preformed and, therefore, present at the time of organ transplantation.

Antibodies to ABO blood-group antigens react with these determinants on vascular endothelium, and, therefore, ABO-incompatible solid organs can be rapidly rejected by humoral mechanisms. In patients who have been transfused or previously transplanted, or in multiparous females, exposure to allogeneic HLA molecules can also result in the production of anti-HLA class I antibodies. These preformed antibodies can lead to acute and hyperacute rejection of grafts expressing the particular HLA molecules recognized by these antibodies. Renal graft survival improves with fewer HLA mismatches. In Figure 21.4, cumulative data for graft survival are plotted as a function of time. Curves represent those groups with the indicated number of mismatches. Therefore, for solid-organ transplants, individuals are not only matched as closely as possible for their HLA types to avert cellular rejection but, it is also necessary to ensure ABO compatibility and to exclude preformed antidonor HLA antibodies in the host. Paradoxically, some patients who have received multiple blood transfusions prior to transplantation appear to develop some form of T-cell tolerance to allogeneic donor HLA alleles; renal graft survival is actually enhanced in these individuals. This is known as the "transfusion effect," and in some centers, pretransplant transfusion and even donor-specific transfusions are routinely carried out.

Transfusion of potential renal transplant recipients carries the risk, however, of inducing undesirable anti-HLA

antibodies in the patient. Testing for anti-HLA antibodies is known as the "crossmatch." In practice, many laboratories crossmatch only for anti-HLA class I antibodies. Crossmatch compatibility to exclude anti-HLA class I antibodies is essential in renal transplantation and is widely practiced in heart/lung transplantation. Crossmatching for liver transplantation is practiced at only some centers, and the evidence that a positive crossmatch predicts allogeneic liver graft rejection has not convinced everyone of its importance in routine matching. Patients awaiting renal transplantation are usually monitored regularly for anti-HLA class I antibodies because the level and specificity of these antibodies can change with time. This monitoring involves regular crossmatching of patient serum against a panel of randomly selected cells bearing different HLA types. The percentage of positively reacting cells is known as the "panel reactivity." When carrying out a crossmatch between a patient's serum and donor cells, many centers test the current as well as "historical peak" serum from the patient. The historical peak is defined as the patient serum sample giving the highest panel reactivity throughout the monitoring period and is thought to be a reflection of previous HLA sensitization. Most centers now prescreen patients on transplant waiting lists for anti-HLA antibodies using MHC-coated beads as a source of antigen and a highly sensitive flow cytometry technology for their detection. In highly sensitized patients with multiple host antidonor antibodies, these unwanted antibodies can sometimes be functionally eliminated using B-cell ablation therapies (anti-CD20 monoclonal antibodies), plasmapharesis, and intravenous gammaglobulin infusions, thus allowing successful transplantation. Similar approaches, coupled with plasmapharesis, are now taken with increasing frequency in transplanting kidneys across the ABO barrier. The role of antibody crossmatching in allogeneic HSC transplantation is less clear, and many centers do not take the class I or class II crossmatch into account when identifying a bone marrow transplant donor. On the other hand, some large centers place considerable importance on a positive crossmatch as a predictor of bone marrow rejection, and it is therefore advisable to crossmatch bone marrow donor-recipient pairs when there is a high risk of rejection (eg, aplastic anemia). Crossmatching is also used to detect anti-HLA antibodies that may cause refractoriness to platelet transfusion with random platelets.

Family Studies in Histocompatibility Testing

The linkage of HLA loci on chromosome 6 means that individuals will usually inherit a set of nonrecombined HLA alleles encoded at linked HLA loci from each parent. This set of genes (the haplotype) is often identifiable in family studies, where all the alleles present on one chromosome cosegregate. In identifying donors for HSC transplantation, testing of family members is essential to determine haplotypes accurately.[188,189] This is because sharing of HLA antigens from different haplotypes is quite common in families, so mismatches within HLA subtypes (ie, allele-level mismatches) are easily overlooked as a result of mistaken haploidentity of siblings or other family members. Because unrecognized HLA mismatching is poorly tolerated in HSC transplantation, high-resolution sequence-based DNA matching (or its equivalent) is required to avoid GVHD.[190,191,192] The impact of HLA on the outcome of HSC transplants has been studied in unrelated donor-recipient pairs by several groups,[193,194] and guidelines for matching have been published by the U.S. National

Marrow Donor Panel.[195] These data show that unrelated matched transplants can be as effective as sibling matched donor-recipient transplants in donor survival. Mismatching beyond a single, or at most two, HLA loci is associated with increased GVHD and inversely with a lower rate of leukemic relapse. Although allogeneic HSC transplantation can be carried out across single-locus mismatches, there is little correlation with the magnitude of a given mismatch (ie, number of polymorphisms between alleles) and the subsequent immune response. Donor-recipient MHC differences of just a single amino acid can provoke strong alloresponses comparable to reactions between vastly different MHC products.[191] An example of haplotyping in a family study is shown in Figure 21.5. Matching for HLA-DP in allogeneic stem cell transplantation appears to improve graft success in both stem cell and renal transplantation,[196,197] but testing for this locus is not routinely carried out clinically for renal transplants and only for HSC when several donors are available and a rational choice of the best donor has to be made.[198,199] HLA-C matching is also important for chronic myeloid leukemia.[200] Typically, an HLA typing laboratory will test for HLA-A, -B, -DRB1, -DRB3, -DRB4, -DRB5, and -DQ loci for HSC transplant matching.[198] Many centers will also insist on HLA-C testing. In the family study shown in Figure 21.5, the mother and father are mismatched at both haplotypes. Among the children, John and Andrew are haploidentical (and therefore phenotypically identical). Jane and Jim share a single haplotype, as do Tom and Jim. Jane's paternal haplotype is a recombinant involving a crossover event between HLA-A and HLA-B. Recombination is observed between HLA-A/B and HLA-B and HLA-DR in about 1% of meiotic events. The implications of this family study are that Andrew and John would be ideal bone marrow donors for each other. However, none of the other siblings would be suitable as a donor for these brothers. Even though there is sharing of a single haplotype between Tom and both Andrew and John, the complete mismatch in the second haplotype would make Tom unsuitable as a donor for HSC transplantation, which requires very close matching of HLA. On the other hand, haplotype mismatching is common in renal transplantation, in which perfect HLA matching is not absolutely required or routinely achievable. However, for renal and other solid organ transplantation, ABO blood group compatibility is usually essential because these determinants are expressed on vascular endothelium where recognition by isohemagglutinins leads to rapid intravascular coagulation and organ failure. When a matched sibling donor does not exist for a patient requiring allogeneic HSC transplantation (70% of cases), searching of the extended family or unrelated bone marrow registries is indicated. The National Marrow Donor

Panel (www.marrow.org) has several million potential donors suitable for unrelated stem cell transplantation; these donors are used in the United States and worldwide. Bone marrow donor registries also exist in Europe, Australia, Hong Kong, and Japan; these registries often provide donors for patients in other parts of the world. Mobilization of stem cells in the blood following administration of hematopoietic growth factors is now widely used to avoid the need for marrow collections from donors.

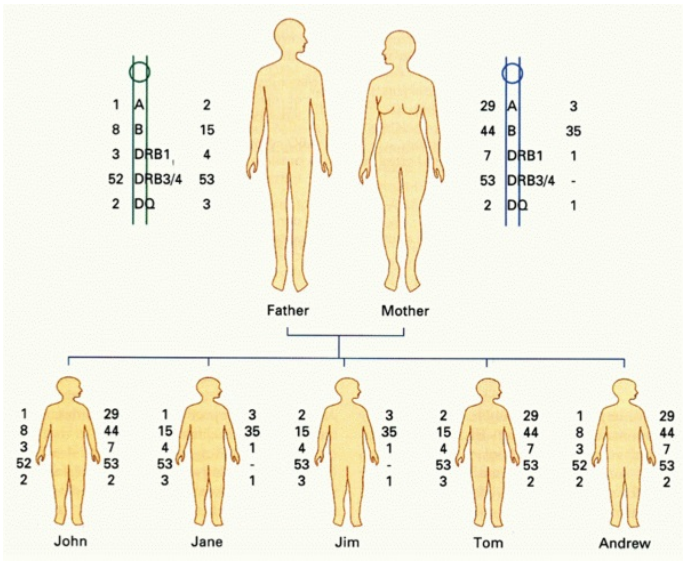

FIG. 21.5. Segregation of Haplotypes in a Family. From McCluskey,[558] with permission.

In the last decade, many HSC transplant protocols have sought to reduce the pretransplant conditioning of patients. There have also been controversial reports indicating dramatic outcomes of HSC transplantation where deliberate KIR-ligand mismatching leads to donor-versus-recipient NK-cell alloreactivity toward cells of hematopoietic origin.[201,202,203,204] The Velardi group in Perugia has championed this approach providing evidence that in the absence of GVHD, a high frequency of donor NK cells in KIR-ligand mismatched transplants can remove recipient's target cells.[202] In particular, HLA haplotype-mismatched hematopoietic transplants can be beneficial in adult acute myeloid leukemia and childhood acute lymphoblastic leukemia leading to the development of adoptive NK-cell transfers as an experimental therapy for graft-versus-leukemia treatment.[205] However, these transplants must be rigorously T-cell depleted, and variable results appear to reflect different transplant protocols, disease parameters, and KIR-mismatching assignment.[203,204,206]

Cord blood banks have also been established around the world. However, cord blood donation of stem cells is often unsuitable for adult transplantation because of limitations in the volume of cord blood collections providing inadequate numbers of stem cells. Many centers will combine different cord bloods that are matched with the recipient as much as feasible to increase the stem cell number. Cord bloods offer the advantage of finding donors faster than adult unrelated registries[197] and theoretically providing banked stem cells from ethnic minority groups that are not well represented in bone marrow donor registries.[198] Cord blood transplants induce less GVHD than bone marrow or peripheral blood stem cell transplants, but posttransplant engraftment is

slower.[196,207] Cord transplants may also tolerate greater levels of HLA mismatching than unrelated bone marrow transplant, but this is dependent on the transfer of sufficient CD34+ stem cells.[208] The results of transplants using bone marrow or peripheral blood stem cells are now considered comparable clinically,[207] but the impact of HLA matching in patients transplanted at early stage in their disease appears to be more marked. Functional tests of HLA compatibility testing for HLA identity at all HLA loci is a daunting task for most laboratories because of the very large number of alleles present in the population. Moreover, in renal transplantation, some mismatches appear to be well tolerated and are associated with long-term graft survival, whereas other mismatches of similar genetic disparity are poorly tolerated and are associated with early rejection.[209,210] Reliable methods for predicting these “taboo” mismatches are not readily available. Similarly, high-resolution HLA typing does not predict all GVHD when selecting suitable unrelated donors for HSC transplantation.[190,211] Therefore, there has been a great deal of interest in developing functional or in vitro cellular tests of overall donor-recipient compatibility. Unfortunately, none of the tests so far developed provides convincing predictability of impending graft rejection or, more importantly, GVHD.

Among the tests used historically for assessing functional compatibility are the mixed lymphocyte reactivity (MLR) test and allogeneic T-helper or cytotoxic T-lymphocyte precursor studies. The MLR or MLC (C = culture) involves measuring T-cell proliferation of host T cells in response to donor lymphocytes and vice versa. In a one-way MLR, the stimulating lymphocytes are irradiated to prevent their proliferation; in the two-way MLR, both stimulator and responder cells are allowed to proliferate. In MLR studies, it is necessary to include controls showing that responder cells can all respond and that stimulator cells can all stimulate across an appropriate barrier such as third-party donor cells. Responses can vary widely, and individual laboratories use their own cutoff values to define negative (ie, nonreactive) and positive (ie, reactive) MLR results.[211] Unfortunately, known HLA mismatches can be present in a negative MLR, and a positive MLR can be obtained between phenotypically HLA-identical transplant pairs. Because the MLR is biased toward measuring HLA class II discrepancies and is notoriously irreproducible,[211] most laboratories have abandoned this test in favor of implementation of high-resolution polymerase chain reaction-based HLA class II typing. Measurement of allogeneic cytotoxic T-lymphocyte or helper T-cell precursor frequencies is carried out at specialized bone marrow transplant centers but is not

universally accepted as being predictive of GVHD.[212,213] The test is labor intensive and requires a skilled technician for reproducibility. Precursor frequencies are estimated by limiting dilution analysis or ELISpot of donor-versus-host lymphocytes (ie, T cells expected to cause GVHD). High precursor frequencies (up to 1 in 10^4 cells) are thought to be associated with a greater risk for acute GVHD.[214] It is possible that precursor studies detect major and minor incompatibilities, and so, theoretically, they might give a broad measure of the transplant barrier, but technical improvements will be required before this test is widely adopted in clinical practice.[215]

The Mhc and Disease

In addition to the control of transplant acceptance or rejection and immune responsiveness, the *Mhc* in the human plays an important role in the etiology of a number of diseases, many of which are autoimmune in nature.[123,216,217,218] Several human diseases are associated with the *Mhc-III* genes because some of the structural genes for enzymes involved in the adrenal steroid biosynthetic pathway (ie, 21-hydroxylase, CYP21A2) map to this region. As many as 200 diseases have well-established genetic linkages to the *Mhc*,[217,219,220,221,222] the most important of which are summarized in Tables 21.6 and 21.7. Recent genome-wide association studies confirm the importance of the HLA-DRB1 locus in rheumatoid arthritis and type 1 diabetes,[71,223,224,225] and fine mapping analysis suggests that a total of five amino acid polymorphisms (three in HLA-DRB1, one in HLA-B, and one in HLA-DPB1), all located in peptide-binding grooves, almost completely explain the MHC association with the risk of rhuematoid arthritis.[226] The precise mechanisms underlying the association of most of these diseases with the particular *Mhc* haplotypes are unknown, but several models have been proposed, including the cross-reactivity of antimicrobial antibodies and the molecular mimicry of

viral antigens that might induce T-cell responses to selfantigens.[227,228,229] The very high incidence of some diseases associated with certain HLA genes assists in the diagnosis as well as the counseling of patients and their families. Several of these diseases are of particular note. Because virtually 100% of patients with narcolepsy have HLA-DQB1*06:02 (associated with HLA-DR2),[230,231] HLA typing can be used as a test of disease exclusion. Thus, a diagnosis of narcolepsy can be excluded with reasonable certainty if the patient does not have HLA-DQB1*06:02. On the other hand, the presence of HLA-DQB1*06:02 is of little predictive value in diagnosis of narcolepsy because this HLA type is relatively common in many populations and occurs frequently in the absence of disease.

TABLE 21.6 Some HLA Disease Associations

Disease	MHC-I	Strength of Association
Ankylosing spondylitis	HLA-B27	+++
Reiter disease	HLA-B27	++
Psoriasis	HLA-C*06	+
Abacavir drug hypersensitivity	HLA-B*57:01	+++
Behcet disease	HLA-B*51	+
Birdshot retinopathy	HLA-A*29	+++
	MHC-II	
Narcolepsy	HLA-DQB1*06:02	++

Insulin-dependent diabetes mellitus	HLA-DQ8	++
	HLA-DQ2	+
	HLA-DR2	-
Rheumatoid arthritis	HLA-DR4	+
Celiac disease	HLA-DQ2	+++
	HLA-DQ8	+
Multiple sclerosis	HLA-DR2	+

HLA, human leukocyte antigen; MHC, major histocompatibility complex

+++ = very strong association that is clinically useful as a diagnostic tool

++ = strong association with likely primary involvement in disease pathogenesis

+ = clear association with likely role in disease pathogenesis

- = negative or protective influence on disease probability

For a more detailed summary of MHC and disease associations see Shiina et al.220

TABLE 21.7 HLA Disease Associations and Relative Risk[a]

Disease	Antigen	Estimated or Relative Risk
Graves disease or myasthenia gravis	B*08:01 DRB1*03:01 DQA1*05:01 DQB1*02:01	4 or 2.5
Multiple sclerosis	DRB1*15:01 DQB1*06:02	4
Multiple sclerosis	DQA1*01:02	4
Psoriasis	C*06:02	5
Celiac disease	DQA1*02:01/DQB* 02:02 (DQ2.2)	1
	DQA1*05:01/DQB1* 02:01 (DQ2.5)	7
SLE	DRB1*15:01	2
Type 1 diabetes or SLE	DRB1*03:0101	4.5

[a]These examples were taken from single nucleotide polymorphism associations reported by de Bakker et al.,71 where the tag single nucleotide polymorphisms and coefficients of determination ($r2$) are also reported. For celiac disease, DQ2.2 only has an effect when in combination with DQ2.5. The relative risk of DQ2.5 changes

depending on the coordinate presence of other DQ types.

SLE, systemic lupus erythematosus.

Ankylosing spondylitis is so strongly associated with the *Mhc-I* allele HLA-B27 and the presence of some bacterial pathogens that it is a popular hypothesis that ankylosing spondylitis is due to the stimulation of particular T cells by HLA-B27-presented bacterial antigens that cross-react on self-tissues. These T cells are then thought to initiate an inflammatory cascade. Despite the strong association of HLA with spondyloarthropathy, critical evaluation of the literature brings a postinfectious etiology into question and certainly more studies are indicated.[232,233] Recent genome-wide studies strongly indicate that a genetic interaction between an enzyme involved in processing MHC-I-associated peptides, ERAP1, and HLA-B27 contributes to disease susceptibility.[234] The tendency of HLA-B27 to form disulfide-linked covalent dimers raises the question whether the resulting cellular pathology related to poor cell surface expression of this MHC-I molecule may be related to the inflammation of joints that is characteristic of this disease.[235,236]

Hereditary hemochromatosis is one of the most common genetic disorders in Caucasian populations (with a prevalence of 1/300 to 1/400). The gene controlling this condition (*HFE*) is *Mhc* linked, mapping approximately three Mb telomeric to the HLA-A locus.[122] The HFE protein is a class I-like molecule, the structure of which has been determined.[237,238] HFE assembles with β2m and is expressed in the intestinal mucosa and placenta, where it plays a role in regulating iron uptake and transport.[239,240] Mice that are homozygous for an induced defect of β2m as well as those with targeted inactivation of the HFE gene suffer from iron overload or hemochromatosis.[241,242,243,244] Mutations at loci other than β2m or HFE also lead to the same disease phenotype.[245] HFE regulates the affinity of the receptor for transferrin, resulting in an alteration of the efficiency of iron transport. The most common molecular defect associated with hereditary hemochromatosis involves a point mutation that results in a Cys282Tyr substitution in the α3 domain of this class I-like molecule.[122] This mutation accounts for >80% of patients with hereditary hemochromatosis.[246] The disruption of the disulfide bond in the α3 domain at this site prevents efficient folding of the molecule and impairs assembly with β2m, resulting in improper HFE protein expression. This leads to a failure to downregulate the affinity of the transferrin receptor for its ligand, transferrin, presumably causing increased iron uptake by cells and tissue damage as a result of iron overload. A second common HFE mutation, 187G, results in a His63Asp substitution and a very slight increase in susceptibility to developing hereditary hemochromatosis, depending on the genotype of the individual.[247] Incomplete penetrance of even the high-risk Cys282Tyr *HFE* genotypes can be partly explained by natural iron deficiency from limited dietary intake and menstrual losses in women.

As summarized in Tables 21.6 and 21.7 and discussed previously, there are a number of autoimmune diseases associated with particular alleles of HLA class II loci, especially with DR and DQ.[221] These diseases include type 1 (insulin-dependent) diabetes mellitus, rheumatoid arthritis, multiple sclerosis, systemic lupus erythematosus, thyrogastric autoimmunity, Sjögren syndrome, and many others. Rheumatoid arthritis is strongly associated with HLA-DR4 subtypes that share a common sequence motif within the DRβ chain,[248] suggesting antigen presentation of self-epitopes by these molecules. The relative risk of severe rheumatoid arthritis is increased in DR4 homozygotes and particularly in compound heterozygotes with high-risk alleles,[249,250] indicating a gene dose effect in susceptibility to autoimmune inflammation.

Although the number of different *HLA* class I and class II alleles that are associated with type 1 diabetes clearly indicates that this relatively common disease has a complex etiology, the identification of a novel *Mhc-II* haplotype in the mutant nonobese diabetic mouse,[251,252,253,254,255] and the recognition that particular TCRs can mediate disease,[256] suggest that a cross-reactive response to a common self- or environmental antigen may play an important role in the etiology of this disease as well. In human type 1 diabetes, the incidence of disease is significantly increased in Caucasians with HLA-DR3-DQ2

and DR4-DQ8 haplotypes.[257,258,259] These haplotypes impart a synergistically increased relative risk when they occur as a heterozygous combination compared to the risk of disease conferred by either haplotype alone.[258,259,260] This raises the possibility of transcomplementation of HLA-DQ gene products producing new molecules involved in antigen presentation.[261] Analysis of large cohorts of patients in genome-wide marker studies offers a promising approach to identify additional genetic factors that act synergistically with HLA allelic linkages in raising the odds of disease susceptibility.[262] Online genomic maps and correlations of associations with particular loci further augments our ability to understand the relative contributions of MHC-linked and MHC-unlinked genes in autoimmune diseases such as type 1 diabetes.

Celiac disease is an underdiagnosed inflammatory disorder affecting the small intestine[263] but resulting from a Th1 hypersensitivity to wheat gluten and related proteins present in barley and rye. Normally manifest in childhood as a failure to thrive, the disease may affect adults quite later in life leading to malabsorption and wasting.[264] Celiac disease can be subclinical, presenting with anemia, osteoporosis, or neurologic symptoms.[263] This disease is strongly associated with HLA-DQ2 and/or HLA-DQ8 (DQ3)[265] as well as with autoantibodies to the enzyme tissue transglutaminase (TG2). Deamidated gluten peptides are presented to CD4+ T cells by HLA-DQ2 or HLADQ8 molecules via macrophages, dendritic cells, and B cells.[266,267] HLA-DQ2 preferentially binds peptides that contain glutamic acid residues at P4 or P6/P7. The dominant gluten peptide is thought to have a low affinity for HLA-DQ2 but this is improved if P6 glutamine is deamidated first.[266,267] HLA-DQ2 forms a network of hydrogen bonds that bind a dominant deamidated gliadin determinant.[268] This leads to enhanced Ag presentation and T-cell recognition with intestinal inflammation in susceptible patients.[266,267,269] The protease resistance of the dominant DQ2-restricted gliadin peptides contrasts with DQ8-associated disease where the dominant gliadin peptides are protease sensitive. The HLA-DQ2-associated and HLA-DQ8-associated forms of celiac disease have their own epitope patterns of deamidation dependence leading to T-cell reactivity. The DQ2-linked peptides possess single residue deamidation at P6 as compared with the preferred deamidation at positions P1 and P9 for DQ8-associated celiac disease.[270] Deamidation of both P1 and P9 to form glutamate residues engenders peptide salt-bridges with HLA-DQ8.[271] Whereas the mechanism of immunopathology of celiac disease is well defined, the exact combination of factors that trigger celiac pathology is still mysterious.[272]

TABLE 21.8 HLA-Linked Drug Hypersensitivity Reactions

	Drug	Adverse Drug Reaction	HLA Association
MHC class I associations	Abacavir	HSS	B*57:01
	Allopurinol	SJS/TEN and HSS	B*58:01
	Carbamazepine	SJS/TEN	B*15:02
	Feprazone	Fixed drug eruption	B22
	Flucloxacillin	Hepatitis	B*57:01
	Sulfamethoxazole	Fixed drug eruptions	A30, B13, Cw6
	Sulfonamides	TEN	A29, B12, DR7

	(including sulfamethoxazole)		
	Levamisole	Agranulocytosis	B27
	Oxicam	SJS/TEN	A2, B12
	Phenytoin	SJS/TEN	B*15:02
MHC class II associations	Aspirin	Asthma	DPB1*03:01
		Urticaria	DRB1*13:02-DQB1*06:09
	Hydralazine	Systemic lupus erythematosus	DR4
	Lapatinib	Hepatotoxicity	DRB1*07:01-DQA1*02:01-DQB1*0202/0203
	NSAIDs	Anaphylactoid and cutaneous reactions	DR11
	Ximelagatran	Elevated alanine aminotransferase	DRB1*07, DQA1*02

HLA, human leukocyte antigen; HSS, allopurinol hypersensitivity syndrome; MHC, major histocompatibility complex; NSAID, nonsteroidal anti-inflammatory drug; SJS, Steven-Johnson syndrome; TEN, toxic epidermal necrolysis.

HLA and Drug Reactions

Recently, a number of adverse drug reactions (ADRs) have revealed strong associations with particular HLA types[273] (Table 21.8). The most notable HLA associations are HLA-B* 57:01 with abacavir hypersensitivity syndrome in the Caucasian population,[274,275,276] HLA-B*15:02 with carbamazepine induced Stevens-Johnson syndrome and toxic epidermal necrolysis in Asian populations,[277,278,279] and HLA-B*58:01 and allopurinol hypersensitivity syndrome and Stevens-Johnson syndrome/toxic epidermal necrolysis.[280,281,282] Odds ratios or relative risks of these associations are greater than 500, 1000, and 800, respectively. These ADRs are all associated with HLA class I allotypes, with evidence of T-cell involvement.

The kinetics of the syndromes are also consistent with T-cell-mediated drug hypersensitivity.[276,283,284,285,286] The systemic features of many HLA-linked ADRs suggest that general mechanisms might mediate these reactions. Abacavirpulsed APCs expressing HLA-B*57:01, but not closely related allotypes, stimulate CD8-positive T cells that are drug-specific.[287] It is now known that abacavir specifically binds the HLA-B*57:01 Ag-binding cleft straddling the central pockets and occupying the F-pocket which normally accommodates a tryptophan anchoring the carboxyl terminus of the peptide.[287a] Consequentially, the chemical environment of the cleft is changed which in turn alters the range of self-peptides that now bind HLA-B*57:01. Accordingly, abacavir induces a dramatic shift in the endogenous peptides selected for binding by HLA-B*57:01. This leads to a state

of “altered self” that stimulates a broad range of CD8+ T cells reactive in a GVHD-like manner, explaining the clinical manifestations of the drug hypersensitivity.[287] The mode of abacavir binding provides a basis for understanding its exquisite specificity in binding to HLA-B*57:01 and not to closely related allotypes with polymorphisms in the C, D, E, or F pockets. It will be interesting to learn whether this represents a general mechanism for HLA-linked drug reactions applicable to other small molecule drugs that might bind specifically to HLA antigen-binding clefts. HLA testing before administration of these drugs is now recommended by many physicians and the U.S. Food and Drug Administration in order to avoid life-threatening ADRs.[273,288] The very high relative risks of abacavir, carbamazepine, and allopurinol ADRs and HLA class I allotypes suggests a very high level of specificity in HLA binding, either directly or through a drug-peptide conjugate(s) that only binds the associated HLA allotype. Interestingly, such high relative risks are not commonplace in HLA allotypes and protective immunity, perhaps because it is unusual for any single determinant or HLA allotype to control protective phenotypes.

In addition to recent progress in recognizing *Mhc* associations with adverse reactions to small molecule drugs and a variety of autoimmune and immune deficiency conditions, further analysis has identified relationships of HLA-linked markers with susceptibility and prognosis in a number of infectious diseases. Among the most striking has been the recognition that delayed progression of human immunodeficiency virus (HIV) infection to acquired immunodeficiency syndrome correlates with possession of HLA alleles that express a molecule with a “HLA-Bw4 motif” (see Table 21.2) containing isoleucine at position 80 along with a gene for the NK-cell receptor KIR3DS1. This observation suggested that KIR3DS1 offered protection early in HIV infection for those patients bearing the appropriate Bw4 allele.[289] More recent observations indicate that patients with such a KIR3DS1/B*04 ile80 genotype also exhibit resistance to late opportunistic infections.[290] Other studies now show that particular *HLA-DRB* alleles as well as *MHC-I* alleles significantly influence hepatitis B and C virus susceptibility, persistence, and response to treatment.[291,292,293]

Mutations in the H2 Region

The rapid pace of improvements in deriving mouse and other models for genetic disease based on the engineering of transgenic, targeted deletion and mutation, and conditional knockout mice emphasizes the importance of understanding the valuable reservoir of *Mhc-I* and *Mhc-II* mutants originally derived by laborious methods and still available for precise studies of the role of the *Mhc* in immune responses. Mutations at the *H2* locus have been identified in animals screened by skin grafting in extensive experiments carried out over a 25-year period.[294,295] By grafting tail skin of siblings to and from each other, spontaneous or induced mutant animals that displayed either “gain,” “loss,” or “gain plus loss” transplantation phenotype were identified. Gain mutants are those that express a new transplantation antigen—thus their skin is rejected by their nonmutant siblings; loss mutants have lost a transplantation antigen—thus they recognize the skin of their siblings as foreign and reject that graft. Gain plus loss mutations give effects in both directions—they reject the skin of their siblings, and their skin is rejected by their siblings as well. In classic studies, Melvold, Kohn, and colleagues screened a large number of mouse progeny.[294,295] Homozygous inbred and F1 animals were examined, yielding a total of 25 *H2* mutations identified at *K*, *D*, *L*, and *Ab* loci, and an additional 80 mutations of non-*H2* histocompatibility genes. Although earlier studies suggested that all *H2* genes might be hypermutable, a more complete retrospective evaluation of the available data suggests that with the exception only of the *H2-K*^{b} gene, the spontaneous mutation rate for *H2* genes was comparable to that for non-*H2* genes. The characterization of these mutant animals, first based on peptide maps and amino acid sequences of the H2 proteins,[296,297,298] and later based on the nucleotide sequences of the cloned complementary DNAs or genes,[159] provided some of the basic biochemical information on which further studies of structure and function and mechanism of gene evolution were based. X-ray structure determination of the H2-K^{bm1} and H2-K^{bm8} mutant proteins suggests explanations for the differences in T-cell recognition that result from what might appear to be subtle amino acid substitutions.[165]

Control of Expression of MHC Molecules

MHC molecules, synthesized in the ER and destined for cell surface expression, are controlled at many checkpoints before their final disposition as receptors available for

interaction with either T cells or NK cells. The classical MHC-I molecules are trimers, consisting of the polymorphic H2 or HLA heavy chain, the light chain β2m, and the assembled self-peptide. Thus, the cell surface expression of the assembled trimer may be reduced by a defect in the synthesis, steady state, or assembly of any of these requisite protein/peptide chains. The first level of MHC-I expression control is transcriptional; interferon-γ-dependent regulation is particularly important.[299] For the most part, MHC-I molecules are ubiquitously expressed. Their expression is dependent on a complex regulatory process that coordinately controls the transcription of both MHC-I and β2m.[300,301] The basis of the

more limited tissue specific expression of MHC-Ib molecules is of interest because of the potential importance in the role of some of the MHC-Ib molecules in tolerance to the placenta. HLA-E and HLA-G, expressed on placenta, and HLA-F, another MHC-Ib with limited tissue specific expression, have been examined in considerable detail.[116,302,303,304,305] Another critical level of control of MHC-I expression is genetic, that is, the genes for a particular chain or key components of the PLC must be present for the trimer to be assembled and then expressed at the cell surface. A decrease in heavy chain synthesis as a result of a structural mutation in a coding (such as HLA-A*30:14L [see Table 21.1]) or in a noncoding region (such as HLA-A*24:02:01:02L) would reveal the simplest level of control. In addition, the light chain is absolutely required for cell surface expression of most MHC-I molecules. Deficiency of β2m in various tumors is a relatively common occurrence.[306,307,308] Induced β2m defective animals (*B2m*$^{o/o}$, "β2m knockouts") lack normal levels of MHC-I expression because of this requirement for cell surface expression.[309,310] In addition, polymorphism of the MHC-I heavy chain may influence the efficiency with which the molecule can interact with the PLC or with which it binds self-peptides, and thus some alleles, because of a decreased ability to be loaded with self-peptides, may not be well expressed at the surface. The rest of the MHC-I biosynthetic pathway is dependent on proper generation of cytosolic peptides by the proteasome and delivery to the ER by TAP, appropriate core glycosylation in the ER, transport through the Golgi, and arrival at the plasma membrane.[311] A number of persistent viruses have evolved mechanisms for subverting this pathway of expression.[312] The herpes simplex virus encodes a protein, infected cell peptide 47,[313,314,315] that blocks the activity of the peptide transporter TAP.[316] Cowpox virus encodes two proteins, CPXV12 and CPXV203, which contribute to the downregulation of host MHC-I, CPXV12 inhibits TAP, and CPXV203 retains MHC-I in the ER.[317,318] The human disease bare lymphocyte syndrome, type I, manifested by chronic lung disease in late childhood, results from genetic lesions in either TAP1, TAP2, or tapasin, also known as TAP-binding protein.[93,319,320,321,322,323] Several proteins encoded by the human CMV, unique short region proteins 2 and 11 (US2 and US11), cause rapid protein degradation of MHC-I molecules.[324] Murine CMV encodes an MHC-I-like protein, m152/gp40, which inhibits MHC-I expression by diverting MHC-I molecules to rapid degradation in the endosome.[325,326]

Other molecules that assist the large DNA viruses in evading either the T-cell or NK-cell immune response include human CMV UL142.[327] Murine CMV[328] encodes a number of open reading frames considered MHC-I homologues that may function to deceive NK cells into the perception of normal MHC-I expression.[2,329,330,331] The adenovirus 2 protein, E3/19K, also functions to block the transfer of folded assembled MHC-I molecules from the ER to the Golgi.[332,333,334,335]

MHC-II molecules are also susceptible to regulation at multiple steps. The clear-cut tissue dependence of MHC-II expression—MHC-II molecules are generally found on cells, which have specific antigen presentation functions such as macrophages, dendritic cells, Langerhans cells, thymic epithelial cells, and B cells, but can also be detected on activated T cells of the human and rat—suggests that transcriptional regulation plays an important role. Extensive studies of the promoter activities of *Mhc-II* genes have defined a number of specific transcriptional regulatory sequences.[336] One transcription factor, MHC class II transcriptional activator (CIITA) is clearly crucial.[300,336,337,338] The expression of CIITA is regulated in a complex fashion, possessing at least three distinct promoters that function in a cell type-specific manner.[339] MHC-II deficiency diseases categorized as bare lymphocyte syndrome, type II, result from lesions in at least four different complementation groups, implicating defects in CIITA, RFX5, RFXAP, or RFXANK, all encoding proteins regulating

MHC-II transcription.[338,340,341,342,343,344] Polymorphisms in MHC-II and the resulting differences in tissue and lineagespecific expression of MHC-II suggest a role in the control of autoimmune disease.[145,345,346,347]

A unique aspect of MHC-II regulation is the need to protect its peptide-binding site from loading with self-peptides in the ER and the requirement to traffic to an acidic endosomal compartment where antigenic peptides, the products of proteolytic digestion of exogenous proteins, can be obtained. These two functions are controlled by the type II membrane protein, invariant chain, Ii,[30,348,349,350] which forms a nine subunit complex consisting of three Ii and three αβ MHC-II heterodimers. The region of Ii that protects the MHC-II peptide-binding groove, the class II-associated invariant chain peptide (CLIP), is progressively trimmed from Ii and is ultimately released from the MHC-II by the catalytic action of HLA-DM in the endosome to allow exchange for peptides generated there. HLA-DO, another MHC-II-like molecule, regulates the repertoire of bound peptides, presumably by modulating the catalytic activity of the DM exchange reaction. The important role of Ii in regulating MHC-II expression has been emphasized by the behavior of induced mutant mice lacking normal Ii[351,352,353] that exhibit a profound defect in MHC-II function and expression.

STRUCTURE OF MHC AND MHC-LIKE MOLECULES

"There is nothing that living things do that cannot be understood from the point of view that they are made of atoms acting according to the laws of physics."

—Richard Feynman[354]

"Love hides in molecular structures, yeah, Love is the answer."

—Jim Morrison[355]

So central are *Mhc* genes and their encoded molecules to both the regulation and the effector function of the immune system that it has been apparent almost since their discovery that an understanding of their structure and structural interactions would be fundamental to a comprehension of their physiologic effects. Structural relationships of MHC molecules came first from understanding serologic differences, then from analysis of cellular immune responses, and subsequently from biochemical studies of the MHC-I and MHC-II chains. Amino acid sequence comparisons

suggested a domain structure for the MHC-I molecules, and an exon/domain correspondence was apparent with the initial identification of genomic and complementary DNA clones.[356] Shortly thereafter, a large number of sequences were determined leading to their alignment and comparison. Databases of these sequences are maintained and updated as indicated in previous sections of this chapter, and searches of standard sequence databases may find *Mhc* gene and protein sequences of numerous species. Expression of recombinant clones encoding MHC molecules in several systems: mammalian cells, insect cells, and bacteria, then permitted the accumulation and purification of molecules for functional, binding and ultimately x-ray structural studies.

A current search of the protein data bank (www.rcsb.org/pdb) for the keyword "histocompatibility" yields threedimensional coordinates of more than 500 MHC/peptide, MHC/peptide/TCR, MHC/peptide/coreceptor, and MHC/peptide/NK receptor complexes that allow an understanding of the function of these molecules in a detailed structural context.[357] However, these structures also pose a number of questions that may only be addressed by additional functional experiments in whole animals complemented by biophysical methods applied in vitro. The molecular biologic, functional, and structural studies have led to the development of the use of MHC multimers as extremely powerful tools for imaging specific T cells or NK cells. The goal of this section of this chapter is to summarize these developments with an eye toward explanation of function by structure and in hopes of revealing some of the current quandaries that continue to confound our understanding of the function of the *Mhc.*

Amino Acid Sequences—Primary Structure

Before the cloning of *Mhc* genes, the biochemical purification and amino acid sequence determination of the HLA-A2, HLA-B7, and H2-K^b MHC-I molecules[358,359] indicated that the MHC molecules had unique amino terminal "domains" and showed similarities to Igs in their membrane proximal regions. Early concerns were to identify the differences between allelic gene products as well as the differences between MHC proteins encoded at different loci.

With the cloning of complementary DNAs and genomic clones for MHC-I molecules[156,360,361,362] and shortly thereafter for MHC-II molecules,[151,363,364,365] the encoded amino acid sequences of a large number of MHC molecules of a number of species quickly became available. The comparison of gene and complementary DNA sequences gave an indication of the exon/intron organization of the genes and explained the evolution of the MHC molecules as having been derived from primordial single domain structures of a unit size of a single Ig-domain (such as the light chain β2m) that duplicated to form the basic unit of the MHC-II chain (two extracellular domains) and the MHC-I chain (three extracellular domains).[129] The canonical MHC-I molecule has a heavy chain (also known as the α chain), which is an intrinsic type I integral membrane protein with amino terminal domains called α1, α2, and α3, is embedded in the cell membrane by a hydrophobic transmembrane domain and extends into the cytoplasm of the cell with a short carboxyl-terminal tail. The light chain of the MHC-I molecule, β2m, is a single domain soluble molecule that is encoded elsewhere in the genome.

The MHC-II molecule consists of two chains embedded in the membrane as type I proteins, an α chain and a β chain. The α and β chains both consist of two major extracellular domains, α1 and α2, and β1 and β2, respectively, each linked to a transmembrane domain and cytoplasmic sequences. An initial analysis of both MHC-I and MHC-II molecules suggests that they are noncovalently assembled heterodimers consisting of four extracellular domains, the two membrane proximal domains (α3 and β2m for MHC-I and α2 and β2 for MHC-II) of each molecule are Ig-like, while the two amino terminal domains (α1 and α2 of MHC-I and α1 and β1 of MHC-II) possess what is known as the MHC-fold. The α1 domains of both MHC-I and MHC-II lack the intradomain disulfide bond characteristic of the other extracellular domains. The cytoplasmic domain of MHC-I molecules can be regulated by splicing and differential phosphorylation or other modification, and is likely to play a role in cell surface stability and cycling between the cell surface and other intracellular compartments.[366,367,368,369,370,371,372] However, analysis of directed mutants of MHC-I in some systems indicates that the cytoplasmic domain is not required for cytoskeletal association or surface recycling.[373] (The cytoplasmic domain of MHC-I molecules is the target for the Nef protein of HIV, and the Nef/MHC interaction results in MHC-I downregulation in HIV-infected cells.[374,375] The MHC-II transmembrane and cytoplasmic domains have clear effects on the level of cell surface expression, the efficiency of antigen presentation, and the rate of lateral diffusion of the molecules in the cell membrane.[376,377] Single particle tracking of MHC-II molecules indicates that such lateral diffusion is governed, at least in part, by interaction with the actin-based membrane skeleton.[378] Amino acid sequence alignments of MHC-I and MHC-II proteins, particularly of the human molecules, are available in a number of databases such as www.ebi.ac.uk/imgt/hla/ and http://www.ebi.ac.uk/ipd/mhc/.

Identification of Peptides Bound by MHC Molecules

Although initial understanding of MHC molecules indicated that they are heterodimers, a complete understanding of their structure and resulting function requires the appreciation that they are, in fact, heterotrimers, in which the third component is a short peptide ranging from eight to roughly 15 amino acids in length. This characteristic of mature MHC-I and MHC-II molecules makes them a unique class of protein molecules because an integral part of their peptide composition and resulting structure derive from a heterogeneous array of peptides delivered to the assembling molecules during their maturation. Many different lines of evidence coalesced over a short period of time to demonstrate that MHC molecules function by binding peptides. From functional experiments, MHC-II-restricted T-cell responses to protein antigens were shown to be dependent on peptide fragments.[379] The first direct evidence of MHC/peptide interactions was that purified MHC-II proteins could

bind synthetic peptides in a specific, saturable, and stable manner[380,381] with measurable affinity and a remarkably slow dissociation rate.[381] For MHC-I molecules, the results were at first less clear, but the realization that some cell lines defective in MHC-I surface expression could be induced to express higher levels of surface MHC-I molecules by exposure to the appropriate peptides[382] led the way for direct measurement of MHC-I peptide binding.[383]

Several laboratories succeeded in developing methods for the partial purification and identification of the peptides that copurified with MHC molecules. A viral, antigenic peptide

was identified bound to the MHC-I molecule H2-K^b by recovering MHC molecules from virus infected cells, fractionating the bound peptides chromatographically, identifying a peak of functional biologic activity in a cytotoxic T-cell assay, and determining the amino acid sequence of the recovered peptide by radiochemical techniques.[384] Another method that was applied to the identification of both virusderived peptides as well as the "motif" of self-peptides by particular MHC-I molecules involved first the isolation of a large amount of detergent solubilized MHC-I using appropriate antibodies, the elution of the bound peptides, their partial purification as pools by reverse phase high pressure liquid chromatography, and the determination of the amino acid sequence of the bound peptides by classic amino terminal sequencing.[385,386,387] The unpredicted and surprising result obtained from these studies of MHC-I-derived peptides was that specific amino acid residues were favored at particular positions of the sequence, depending on the MHC-I molecule from which the peptides were obtained, and that the length of the bound peptides was well defined and short, ranging from 8 to 10 amino acids. From such experiments, a number of peptide "motifs" of peptides bound to particular MHC-I molecules and allelic products were identified. Often, specific amino acids were identified at particular Edman degradation steps, indicating a common, highly preferred residue at the same spacing from the amino terminus of the peptide. Thus, the peptide "motif" could be determined even from heterogeneous pools of peptides eluted from particular MHC-I molecules. Further refinements in methodology have included the application of mass spectrometry to the identification and sequencing of individual peptides.[388,389] Alternative approaches for identifying peptide motifs include the use of soluble analogs of MHC-I molecules to ease the purification[390,391] or the use of peptide display libraries to identify those peptides that can bind the MHC.[392,393] With steady improvements in technology, including the use of transfected soluble versions of MHC-I molecules, immunoaffinity purification of the MHC-I molecules of interest, tandem reverse phase high pressure liquid chromatography and further identification and sequencing by tandem mass spectrometry, particularly MHC-I motifs, as well as tumor antigen peptides, may now be identified routinely.[394] A summary of MHC-I peptide motifs is given in Table 21.9. Regularly maintained online databases of MHC-I peptide motifs may be found at several sites (www.imtech.res.in/raghava/mhcbn/links.html and www.syfpeithi.de).[395] Antigenic peptides that represent those observed as tumor antigens

and available for recognition by T cells are summarized at www.cancerimmunity.org/peptidedatabase/differentiation.htm. In addition, the immune epitope database (www.immuneepitope.org)[396] offers a regularly updated and curated Web site that describes MHC motifs, allows evaluation of new proteins for MHC epitopes, and provides new computational tools for such evaluation. An algorithm that allows the prediction of candidates for MHC-I-restricted peptides based on the amino acid sequence of the protein of interest is also available (www-bimas.cit.nih.gov/molbio/hla_bind/).[397] The distinction between "motif" residues of an MHC-restricted peptide and "anchor" residues is an important one. Motif refers to those amino acid residues that are identified based on the sequences of self-peptide or antigenic peptides that have been demonstrated to bind or copurify with a particular MHC molecule. Anchor implies a biophysical function of the particular amino acid residue as specifically interacting with a particular part of the MHC molecule itself. The designation of a residue as an anchor residue may be inferred by analysis of binding to peptide variants in the context of the parental peptide. Alternatively, anchors can be defined from a knowledge of the x-ray structure of the peptide complexed to the MHC-I molecule, and predictions of likely peptide motifs for MHC molecules whose sequence is known but whose structure has not yet been determined can be made by comparison to known structures.

[a]Peptide-binding motifs for the indicated MHC class I molecules are shown in the single amino acid code. Position refers to the amino acid position of the peptide from the amino terminus. Only the most common residues are shown. Assignments in parenthesis are less common than the others. These motifs are taken from the more extensive summary of www.syfpeithi.de/, www.imtech.res.in/raghava/mhcbn/links.html, and Biddison and Martin.562 Full sequences of proteins may be queried for MHC peptides presented by particular alleles with http://bimas.dcrt.nih.gov/molbio/hla_bind/, www.immuneepitope.org/, or www.mpiib-berlin.mpg.de/MAPPP/expertquery.html.

HLA, human leukocyte antigen; MHC, major histocompatibility complex.

The identification of MHC-II-bound self-peptide-or antigenic peptides by biochemical methods similar to those employed for MHC-I molecules has been proved more difficult because the MHC-II molecules do not have the rigorous requirements for a defined amino terminus or restricted length. Whereas MHC-I molecules bind peptides with a particular motif residue at a specific position as defined by the amino terminus, resulting in the ability to identify the dominant residue at a particular step in the Edman degradation even amidst a pool of peptides, MHC-II molecules bind peptides with "ragged ends," and little information is obtained from the standard methods of sequencing of pools of peptides.[398,399,400,401] Thus, more precise fractionation of the peptides released from purified MHC-II molecules is required. Identification of MHC-II/peptide-binding motifs by bacteriophage display is also possible.[402] In accord with the view that MHC-II molecules present peptides derived from an "outside in" pathway, many of the peptides that copurify with MHC-II molecules represent molecules derived from the extracellular milieu or the medium in which the cells were grown. Analysis of MHC-II/peptide complexes with cloned T cells and monoclonal antibodies with MHC/peptide specificity reveals that, in part because of the ability of MHC-II molecules to accommodate peptides with extensions at their amino and carboxyl-termini, and in part because of the smaller role that anchor residues seem to play in peptide binding by MHC-II molecules, occasionally even a unique peptide can bind a particular MHC-II molecule in more than one frame.[403,404,405,406] As a result of structural studies (summarized in the following) and compilation of sequences of those peptides bound by particular MHC-II molecules, the general conclusion is that MHC-II molecules all have binding pockets identifiable for the particular allelic product. For some alleles, such as HLA-DR1 and IA^d, these pockets are spaced at position P1, P4, P6, and P9 (or i, i + 3, i + 5, i + 9). (Some analyses, borne out in part by structural studies, suggest that a pocket at P7 [i + 6] may also contribute to the energy of binding.) Because of the complexity and potential degeneracy of peptide motifs for MHC-II molecules, more elaborate schemes have been devised for predicting those peptides that may bind to particular MHC-II molecules.[407] A summary of identified peptide-binding motifs for MHC-II molecules is in Table 21.10, but for some alleles, the analysis of MHC-II binding peptides is not straightforward and demands sophisticated algorithms for identifying potential antigenic peptides from new proteins. The site www.imtech.res.in/raghava/mhcbn/links.html tabulates a number of links to various servers for predicting likely peptide epitopes for particular MHC-I and MHC-II molecules. Implicit in the description of MHC-I and MHC-II peptide motifs is that the bound peptides bind to the MHC molecule only in an amino to carboxyl-terminal orientation, that is, that all peptides

bound to MHC molecules bind with the amino terminus at the lefthand side of the peptide-binding groove, in the canonical structural representation that will be described in further detail subsequently. However, a recent analysis employing both x-ray crystallography and nuclear magnetic resonance indicates that the CLIP peptide may undergo orientational inversion, binding dynamically in the carboxyl to amino as well as the amino to carboxyl direction.[408]

High-Resolution Structures

MHC-I Molecules

A most graphic description of the relationship of form to function of the MHC molecules was made by Bjorkman et al.[409,410] who determined the three-dimensional structure of the human MHC-I molecule, HLA-A*02:01, by x-ray crystallography. For these studies, the extracellular, soluble portion of the type I membrane-associated molecule was purified by papain cleavage from the surface of tissue culture cells. At the time, there was not a clear appreciation of the role of peptide either in the assembly of the molecule or of the nature of the recognition of the MHC molecule by TCRs or, for that matter, NK receptors. Despite the fact that the first purified HLA-A2 molecules possessed a heterogeneous mixture of bound peptides, protein from these preparations crystallized readily, and electron density maps calculated from the diffraction data were interpretable, allowing modelling of the backbone molecular structure. The most important insight in the interpretation of the derived electron density map was that part of the electron density, and thus part of the structure, was due to this mixture of peptides bound tightly by the molecule, and that this density could not be modeled based on the known amino acid sequence of HLA-A2.

This first MHC-I structure clarified several important aspects of the mechanism by which the MHC-I molecule carries out its peptide binding function. The amino terminal domains (α1 and α2) form a unitary binding site for peptide. This domain unit (also called a “superdomain”) consists of a floor of eight strands of antiparallel β-pleated sheet that supports two α-helices, one contributed from the α1 domain and one from the α2 domain, aligned in an antiparallel orientation. The membrane proximal α3 domain has an Ig C-type fold and pairs asymmetrically with the other Ig domain of the molecule contributed by β2m. The nature of recognition by T-cells was suggested by comparing the location of those amino acid residues that had been characterized as being strong elements in T-cell recognition, residues that distinguished closely related allelic gene products, and amino acid residues that had been identified as those that were responsible for the transplant rejection of the mutants of the *H2-K^b* series.[409] Amino acid residues of the MHC-I molecule responsible for T-cell recognition were clearly classified into one of two categories or an overlapping set: those residues that were “on the top of the molecule,” exposed to solvent and available for direct interaction with the TCR, and those residues whose side chains pointed into the peptide binding groove and might be considered crucial in the peptide-binding specificity of the particular MHC molecule. The original publications, based on a structure determined to a resolution of 3.5 Å, focused mainly on the general structural outline of the molecule. More recently, structures of a wide variety of MHC-I molecules of different species including human, mouse, rat, and chicken, complexed with specific peptides, have been determined. Ribbon diagrams of HLA-A2 as

seen from the side (Fig. 21.6A) and from the top (Fig. 21.6B), complexed with a unique synthetic peptide, indicate the design of the entire molecule: the peptide-binding site is supported by the β-sheet floor, and the floor in turn is supported by the two Ig-like domains, the α3 domain of the heavy chain and the β2m light chain. (In the canonical view of the MHC-I, HLA-A2 molecule shown in Fig. 21.6B through D, the amino terminal residue of the bound peptide lies to the left, and the carboxyl terminal residue lies to the right.)

The comparison of this structure with that of the closely related human MHC-I molecule, HLA-A*68:01 (see Table 21.2), suggested that surface depressions in the groove of the MHC-I molecule, now designated pockets A through F, would be available for interactions with some of the side chains of the bound peptide.[411,412] These six pockets are illustrated in Fig. 21.6C and with bound peptide in Fig. 21.6D. Concomitant with the determination of the x-ray structure of the human MHC-I molecule, HLA-B*27:05,[413,414] the motif of the peptides that were recovered from this molecule was determined, permitting the more precise modeling of the bound peptide in the cleft of the MHC-I. For HLA-B27, this was of particular interest because the bound peptides had a strong overrepresentation of arginine at position 2,

and scrutiny of the HLA-B27 structure suggested that the amino acid residues lining the B pocket, particularly glutamic acid at position 45 as well as cysteine 67, were complementary to the long, positively charged arginine side chain of the peptide amino acid at that position. Structural studies supported a view of MHC-I/peptide binding in which the side chain of the carboxyl-terminal residue of the bound peptide sits deep in the F pocket. In addition, the amino terminal amino group of the peptide forms hydrogen bonds with the hydroxyl groups of conserved amino acids tyrosine 59 and tyrosine 171 that line the A pocket. A hydrogen bond from the amino group of conserved tryptophan 147 to the backbone carbonyl oxygen of the penultimate peptide amino acid (usually position 8) also seems important, as do charge interactions and hydrogen bonds of the free carboxyl group at the carboxyl terminus of the peptide with tyrosine 84, threonine 143, and lysine 146.

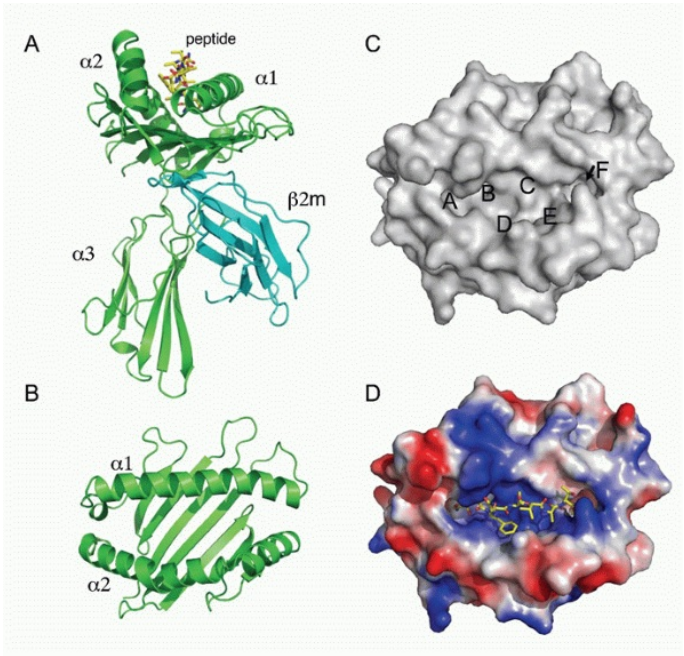

FIG. 21.6. Structure of HLA-A*02:01. A: Ribbon representation of HLA-A2 heavy chain *(green)*, β2m light chain *(cyan)*, and bound peptide *(yellow)*. **B:** Ribbon representation of the peptide-binding groove. **C:** Surface representation of the binding groove with pockets labeled. **D:** Surface representation of binding groove colored by electrostatic charge (*red*, acidic; *blue*, basic) with peptide shown in stick illustration. Figure generated from protein data bank[559] structure 2BSV using PyMOL.[560]

Other structures of MHC-I molecules were determined involving complexes produced with homogeneous peptide, assembled either in vitro from bacterially expressed proteins with

synthetic peptide[415] or exploiting MHC proteins expressed in insect cells.[416,417] The structures determined with homogeneous peptide confirmed the impression obtained from the structures obtained from molecules with heterogeneous self-peptides. Examination of the H2-K^b molecule complexed with synthetic, known antigenic peptides derived either from Sendai virus, vesicular stomatitis virus, or chicken ovalbumin revealed that the same MHC molecule can bind peptides of different sequence, length, and structure by virtue of their conserved motif residue side chains. Although small conformational changes of the MHC are detectable on binding the different peptides, the main distinction in the recognition of different peptides bound by the same MHC molecule is due to the location, context, size, and charge of amino acid side chains that are anchored in the MHC pockets. Conversely, solvent-exposed side chains contribute to the unique structure of the surface of the molecule available for interaction with TCR and other receptors.

The most consistent rule learned from the first x-ray structures and complemented by peptide recovery and early binding studies was that the carboxyl-terminal amino acid side chain of the MHC-I-bound peptide was embedded in the F pocket. A recent study revealing that the MHC-I molecule H2-D^b binds a pentapeptide well anchored in the F pocket, but lacking amino terminal interactions, is consistent with this view.[418] However, other studies indicate that MHC-I molecules may bind longer peptides that extend beyond the residue anchored in the F pocket,[419] an observation confirmed by a crystallographic structure.[420] More recently, the lack of an absolute requirement for a free C-terminal amino acid has been exploited in the engineering of single chain molecules in which peptide, β2m, and the MHC-I heavy chain are covalently linked. These molecules have unusual thermal stability and are effective MHC/peptide immunogens.[421] An additional variation on the theme of MHC-I binding peptides based on particular anchor residues includes the demonstration that glycopeptides, bound to MHC-I via amino acid side chains and termini, can expose their carbohydrate moieties to solvent and be available for TCR interaction.[422,423,424] An example of a 13-residue peptide bound to its MHC-I-presenting element, the rat MHC-I molecule, RT1-Aa, was crystallized and shown to produce a peptide/MHC complex with a large central bulge. Two different complexes consisting of the same MHC and peptide reveal significantly different conformations in this central bulge region.[425] "Bulged" viral peptides have also been characterized in complex with human MHC-I structures of HLA-B35 allotypes complexed with 13-mer and 11-mer peptides.[426,427] TCR recognition of such bulged peptides can involve conformational adjustments of the TCR in recognizing a fairly rigid peptide[426] or "crumplings" of the bound peptide by a largely rigid face of the TCR upon binding the MHC-I/peptide complex.[428] Another set of modified peptides that can be bound by MHC-I molecules and presented to TCR includes self-peptides modified by phosphorylation.[429,430] Although the fundamental topology of MHC-I structure and its interactions with antigenic peptide have been solved by the classic structures mentioned previously, many more MHC-I/peptide complexes have been studied crystallographically in order to define the details of particular interactions with antigenic peptides. A number of structures at a resolution of 1.40 Å or better have been deposited in the protein database. Structure determination of representative single-chain peptide-β2m-MHC-I,[431] and of MHC-I molecules containing photolabile peptides that can be exchanged with other peptides easily,[432] reinforce our basic understanding of the structure of MHC-I/peptide complexes.

MHC-II Molecules

Before any MHC-II structure had been determined experimentally, a model was constructed based on the alignment of amino acid sequences and the available MHC-I three-dimensional structure.[433] This model made several valid predictions that were borne out by the subsequent x-ray structure determination of HLA-DR1.[434] MHC-II clearly showed similarity to MHC-I and formed its binding groove by the juxtaposition of the α1 and β1 domains. The position of the electron density representing the heterogeneous peptide that copurified with the HLA-DR1 was identified. Figure 21.7A and C show a ribbon diagram of HLA-DR1 with a homogeneous bound peptide. In comparison to the MHC-I structure (see Fig. 21.6), the peptides bound to the MHC-II molecule extend through the binding groove rather than being anchored at both ends.

A comparison of the α-carbon backbone of the peptide-binding region of an MHC-I structure with that of an MHC-II structure is shown in Figure 21.8. The structures are very similar

although the binding domain is built of the α1 and α2 domains from the same chain (for MHC-I) or of the α1 and β1 domains that derive from two chains (for MHC-II). The location of polymorphic residues can be determined by variability plots based on multiple sequence alignments, as originally suggested by Wu and Kabat.[435] The current bioinformatics approach to variability prefers to calculate *Shannon entropy*, a function that describes the degree of unpredictability of an event.[436,437] For protein sequence

alignments, Shannon entropy provides a sensitive measure of the diversity of particular amino acid positions.[438] Several online tools are available for implementing and displaying the results of such calculations (http://bio.dfci.harvard.edu/Tools/svs_help.html; http://imed.med.ucm.es/Tools/svs_help.html; and http://consurfdb.tau.ac.il/). Comparative ribbon diagrams (Fig. 21.9), in which the location of the amino acid residues that are polymorphic for the human MHC-I and MHC-II chains are indicated with a color map, show that the bulk of MHC polymorphism derives from amino acid variability in regions that line the peptidebinding groove. This suggests that MHC polymorphism is required to allow the MHC molecules, and as a result, the organism and its species, to respond to a changing antigenic environment.

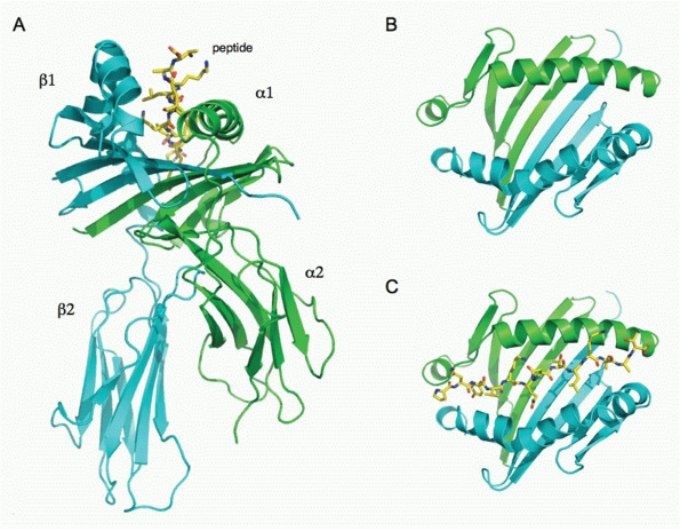

FIG. 21.7. Color Ribbon Representation of HLA-DR1. A: Side view. α chain is in *green;* β chain is in *blue;* peptide in stick representation in *yellow*. **B:** Top view. **C:** Top view with bound peptide (PKYVKQNTLKLAT) visualized. The illustration was made with PyMol[560] based on the protein data bank[559] coordinates of 1DLH.

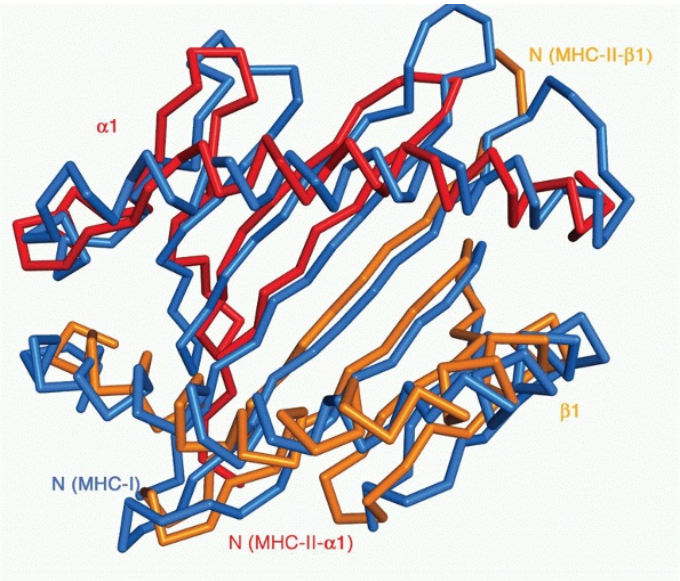

FIG. 21.8. Comparison of α-Carbon Backbone of MHC-I and MHC-II molecules. The α1α2 domains of MHC-I (human leukocyte antgien [HLA]-A2, PDB 3HLA) and the α1 and β1 domans of MHC-II (HLA-DR1, PDB 1DLH) were superposed with PyMOL[560] and displayed as a Cα carbon representation. MHC-I is *blue*, the α1 domain of MHC-II is *red*, and the β1 domain of MHC-II is *orange*.

As with MHC-I, a further understanding of the details of the interactions of peptides with the MHC-II molecule came from crystallographic studies of molecules prepared with

homogeneous peptide—in the first case HLA-DR1 complexed with an antigenic peptide derived from the hemagglutinin of influenza virus.[439] Based on this structure, a set of pockets was initially designated, numbered for the peptide position that is bound. For the influenza peptide studied in this example, the major interactions were from peptide positions 1, 4, 6, 7, and 9 that are indicated in Figure 21.10. The deep P1 pocket accommodates the tyrosine (the third position of the peptide PK**Y**VK**Q**N**T**L**K**L**A**T) and the pockets indicated by 4, 6, 7, and 9 fit the Q, T, L, and L residues, respectively. MHC-II exploits a similar mode of binding as compared with MHC-I, but there are key differences. MHC-II lacks the requirement for free amino and carboxyl termini of the peptide, the peptide conformation is relatively extended (like that of a type II polyproline helix), and the MHC-II forms number of hydrogen bonds between conserved amino acids that line the binding cleft and the main chain (ie, amino nitrogen and carbonyl oxygen) atoms of the peptide. Although the pocket designations refer specifically to the features of the MHC-II molecule surface, occasionally the cognate peptide positions that reside in such pockets are given the same names.

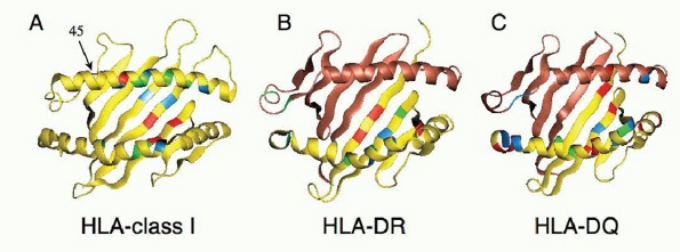

FIG. 21.9. Location of Polymorphic Amino Acid Residues in MHC-I and MHC-II molecules. Variability plots were calculated as described by Kabat and Wu[435] and level of variability illustrated on ribbon diagrams (generated in QUANTA 2000 [Accelrys] of 3HLA[412] [HLA-class I], 1DLH[439] [HLA-DR], and 1JK8 [HLA-DQ]) where greatest variability is *red*, intermediate is *green*, and least is *blue*.

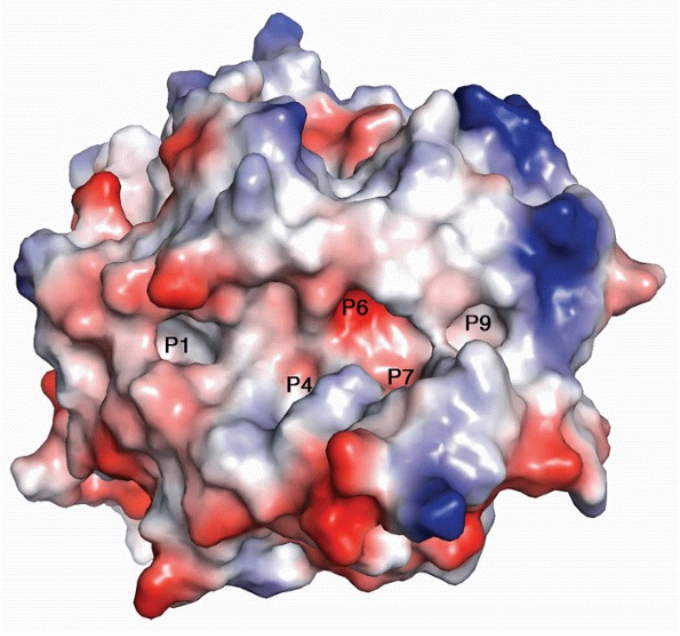

FIG. 21.10. Location of Pockets in HLA-DR1 Based on the Cocrystal of HLA-DR1 with a Peptide Derived from the Influenza Hemagglutinin. An electrostatic surface representation of HLA-DR1 (1DLH) generated in PyMOL[560] is shown with the positions of pockets P1, P4, P6, P7, and P9 indicated.

Among the most provocative observations from the first MHC-II structures was that the molecule was visualized as a dimer of dimers, and this moved a number of investigators to consider the possibility that activation of the T cell via its receptor might require the dimerization or multimerization of the TCR, an event thought to be dependent on the propensity of the MHC/peptide complex to self-dimerize. The simple elegance of this dimer of dimers is illustrated in Figure 21.11. Several arguments support the dimerization hypothesis: the finding of a dimer of dimers in the crystals of HLA-DR that formed in several different space groups,[434,439] the observation that a TCR Vα domain formed tight dimers and in its crystals formed dimers of the dimers,[440] the demonstration of the ability to immunoprecipitate MHC-II dimers from B cells,[441] the apparent requirement for purified MHC-I dimers for stimulation of a T cell in an in vitro system,[442] and the finding that MHC-II/peptide/TCR complexes could form higher order multimers in solution as detected by quasielastic light scattering.[443] However, a number of strong counterarguments draw this hypothesis into question. Many MHC-II molecules other than HLA-DR1 that have been crystallized do not seem to form the same kind of

dimer of dimers in their crystals.[444,445] Modes of MHC-II dimerization with distinct topology that would preclude simultaneous interaction with multiple TCRs on the same T cell have been observed. None of the MHC-I molecules that have been examined by x-ray crystallography show dimers in the same orientation as the MHC-II ones reported. A different Vα domain fails to dimerize even at high concentration.[446] Many reported x-ray structures of MHC/peptide/TCR complexes[447,448,449,450] fail to show dimerization. Despite the simple elegance of the dimer hypothesis, it is clear that additional experimentation will be required to understand the topologic requirements for T-cell activation through the αβ TCR.

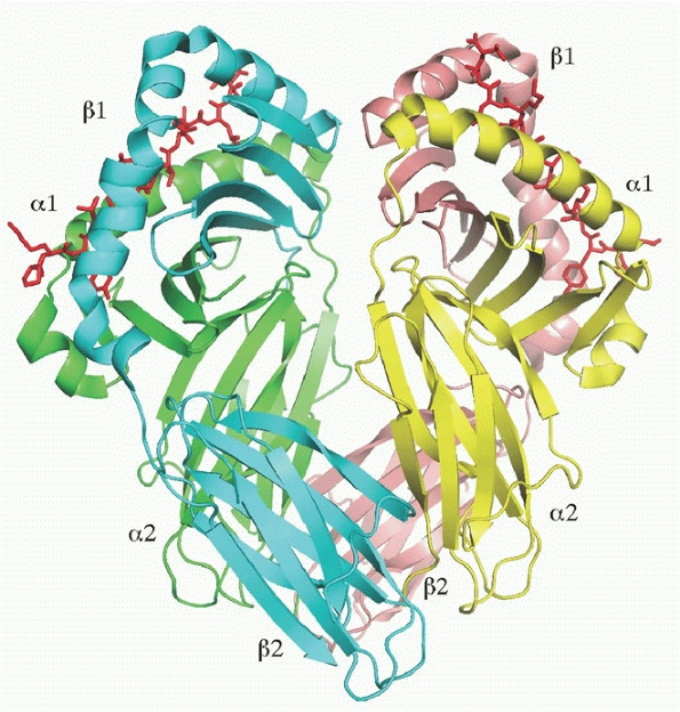

FIG. 21.11. Ribbon Diagram of the Structure of HLA-DR1 showing the dimer of dimers and the individual domains of the protein. α chains are in *green* and *yellow;* β chains are in *blue* and *salmon*. Peptide in stick representation is in *red*. The illustration was generated from PDB 1DLH with PyMOL.

Recent additions to the library of MHC-II structures include the I-A^{97} molecule, a unique MHC-II that provides one link in the susceptibility to insulin-dependent diabetes in the mouse model.[451,452] Although the structure fails to provide direct evidence to explain the linkage to diabetes, it suggests that the novel repertoire of peptides bound by this MHC-II molecule reveals unique features of a wider peptide binding groove and resulting relatively low-affinity interaction with peptide. Until recently, all of the MHC-II/peptide structures revealed bound peptide in a canonical left to right, amino to carboxyl orientation. A detailed analysis of HLA-DR1 molecules bound to the CLIP 106 to 120 peptide revealed crystals in two different forms, which on solution and refinement indicated that this peptide could interact in either of two distinct orientations (Fig. 21.12).[408] This exception to the general rule of left to right, amino to carboxyl orientation, may reflect the unique role that the CLIP peptide must play in protecting the MHC-II-binding site while simultaneously being available for DM-mediated peptide exchange in the endosome.

MHC-Ib Molecules

H2-M3

To this point, our description of MHC-I molecules has focused on the classical MHC-Ia molecules, represented by HLA-A, HLA-B, and HLA-C in the human, and by H2-K, H2-D, and H2-L in the mouse. Several MHC-Ib molecules for which three-dimensional structures have been determined are of particular interest, the CD1 molecules,[453,454] H2-M3,[137,455] MICA,[456,457] FcRn,[458] and Rae-1.[459] Other molecules that are thought to show structural relatedness to the MHC-I fold but whose x-ray structures have not yet been reported include the stress-induced molecules H-60[173] and MULT1,[460] and the mucosally expressed MR1 molecule that selects invariant T cells in the gut.[461] H2-M3 is of particular note because of its ability to bind and present peptide antigens that contain amino terminal N-formyl groups. H2-M3 was originally identified as the MHC-Ib molecule that presents an endogenous peptide derived from the mitochondrially encoded protein ND1 known as maternally transmitted factor.[137,462] Thus, it was of interest to understand in structural terms how this molecule binds such N-formylated peptides.[455,463] The crystal structure of H2-M3 complexed with an

N-formylated nonamer peptide, fMYFINILTL, revealed that the structure of the A pocket, highly conserved among MHC-Ia molecules, which have tyrosine 7, tyrosine 59, tyrosine 159, tryptophan 167, and tyrosine 171, is quite different so that it can accommodate the N-formyl group in the A pocket. In particular, H2-M3 has an A pocket reduced in size and lined by hydrophobic residues, leucine at 167 and phenylalanine at 171, and leucine 16. These structural features cause the amino terminal nitrogen of the formylated peptide to be positioned where the peptide position 2 amino nitrogen would lie in a MHC-Ia molecule. Thus, the unique peptide selectivity of H2-M3 is explained in structural terms.

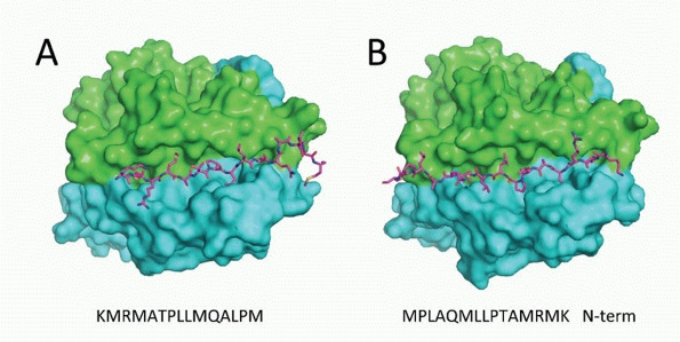

FIG. 21.12. MHC-II Binds Class II-Associated Invariant Chain Peptide in Either N to C or C to N Orientation. The structures of HLA-DR1 bound to the CLIP 106 to 120 peptide in either the N to C **(A)** or C to N **(B)** orientation is illustrated. α1 domain is in *green*; β1 domain is in *cyan*. Peptide sequences are shown at the bottom.

CD1

Another MHC-Ib molecule of great interest is CD1, representative of a class of MHC-I molecules that map outside of the MHC, that have limited tissue-specific expression, and that are capable of interaction with both αβ and γδ T cells.[464] In the human, there are two clearly distinct groups of CD1 molecules: one consisting of CD1a, CD1b, CD1c, and CD1e; and another of CD1d alone.[465] In the mouse and rat, only CD1d is expressed.[466] As a group, these are β2m-associated chains that bind hydrophobic antigens, primarily glycolipids, with the lipid moiety embedded in the CD1 heavy chain and the carbohydrate portion exposed to solvent. CD1a, CD1b, and CD1c are capable of binding and presenting various nonpeptidic mycobacterial cell wall components such as mycolic acid containing lipids and lipoarabinomannan lipoglycans.[467,468] NK T cells, a subset of αβ-TCR-bearing T cells, of independent lineage and defined by the expression of the NK1.1 marker, are restricted to CD1 recognition.[469] The crystal structures of both mouse and human CD1d1 have been determined,[453,470] revealing classic MHC-I structures with the basic protein fold and β2m association quite similar to that of the MHC-Ia molecules. Consistent with its apparent biologic function of binding hydrophobic lipid-containing molecules, its binding groove is somewhat narrower and deeper than that of either MHC-Ia molecules or MHC-II molecules. The backbone configuration of the α1α2 domain structure of CD1 is shown in Figure 21.13, where it is compared to the homologous region of H2-K^b, HLA-DR1, and another MHC-Ib molecule, a neonatal Fc receptor (FcRn). The structure of a number of CD1-glycolipid complexes

have been determined, and human and mouse CD1 molecules bound to different glycolipids have been compared.[466] The depth of the groove of CD1 results from the merging of pockets to form what have been termed the *A′ and F′ pockets* in place of the MHC-Ia A through F pockets. This A′ pocket is about the size of the binding site of a nonspecific lipid binding protein.

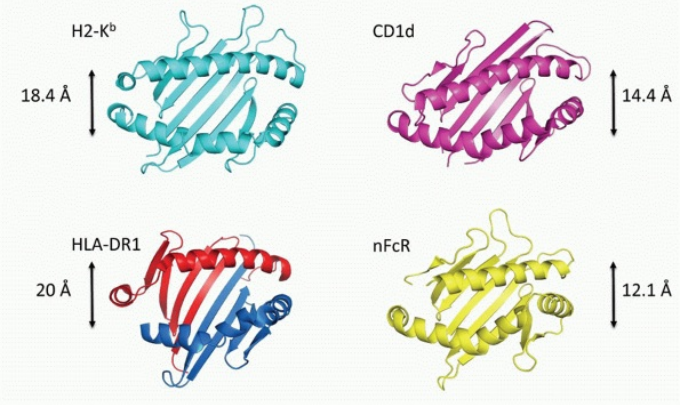

FIG. 21.13. Comparison of the Ribbon Representations and Size of the Potential Peptide-Binding Cleft. MHC-I molecule H2-K^b (2vaa), MHC-II HLA-DR1 (1DLH), and MHC-Ib molecules CD1d (1Z5L) and FcRn (1EXU) are compared. Approximate maximal distances separating the two helices are indicated.

In an effort to understand more precisely how CD1 molecules bind lipid antigens, Gadola et al.[454] crystallized human CD1b complexed with either phosphatidylinositol or ganglioside GM2 and determined their x-ray structures. The structures were essentially identical for the CD1b heavy chain and β2m in the two complexes, and revealed a network of four hydrophobic channels at the core of the α1α2 domain, which accommodate four hydrocarbon chains of length from 11 to 22 carbon atoms. These channels are called A', C', and F' for the three analagous to the A, C, and F pockets of the MHC-Ia molecules, and a fourth, termed *T'* which is a distinct tunnel. Illustrations of the binding groove with the bound alkyl chains is shown in Figure 21.14, which shows views of the binding pockets of CD1a, b, and d with different ligands. These structures illustrate how the

binding site of a classical MHC-I molecule may have evolved from (or to) the binding site of molecule like CD1 to provide antigen selectivity for a distinct set of molecules that would be common to a set of important mycobacterial pathogens. Complexes of CD1 with their cognate NK TCR have been reported and will be discussed subsequently.[471,472,473,474]

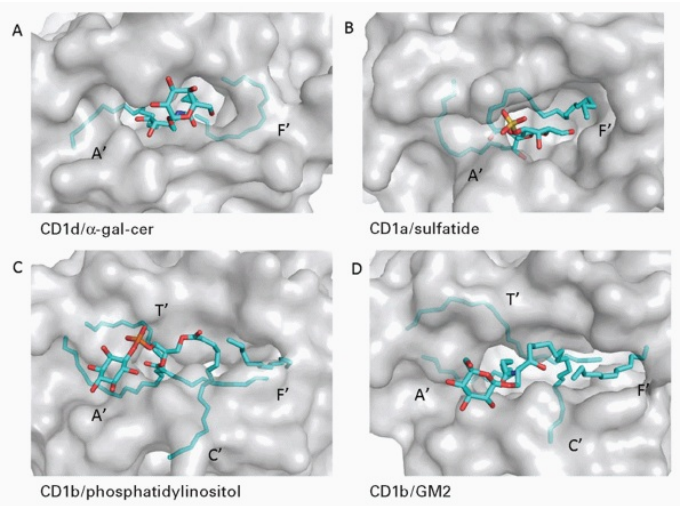

FIG. 21.14. Tunnels and Pockets of CD1 Molecules. Structures of **(A)** CD1d with α-galactosyl ceramide (1Z5L), **(B)** CD1a with sulfatide (1ONQ), **(C)** CD1b with phosphatidylinositol (1GZQ), and **(D)** CD1b with ganglioside GM2 are shown, with pockets A', C', and F' indicated and tunnel T'.

Neonatal Fc Receptor

Another example of an MHC-Ib molecule, noteworthy because it exemplifies a novel function of MHC molecules, is the FcRn. Originally described in the rat as a molecule of the intestinal epithelium that is involved in the transport of colostral Ig from the lumen to the bloodstream,[475,476] homologues in the mouse and human have also been described,[477,478,479] and the structure of the rat molecule has been determined crystallographically[458] (Fig. 21.15). As suggested by the amino acid sequence similarity of the FcRn to MHC-I proteins, the three-dimensional structure revealed considerable similarity to MHC-Ia molecules.[458] Specifically, α1 and α2 domains have similar topology to the MHC-I molecule, although, as discussed previously, what would be the peptide-binding groove in the MHC-Ia molecules is closed tightly and lacks space sufficient for a ligand. The most provocative feature of the structure of the FcRn/Fc complex is that the MHC-I-like FcRn interacts with the Fc through contacts from the α2 and β2m domains to interact with the Fc $C_\gamma2$-$C_\gamma3$ interface. As compared to the structure of the unliganded Fc, the complex reveals both conformational changes in the Fc and the presence of several titratable groups in the interface that must play a role in the pH-dependent binding and release of Ig molecules from the FcRn. The FcRn has taken the MHC-I fold and diverted its function for an interaction with the Fc of the Ig. Amino acids at what would classically be considered the "righthand side" of the peptide-binding groove make contact with the Fc interface that lies between $C_\gamma2$ and $C_\gamma3$ domains. The FcRn serves as an excellent example of similar structures in the immune system being diverted for alternate purpose. The importance of the FcRn has been underscored by observations of differences in the serum half-life of Ig in animals that, as a result of an induced deletion of β2m, lack the normal expression FcRn as well and seem to metabolize serum Ig aberrantly.[480]

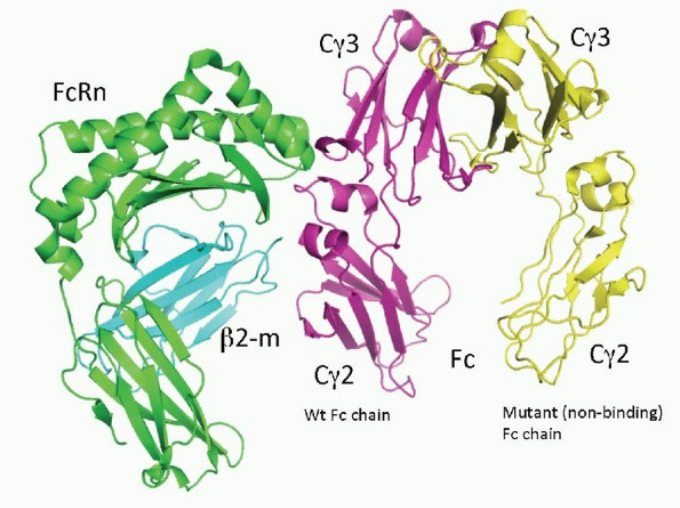

FIG. 21.15. Structure of the Rat Neonatal Fc Receptor Complexed with Fc. Ribbon diagram of rat neonatal Fc receptor complexes with the Fc heterodimer consisting of the wild-type and nonbinding chains. This is from PDB 1I1A.

MILL MHC-Like Molecules

A novel set of MHC-Ib-like genes designated *Mill* (*M*HC class *I*-*l*ike located near the *l*eukocyte receptor complex) has recently been identified in both mice and rats.[481,482,483] These encode MICA/B-like glycophosphatidylinsol-linked cell surface molecules that are associated with β2m and do not require TAP for cell surface expression. Their function remains unclear, although further examination indicates the presence of two family members, Mill1 and Mill2, observed on cycling thymocytes, proliferating smooth muscle cells and fibroblasts.[484]

M10 Proteins

The robust MHC fold seems to possess both the stability and flexibility requisite for the molecular function of binding ligands such as peptides, glycopeptides, phosphopeptides, and glycolipids as well as for subsequent interactions with macromolecular receptors such as NK

receptors and TCRs. Likely, these qualities have allowed its adaptation for distinct function related to a class of MHC-Ib molecules, the M1 and M10 families, some members of which are associated with the V2R mouse pheromone receptors. The structure determination of M10.5 revealed a β2m-associated MHC-I-like molecule with clear three-dimensional similarity to the MHC-I molecule H2-D^d.[485]

MHC-Iv Molecules

Because viruses are constantly engaged in a struggle for survival in their interplay with the immune system of their hosts, there is little surprise to note that pathogenic eukaryotic viruses can evolve numerous approaches to evade the immune response. MHC and structurally related molecules are produced not only by vertebrates but also by CMVs, large DNA viruses of the β-herpesvirus family, which have coevolved with their vertebrate hosts over millennia and are exquisitely adapted to persist in the face of host immune responses. 2 Viral MHC-I-like molecules have been identified bioinformatically from amino acid sequences of the open reading frames predicted from genome sequence data. A number of putative MHC-Iv molecules, including UL18 and UL142 of the human CMV,[327,486] members of the "m145 family" of the mouse CMV1[487,488] the 2L molecule of tanapox,[489] and the U21 molecule of human herpesvirus 7,[490] may modulate the immune response of the host. In some cases, such as the UL18 protein of human CMV and the m144 protein of mouse CMV, the sequence homology to bonafide MHC-I molecules is sufficiently strong to unambiguously identify them as MHC-I like. However, in most cases, such as with the m145 family of mouse CMV, the sequence homology to MHC-I is very weak, and relatedness to MHC-I was originally based on structure prediction algorithms alone. We term these virally encoded MHC-I-like molecules MHC-Iv

to reflect their distinct evolutionary history, their structural deviation from typical MHC-I molecules, and their role in evading host immune responses. A survey of DNA sequences of 11 genes obtained from 26 wild murine CMV isolates and laboratory strains indicated that several of the *MHC-Iv* genes (m144, m145, and m155) revealed significant sequence variation, consistent with the view that this variation may offer some immune-evasive benefit to the virus.[491]

Structural characterization of MHC-Iv molecules begins with an evaluation of the requirement for β2m and/or peptide for stable expression. The UL18 is associated with both β2m and peptide, whereas m144 may be associated only with β2m but does not require β2m for cell surface expression. The structure of m144 has been reported,[487] revealing the preservation of all structural elements of the MHC-I fold (Fig. 21.16). The cleft of m144 does not seem capable of binding peptides as the groove is narrow and critical tyrosine residues are not conserved, results consistent with earlier biochemical studies.[492] A unique disulfide anchors the α1 helix to the β sheet. The structure of m157, a CMV MHC-I-like immunoevasin that binds the Ly49H activation receptor of C57BL/6 mice and the Ly49I inhibitory receptor of 129/J mice, has been reported.[493] This β2m-independent, peptide-free MHC-Iv molecule reveals the major features of the MHC-I fold with some unique aspects, in particular a novel amino terminal α helix. How it binds its Ly49 ligands remains unclear. The m153 protein of mouse CMV, also a member of the m145 family, reveals novel adaptations of the MHC-I fold.[1] The m153 protein does not require β2m or peptide and, in contrast to other MHC-I molecules, is a noncovalent dimer. The monomers are associated in a head-to-tail fashion. An extended N-terminus contains a unique disulfide that anchors it to the α3 domain. The m153 structure hints tantalizingly of more surprises to come as structures of other MHC-Iv molecules become available. Other MHC-Iv proteins whose structure have been determined include the 2L tanapox virus protein that binds the inflammatory cytokine TNF-α[489] and the mouse CMV-encoded m152, which sequesters both classical MHC-I and the stressinduced NKG2D ligand, RAE-1, from the cell surface.[494]

In those cases where functions have been elucidated, MHC-1v molecules have been shown to act as immunoevasins that inhibit the NK cell to enable virus survival and persistence in the host. Both UL18 and UL142 inhibit human NK function, the former by binding to the inhibitory receptor LIR-1. The mode of action of UL142 remains to be determined.[327] The m157 binds to the inhibitory NK receptor Ly49I in mouse strains susceptible to viral infection but remarkably serves as a target for the activating NK receptor Ly49H expressed in resistant

strains. The m144 protein has also been shown to inhibit NK activation,[495,496] but the ligand remains to be identified.

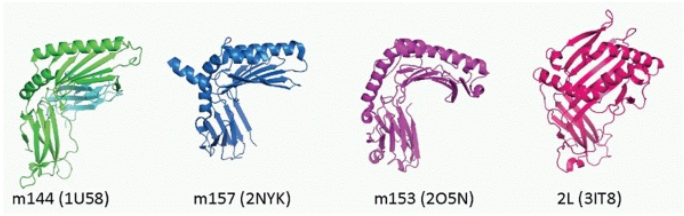

FIG. 21.16. Comparison of MHC-Iv Molecules. Structures of MHC-Iv chains of m144 (1U58), m153 (2O5N), m157 (2NYK), and the 2L protein of tanapox virus (3IT8) were superposed and are illustrated as ribbon diagrams.

Complexes of MHC Molecules with Ligands

The most recent and exciting developments in MHC biology include the detailed description of the interactions of MHC-I and MHC-II molecules with their receptors and coreceptors on cells of the innate and adaptive immune system. Our structure/function survey will be completed by brief descriptions of the interactions of MHC-I and MHC-II molecules with αβ TCRs, with the T-cell coreceptors CD8 and CD4, and of MHC-I molecules with NK receptors. Details of the interactions of a number of CD1 molecules with their glycolipid antigens and specific NK T-cell receptors shed light on the biology and evolution of these molecules. A brief description of interactions of MHC-II molecules with superantigen will follow. Each of these structural studies complements a host of biologic experiments that have led to an appreciation of the importance of understanding the structural basis of these immune reactions.

MHC/T-Cell Receptor Interactions

Second to the initial visualization of the structure of the MHC-I molecule HLA-A2 by crystallographic analysis, the images of TCR/MHC/peptide complexes initially reported some 15 years ago clarified the phenomenologic details of T-cell recognition, antigen specificity, and MHC restriction. The initial structures were determined in several systems,[447,448,449,497,498] and there remains ongoing interest in the details of particular TCR/MHC interactions. The first examples were of MHC-I-restricted TCR, one from the mouse[448] and one from the human.[447] The mouse MHC-I molecule H2-K^b was analyzed in complex with a self-peptide, dEV8, and a TCR known as 2C,[448,499] and the human

HLA-A2 complexed with the Tax peptide was studied with its cognate TCR derived from a cytolytic cell known as A6.[447] These structures offered a consistent first glimpse at the orientation of the TCR on the MHC/peptide complex, but additional structures, including that involving a murine MHC-II-restricted TCR suggest that more molecular variations may exist. As a canonical example of the MHC/peptide/TCR complex, we include an illustration of the H2-K^b/dEV8/2CTCR complex[499] (Fig. 21.17). This illustration shows that the complementarity determining regions (CDRs) of the TCR (labeled 1α, 2α, 3α for CDRs of Vα and 1β, 2β, and 3β, for the CDRs of Vβ, respectively) sit symmetrically on the MHC/peptide complexes. For the H2-K^b/dEV8/2CTCR complex, the region contacted by the CDRs of the Vα domain of the TCR lie to the left and that contacted by the CDRs of the Vβ domain lie to the right. The regions contacted by CDR3, labeled 3α and 3β, are at the center of the bound peptide, whereas the regions contacted by CDR1 and CDR2 of both Vα and Vβ lie peripherally. Footprints of other TCR have been reviewed elsewhere.[357]

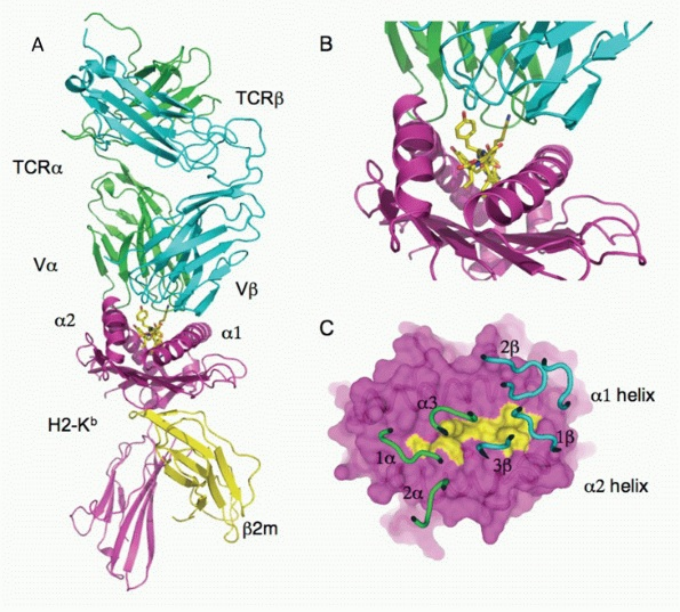

FIG. 21.17. Structure of an MHC-I/Peptide/T-Cell Receptor (TCR) Complex and the TCR Footprint on the MHC/Peptide. The structure of the H2-K^b/dEV8/2CTCR complex (2TCR) is displayed. **A:** The complex complex. **B:** A close-up of the MHC/peptide/TCR interface. **C:** The surface of the MHC *(magenta)*/peptide *(yellow)* complex with the complementarity determining region loop of the TCR Vα *(green)* and Vβ *(blue)* shown and labeled.

With the publication of additional MHC/peptide/TCR structures,[357] additional points have emerged: 1) There is considerable variability in the orientation of the TCR Vα and Vβ domains with respect to the MHC/peptide complex. Although the first MHC-II/peptide/TCR structure suggested that an orthogonal disposition, in which Vβ makes the great majority of contacts with the MHC-II α1 domain and the Vα predominantly interacts with the β1 domain, might be the preference for MHC-II/TCR interactions,[449] additional MHC-II/peptide/TCR structures[450,497] suggest that this disposition is not indicative of MHC-II as compared to MHC-I but rather reveals the wide variety of possibilities. 2) Considerable plasticity in the conformation of the CDR loops of the TCR, particularly long CDR3 loops, is observed in the comparison of TCR free or bound to their cognate MHC/peptide ligands.[499,500] A striking example of this is illustrated by the structure of the KB5-C20 TCR alone as compared to its complex with H2-K^b/peptide (Fig. 21.18).

Structural Insights into Alloreactivity

During T-cell development, TCRs destined to be useful to the host are selected for weak reactivity with one or more self-peptides complexed with cell surface host major histocompatibility (MHC/peptide) molecules. TCR selection is customized in each individual because of extensive polymorphism in MHC molecules that is designed to diversify peptide repertoire and optimize immune responsiveness. Thymic selection and MHC polymorphism conspire to generate antimicrobial T-cell responses that are genetically restricted to recognizing host MHC molecules while retaining Ag-specificity. MHC restriction has been a central paradigm of T-cell immunity and was the basis for the 1996 Nobel Prize awarded to Peter Doherty and Rolf Zinkernagel.

Unfortunately for transplant clinicians and their patients, the rule of MHC restriction is violated when T cells are exposed to allogeneic MHC/peptide complexes. Remarkably, up to 10% of naive T cells react strongly against allogeneic MHC/peptide in vitro (mixed lymphocyte reaction) and in vivo leading to allograft rejection and GVHD. This reaction, known as T-cell alloreactivity, is why MHC molecules were initially called transplantation or histocompatibility molecules and has puzzled immunologists for decades.

There are two main historical theories to explain the high frequency of alloreactive T cells. The first, proposed in 1977,[183] postulated that a single allogeneic MHC molecule

could give rise to multiple binary complexes with cell surface molecules, creating "neoantigenic determinants" recognized by clonally distinct T cells. This has been reinterpreted in a "peptide-centric" hypothesis whereby as a single MHC molecule presents disparate peptides recognized by multiple different T-cell clones. The "multiple binary complex" model implies the TCR interacts with a set of amino acids shared by self- and allogeneic MHC molecules, so the crossreaction depends crucially on the peptide antigen. However, it was later suggested that alloreactive T cells might focus on polymorphic residues exposed on the allogeneic MHC molecule itself, the so-called high determinant density model in which the TCR focus is "MHC centric," and the peptide is largely irrelevant.[501]

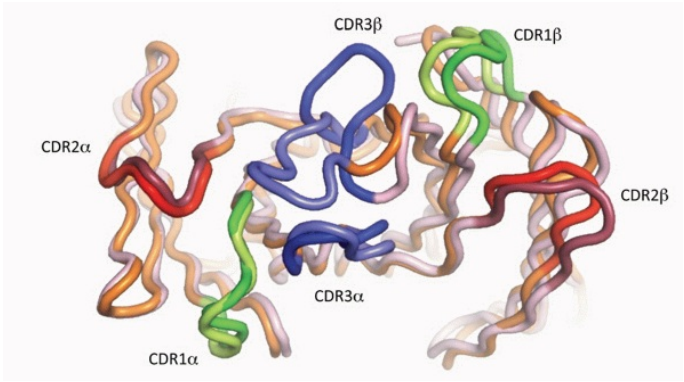

FIG. 21.18. Complementarity Determining Region (CDR)3 Plasticity. Backbone tracings of the KB5-C20 T-cell receptor CDR loops free (1KB5) or bound to the major histocompatibility/peptide complex (1KJ2) are superposed. Unliganded forms are in *darker colors*. The largest conformational difference is seen in the CDR3β loop.

Colf et al.[502] solved the structure of the 2C TCR in complex with its known allogeneic ligand, H2-L^d-QL9, and then compared it to the structure of 2C in complex with its positively selecting ligand, H2-K^b-dEV8, and thus were able to provide important insight into the structural basis of alloreactivity. These two TCR footprints were typical of known MHC/peptide/TCR structures but differed from each other in a number of ways. For instance, each chain of 2C made contacts with one MHC α helix of H2-L^d-QL9, whereas both chains contacted both α helices in H2-K^b-dEV8. The geometry of 2C adopted a more perpendicular orientation on H2-L^d-QL9, and there was a relative rotation of H2-K^b-dEV8 by 20 degrees. The alloreactive complex reveals that both peptide-centric and MHC-centric interactions underpin direct T-cell allorecognition by the 2C receptor but with a heavy emphasis on MHC-centric interactions. Most surprising, however, was the small number of shared contacts between the two structures, implying a limited role for mimicry between cognate and allogeneic MHC/peptide. The H2-K^b and H2-L^d have 31 amino acid differences, and there is no sequence similarity between the H2-K^b-restricted octamer self-peptide, dEV8, and the H2-L^d-restricted nonamer, QL9. Given these differences, it was a fair bet that the cross-reactivity of 2C on H2-K^b-dEV8 and H2-L^d-QL9 would depend upon plasticity in the CDR3 regions of the TCR as documented in comparisons of bound and free TCRs, including 2C. Surprisingly, this was not the case as the TCR actually adopted very similar conformations in the two structures. In contrast to the findings with the alloreactive murine, 2C TCR, alloreactivity of the natural human LC13 TCR is based on striking molecular mimicry between the cognate and alloantigens.[503] The LC13 recognizes an Epstein-Barr viral peptide complexed with self-HLA-B*08:01 but also alloreacts with B44 allotypes (HLA-B*44:02 and 44:05) bound to an endogenous allopeptide from an adenosine triphosphate-binding cassette protein ABCD3. HLA-B*08:01, and the closely related allotypes HLA-B*44:02 and HLA-B*44:05, are distinguished by numerous polymorphisms and the LC13-reactive viral and endogenous peptides are unrelated in their sequence. Nonetheless, the LC13 TCR bound the allogeneic and cognate virus-specific HLA-peptide structures in a very similar manner.[503] Moreover, there was mimicry of the viral peptide by the allopeptide. Hence, this study demonstrates that recognition of allogeneic and cognate HLA-peptide structures can occur via molecular

mimicry, even in the face of polymorphism and disparate peptide ligands.[503] Interestingly, another HLA-B*08:01-restricted TCR (CF34) with the identical Epstein-Barr virus-peptide specificity as LC13 lacks B44 reactivity because it arises when HLA-B44 is coinherited in trans with HLA-B8. Docking of the CF34 TCR focused on the N-terminus of the HLA-B*08:01-peptide while LC13 docked over the C-terminus of the viral peptide bound by HLA-B*08:01.[504] This corresponds with CF34 engagement of a polymorphic region distinguishing HLA-B8 from HLA-B44, revealing a topographical image of shifting TCR specificity to accommodate T cell self-tolerance.[504]

The role of molecular mimicry and the relative importance of peptide-centric versus MHC-centric bias in T-cell allorecognition is likely to vary in different systems. Hence, it is likely that the nature of the polymorphisms between cognate and allogeneic MHC allotypes will affect TCR focus. Thus, closely related MHC allotypes that differ by as little as one amino acid (eg, H2-K^b mutants in mice; HLA-A2, B44, and B27 families in humans) are set up for MHC mimicry to be a key component of T-cell allorecognition where *specificity* is likely to be peptide centric. For example, HLA-B*44:02 and B*44:03 allotypes differ by only a single amino acid and yet stimulate strong mutual allogeneic T-cell responses. Indeed, the potency of T-cell alloresponses between closely related MHC allotypes probably occurs because positive selection of host T cells is purposely designed to create a repertoire responsive to subtle changes in peptide display. Therefore, closely related MHC allotypes, with differences in both peptide repertoire and MHC/peptide conformation of a shared repertoire, play straight into nature's design for T-cell recognition.

Important questions concerning the nature of T-cell signaling mediated by engagement of the TCR by MHC/peptide complexes remain. What are the molecular and biophysical determinants of agonist as compared with antagonist activity of particular MHC/peptide ligands? Although it is clear that a number of parameters such as binding kinetics, half-life, and affinity (both two dimensional and three dimensional) as well as coreceptor contributions may play a role in the outcome of TCR engagement by MHC/peptide complexes, and the additional role of receptor clustering may contribute to such signaling, the precise contribution of each of these factors has not been established. A provocative approach to the question of the role of the geometry of docking of the TCR onto the MHC/peptide complex has been addressed in the analysis of the relationship of stimulatory parameters of four different peptides bound to H2-L^d with respect to the three-dimensional structure of the relevant MHC/peptide/TCR complex.[505] One of the four peptides failed to induce signaling, and remarkably, the TCR docked onto the MHC/peptide in a unique docking geometry. The authors interpreted these results to demonstrate the relationship between TCR/pMHC docking geometry, peptide cross-reactivity, and signaling as well as explaining the basis for germline bias in TCR/MHC interactions.

MHC/Coreceptor Complexes

The major coreceptors for recognition by αβ TCRs are CD8, which interacts with MHC-I molecules, and CD4, which interacts with MHC-II. Coreceptor function plays a role in signaling the T cell in addition to contributions the MHC/coreceptor interaction may provide in increasing apparent avidity between the MHC/peptide and the TCR. CD8, the coreceptor on MHC-I-restricted αβ T cells, exists as a cell surface homodimer of two α chains or a heterodimer of α and β chains and plays an important role both in the activation of mature peripheral T cells as well as in the thymic development of MHC-I-restricted lymphocytes.[506,507] Mature peripheral CD8 T cells express significant amounts of CD8αβ, whereas other lymphocytes, such as intraepithelial lymphocytes in the gut, predominantly express the CD8αα homodimer. The CD8αβ heterodimer is considered the relevant functional coreceptor on peripheral T cells. The three-dimensional structures of human and mouse MHC-I/CD8αα complexes have been described,[508,509] and more recently, a complex of mouse MHC-I/CD8αβ has been reported.[58] These structures localize the binding site of the CD8 Ig-like αα homodimer or CD8αβ heterodimer to a region on an exposed loop of the MHC-I α3 domain. This interaction is illustrated in Figure 21.19, which shows the flexible loop of residues 223 to 229 clamped into the CD8 combining site. This is one of relatively few examples of an non-Ig, Ig-like molecule exploiting an Ig-like heterodimer interface to bind another ligand. The structural identification of the CD8αα and CD8αβ on the MHC-I provides a context for understanding the contribution of CD8, which binds the kinase Lck through the cytoplasmic domain of its α chain to T-cell signaling.

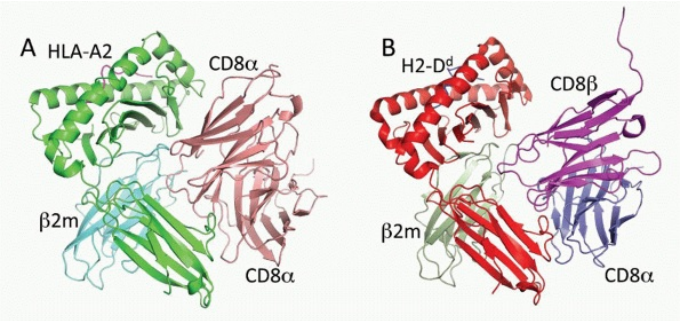

FIG. 21.19. CD8αα and CD8αβ Bind the Same Site on the MHC-Iα3 Domain. The MHC-I interactions with the CD8αα (PDB 1AKJ) homodimer **(A)** and CD8αβ (PDB 3DMM) heterodimer **(B)** are shown.

The T-cell coreceptor associated with cells restricted to MHC-II antigens, CD4, has also been the subject of detailed structural studies, in part, because of its role as a receptor for attachment and entry of HIV.[510] The x-ray structure determination of the complete extracellular portion of the molecule (domains D1 through D4) indicates a degree of segmental flexibility between domains D2 and D3, and both crystallographic and biochemical data suggest that dimerization of cell surface CD4 occurs.[511] These results have been interpreted to support a role for CD4-mediated MHC-II-dependent dimerization in facilitating TCR dimerization and signaling. Although a mixed species structure of human CD4 D1-D2 domains with a mouse MHC-II molecule was reported at low resolution some years ago,[63] only recently, employing an affinity matured human CD4 molecule have diffraction quality crystals of human MHC-II/human CD4 D1-D2 molecules been obtained[64] (Fig. 21.20). This recently determined human MHC-II/hCD4 structure is remarkably similar to the low-resolution mixed species structure determined more than 10 years earlier. Both structures reveal the focus of the CD4 interaction on a stretch of amino acid residues on the Ig-like β2 domain of the MHC-II molecule. Earlier mutagenesis and functional studies of CD4-dependent MHC-II-mediated T-cell activation

also implicated a region on the α2 domain of MHC-II.[61,512] Although the α2 domain residues do not directly interact with CD4 in these structures, it is conceivable that they play some indirect role in MHC multimerization that may contribute to signaling.

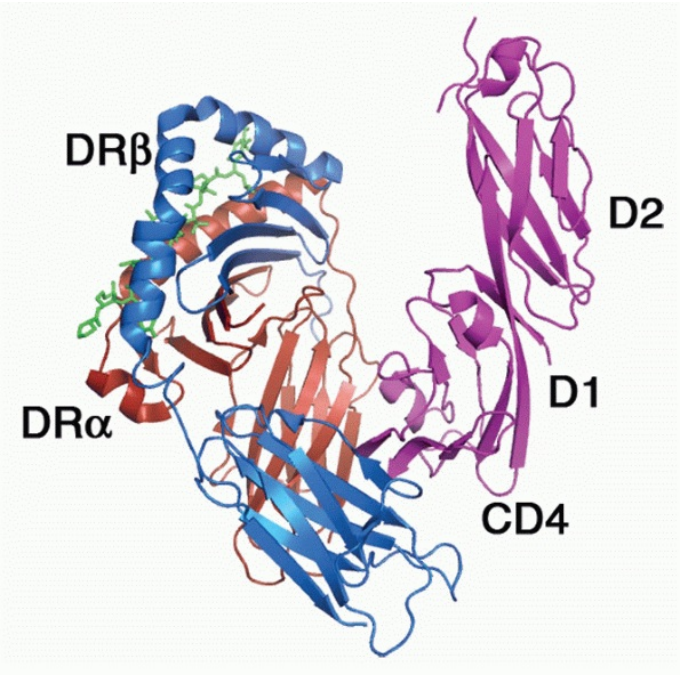

FIG. 21.20. CD4 Interacts Directly with the β2 Domain of MHC-II. A ribbon illustration of a complex of human CD4 with HLA-DR1 (PDB 3S5L) is shown. The HLA-DRα chain is in *firebrick*, HLA-DRβ chain in *blue*, peptide in *green*, and CD4 in *magenta*.

MHC/Natural Killer Receptor Complexes

NK cells provide a first line of defense against virus-infected and host cells, and their recognition of such targets is dependent on a balance of NK activating and inhibitory receptors.[513,514] In addition to their expression on NK cells, some of the NK receptors are also expressed on subsets of T cells and other hematopoietic cells. In general, each of these classes of NK receptors also falls into two different structural groups: the Ig-like receptors and the C-type lectin-like receptors. Because of their functional interactions with MHC-I and MHC-I-like molecules, and because several different systems have evolved to recognize MHC-I molecules differently, it is worthwhile to examine the recently determined structures of several MHC-I/NK receptor complexes.

In the human, the major NK receptors fall into several categories: those of the NKG2 family, the NKp molecules, and the KIRs. The NKG2 family molecules are C-type lectin-like molecules that recognize ligands grouped broadly as the NKG2D ligands, which include the MHC-like molecules, MICA and MICB, as well as the ULBP family of stress-induced molecules. NKp molecules include NKp30, NKp44, and NKp46, all members of the Ig superfamily. The KIR molecules, also Ig superfamily members, bind either HLA-C, or for the KIR3 subfamily, HLA-B molecules. Because the focus of this chapter is members of the MHC protein family, we will restrict our discussion of the human NK receptor/ligand interactions to the NKG2/MIC and ULBP complexes and to the KIR2D and KIR3D/MHC interactions.

The activating receptor, NKG2D, interacts with MICA, a stress-induced MHC-I-like molecule, allowing NK cells to eliminate virus-infected or tumor cells that are marked by the surface expression of MICA. The structure of the human NKG2D/MICA complex reveals that the homodimeric binding site of NKG2D recognizes the surface α-helical superdomain, in an orientation similar to that by which TCR see MHC-I molecules[456] (Fig. 21.21). This structure shows remarkable similarity to that of the hNKG2D bound to another MHC-Ib protein, ULBP3.[515] Similarly, the mouse NKG2D interacts, in a similar orientation, with the murine stress-induced molecule, RAE-1β.[459]

The short KIRs (eg, KIR3DS and KIR2DS molecules) are considered activating receptors because they have the potential to interact with the DAP12 signal-transducing molecule, and the long KIRs (eg, KIR3DL and KIR2DL) are inhibitory because they have cytoplasmic domains that contain immunoreceptor tyrosine-based inhibitory motifs. KIR2DL1 and KIR2DL2 have been studied extensively. They interact with the human MHC-I molecules HLA-C*04 and HLA-C* 03, respectively, and show some preferences for MHC-I molecules complexed with particular peptides. Among the polymorphic amino acid residues that distinguish HLA-C* 03 and HLA-C*04 are Asn80 of -C*03 and Lys80 of -C*04. Thus, it was of interest when the structures of HLA-C* 03/KIR2DL2[104] and HLA-C*04/KIR2DL1 complexes were reported.[105] The KIR2DL2/HLA-C*03 interaction is illustrated in Figure 21.22. The important conclusions from this structure and those of similar KIR2DL complexes is that the recognition of MHC-I is via amino acid residues of the

elbow bend joining the two Ig-like domains of the KIR, and that residues that vary among different KIRs determine the molecular specificity of the interaction with the particular allelic product of HLA-C. In addition, the interaction of the KIR with the HLA-C is also modulated by the particular bound peptide, explaining the results of binding/peptide specificity studies. Structural understanding of the KIR3 molecules, which have three extracellular Ig-like domains, eluded the field for many years. Recently, a molecular complex of HLA-B*57:01 with KIR3DL1 has been reported (see Fig. 21.22). This structure reveals the contribution of the D0 amino terminal domain of KIR3DL1 in recognizing a region of the MHC-I with limited polymorphism, the D1 domain accommodates a region with sequence variation, and the D2 domain shows high complementarity.

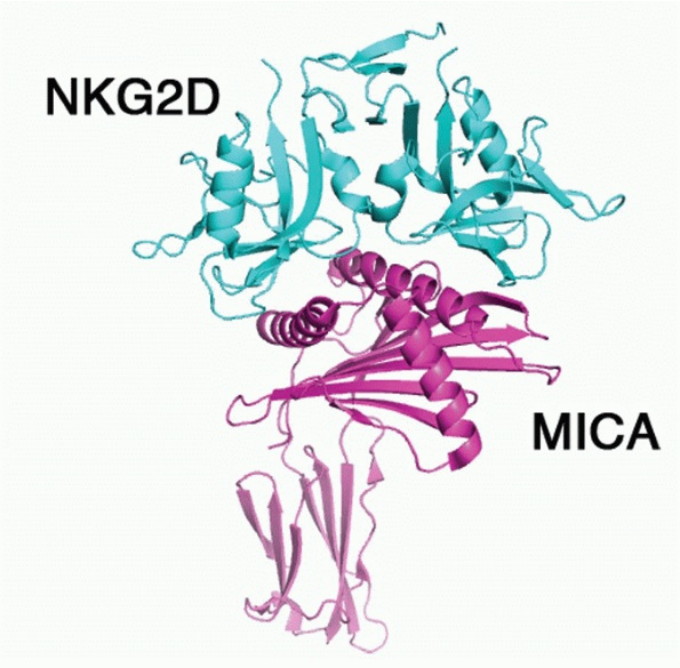

FIG. 21.21. The NKG2D sees the MHC-Ib MICAα-Helical Superdomain. The structure of the human NKG2D/MICA complex (PDB 1HYR) reveals the homodimer NKG2D sitting asymmetrically astride the MICA α-helical superdomain. The NKG2D domains are in *cyan* and MICA in *magenta*.

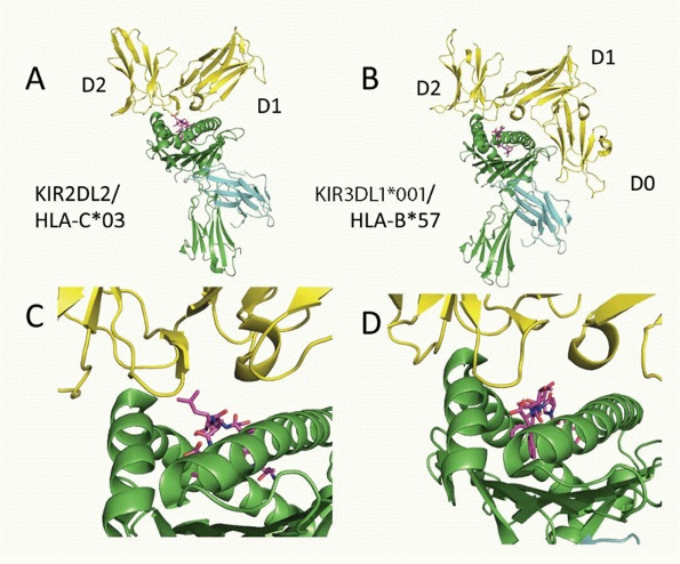

FIG. 21.22. KIR2DL2 and KIR3DL1 Interact Similarly with Their MHC-I/p Ligands. KIR2DL2 complexed with HLA-C*03 (PDB 1EFX) **(A,C)** and KIR3DL1 complexed with HLA-B*57:01 (PDB 3VH8) **(B,D)** are shown to illustrate the overall interactions **(A,B)** and close-ups of the contact with bound peptide **(C,D)**.

The mouse exploits a set of NK receptors of a different structural family to provide the same function. In particular, the predominant, and best studied, mouse NK receptors are those of the Ly49 family. Functional experiments had demonstrated that Ly49A interacts with the MHC-I molecule, H2-D^d, and also that for appropriate interaction, H2-D^d needs to be complexed with a peptide. In contrast to human NK recognition, however, surveys of H2-D^d-binding peptides revealed little if any peptide preference or specificity. This would explain the function of the NK inhibitory receptor in that they are at baseline chronically stimulated by normal

MHC-I on somatic cells, turning off the NK cell. When MHC-I is dysregulated by tumorigenesis or by pathogenic infection, the lower level of surface MHC-I diminishes the NKIR-mediated signal, and the NK cell is activated. The structure of the mouse Ly49A inhibitory receptor in complex with its MHC-I ligand, H2-D^d (Fig. 21.23), reveals several crucial features of the interaction: 1) the Ly49A C-type lectin-like molecule is a homodimer; 2) the Ly49A molecule makes no direct contact with residues of the MHC-bound peptide; and 3) in the x-ray structure, there are two potential sites for Ly49A interaction with the MHC molecule: site 1 at the end of the α1 and α2 helices, and site 2, an extensive region making contact with the floor of the peptide binding groove, the α3 domain of the MHC-I molecule, and the β2m domain as well. The ambiguity suggested by the x-ray structure has been resolved by extensive mutagenesis studies that are consistent with the view that site 2 is functionally significant.[516,517] Recently, several other NK receptors have been studied structurally. These include the Ly49I inhibitory receptor, which interacts functionally with H2-K^b. The Ly49I has been crystallized without a ligand, revealing a basic fold similar to that of Ly49A but with a somewhat different dimeric arrangement.[518] The Ly49C, another murine NK inhibitory receptor, has been examined in complex with its H2-K^b ligand.[519] Differences between H2-K^b/Ly49C and H2-D^d/Ly49A suggest different modes of NK receptor binding to MHC-I depending on whether the interaction is “cis” (ie, between the NK receptor and the MHC-I on the same NK cell) or “trans” (between the NK receptor on the NK cell and the MHC-I on its target).[520]

MHC-II Superantigen Complexes

Superantigens are molecules, frequently toxic products of bacteria, which bind MHC molecules on the cell surface and are then presented to a large subset of T cells, usually defined by the expression of a particular family of TCR V regions.[521] Most of the known superantigens bind MHC-II molecules, although one, the agglutinin from *Urtica dioica*, the stinging nettle, can be bound by both MHC-I and MHC-II molecules and presented to T cells of the Vβ8.3 family.[522] Its structure in complex with carbohydrate ligand has been reported.[523,524] MHC-II interactions with superantigens, such as those derived from pathogenic bacteria, are the first step in the presentation of the multivalent array of the APC-bound superantigen to T cells bearing receptors of the family or class that can bind the superantigen.[521] A number of structural studies examining the interaction

of superantigen both with their MHC-II ligands and with TCR have been reported.[525] Structural analysis of crystals derived from staphylococcal enterotoxin B complexed with HLA-DR1[526] and from toxic shock syndrome toxin-1 complexed with HLA-DR1[527] revealed that the two toxins bind to an overlapping site, primarily on the MHC-II α chain, and indicated that the staphylococcal enterotoxin B site would not be expected to be influenced by the specific peptide bound by the MHC, although the toxic shock syndrome toxin-1 site would. The view that superantigens exert their biologic effects by interaction with conserved regions of the MHC-II molecule as well as with conserved regions of the TCR has been challenged by the determination of two structures, that of *S. aureus* enterotoxin H complexed with HLA-DR1[528] and that of streptococcal pyrogenic toxin C in complex with HLA-DR2a.[529] Both of these studies indicate that these superantigens can interact with the MHC-II β chain through a zinc-dependent site that includes superantigen contacts to bound peptide. Our understanding of superantigen interactions has been augmented by the determination of ternary structures of MHC-II/superantigen/TCR complexes for two examples, that of the *Mycoplasma arthritidis* mitogen in complex with HLA-DR1 and TCR,[530] and that of *Staphylococcus aureus* enterotoxin H complexed with HLA-DR1 and TCR.[531] In both of these cases, the superantigen interacts with the MHC-II and with both TCR Vα and Vβ domains.

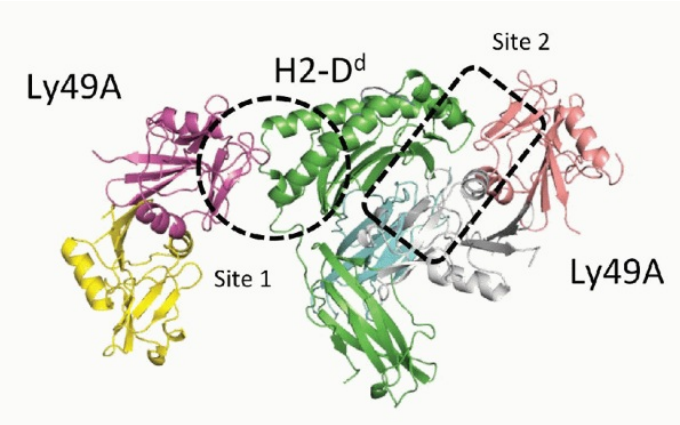

FIG. 21.23. Structure of the H2-D^d/Ly49A Complex Reveals an Alternate Site for MHC/Natural Killer Receptor Interaction. The structure of the complex (PDB 1QO3) is shown, illustrating both potential sites of interaction.

MOLECULAR INTERACTIONS OF MHC MOLECULES

Assays for Molecular Interactions

Whereas the crystal structures provide a vivid static illustration of the interactions of MHC molecules with their peptide, FcRn, CD8, CD4, superantigen, NK receptor, and TCR ligands, the dynamic aspects of these binding steps can be approached by a variety of biophysical methods.[532] It is important to note that affinities and kinetics of interaction of MHC/peptide complexes for TCR have been determined by several methods in a variety of systems.[533,534,535,536,537,538,539,540] In addition, MHC interactions with NK receptors[101,102,541,542] have been quantified by similar techniques. Although there are clear differences in the affinity and kinetics of binding of different TCR and NK receptors for their respective cognate MHC/peptide complexes, the generally consistent findings are that the affinities are low to moderate (ie, $K_d = 5 \times 10^{-5}$ to 10^{-7} M) and are characterized by relatively rapid dissociation rates (ie, $k_d = 10^{-1}$ to 10^{-3} sec^{-1}). Recently, attention has been drawn to the differences in measuring interactions with one component in solution (three-dimensional affinity) as compared with measurements made between multivalent displays of the interactions on two surfaces, such as might mimic the apposition of two cells. Methods exploiting microscopic techniques[543,544] or a micropipette adhesion frequency assay[545,546] suggest that the biologic readout of T-cell activation may be more readily correlated with twodimensional rather than three-dimensional measurements of MHC/TCR affinities.

Multivalent MHC/Peptide Complexes

A major development in the past several years has been the engineering and application of multivalent MHC/peptide complexes for the identification, quantification, purification, and functional modulation of T cells with particular MHC or MHC/peptide specificity. Two general approaches have been exploited: one based on the enzymatic biotinylation of soluble MHC/peptide molecules generated in bacterial expression systems that are then multimerized by binding of the biotinylated molecules to the tetravalent streptavidin,[547] and another based on the engineering of dimeric MHC/Ig fusion proteins.[548] These reagents can be used in flow cytometric assays that permit the direct enumeration of MHC/peptide-specific T cells taken directly ex vivo. In either of these methods, multivalent MHC/peptide complexes are generated, and the relatively weak intrinsic affinity of the MHC/peptide complex for its cognate TCR is effectively magnified by the gain in avidity obtained by the increase in valency. For MHC-I molecules, the technology has been so reliable in producing multivalent (tetrameric) molecules loaded homogeneously with synthetic peptides that a wide variety of specific MHC-I/peptide multimers are available either from a resource facility sponsored by the National Institute of Allergy and Infectious Diseases (www.niaid.nih.gov/reposit/tetramer/index.html) or from commercial suppliers that offer either

the tetramer, Ig multimer, or a pentamer preparation. The MHC-I/peptide multimers have also been exploited for identification of specific populations of NK cells and for assignment of various NK-receptor specificities.[549,550,551,552] For some MHC-II molecules, similar success has been achieved in the production of such multimers, using insect cell or mammalian cell expression systems for molecules produced by either the tetramer or Ig chimera strategy.[553,554,555,556,557] MHC-II/peptide tetramers can be effectively used for a variety of CD4 T-cell applications, but some TCRs (particularly those involved in autoimmune diseases) have an affinity for their cognate MHC-II/peptide that is beneath the threshold for detection.[545] Also, the potential for the same peptide binding to one MHC-II in multiple frames generates difficulties in the engineering and preparation of effective MHC-II tetramers.[406]

CONCLUSION

We have surveyed the *Mhc* as a genetic region and a source for molecules crucial to immune regulation and immunologic disease. These genes reflect the panoply of mechanisms involved in the evolution of complex systems and encode cell surface proteins that interact via complex orchestration with small molecules including peptides and glycolipids as well as with macromolecular receptors on T cells and NK cells. The MHC-I molecules provide the immune system with a window for viewing the biologic health of the cell in which they are expressed, and MHC-II molecules function as scavengers to taste and display the remnants of the cellular environment. Viruses and bacterial pathogens contribute enormously to the genetic dance—

they modulate and compete in the control of MHC expression, sometimes exploiting MHC mimics that they have acquired—and the host by adjusting its T-cell and NK-cell repertoire on the time scale of both the individual organism and the species, resisting the push to extinction. The immune system, dynamically, resourcefully, and creatively provides, through the concerted action of its MHC molecules, TCRs, NK receptors, and antibodies as well as a host of other regulatory molecules, an organ system vital not only to the survival of the individual but also to the success of the species. As we understand better the molecular functions of the MHC, we should better understand rational approaches to manipulating the immune system in the prevention, diagnosis, and treatment of immunologic and infectious diseases.

Chapter 22

Antigen Processing and Presentation

Ted H. Hansen

Paul A. Roche

ANTIGEN PRESENTATION PATHWAYS

As part of the adaptive immune response, T cells mount immune responses to diseased cells and abnormal cells. Remarkably, the mechanism by which T cells discriminate self from non-self is based on pathogen- or tumor-derived proteins displayed on the cell surface by self-major histocompatibility complex (MHC) molecules. More specifically, when T cells detect diseased cells displaying MHC molecules loaded with peptides derived from foreign peptides, effector mechanisms are initiated to eliminate the diseased cell. By contrast, T cells that detect cells displaying MHC molecules loaded with peptides derived from self-proteins are either eliminated during ontogeny by negative selection or suppressed by peripheral tolerance mechanisms. Thus, at the molecular level, the T-cell receptors on T cells discriminates MHC loaded with self- versus non-self-peptides displayed at the cell surface of normal and diseased cells. The mechanisms by which peptide ligands for MHC molecules are generated is referred to as *antigen processing*, whereas the mechanism by which peptide/MHC complexes are displayed at the cell surface is called *antigen presentation*.

To assure the appropriate effector mechanism is generated to detect cells infected with pathogens in the cytosol or endocytic compartments, the antigen presentation pathways for classical cluster of differentiation (CD)8+ versus CD4+ T cells are different. More specifically, antigen derived from intracellular pathogens is typically bound to MHC-I proteins that are uniquely detected by CD8 T cells, whereas antigen derived from extracellular pathogens is typically bound to MHC-II proteins that are uniquely detected by CD4 T cells. To preferentially bind peptides derived from proteins synthesized inside the cell, the processing of peptides that bind MHC-I proteins occurs in the cytosol and the loading of these peptides occurs in the endoplasmic reticulum (ER). This pathway is commonly referred to as the classical MHC-I antigen-binding pathway. By contrast, to preferentially bind peptides from proteins synthesized outside the cell, the processing and loading of antigenic peptide ligands for MHC-II proteins occurs in an endocytic pathway terminating in the lysosomes. This pathway is typically referred to the classical MHC-II antigen-binding pathway. The differences between the MHC-I and MHC-II antigen presentation pathways are determined by their differential interaction with molecular chaperones. These same molecular chaperones enforce the quality control of antigen presentation to assure appropriate T cells are activated for detection and elimination of pathogen-infected cells or tumors.

ANTIGEN PROCESSING AND PRESENTATION BY MAJOR HISTOCOMPATIBILITY CLASS I (MHC-I) PROTEINS

Origin of MHC-I binding peptides

As detailed in Chapter 21, MHC-I proteins preferentially bind peptides of 8 to 10 amino acid lengths, and which peptides bind is determined by MHC-I allele-specific polymorphic residues that form the architecture of its peptide binding groove. Each MHC-I allele typically binds peptides with a consensus binding motif requiring a relatively specific amino acid central anchor and a C-terminal hydrophobic amino acid. Given the lack of restraints in most peptide positions and the large number of proteins synthesized by each cell relative to the number of MHC molecules, the selective processes controlling which peptides get presented is of considerable importance for the detection of pathogens and malignancies.

The source of the peptides that get presented during infection has been a question of considerable investigation. It has been known for some time that MHC-I-binding peptides are derived from membrane-bound, secreted, cytosolic, and nuclear proteins that are almost exclusively generated by the proteasome in the cytosol. However, the uncertainty of peptide source is based on two apparently incongruent observations. Most proteins from which MHC-I-binding peptides are derived have slow rates of turnover in cells ranging from hours to days; viral-derived peptides are presented by infected cells to CD8 T cells within a few minutes. This disparity between the degradation versus presentation kinetics is potentially explained by cumulative observations that a fraction of newly synthesized polypeptides are rapidly degraded, providing a peptide reservoir sufficient to support a robust CD8 T-cell response. Supporting evidence for this conclusion comes from studies that block protein synthesis with cycloheximide and detected a rapid decrease in the peptide supply for MHC-I binding.[1,2] One of the more elegant ways to monitor peptide transport into the ER was by transporter associated with antigen presentation (TAP) mobility in the ER membrane by photobleaching; establishing TAP mobility was proportional to the peptides in the cytosol. This assay was used to show a 90% reduction in peptide supply after 30 m treatment with cycloheximide, thus kinetically linking presentation closely to translation.[3] Indeed, there are now several reports that within 30 minutes after synthesis, antigenic peptides are presented at

the cell surface at levels that activate T cells.[4,5] What remained unclear from these studies is the biochemical and mechanistic basis for the generation of these rapidly transcribed proteins from which MHC-I-binding peptides are derived.

In a model that has gained wide acceptance, Yewdell and colleagues proposed that a rapid supply of MHC-I ligands is derived from aberrant protein production they termed defective ribosomal products or DriPs.[6,7] In their model, it was speculated that DriPs could be derived from unfolded or misfolded proteins of the proper sequence and length, proteins with errors in sequence or posttranslational modifications, prematurely terminated proteins, and proteins translated from the wrong start codon.[8] Regarding aberrant translations, there is evidence that MHC-presented peptides can arise from alternative reading frames, generating what has been called cryptic epitopes.[9] For example, Schwab et al. showed that inhibition of the eukaryotic translational initiation factor eIF2α resulted in the synthesis of cryptic peptides and intriguingly, viruses inhibit host translation by inactivating eIF2α.[10,11] However, most MHC-I-

presented peptides have native amino acid sequence and are derived from standard messenger ribonucleic acid (mRNA) translation products, suggesting cryptic epitopes represent only a minor component of MHC-presented peptides. In addition, the contribution of peptides derived from misfolded proteins in the secretory pathway is also likely modest. Although antigenic peptides from misfolded tyrosinase were found to be preferentially presented,[12] other studies show that several mutations causing misfolding do not lead to enhanced antigen presentation. Furthermore, ER quality control is typically too slow to account for the rapid supply of MHC-I-binding peptides.[13] The reason for this kinetic delay is that substrates for ER-associated degradation (ERAD) must be 1) translocated into the ER, 2) detected presumably by ER chaperones as being misfolded, 3) ubiquitinated and extracted from the ER, and 4) degraded by the proteasome in the cytosol. Thus the predominance of MHC-I-presented peptides likely does not come from cryptic epitopes or misfolded ER proteins identified by ER quality control.

To obviate trafficking into the ER, misfolded secretory proteins could be degraded rapidly based on degron detection such as unshielded hydrophobicity.[14] Alternatively, early in translation a lack of signal recognition particle engagement could lead to the mistargeting of secretory proteins to the cytosol. In support of this model, Schlosser et al.[15] showed that an epitope encompassing the signal peptidase cleavage site was efficiently presented by MHC-I proteins. To rapidly generate peptides, it has been speculated that cells may have select ribosomes called “immunoribosomes.”[16] Such immunoribosomes might be more adept at generating peptides with TAP access perhaps by compartmentalization and/or targeting proteins to the 20S proteasome for immediate destruction. In any case, there is considerable evidence that antigenic peptides can be rapidly presented by MHC-I within minutes after translation of the protein source. The physiologic significance of this rapid kinetics of antigen presentation is that it allows CD8 T cells to kill virus-infected cells before viral replication is completed and progeny are released. However, whether the production of peptides bound to MHC class I molecules is a deliberate process for degrading defective translation products and/or a stochastic event of normal protein translation remains to be determined.[17]

Peptide Trimming in the Cytosol

Degradation of cellular and antigenic peptides bound to MHC-I is largely mediated in the cytosol by the proteasome. The proteasome is responsible for the degradation of the majority of cytosolic and nuclear proteins, and in most cases proteasome targeted proteins are ubiquitinated. Ubiquitin (Ub) is typically coupled to internal lysine residues of proteins substrates, but coupling can also occur at the N terminus or on internal cysteine, serine, or threonine residues.[18,19,20,21] In this orchestrated process, activated Ub is transferred from one predominant Ub-activating enzyme (E1) to one of 30 to 40 mammalian Ub conjugating enzymes (E2s) and then to the substrate that is bound by one of hundreds of different ubiquitin protein ligases (E3s). The E3s are the major determinant of substrate specificity. This process can be repeated to form polyUb chains whereupon the next Ub moiety is added to one of the seven internal lysine residues of Ub. Proteins coupled with polyUb chains of four or more Ub moieties linked through Lys48 Ub residues are the prototypic signal for proteasome mediated degradation.

The cylindrical 20S catalytic particle (CP) of the proteasome is formed by four stacked rings

of seven subunits each. The inner two rings of the 20S proteasome are assembled from the beta subunits, three of which have catalytic activity with chymotryptic, tryptic, or caspase activity. Thus each proteasome has six active sites with the ability to cleave after most types of peptide bonds, although to differing efficiencies based on flanking residues. The catalytic sites are exposed to the interior of the central chamber of the 20S cylinder. The two outer rings of the 20S proteasome are assembled from alpha subunits forming a pore of 13 Angstrom, mandating protein substrates be partially denatured prior to entering the interior of the chamber. The gate of the 20S CP is normally closed, and access to the interior of the 20S proteasome is controlled by the complex of proteins termed the 19S regulatory particle that binds to each end of the 20S cylinder. The full assemblage of 19S-20S-19S complex constitutes the 26S proteasome. The lid of the 19S regulator particle binds and deubiquitinates protein substrates before they gain entry in the 20S CP; the base of the 19S regulatory particle contains ATPases that promote substrate unfolding and open the gate of the 20S CP to provide access of denatured protein substrates to the catalytic activity of the inner chamber.

The evolutionarily conserved function of the proteasome is for recycling amino acids and ubiquitin moieties. However, in mammals, modifications to the proteasome have been made to promote antigen presentation. In response to interferon (IFN)γ stimulation that occurs during inflammation, three catalytic subunits of the constitutively expressed proteasome are replaced by IFNγ-induced homologs forming what is called the immunoproteasome. More specifically, subunits β1, β2, and β5 of the constitutive proteasome are replaced by subunits β1i (LMP2), β2i (MECL-1), and β5i (LMP7) of the immunoproteasome. Suggesting an immunologic function,

region of the mouse and human MHCs juxtaposed to genes encoding the TAP heterodimer. Consistent with their immunologic relevance, the immunoproteasomes display enhanced cleavage of protein substrates after hydrophobic and basic amino acids, thus generating peptides with C-terminal residues preferred for binding to many MHC-I alleles. IFNγ stimulation also induces the expression of PA28α and PA28β that form the 11S regulatory particle, which can also bind to either end of the 20S CP. Interestingly, the PA28 regulatory particle does not contain ATPases, but it does induce conformational changes to open the 20S CP gate. Thus, PA28 may function to prevent the overdigestion of short peptides. This is an important issue, as it has been estimated that a nonamer peptide in the cytosol has a half-life of only 7 seconds.[22] However, studies testing PA28α/β-deficient mice demonstrated that PA28α/β is not required for overall antigen presentation during virus infection, but may affect degradation of select substrates.[23] In any case, the inclusion of the IFNγ-inducible β subunits into the 20S CP of immunoproteasome enhances antigen presentation by generating peptides with preferred C-terminal anchor residues, and in some same cases inclusion of the PA28 regulatory particle may prevent overdegradation of immunologically relevant proteins.

The proteasome generates the final C-terminal cleavage of most MHC-I-binding peptides. A recently reported exception to this is the generation of the tumor antigen MAGE-A3 by insulin-degrading enzyme.[23] Whereas insulin degrading enzyme is solely responsible for the generation of the human leukocyte antigen (HLA)-A1-restricted MAGE-A3 epitope, the HLA-B40-restricted MAGE-A3 epitope was proteasome dependent. Although there are several N-

terminal proteases in the cytosol, they have only a limited role in generation of the MHC-I-binding peptides. More specifically, tripeptidyl peptidase II, leucine amino peptidase, bleomycin hydrolase, and puromycin-sensitive aminopeptidase have all been found to affect generation of select MHC-I-binding epitopes, but these proteases have an overall negative effect on antigen presentation by MHC-I. Interestingly, the metalloprotease nardilysin that cleaves substrates on the N-terminus of arginine residues in dibasic pairs was implicated in three cytotoxic T lymphocyte epitopes and may be more generalizable given the preference for basic N-terminal resides for MHC-I binding.[24] However, as noted in the following, significant N terminal trimming of MHC-I-binding peptide occurs after transport from the cytosol into the ER.

Peptide Transport into the Endoplasmic Reticulum

Landmark studies of the mutagenized and immunoselected mouse cell line RMA-S resulted in the discovery of how peptides are transported from the cytosol into the ER lumen.[25,26,27] The low level of surface expression of MHC-I molecules by RMA-S that could be rescued by either low temperatures or culturing with known MHC-I-binding peptides was attributed to lack of peptide transport by TAP. TAP is a member of the adenosine triphosphate (ATP) binding cassette family. Mechanistically, hydrolysis of ATP is required both for peptide binding to the cytosolic face of TAP as well as peptide transport into the ER. Structurally, TAP is a heterodimeric complex of TAP1 and TAP2 subunits both encoded within the central region of the MHC of mouse and human. The translocation pore of TAP is formed by six transmembrane domains of each subunit, whereas the remaining transmembrane domains (four for TAP1 and three for TAP2) are involved in interaction with peptide loading complex (PLC).[28] Awaiting transport, both the N- and C-termini of peptides are bound to TAP[29]; peptides with higher affinity for binding TAP have a greater likelihood of transport, MHC binding, and presentation to T cells during infection.[30,31] TAP typically transports peptides of 8 to 16 residues, although longer peptides are less efficiently transported. As discussed in the next section, peptides with N-terminal extensions are trimmed in the ER.

Peptide Trimming in the Endoplasmic Reticulum

As noted previously, TAP transports many peptides with C-terminal hydrophobic residues required for MHC binding, but with N-terminal extensions, which need to be cleaved to conform to the MHC-binding motif of the expressed alleles. It is now clear that N-terminal trimming within the ER is carried out by the ER-associated aminopeptidase (ERAAP; ERAP1 in mice and ERAP1 in humans). Interestingly, unlike other aminopeptidases, ERAP1 preferentially cleaved peptides of 9 to 16 amino acids thus matching the same peptide length preference as transported by TAP.[32] More specifically, ERAP1 was found to degrade a model 13-mer to a 9-mer and then stop, an apparent adaptation to maximize optimal MHC-I binding. The length preference of ERAP1 could be explained by extended peptides binding to MHC-I before N-terminal trimming. However, this model is not supported by structural analyses of ERAP1 and the location of its active site.[33] Alternatively, recent analyses support a “molecular ruler” model. In this model, a hydrophobic pocket of ERAP1 binds the C-terminal peptide residue thereby positioning the peptide so that N-terminal cleavage occurs about nine amino acids away.[32,33] Thus, ERAAP/ERAP1 has unique structural features explaining its ability to trim extended peptide precursors while sparing ones of optimal length for MHC-I

binding. As further evidence of their specialized functions in antigen presentation by MHC-I proteins, ERAP1 preferentially binds and processes peptides with hydrophobic C-terminal residues consistent with the majority of the TAP-transported MHC-I-binding peptides. Interestingly, humans have a second ER-associated peptidase with homology to ERAP1 designated ERAP2.[34] ERAP2 preferentially binds peptides with C-terminal basic residues and thus may function in human cells to provide peptides for HLA-A3, -Aw68, and -B27 alleles that bind such peptides. Additionally, in humans the combined activity of both ERAP1 and ERAP2 (most likely as heterdimers) is required for the presentation of certain epitopes.[35] By contrast, in mice ERAAP/ERAP1 is sufficient to service their MHC-I alleles, all of which bind peptides with hydrophobic C-termini. As additional evidence for their tailoring for MHC-I-antigen presentation, the expression and trimming activity of ERAP1 and ERAP2 are upregulated upon IFNγ stimulation.

The impact of ERAP on specific epitopes and the overall MHC-binding peptide repertoire has been analyzed using

cell lines[36,37] and ERAAP-knockout mice.[38,39] These studies have shown that cytotoxic T lymphocyte detection of some but not all MHC-I/peptide complexes are ERAP1-dependent. For example, in vitro ribonucleic acid interference experiments suggested that ERAP1 is involved in formation of onethird of peptide/MHC-I complexes.[36,37] ERAAP-deficient mice had a 20% lower expression of K^b, D^b, K^d, and D^d alleles at the cell surface but a 70% lower expression of L^d. Of these mouse alleles, only L^d preferentially binds peptides with the motif of Pro in the second position, although about 20% of human HLA alleles also prefer peptides with a Pro in the second position. Notably, peptides with Pro in the second position are only transported by TAP with N-terminal extensions and are thus dependent upon ERAP1 for their generation. In vivo relevance of this conclusion was demonstrated by the observation that ERAAP-deficient BALB/c mice were found to be susceptible to *Toxoplasma gondii* infection resulting from the fact that the immunodominant epitope presented to CD8 T cells is L^d restricted.[40] Interestingly the ERAAP-deficient mice were also found to present several unique peptides that elicited potent CD8 T-cell responses demonstrating ERAAP functions, as a peptide editor altering the repertoire of peptides presented.[38]

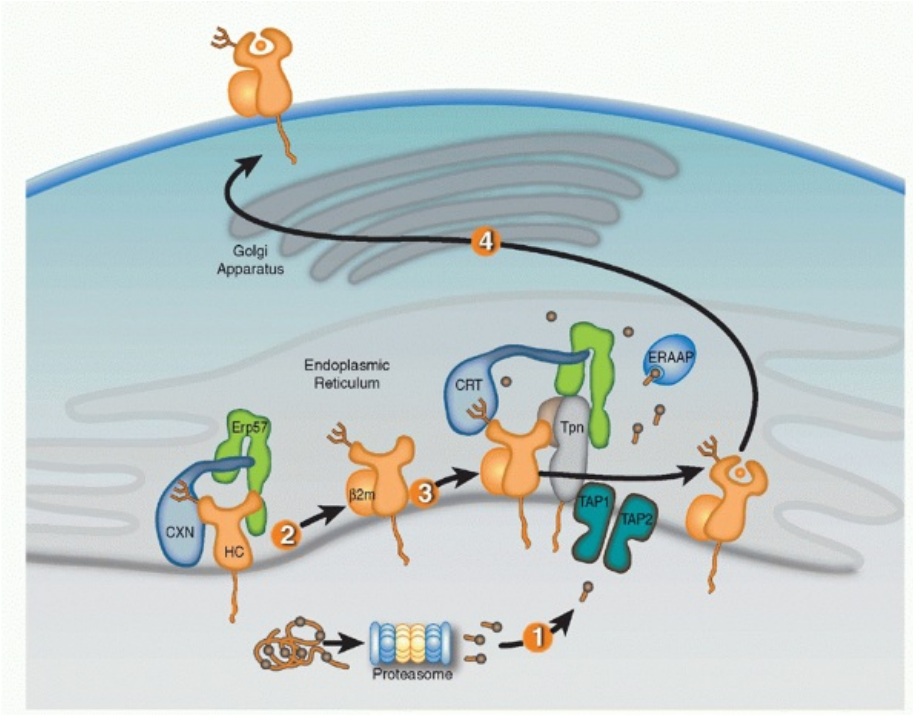

FIG. 22.1. Schematic Representation of the Sequential Events of Antigen Processing and Presentation by Major Histocompatibility Complex (MHC)-I Proteins. 1: Peptides are processed by the proteasome and translocated into the ER by TAP1/TAP2 heterodimers. **2:** MHC-I heavy chains (HCs) awaiting assembly with β2m are bound to calnexin (CXN)/ERp57 complexes. **3:** After assembly with β2m, HC/β2m heterodimers enter the peptide loading complex wherein tapasin (Tpn) bridges HC with transporter associated with antigen presentation (TAP)/TAP2, and calreticulin (CRT)/ERp57 complexes bridge HC with Tpn. **4:** Following the binding of a suitable peptide, which may require final N-terminal trimming by ERAAP, fully assembled MHC-I proteins (HC/β2m/peptide) traffic to the plasma membrane via the secretory pathway.

Chaperone-assisted Peptide Loading in the Endoplasmic Reticulum

Full assembly of the MHC-I heavy chains (HCs) with β2m and peptide within the ER is orchestrated by molecular chaperones that keep folding intermediates in a conformation capable of attaining full assembly (Fig. 22.1). Nascent HCs are transiently associated with the membrane-anchored

lectin calnexin (CXN) that, like its soluble paralog calreticulin (CRT), functions as a general chaperone for assembly of oligomeric glycoproteins. Quality control of glycoprotein assembly by CXN and CRT is carried out by monitoring terminal glucose residues on their N-linked glycans. More specifically, the folding sensor UDP-glucose glycoprotein glucotransferase allows incompletely assembled substrates to reassociate with CXN or CRT, and cycles of glucose addition and removal continue until substrates are either correctly folded and assembled or targeted for ERAD. After the MHC-I HC assembles with β2m, the HC/βm heterodimer exchanges CXN for CRT and enters the PLC consisting of CRT, ERp57, tapasin (Tpn), and TAP.[41,42,43,44] Optimal antigen presentation by MHC-I is dependent upon all

four components of the PLC (Tpn, TAP, CRT, and ERp57) that function to improve peptide loading in MHC-I proteins and their surface display.[45,46]

Knockout cell lines, genetically deficient mouse strains, and mutagenesis studies have provided key insights in the selective roles of PLC components in MHC-I assembly. CRT association with MHC-I proteins is dependent upon the N-linked glycan at residue Asn86 of the HC. Interestingly, the location of the glycan is important for CRT but not CXN association with HCs, likely reflecting geometric constraints imposed by PLC assembly. CRT-deficient cells have suboptimal peptide loading resulting in reduced surface MHC-I expression.[47] ERp57 is a thiol oxidoreductase that mediates disulfide bond formation of different substrates and is commonly associated with CXN and CRT. Interestingly, however, the function of ERp57 as a component of the PLC appears to be independent of the MHC-I redox state. ERp57 forms a disulfide bond with Tpn that is required for PLC construction.[48,49] It was originally proposed that the ERp57-Tpn complex prevents reduction of the α2 disulfide HC bond, thereby keeping HC in a peptide-receptive state.[50] However, other studies have detected little evidence the ERp57 controls redox state of MHC-I and more recently, the crystal structure of the ERp57-Tpn complex suggests that the role of the ERp57 in the PLC is structural, facilitating recruitment of peptide-accessible MHC-I.[49,51,52] As a likely reflection of its fundamental role in PLC construction, ERp57-deficient cells were found to have impaired peptide loading, surface expression, and antigen presentation by MHC-I proteins.

Tpn, an MHC-I-dedicated molecular chaperone, is required to bridge β2m-assembled HCs with TAP.[53] Playing a redundant role with other members of the PLC, Tpn also functions in ER retention of MHC with suboptimal peptide cargo.[54,55] Perhaps most importantly, Tpn functions as a peptide editor by stabilizing peptide-accessible MHC-I proteins and optimizing peptide cargo before release from the PLC. The mechanism of peptide editing by Tpn of MHC-I proteins was revealed using recombinant Tpn tethered to HLA,[56] and using recombinant Tpn-ERp57 conjugates added to Tpn-deficient cells.[57] These and other reports support the model that Tpn promotes the peptide exchange of MHC molecules in an affinity-dependent manner. The consensus model is that Tpn stabilizes the peptide binding groove of MHC-I in an “open” peptide-accessible conformation. The association of Tpn with peptide-accessible MHC-I then promotes peptide exchange until a peptide of suitable affinity binds to complete the folding of the ligand binding groove. This peptide-induced folding then induces the release of fully assembled MHC-I from the PLC. Logistically, how peptide editing by Tpn might occur was provided by mutagenesis studies of the MHC-I/Tpn interaction site. Two sites on the HC are critical for Tpn interaction: one site is in the α3 domain (residues 227 and 229) and the other in the α2 domain (residues 128-136)[43,58,59] (Fig. 22.2A). Based on the location of the latter site and molecular dynamic modeling, it has been theorized that the α2 interaction site might function as a folding sensor for C-terminal peptide anchoring in the MHC-I F pocket.[60,61] Consistent with this model, polymorphisms within the F pocket can have a profound effect of Tpn dependencies of different MHC-I alleles.[62] Based on mutagenesis and structural analyses, a credible model was constructed by Dong et al. of the MHC-I/PLC interactions[52] (see Fig. 22.2).

Although Tpn within the PLC is thought to enforce most of the quality control of antigen

presentation by MHC-I, there are also adjunct pathways. For example, the sensor UGT1 that adds a terminal glucose to unfolded ER proteins for rebinding CRT has been recently implicated in the quality control of antigen presentation by MHC-I. In support of this conclusion, using in vitro assays with recombinant components, UTG1 was reported to preferentially reglucosylate MHC-I proteins loaded with suboptimal peptides.[63] Also, as a post-ER quality control pathway, CRT was reported to use a KDEL-dependent mechanism to recycle suboptimally loaded MHC-I proteins from the early Golgi back the ER for improved peptide binding.[64]

Viral Immune Evasion of Antigen Presentation

As noted previously, several molecular components of antigen presentation were coopted from physiologic pathways of protein degradation and quality control. Using elegant mechanisms, viruses express diverse proteins that coopt these same pathways of protein degradation and quality control to evade immune detection by CD8 T cells.[65] Indeed, the specificity and potency of immune evasion proteins impairing antigen presentation makes them efficacious probes for physiologic pathways of relevance for MHC expression. Most of the well-characterized immune evasion proteins are expressed by deoxyribonucleic acid viruses with large genomes, particular viruses capable of latency or host coexistence. Strikingly, immune evasion proteins block several different steps of the antigen presentation pathway by MHC-I proteins (Fig. 22.3). For example, Epstein-Barr virus and Kaposi sarcoma-associated herpesvirus express proteins during latency that escape cytotoxic T lymphocyte detection by containing sequences that inhibit proteasome processing.[66,67,68,69,70] Alternatively, blocking peptide transport by inhibiting TAP function is a commonly used immune evasion strategy. For example, ICP47 of herpes simplex virus binds the cytosolic side of TAP and blocks peptide and not ATP binding,[71,72,73,74,75,76] whereas US6 of human cytomegalovirus (HCMV) binds the luminal side of TAP and induces a conformational change resulting in inhibition of ATP hydrolysis

and peptide translocation.[77,78,79,80,81] As a third mechanism of TAP blocking, UL49.5 of bovine herpesvirus induces TAP degradation.[82] There are also published examples of immune evasion proteins inhibiting Tpn function. For example, US3 of HCMV binds to Tpn and impairs optimization of peptide loading,[83,84] whereas E3-19K of AdV inhibits the ability of Tpn to bridge MHC-I with TAP.[85]

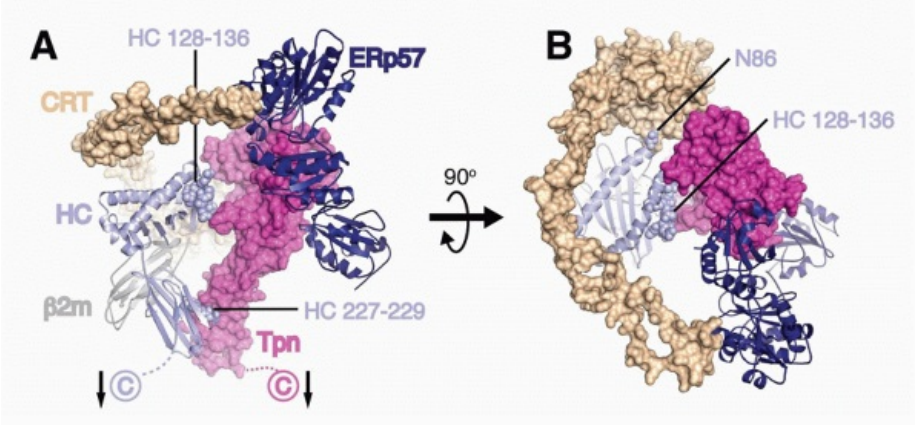

FIG. 22.2. A Model of the Peptide Loading Complex Based on Known Structures and Mutagenesis Data of Interaction Sites.[52] Heavy chains (HCs), β2m, and ERp57 are shown as ribbons, while calreticulin (CRT) and tapasin (Tpn) are shown as Connolly surfaces (1.4 Å probe). HCs and Tpn are membrane anchored as indicated with *arrows*, whereas transmembrane interactions between Tpn and TAP (not shown) attach the phospholipase C (PLC) components to TAP. HC sites predicted by mutagenesis studies to interact with Tpn (residues 227 to 229 and 128 to 136) and CRT (N86) are indicated as *spheres*. The long flexible P domain of CRT extends above the major histocompatibility complex (MHC)-I peptide binding platform before it noncovalently binds to ERp57, which is covalently attached to Tpn. **A:** PLC components are shown from the side to highlight Tpn contacts to the HC α2 and α3 domains. **B:** PLC components shown from above reveal coordinated chaperone binding of both MHCI α-helices near the antigenic peptide's C-terminus. The figure was rendered by Drs. William McCoy IV and Daved Fremont using Protein Data Bank (PDB) files kindly provided by Drs. Karin Reinisch and Peter Cresswell. The structures of the Tpn/ERp57 complex was published in Dong et al.,[52] the structure of CRT was modeled using PHYRE2[235] on its homolog calnexin,[236] and human leukocyte antigen-A2[237] is shown as a representative HC. It should be noted that the HC conformation shown is that attained after peptide occupancy, as the peptide-accessible HC conformation that binds the PLC has not been resolved.

Immune evasion proteins also employ strategies to misdirect trafficking of MHC-I proteins. For example, the aforementioned E3-19K protein of AdV binds MHC-I proteins and blocks their transport out of the ER.[86,87,88,89,90] Interestingly, cowpox virus expresses two different immune evasion proteins targeting MHC-I proteins that function in tandem. Cowpox virus 12 is a TAP function blocker that curtails peptide supply, whereas cowpox virus 203 returns fully assembled MHC-I proteins from the Golgi back to the ER.[91,92,93,94] To also misdirect assembled MHC-I proteins, the Nef protein of human immunodeficiency virus and gp48 protein of murine cytomegalovirus shuttle assembled MHC-I proteins from the Golgi to the lysosome.[95,96,97]

Interestingly, the aforementioned immune evasion proteins for the most part do not have cellular homologs, making it difficult to track their evolution. Striking exceptions to this

generality are the viral ER ubiquitin ligases called the viral MARCH (*m*embrane-*a*ssociated *R*ING-*CH*) proteins. The extensive family of MARCH proteins includes viral and cellular homologs that share a transmembrane orientation and a highly conserved atypical RING domain that confers E3 ubiquitin ligase activity.[98,99,100] Viral proteins mK3 of MHV68, and proteins kK3 and kK5 of Kaposi sarcoma-associated herpesvirus that function as immune evasion proteins were the founding members of the MARCH protein family.[101,102,103] Mechanistically, mK3 binds to TAP and awaits the entry of MHC-I into the PLC after which mK3 ubiquitinates the cytosolic tail of MHC-I HCs and thus induces their dislocation to the cytosol and degradation in the cytosol (ie, ERAD).[104,105,106,107] Of note, the extensively studied US2 and US11 proteins of HCMV also target ERAD of MHC-I proteins by recruiting cellular E3 ligases.[108,109,110,111,112,113] Indeed, studies of US2, US11 and mK3 continue to provide molecular insights into various mechanisms by which ERAD substrates are detected in the ER and dislocated to the cytosol.[114,115] In contrast to ERAD, the kK3 and kK5 MARCH ligases of Kaposi sarcoma-associated herpesvirus induce endocytosis and lysosomal degradation of MHC-I proteins. Interesting, kK3 like mK3 appears to ubiquitinate only MHC-I proteins, whereas kK5 targets other surface receptors including the T cell costimulation molecule CD86 (B7.2) as well as natural killer cell ligands, MHC class I-related chain A or B (MICA, MICB), and newly defined ligand for NKp80, activationinduced C-type lectin (AICL).[116] Inhibition of natural killer responses is of importance to the virus because downregulation of MHC-I proteins renders cells susceptible to natural killer cell lysis. Mechanistic studies of viral MARCH

proteins have provided several molecular insights into ubiquitin-dependent degradation pathways of particular relevance to antigen processing. In addition, there are about 10 cellular MARCH protein homologs in humans and mice, many of which detect immune receptors.[98,99,100] For example, as mentioned in the MHC-II section, MARCHI regulates MHC-II expression in B cells and dendritic cell (DC) subsets.[117,118,119] Thus, viral MARCH proteins were stolen from the host and adapted by the virus to function as immune evasion proteins using similar mechanisms.

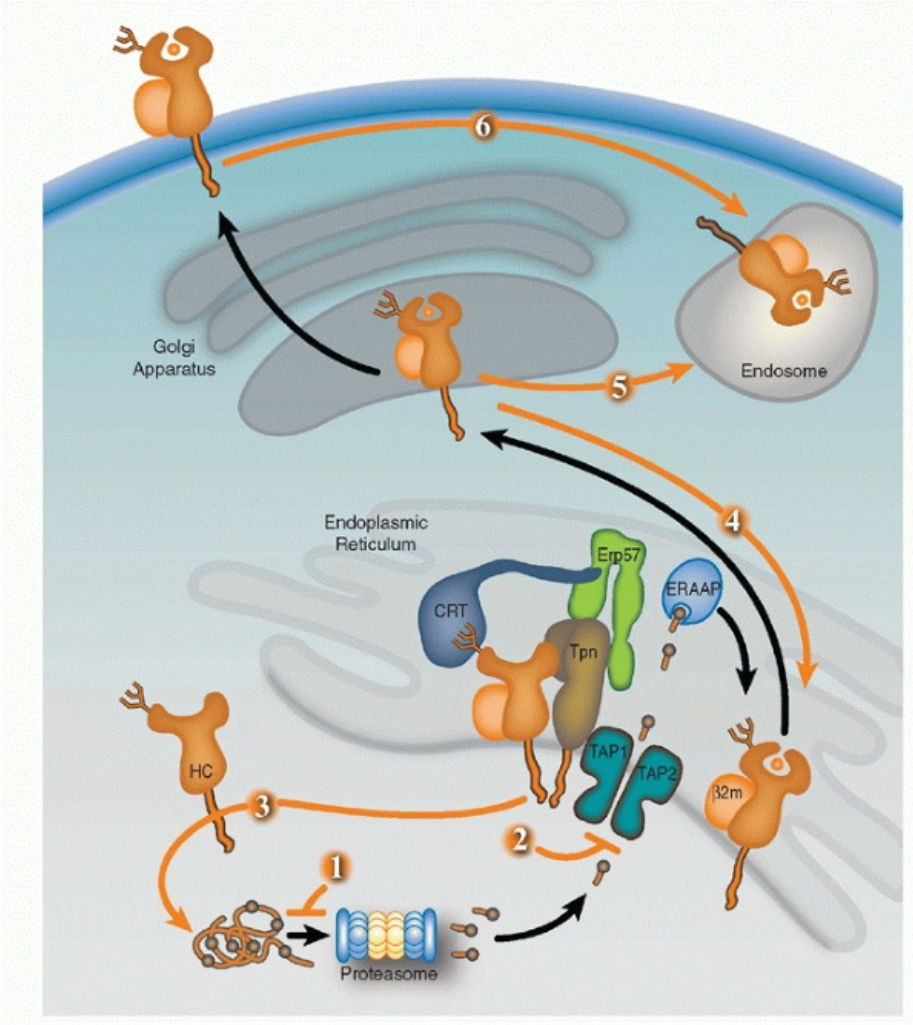

FIG. 22.3. Immune Evasion Strategies Used by Viral Proteins to Block Antigen Presentation by Major Histocompatibility Complex (MHC)-I Proteins. *Black arrows* demarcate physiologic pathways for antigen presentation, whereas the *numbered red arrows* demarcate reported immune evasion strategies by virus proteins. **1:** Blocking of antigen processing by the proteasome (examples are the EDNA1 protein of Epstein-Barr virus or the LANA1 protein of Kaposi sarcoma-associated herpesvirus). **2:** Blocking peptide transport by transporter associated with antigen presentation (examples include the ICP47 protein of herpes simplex virus, US6 protein of human cytomegalovirus, cpxv12 protein of cowpox virus, UL49.5 protein of bovine herpesvirus, and BNFL2a protein of Epstein-Barr virus). **3:** Dislocation of MHC-I proteins from the endoplasmic reticulum (ER) to the cytosol for proteasome-mediated degradation (examples are US2 and US11 proteins of human cytomegalovirusand mK3 protein of MHV68). **4:** ER retention and retrieval of MHC-I proteins (examples are E3-19K protein of AdV and the cpxv203 protein of cowpox virus). **5:** Mistrafficking of MHC-I proteins from the Golgi to an endosomal compartment (examples include gp48 protein of murine cytomegalovirus and Nef protein of human immunodeficiency virus-1). **6:** Rapid internalization of MHC-I proteins from the cell surface to an endosomal/lysosomal compartment (examples are kK3 and kK5 proteins of Kaposi sarcoma-associated herpesvirus).

ANTIGEN PROCESSING AND PRESENTATION BY MAJOR HISTOCOMPATIBILITY CLASS II (MHC-II) PROTEINS

Source of Antigen for MHC-II Presentation

As a general rule, the antigen-processing machinery that is utilized by MHC-I is specialized for the degradation, importation, and binding of peptides that are derived from antigens present in the cytosol of host cells. Although many viruses and bacteria thrive in the cytosol of infected cells, there are pathogens (such as *Toxoplasma gondii*) that reside in membrane-encapsulated intracellular compartments and do not access the cytosol.[120] Furthermore, almost any foreign material (including live or dead pathogens, fragments of apoptotic cells, or soluble proteins) can enter the cell by endocytosis and are therefore sequestered from the cytosol. It is for recognition of antigens such as this that MHC-II molecules exist; MHC-II binds peptides derived from antigens that gain access to intracellular compartments in cells by a variety of endocytic pathways.[121] Fluid-phase macropinocytosis is a process whereby extracellular fluid is taken up by plasma membrane protrusions that bring extracellular fluids and soluble proteins into the cell by endocytosis. Once internalized, macropinosomes fuse with early endosomes, thereby releasing their contents to the endocytic pathway. Immature (resting) DCs are particularly efficient in their capacity for macropinocytosis that enhances their significance as “sentinals” of the immune system.[122] Upon activation by encounter with foreign organisms, DCs greatly suppress macropinocytosis,[122,123,124] thereby limiting the ability of the activated DCs to sample their microenvironment and restricting the repertoire of antigenic peptides presented to T-lymphocytes.

As one can imagine, macropinocytosis is not a particularly efficient mechanism of antigen uptake. B cells possess antigen-specific receptors (immunoglobulins) that permit specific antigen internalization and presentation to T cells that can be 1000 times more efficient than fluid-phase endocytosis.[125] Curiously, the function and fate of B cells that generate specific MHC-II peptide complexes following immunoglobulin-mediated antigen uptake versus fluid-phase uptake of the same antigen differ significantly,[126] highlighting the importance of the receptor-mediated antigen uptake pathway in B cells. Similarly, macrophages and DCs express Fc receptors and complement receptors that allow efficient phagocytosis of large extracellular particles such as antibody-coated organisms or even apoptotic cells. Following endocytosis, the phagosome fuses with the membrane of a lysosome, forming a degradative phagolysosome that neutralizes and degrades internalized antigens into peptides.[127] Other surface receptors, such as mannose receptors[122,128,129] and DEC-205[130] on DCs, also allow for efficient antigen binding and uptake onto the endocytic pathway, and these receptors have been exploited as a vehicle to efficiently deliver bring foreign vaccine antigens into the MHC-II processing pathway in antigen-presenting cells (APCs).[131]

While antigens entering the endocytic pathway by phagocytosis, macropinocytosis, and receptor-mediated endocytosis give rise to the majority of peptides that bind to MHC-II, there is increasing evidence that cytosolic antigens are capable of entering endosomal MHC-II processing compartments and are degraded there into MHC-II-binding peptides. The most likely cellular mechanism responsible for this phenomena is process termed autophagy.[132,133] Macroautophagy is constitutively active in DCs and is a process that

leads to the “engulfment” of aggregated cytosolic protein complexes to form an autophagosome. Like phagosomes from extracellular antigens, the autophagosome fuses with a lysosome and results in the degradation of autophagosome contents into antigenic peptides.[134,135] A related process, termed chaperone-mediated autophagy, results from the direct import of cytosolic proteins into the lumen of endo/lysosomes and is facilitated by the chaperone protein hsc-70 and the lysosomal integral membrane protein Lamp2a.[136] Once inside this organelle, the imported protein is degraded into antigenic peptides just like “conventionally” internalized antigens. While this pathway clearly functions in vitro, the extent to which autophagy participates in MHC-II-restricted immune responses remains to be established.

MHC-II Assembly and Transport to the Endosomal Pathway

Because MHC-II is specialized to bind peptides generated in the endocytic pathway, there must be mechanisms in APCs to prevent the premature binding of peptides to MHC-II as the molecules assemble in the ER and traffic through the Golgi apparatus before their delivery to endosomal peptide loading compartments. In addition to the inability of MHC-II to bind to TAP/tapasin and other members of the MHC-I-peptide loading complex, MHC-II is unique in that it binds to a transmembrane chaperone protein termed the invariant chain (Ii). It is the association of Ii with the MHC-II-peptide binding site that prevents MHC-II molecules in the early secretory pathway from binding peptides.[137,138] Indeed, failure of newly synthesized MHC-II to bind Ii allows for the presentation of ER-imported peptides to CD4 T cells by MHC-II.[139] A specific region of Ii, termed the class II-associated Ii peptide (CLIP), serves to block the peptide-binding groove of nascent MHC-II molecules until it is ready for removal in endo-/lysosomes. The MHC-II-CLIP complex has been crystallized, and as one might expect, the structure of this complex is nearly identical to that of a MHC-II molecule containing an “antigenic” peptide.[140] As the name implies, unlike the highly polymorphic MHC-II molecule itself, Ii is nonpolymorphic. However, the human Ii mRNA can initiate protein synthesis using one of

two translation initiation sites (Fig. 22.4A), leading to generation of a major 33 kDa form of Ii (Ii-p33) as well as a minor population of larger Ii molecules whose translation is initiated using an upstream methionine (Ii-p35[141]). The use of alternative translation initiation sites appears to be unique to humans, as it is not seen in rodents.[142] Furthermore, alternative mRNA splicing in all species examined can give rise to an additional 8 kDa domain in each form of Ii, leading to the production of Ii-p41 and (in humans) Ii-p43.[143,144] This additional exon encodes a domain (see subsequent discussion) that regulates the activity of proteases in endo-/lysosomes.

The Ii molecule itself forms a trimer even in the absence of MHC-II, and each constituent subunit of this trimer contains either Ii-p33, -p35, -p41, or -p43 isoforms (see Fig. 22.4B). Ii homotrimers and mixed heterotrimers are generated, and each trimer contains an Ii molecule whose presence in the trimer is proportional to its level of expression.[145,146,147] Onto this “scaffold” of an Ii trimer, pairs of MHC-II αβ heterodimers assemble, ultimately forming a mature, nine-chain MHC-II-Ii complex.[148] The partially formed MHC-II-Ii complex containing an Ii trimer and only one or two αβ heterodimers is retained in the ER by interacting with the

chaperone calnexin,[149] presumably allowing the MHC-II molecule additional time to form a fully functional MHC-II-Ii nonamer. In addition, the longer p35 and p43 forms of human Ii contain an ER retention motif, and free Ii trimers containing one of these longer Ii forms are retained in the ER.[150,151] Curiously, completely folded MHC-II-Ii nonamers containing one of

these longer Ii isoforms are capable of exiting the ER and moving to antigen-processing compartments,[147,152] demonstrating that assembly with MHC-II masks the ER-retention motif on the Ii trimer.

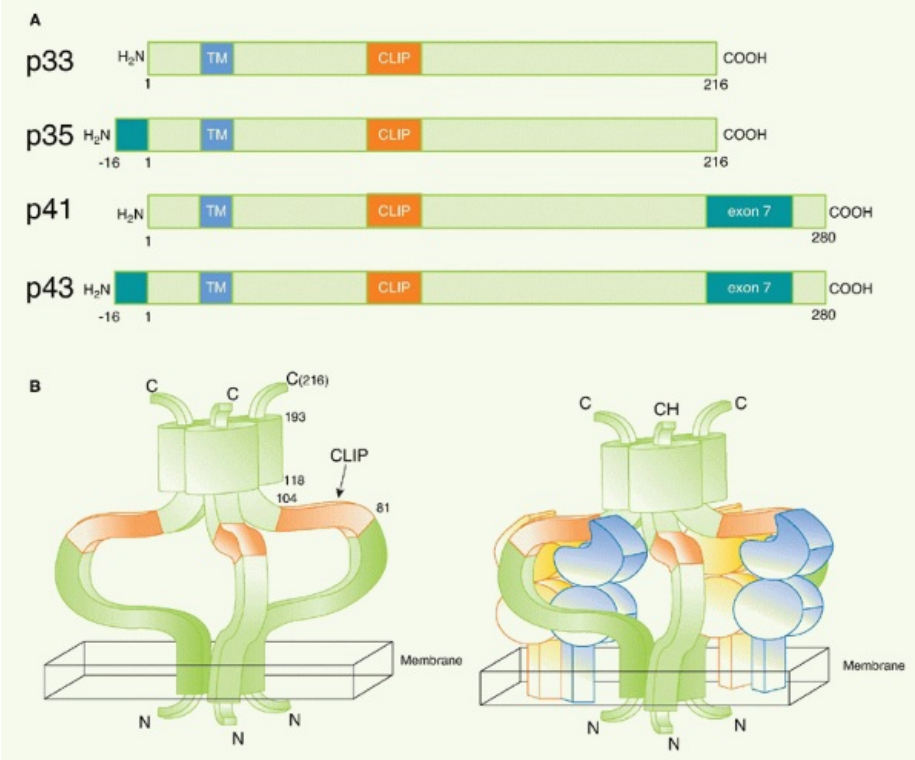

FIG. 22.4. Structure of Invariant Chain (Ii) and Major Histocompatibility Complex (MHC)-II-Ii Complexes. A: The major 216 amino acid form of human Ii is the 33 kDa Ii-p33 isoform. The use of an upstream initiation methionine results in the generation of Ii-p35 (which contains an endoplasmic reticulum-retention motif), and alternative splicing of each of these isoforms leads to the generation of Ii-p41 and Ii-p43 forms of Ii that possess proteinase inhibitor activity. The relative positions of the transmembrane domain (TM) and class II-associated Ii peptide region of each isoform of Ii are indicated. **B:** Models of Ii trimer (*left panel*) and the MHC-II-Ii complex (*right panel*). Only two of the three pairs of MHC-II αβ dimers are shown bound to the Ii trimer. The model shows the peptide-binding groove of MHC-II αβ dimers occupied by the CLIP region of Ii. (From Cresswell P. The biochemistry and cell biology of antigen processing. In: Paul WE. *Fundamental Immunology.* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003:613-629, reprinted with permission).

Ii association does more for MHC-II than simply prevent premature peptide binding. Assembly with Ii is critical for some alleles of MHC-II to fold property and achieve competence to leave

the ER, thus revealing a role for Ii as an assembly/folding molecular chaperone.[153] After leaving the ER, the MHC-II-Ii complex moves through the Golgi apparatus and is targeted to the endosomal pathway[150,154] (Fig. 22.5A). It is likely that MHC-II-Ii complexes arrive in the endocytic pathway by two distinct mechanisms and the relative contribution of each pathway may be cell-type specific. Some MHC-II-Ii complexes target directly from the trans-Golgi network to endosomes,[155,156] while other complexes move from the trans-Golgi network directly to the plasma membrane and enter endosomes only after endocytosis.[157] The movement of MHC-II-Ii complexes to the endosomal pathway is facilitated by recognition of two dileucine sorting motifs present in the cytosolic domain of every isoform of Ii.[158,159] The machinery that recognizes these motifs in the trans-Golgi network remains to be defined; however, it is clear that these motifs are recognized at the plasma membrane by the AP-2 adaptor protein complex.[160,161] This protein complex serves as a linker between Ii and the clathrin-mediated endocytosis pathway and serves to deliver plasma membrane-localized MHC-II-Ii to the early endosomes. Recognition and internalization of MHC-II-Ii from the plasma membrane is efficient and rapid,[157] and as a consequence of this, very little MHC-II-Ii is present on the plasma membrane of APCs at any given moment.

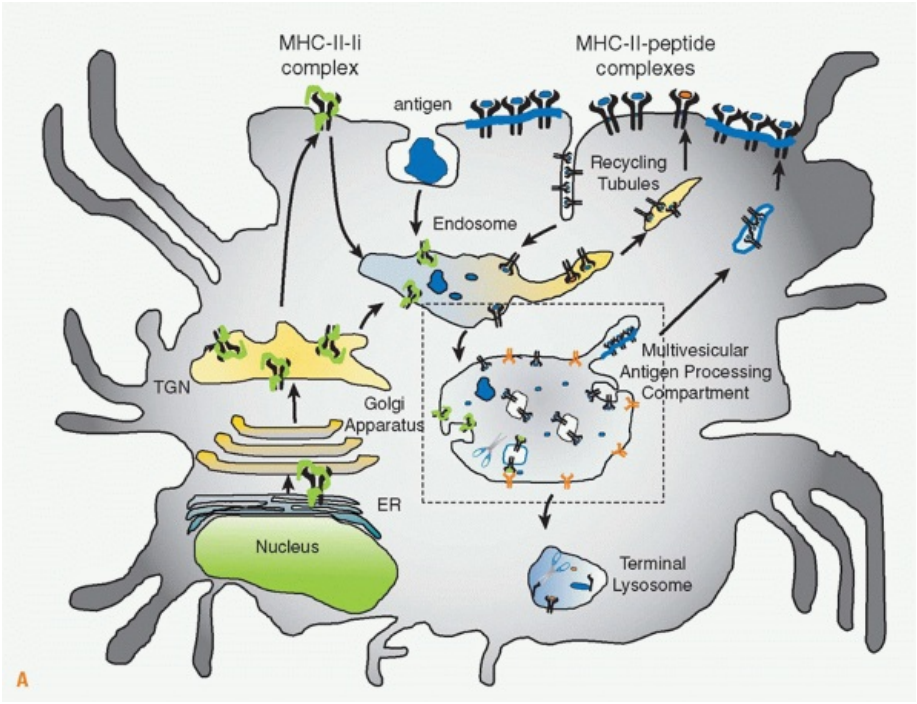

FIG. 22.5. Transport of Major Histocompatibility Complex (MHC)-II in Antigen-Presenting Cells. A: MHC-II associates with Ii in the endoplasmic reticulum, moves through the Golgi apparatus to the plasma membrane, and enters the endocytic pathway by clathrin-mediated endocytosis. Some fraction of MHC-II can also access these endocytic compartments directly from the Golgi apparatus/trans-Golgi network. Antigens access these same endocytic compartments by a number of different endocytosis pathways. The MHC-II-invariant chain (Ii) complex moves to late endosomal/prelysosomal antigen-processing compartments in which Ii is degraded, the MHC-II-associated class II-associated Ii peptide (CLIP) fragment of Ii is removed by DM,

and peptides derived from foreign antigens then bind to MHC-II (this compartment is highlighted in *panel B*). MHC-II-peptide complexes leave these intracellular antigen-processing compartments via vesicles or tubules that fuse with the plasma membrane, thereby delivering MHC-II-peptide complexes on the antigen-presenting cell surface. Once at the surface, MHC-II-peptide complexes can recycle between the plasma membrane and the endosomal system, potentially exchanging antigenic peptides. Some fraction of internalized MHC-II is also targeted for degradation in terminal lysosomes. *(continued)*

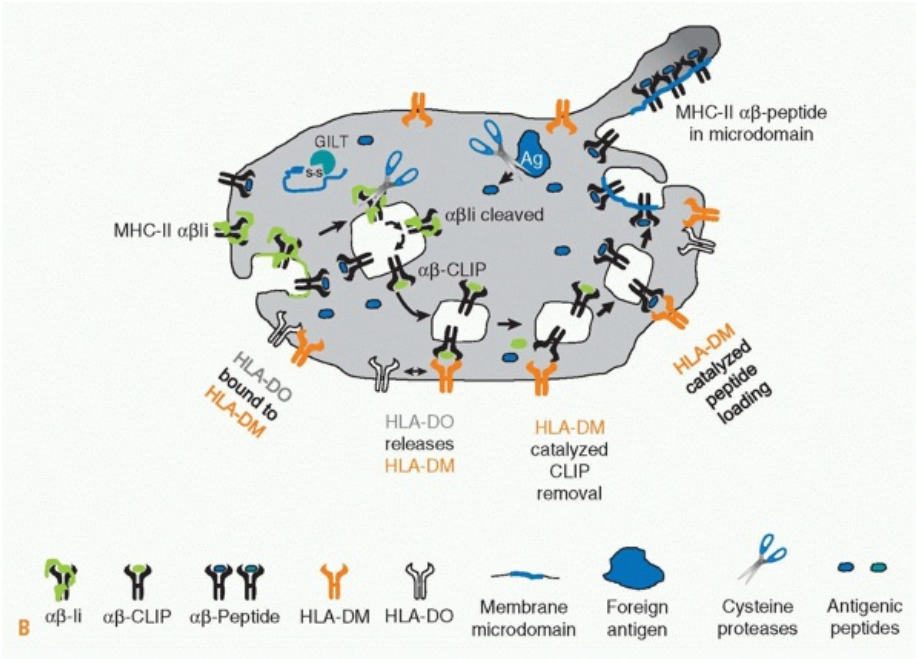

FIG. 22.5. *(continued)* **B:** Binding of peptides to MHC-II in antigen-processing compartments. The multivesicular antigen-processing compartment highlighted in *panel A* is shown here. MHC-II-Ii complexes are targeted to intraluminal vesicles of late endosomal multivesicular antigen-processing compartments where Ii proteolysis is initiated. This process results in the generation of MHC-II-CLIP complexes that are subject to editing by DM. DO binds to DM during intracellular transport and dissociates at the low pH of these compartments, thereby liberating free DM that catalyzes the removal of CLIP from the MHC-II-CLIP complex. DM also stabilizes the structure of peptide-free MHC-II until highaffinity peptide binding. Disulfide bonds present in protein antigens can be reduced by IFNγ-induced thiol reductase, thereby enhancing the formation of antigenic peptides generated by proteolysis. In this cartoon MHC-II, DM, and DO have particular membrane distributions; however, whether these distributions are maintained in all antigen-presenting cells and whether the reactions highlighted here occur on the indicated membranes remains to be determined. MHC-II molecules present in antigenprocessing compartments are present in distinct membrane microdomains, and after peptide binding, microdomain-associated MHC-II is transported to the plasma membrane in vesicles or tubules that bud from the limiting membrane of the antigen processing compartments (DM, HLA-DM; DO, HLA-DO).

Removal of Invariant Chain in Antigen-Processing Compartments

Regardless of the mechanism responsible for delivering MHC-II-Ii to endosomes, Ii must be removed in order to allow antigenic peptides to bind to nascent MHC-II. Ii is

degraded in discrete steps by proteolysis in acidic endosomes (see Fig. 22.5B), with proteolysis initiated at the luminal C-terminus of Ii in earlier endosomes and Ii degradation completed in more acidic late endosomal/prelysosomal structures. In vitro studies have shown that many different proteinases are capable of degrading Ii; however, in vivo, the initial cleavage of Ii is initiated by a proteinase whose activity in insensitive to the protease inhibitor leupeptin while additional cleavage is strictly leupeptin-dependent.[162] Leupeptin treatment of living APCs results in the accumulation of a 21 kDa Ii degradation intermediate that retains the nonameric MHC-II-Ii stoichiometry and is unable to bind antigenic peptides.[152] After the initial cleavage of Ii, a variety of proteinases can cleave the remaining MHC-II-associated Ii molecule; however, the terminal stages of Ii degradation in B cells and DCs are dependent on the cysteine proteinase cathepsin S.[163] Inhibition of cathepsin S activity or analysis of DCs isolated from cathepsin S-deficient mice reveal the accumulation of a 10 kDa Ii degradation product, highlighting the importance of this proteinase in Ii degradation. Curiously, MHC-II-expressing epithelial cells in the thymus do not rely on cathepsin S for Ii degradation but require cathepsin L for terminal Ii degradation.[164]

Proteolysis of Ii from both the luminal C-terminus and from residues adjacent to the luminal Ii transmembrane domain ultimately leaves a small fragment of Ii bound to MHC-II. This class II-associated Ii polypeptide, termed CLIP, is bound to the peptide-binding groove of MHC-II and serves as a "placeholder" to occupy the peptide-binding site until antigenic peptides are available to bind (see Fig. 22.4). While some MHC-II alleles have a very low affinity for CLIP and CLIP spontaneously dissociates from MHC-II,[165] in most cases CLIP must be actively removed from the peptide-binding site of MHC-II prior to antigenic peptide binding. A seminal finding in antigen processing and presentation came in 1994 with the discovery of HLA-DM (DM).[166,167] HLA-DM (known as H-2M in mice) is a nonpolymorphic transmembrane heterodimer whose α- and β-subunits are encoded in the MHC gene locus.

Like MHC-II, DM is expressed exclusively in APCs. An important function of DM is to facilitate the removal of CLIP from the MHC-II-CLIP complex.[168,169] DM functions enzymatically, and while the precise mechanism by which DM promotes CLIP dissociation from MHC-II remains to be completely elucidated, it is thought that DM disrupts the hydrogen bonding network in the peptide binding groove of MHC-II and thereby enhances the kinetics of CLIP dissociation from MHC-II.[170] Not only does DM catalyze CLIP removal from MHC-II, but DM also facilitates the dissociation of weakly bound antigenic peptides from MHC-II[168,170,171]; it is for this reason that DM has been termed a "peptide editor." Unlike the MHC-II molecule itself, DM contains a tyrosine-based endocytic sorting motif in its cytosolic domain that directly interacts with clathrin-associated adaptor proteins.[172] The presence of this signal allows for the entry of DM into the endocytic pathway after arrival at the cell surface. Most DM is localized in late endocytic compartments[173] that contain MHC-II-CLIP complexes,[174] and the

activity of DM is enhanced by the low pH of these later endocytic compartments.[168,169,175] DM editing activity in APCs can be regulated by its association with another MHC-encoded transmembrane protein termed HLA-DO (DO; H-2O in mice[176]). While the precise function of DO in antigen processing and presentation remains to be defined, in vitro studies have shown that DO binds to DM and inhibits the ability of DM to catalyze CLIP removal.[177,178] Like DM, DO expression is relatively restricted to APCs. Unlike MHC-II-Ii or DM, DO does not contain any intrinsic endo-/lysosomal sorting motifs. Instead, DO associated with DM in the ER and DM serves to "escort" DO to antigen-processing compartments.[179] It is in the low pH of these compartments that DO dissociates from DM, thereby enhancing DM activity. In this respect, DO acts as an inhibitor of DM function in much the same way that the CLIP region of Ii acts as an inhibitor of MHC-II peptide binding.

Antigen Processing and Peptide Loading onto MHC-II

While MHC-II in lysosome-like antigen-processing compartments must be "prepared" for peptide binding (by degrading MHC-II-associated Ii and removing CLIP by DM), internalized foreign antigens must be similarly prepared for binding to the nascent MHC-II molecule. This task is initiated by proteolysis by any number of endocytic proteinases. Antigen-processing compartments have a pH between 4.5 and 6.5, and most proteinases in these compartments have enzymatic activity optima at this pH. There is remarkable diversity in the proteinase pool in these compartments and great redundancy in the ability of distinct proteinases to degrade particular proteins. For this reason, it has been difficult to identify specific proteinases whose activity is required to generate specific antigenic peptides. There are exceptions to this, however, as asparaginyl cysteine endoprotease is required for the generation of an immunodominant epitope to tetanus toxoid[180] and both cathepsin L and cathepsin S affect quantitative and qualitative differences in the repertoire of peptides bound to MHC-II molecules.[181] It is also a known fact that many internalized foreign (and self-) antigens contain intrachain disulfide bonds, and reduction of these bonds would alter protein conformation and render a protein more (or less) sensitive to proteolysis in antigen-processing compartments. As its name implies, the expression of IFNγ-induced thiol reductase, GILT, can be induced by exposure to IFNγ.[182] This thiol reductase is expressed in antigen-processing compartments in APCs, and the activity of GILT is important for the presentation of antigenic epitopes that are generated from proteins that contain many intrachain disulfide bonds.[183]

Just as important as generation of antigenic peptides is the ability of the antigen-processing compartment to limit excessive proteolytic degradation of antigenic peptides. While asparaginyl cysteine endoprotease positively regulates expression tetanus toxoid epitopes, this same proteinase destroys expression of the immunodominant epitope of myelin basic protein,[184] a protein thought to be involved in the demyelinating autoimmune disease multiple sclerosis. Clearly, the proteinase activity of antigen-processing compartments must be sufficient to generate antigenic peptides capable of binding to MHC-II but not so great as to completely destroy these same epitopes. Measurement of proteinase activity in various APC subtypes has revealed that macrophages have high proteinase activity and efficiently degrade proteins, but are relatively pool generators of antigenic peptides.[185] By contrast,

DCs and B cells possess less proteinase activity, degrade proteins less efficiently, and are superb generators of antigen peptides.[185,186] This specialization of limiting proteinase activity helps DCs function as initiators of naïve T-cell activation and B cell capacity for immunoglobulin class switching after encounter with antigen-specific T cells.

It has been proposed that binding to the MHC-II molecules can serve as a mechanism to preserve the integrity of antigenic peptides. The peptide-binding groove of MHC-II is open, and in vitro binding experiments have shown that MHC-II is capable of binding to unfolded (but otherwise intact) protein antigens.[187] The association of distinct regions within a full-length (unfolded) protein with the peptidebinding site of MHC-II could therefore protect these regions from proteolytic degradation by endo-/lysosomal proteinases. This model of "bind first trim later" has been championed as a major mechanism of peptide loading onto MHC-II[188] and has been supported by experimental studies in B cells[189]; however, the extent to which "bind first trim later" versus "trim first bind later" predominates in distinct APC subsets and for different antigens remains to be determined.

Curiously, the Ii molecule itself also can serve to limit proteinase activity of antigen-processing compartments. The additional exon that is present in Ii isoforms that are products of alternative splicing (Ii-p41 and Ii-p43) encodes a domain that functions as an inhibitor of cathepsin L.[190,191] In vitro studies showed that coexpression with Ii-p41 inhibits the kinetics of Ii-p33 degradation,[192] a finding that is consistent with the role of Ii-p41 as a proteinase inhibitor. However, no defects in function have been identified using APCs isolated from mice expression only the Ii-p41,[193] leaving the importance of this domain in APC function an open issue.

DCs are particularly interesting APCs in that they can regulate their proteinase activity upon cell activation. Immature (resting) DCs are highly phagocytic and have a remarkable capacity for macropinocytosis. Nevertheless, these cells have little proteinase activity and are relatively inefficient generators of antigenic MHC-II-peptide complexes, potentially allowing them to serve as a "depot" for antigen internalized while the cell is in the quiescent state. It has even been shown that internalized proteins can remain intact in immature DCs for days.[194,195] Activation of the immature DC by any of a number of mechanisms (either by toll-like receptor signaling or stimulation by activated T cells) leads to a number of changes in the cell, with perhaps the most important being the activation of the vacuolar proton ATPase.[196] Activation of this ATPase leads to the acidification of antigen-processing compartments, enhances the activity of endo-/lysosomal proteinases that have low pH optima, and leads to the degradation of internalized antigens to form antigenic peptides capable of binding to MHC-II. Other changes also take place following activation of immature DCs, including downregulating expression of the endogenous cysteine proteinase inhibitor cystatin C[197] and reorganizing the internal membrane structure of the antigen processing compartments[198]; however, it is likely that acidification of these compartments is the major mechanism leading to enhanced antigen processing, peptide generation, and formation of MHC-II-peptide complexes upon DC activation.

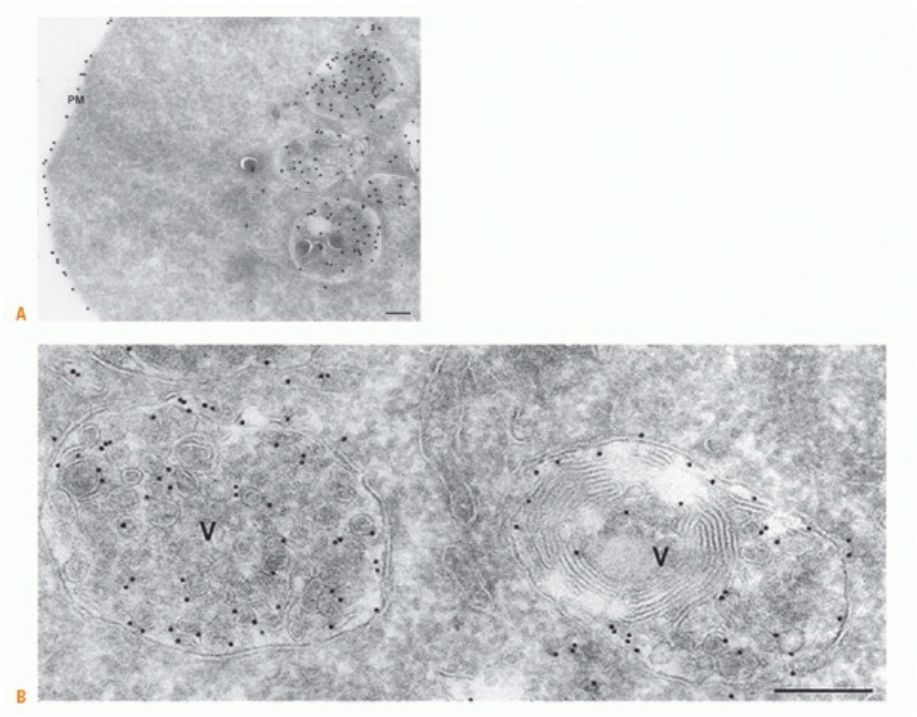

FIG. 22.6. Structure of Multivesicular Antigen-Processing Compartments. A: Ultrathin cryosections of a human B-cell line were stained with antibodies recognizing DM (10 nm gold) and total major histocompatibility complex (MHC)-II (15 nm gold). The plasma membrane stains almost exclusively for MHC-II while various forms of multivesicular antigen-processing compartments contain both MHC-II and DM (reprinted with permission Kleijmeer et al., *Methods*, 1996). **B:** Ultrathin cryosections of a mouse immature DC line were stained with antibodies recognizing MHC-II (10 nm gold). MHC-II staining is observed on the limiting membrane as well as in the intraluminal vesicles of a multivesicular body (*left*) and the numerous intraluminal membrane sheets in a multilamellar endosome (*right*) (reprinted with permission Kleijmeer et al.[198]).

Delivery of MHC-II to the Cell Surface

The sites of antigenic protein degradation and subsequent binding of peptides onto nascent MHC-II are commonly referred to as antigen-processing compartments. At one time, it was thought that APCs possessed a “special” compartment that served as the major antigen-processing compartment[199]; however, it is now clear that “antigen-processing compartments” refer to a heterogenous collection of intracellular (generally acidic) organelles that permit peptide binding onto MHC-II.[200] These organelles generally have characteristics of typical late endosomes/prelysosomes found in all cell types (Fig. 22.6); however, in APCs these organelles contain the specialized protein machinery required for antigen processing and presentation such as MHC-II, DM, DO, GILT, and Ii-processing enzymes. A “typical” antigenprocessing compartment is a late endosomal multivesicular body (MVB), an organelle that possesses intraluminal vesicles encapsulated in a limiting membrane.[201] These compartments can also have a multilamellar structure, containing numerous membrane sheets contained within an even

more acidic lysosome-like organelles. Curiously, the in DCs majority of MHC-II is present on the intraluminal vesicles of these MVBs while the CLIP editor DM and MHC-II-peptide complexes are enriched on the MVB-limiting membrane.[198] Although most MHC-II and DM are present on distinct MVB membranes, it is unclear on which membranes the process of Ii proteolysis, CLIP release, and peptide binding to MHC-II occurs. For example, while there is in vitro evidence that DM primarily interacts with MHC-II when these proteins are on the same membrane,[202,203] whether this is the intraluminal vesicle or the MVB-limiting membrane remains to be determined.

The presence of MHC-II-peptide complexes on the intraluminal vesicles of MVB presents a topological problem for the APC, as direct fusion of the MVB with the plasma membrane would release the intraluminal vesicles from these compartments to the extracellular space. Such a process would effectively result in the secretion of MHC-II from the APC. This process does occur in DCs with some frequency, and these secreted intraluminal vesicles are termed exosomes that are capable of stimulating naïve T cells in vivo.[204] While APC-derived exosomes are being utilized as cell-free vaccines,[205] their physiologic role remains to be unambiguously determined. The majority of MHC-II in antigen-processing compartments is not released as exosomes, but is instead either degraded following fusion of the MVB with lysosomes or inserted into the plasma membrane by “vesicle”-mediated protein transport. While vesicles containing intracellular MHC-II have been observed to fuse with the plasma membrane,[206] in APCs such as DCs it is likely that these “vesicles” are actually tubules that bud from the MVB membrane and subsequently fuse with the plasma membrane. The tubulation of these compartments is stimulated in DCs by APC activation,[198,207,208] and the encounter of DCs with T cells leads to the fusion of these tubules directly to the plasma membrane region at the point of DC:T-cell contact,[208] thereby delivering MHC-II-peptides generated in DCs directly to the site of T-cell receptor concentration at the immunologic synapse.

The cellular processes that govern the movement of MHC-II to the surface of APCs are similar to those that govern the movement of any late endosomal protein the surface of any cell. In some cases, the machinery regulating discrete transport steps remains a mystery while other steps are more well characterized. For example, the mechanism leading to the delivery of intraluminal vesicle-bound MHC-II back to the MVB0limiting membrane (from which tubules are formed) is termed back-fusion,[209] and the proteins and lipids that regulate this curious process remain to be identified. By contrast, it is known that the ability of MHC-II to insert into the plasma membrane is regulated by the small GTPase ARL14/ARF7 that couples the tubulovesicle membrane with the actin cytoskeleton.[210] Like other vesicle-mediated protein transport steps, microtubules and dynein/kinesin motors[211] as well as actin and myosin motors[212] are important for the locomotion of MHC-II into and out of antigen-processing compartments.

Once at the plasma membrane, MHC-II-peptide complexes are poised to interact with antigen-specific T-cell receptors. MHC-II-peptide complexes are clustered on the plasma membrane[195,213] and associate with distinct lipid raft-[214] and tetraspanin-membrane[215]

microdomains, thereby locally concentrating MHC-II on the cell surface. Biochemical studies have revealed that MHC-II associates with these membrane microdomains while still present in antigen-processing compartments even before antigenic peptide binding.[216] This finding is consistent with the observation that MVBs contain large amounts of cholesterol, a major constituent of lipid raft membrane microdomains. [217] While lipid raft- and tetraspanin-microdomain associations are important for the T-cell stimulatory function of APCs,[214,218] the molecular signals leading to membrane microdomain association of MHC-II remain to be determined.

MHC-II-peptide complexes are generated and reside in a relatively hostile (acidic, proteinase-rich) environment, and therefore it is not surprising that cell surface MHC-II has a relatively long half-life.[219,220] While this is true on activated B cells and mature DCs, MHC-II on the surface of immature DCs has a significantly reduced half-life. This is likely due to rapid endocytosis and lysosomal degradation of surface MHC-II in resting (immature) DCs.[221,222] The dichotomy between the endocytosis and survival of MHC-II in immature and mature DCs can be explained in part by the fact that internalized MHC-II is ubiquitinated in immature DCs and targeted for lysosomal degradation while internalized MHC-II is not ubiquitined in mature DCs and efficiently recycles back to the plasma membrane.[223,224] The E3 ubiquitin ligase March-I, whose expression appears to be limited to APCs, ubiquitinates the cytosolic domain of the MHC-II β-chain in APCs,[118] thereby preventing the recycling of internalized MHC-II and targeting ubiquitinated MHC-II for lysosomal degradation.[225] This mechanism ensures that the kinetics of MHC-II synthesis and degradation in immature DCs are similar and provides a means to halt the degradation of relevant MHC-II-peptide complexes upon DC activation.

Simply because MHC-II has a long half-life in B cells and DCs does not mean that these molecules do not internalize. In these APC subtypes, internalized MHC-II efficiently recycles from early (recycling) endosomes back to the plasma membrane,[221] thereby limiting their delivery to lysosomes and prolonging MHC-II half-life. The ability of internalized MHC-II to exchange one peptide for another in endosomes has been demonstrated in vitro[226,227]; however, it remains to be determined whether peptide exchange onto recycling MHC-II in vivo is a significant mechanism of peptide loading onto MHC-II. There is convincing evidence, however, that certain protein epitopes are primarily presented by recycling MHC-II.[228] Unlike presentation of epitopes from “classically processed” antigens, presentation of these epitopes does not require neosynthesis of MHC-II and is independent of Ii expression or DM activity. A particularly intriguing example of this pathway can be found in the analysis of an immunogenic epitope presentation of the influenza virus hemagglutinin,[228] in which presentation of one epitope is via the classical (late endosomal) processing and presentation pathway while another is presented via a nonclassical (early endosomal) recycling pathway.

Alternate Pathways of Antigen Presentation

In this chapter, we have reviewed what is typically called the classical MHC-I and MHC-II antigen-processing and -presentation pathways. In addition to these pathways, there are also interesting alternative antigen-presentation pathways. Although not the focus of this chapter,

these nonclassical pathways provide clear evidence that antigen presentation is more complex than a simple dichotomy of the two classical pathways. The most extensively studied of these alternative pathways is cross-presentation, a process by which CD8 T cells present exogenous antigen taken up by professional APCs such as DCs. Cross-presentation is critical for initiating CD8+ immune responses to pathogens that do not infect professional APCs or tumors that do not arise in professional APCs. Although several details remain unsolved, cell biologic approaches suggest that the loading of crosspresented antigens occurs by several different pathways each with hybrid features of both of the classical pathways.[229,230,231]

The presentation of lipid antigens by MHC-I like CD1 molecules also occurs by a nonclassical pathway.[232,233] Human CD1a, CD1b, and CD1c isoforms present bacterial lipids to conventional αβ T cells, whereas CD1d presents endogenous and microbial lipids to invariant natural killer T cells. Interestingly, disparate targeting motifs in their cytoplasmic tails facilitate the binding of lipid antigens in the early endosomes by CD1a, in the late endosome/lysosome by CD1b and CD1d, and at both sites by CD1c. This diversity of location of lipid antigen binding by different human CD1 isoforms allows surveying of different endosomal compartments for microbes. The assembly of CD1 isoforms in the ER uses molecular chaperones CXN, CRT, and ERp57 similar to the classical MHC-I pathways. As expected, the processing and loading of lipid antigens presented by CD1 isoforms requires unique players.[234] However, the trafficking of CD1 isoforms between the plasma membrane and endosomal compartments to acquire lipid antigens has parallels with the classical MHC-II pathway. In sum, with the underlying goal of providing maximal immunity for detection and protection against diverse pathogens, mammals have two classical and other nonclassical pathways of antigen presentation.

ACKNOWLEDGMENTS

The authors thank Drs. Peter Cresswell and Karin Reinisch for sharing Protein Data Bank (PDB) files with the model shown in Figure 22.3, Dr. William McCoy IV for his rendering of Figure 22.3, and Dr. Janet Connolly for professional editing.

Chapter 23

Immunogenicity and Antigen Structure

Jay A. Berzofsky

Ira J. Berkower

THE NATURE OF ANTIGENIC DETERMINANTS RECOGNIZED BY ANTIBODIES

Haptens

In the antigen-antibody binding reaction, the antibodybinding site is often unable to accommodate the entire antigen. The part of the antigen that is the target of antibody binding is called an antigenic determinant, and there may be one or more antigenic determinants per molecule. To study antibody specificity, we need to have antibodies against single antigenic determinants. Small functional groups that correspond to a single antigenic determinant are called haptens. For example, these may be organic compounds, such as trinitrophenyl or benzene arsonate, a monosaccharide or oligosaccharide such as glucose or lactose, or an oligopeptide such as pentalysine. Although these haptens can bind to antibody, immunization with them usually will not provoke an antibody response (for exceptions, see Goodman[1]). Immunogenicity often can be achieved by covalently attaching haptens to a larger molecule, called the carrier. The carrier is immunogenic in its own right, and immunization with the hapten-carrier conjugate elicits an antibody response to both hapten and carrier. However, the antibodies specific for hapten can be studied by equilibrium dialysis using pure hapten (without carrier) or by immunoprecipitation using hapten coupled to a different (and non-cross-reacting) carrier or by inhibition of precipitation with free hapten.

This technique was pioneered by Landsteiner[2] and helped to elucidate the exquisite specificity of antibodies for antigenic determinants. For instance, the relative binding affinity of antibodies prepared against succinic acid-serum protein conjugates shows marked specificity for the maleic acid analog, which is in the cis configuration, as compared to the fumaric acid (trans) form.[3] Presumably, the immunogenic form of succinic acid corresponds to the cis form.[3] This ability of antibodies to distinguish cis from trans configurations was reemphasized in later studies measuring relative affinities of antibodies to maleic and fumaric acid conjugates[4] (Table 23.1A). Table 23.1B shows the specificity of antibodies prepared against p-azobenzenearsonate coupled to bovine gamma globulin.[5] As the hapten is coupled through the p-azo group to aromatic amino acids of the carrier, haptens containing bulky substitutions in the para position would most resemble the immunizing antigen. In fact, p-methyl-substituted benzene arsonate has a higher binding affinity than unsubstituted benzene arsonate. However, methyl substitution elsewhere in the benzene ring reduces affinity, presumably due to interference with the way hapten fits into the antibody-binding site. Thus, methyl substitutions can have positive or negative effects on binding energy, depending on where the substitution occurs. Table 23.1C shows the specificity of antilactose antibodies for lactose versus cellobiose.[6] These disaccharides differ only by the orientation of the hydroxyl

attached to C4 of the first sugar either above or below the hexose ring. The three examples in this table, as well as many others,[1] show the marked specificity of antibodies for cis-trans, ortho-meta-para, and stereoisomeric forms of the antigenic determinant.

Comparative binding studies of haptens have been able to demonstrate antibody specificity despite the marked heterogeneity of antibodies. Unlike the antibodies against a multideterminant antigen, the population of antibodies specific for a single hapten determinant is a relatively restricted population due to the shared structural constraints necessary for hapten to fit within the antibody-combining site. However, the specificity of an antiserum depends on the collective specificities of the entire population of antibodies, which are determined by the structures of the various antibody-binding sites. When studying the cross-reactions of hapten analogs, some haptens bind all antibodies but with reduced K_A. Other hapten analogs reach a plateau of binding because they fit some antibody-combining sites quite

well but not others (see discussion of cross-reactivity in Chapter 7). Antibodies raised in different animals may show different cross-reactivities with related haptens. Even within a single animal, antibody affinity and specificity are known to increase over time following immunization under certain conditions.[7] Thus any statements about the cross-reactivity of two haptens reflect both structural differences between the haptens that affect antigen-antibody fit and the diversity of antibody-binding sites present in a given antiserum.

TABLE 23.1 Exquisite Specificity of Antihapten Antibodies

Hapten	Structure	K_{rel} of Antibody Specific for	
A.		Maleic (cis)	Fumaric (trans)
	Maleanilate	1.0	<0.01
	Fumaranilate	<0.01	1.0
B.		Parasubstituted benzene arsonate	
	Benzene arsonate	1.0	
	o-Methyl benzene arsonate	0.2	
	m-Methyl benzene arsonate	0.8	
	p-Methyl benzene arsonate	1.9	
C.		Lactose

Carbohydrate Antigens

The antigenic determinants of a number of biologically important substances consist of carbohydrates. These often occur as glycolipids or glycoproteins. Examples of the former include bacterial cell wall antigens and the major blood group antigens, whereas the latter group includes "minor" blood group antigens such as Rh. In addition, the capsular polysaccharides of bacteria are important for virulence and are often targeted by protective antibodies. A number of spontaneously arising myeloma proteins have been found to show carbohydrate specificity, possibly reflecting the fact that carbohydrates are common environmental antigens. In the days prior to hybridoma technology, these carbohydratespecific myeloma proteins provided an important model for studying the reaction of antigen with a monoclonal antibody.

Empirically, the predominant antigenic determinants of polysaccharides often consist of short oligosaccharides (one to five sugars long) at the nonreducing end of the polymer chain.[8] This situation is analogous to a hapten consisting of several sugar residues linked to a large nonantigenic polysaccharide backbone. The remainder of the polysaccharide is important for immunogenicity, just as the carrier molecule was important for haptens. In addition, branch points in the polysaccharide structure allow for multiple antigenic determinants to be attached to the same macromolecule. This is important for immunoprecipitation by lattice formation, as discussed in Chapter 5. Several examples illustrating structural studies of oligosaccharide antigens are given later.

The technique used most widely to analyze the antigenic determinants of polysaccharides is called hapten inhibition.[8] In this method, the precipitation reaction between antigen and antibody is inhibited by adding short oligosaccharides. These oligosaccharides are large enough to bind with the same affinity and specificity as the polysaccharide, but because they are monomeric, no precipitate forms. As more inhibitor is added, fewer antibody-combining sites remain available for precipitation. Using antiserum specific for a single antigenic determinant, it is often possible to block precipitation completely with a short oligosaccharide corresponding to the nonreducing end of the polysaccharide chain. Besides showing the "immunodominance" of the nonreducing end of the chain, this result also shows that the structure of the antigenic determinant of polysaccharides depends on the sequence of carbohydrates and their linkage, rather than their conformation. For inhibition by hapten to be complete, the antigen-antibody system studied must be made specific for a single antigenic determinant. For optimal sensitivity, the equivalence point of antigen and antibody should be used.

We illustrate the types of carbohydrate antigens encountered by examining three classic examples in more detail: the salmonella O antigens, the blood group antigens, and dextrans that bind to myeloma proteins.

Immunochemistry of Salmonella O Antigens

The antigenic diversity among numerous salmonella species resides in the structural differences of the lipopolysaccharide (LPS) component of the outer membrane.[9] These molecules are the main target for antisalmonella antibodies. The polysaccharide moiety contains the antigenic determinant, whereas the lipid moiety is responsible for endotoxin

effects. The chemical structure of LPS can be divided into three regions (Fig. 23.1). Region I contains the antigenic O-specific polysaccharide, usually made up of repeated oligosaccharide units, which vary widely among different strains. Region II contains an oligosaccharide "common core" shared among many different strains. Failure to synthesize region II oligosaccharide or to couple completed region I polysaccharide to the growing region II core results in R (rough) mutants, which have "rough" colony morphology and lack the O antigen. Region III is the lipid part, called lipid A, which is shared among all salmonellae and serves to anchor LPS on the outer membrane. Early immunologic attempts to classify the O antigens of different salmonellae revealed a large number of cross-reactions between different strains. These were detected by preparing antiserum to one strain of salmonella and using it to agglutinate bacteria of a second strain. Each cross-reacting determinant was assigned a number, and each strain was characterized by a series of O antigen determinants (in aggregate, the "serotype" of the strain) based on its pattern of cross-reactivity. Each strain was classified within a group, based on sharing a strong O determinant. For example, group A strains share determinant 2, whereas

group B strains share determinant 4 (Table 23.2). However, within a group, each strain possesses additional O determinants, which serve to differentiate it from other members of that group. Thus, determinant 2 coexists with determinants 1 and 12 on *Salmonella paratyphi* A. This problem of cross-reactivity based on sharing of a subset of antigenic determinants is commonly encountered in complex antigen-antibody systems. The problem may be simplified by making antibodies monospecific for individual antigenic determinants. To do this, antibodies are absorbed to remove irrelevant specificities, or cross-reactive strains are chosen that share only a single determinant with the immunizing strain. The reaction of each determinant with its specific antibody can be thought of as an antigen-antibody system. Thus, for the strains shown in Table 23.2, antiserum to *Salmonella typhi* (containing anti-9 and anti-12 antibodies) may be absorbed with *S. paratyphi* A to remove anti-12, leaving a reagent specific for antigen 9 (see Table 23.2). Alternatively, the unabsorbed antiserum may be used to study the system antigen 12-anti-12 by allowing it to agglutinate *S. paratyphi* B, which shares only antigen 12 with the immunogen. Because the other determinants on *S. paratyphi* B were absent from the immunizing strain, the antiserum contains no antibodies to them.

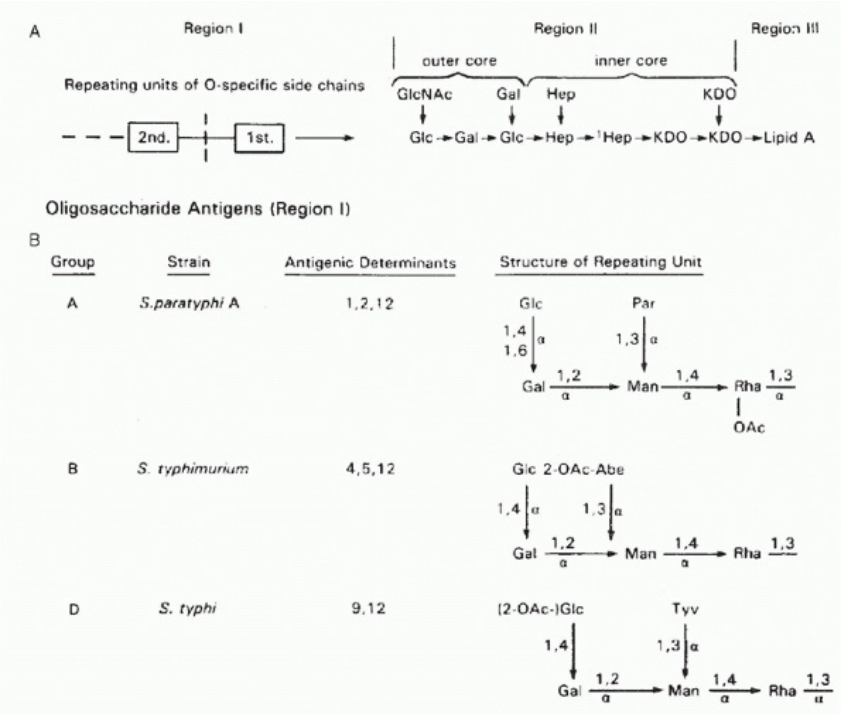

FIG. 23.1. Structure of Salmonella Lipopolysaccharide. Region I contains the unique O-antigen determinants, which consist of repeating units of oligosaccharides. These are attached to lipid moiety through the core polysaccharide. Three examples of oligosaccharide units are shown.[9] (Part A adapted from Kabat,[8] with permission; part B based on Jann and Westphal.[9])

TABLE 23.2 Salmonella Q Antigen Serotyping

Salmonella Strain	Serogroup	O Antigenic Determinants
S. paratyphi	A	A 1, 2, 12
S. paratyphi	B	B 1, 4, 5, 12
S. typhi	D	9, 12

Antiserum	Absorbed	Tested on	Single Determinant Measured
Anti-*S. typhi*		*S. paratyphi* B	12
Anti-*S. typhi*	*S. paratyphi* A	*S. typhi*	9

Once the antigen-antibody reaction is made specific for a single determinant, a variety of oligosaccharides can be added

to test for hapten inhibition. Because the O antigens contain repeating oligosaccharide units, it is often possible to obtain model oligosaccharides by mild chemical or enzymatic degradation of the LPS itself. Once the most inhibitory oligosaccharide is found, its chemical structure is determined. Alternatively, a variety of synthetic monosaccharide, disaccharide, trisaccharide and oligosaccharides are tested for hapten inhibition of precipitation. For example, as shown in Table 23.3, antigen 1-anti-1 antibody precipitation is inhibited by methyl-α D-glucoside. Therefore, various disaccharides incorporating this structure were tested, of which α-D-Glu-(1 → 6)-D-Gal was the most inhibitory. Then various trisaccharides incorporating this sequence were tested. The results indicate the sequence and size of the determinant recognized by anti-1 antibodies to be a disaccharide with the previously discussed structure. The test sequences can be guessed by analyzing the oligosaccharide breakdown products of the LPS, which include tetramers of D-Glu-D-Gal-D-Man-L-Rham. The results in Table 23.3 also suggest that the difference between determinants 1 and 19 is the length of oligosaccharide recognized by antibodies specific for each determinant. This hypothesis is supported by the observation that determinant 1 is found in some strains with, and in other strains without, determinant 19; whereas determinant 19 is always found with determinant 1. As shown in Table 23.3, determinant 19 requires the full tetrasaccharide for maximal hapten inhibition, including the sequence coding for determinant 1. Besides identifying the antigenic structures, these results indicate that there is variation in the size of different antigenic determinants of polysaccharides.

TABLE 23.3 Analysis of Salmonella O-Antigen Structure by Hapten Inhibition

	Antigen System	
Maximum Inhibition by Hapten (%)	**1: anti-1**	**19: anti-19**
d-Glu	—	0
Me-α-D-Glu	35	10
α-D-Glu(1 → 6)-D-Gal	80	25
Glu.Gal.Man	80	70
Gtu.Gal.Man.L-Rham	>70	>70
Deduced structure	α-D-Glu(1 → 6)-D-Gal	D-Glu-D-Gal-D-Man-L-Rham

Blood Group Antigens

The major blood group antigens A and B were originally detected by the ability of serum from individuals lacking either determinant to agglutinate red blood cells bearing them (for reviews, see Kabat,[8] Springer,[10] Marcus,[11] and Watkins[12]). In addition, group O individuals have an H antigenic determinant that is distinct from A or B types, and individuals in all three groups may have additional determinants such as the Lewis (Le) antigens. Although the ABH and Le antigenic determinants are found on a carbohydrate moiety, the carbohydrate may occur in a variety of biochemical forms. On cell surfaces, they are either glycolipids that are synthesized within the cell (AB and H antigens) or glycoproteins taken up from serum (Le antigens). In mucinous secretions, such as saliva, they occur as glycoproteins. Milk, ovarian cyst fluid, and gastric mucosa contain soluble oligosaccharides containing blood group reactivity. In addition, these antigens occur frequently in other species, including about half of the bacteria in the normal flora of the gut.[10] This widespread occurrence may account for the ubiquitous anti-AB reactivity of human sera, even in people never previously exposed to human blood group substances through transfusion or pregnancy.

The immunochemistry of these antigens was simplified greatly by the use of oligosaccharides in hapten inhibition studies. Group A oligosaccharides, for example, would inhibit the agglutination of group A red blood cells by anti-A antibodies. They could also inhibit the immunoprecipitation of group A-bearing glycoproteins by anti-A antibodies. Because the oligosaccharides are monomeric, their reaction with antibody does not form a precipitate but does block an antibody-combining site.

The inhibitory oligosaccharides from cyst fluid were purified and found to contain D-galactose, L-fucose, N-acetylgalactosamine, and N-acetylglucosamine. The most inhibitory oligosaccharides for each antigen are indicated in Figure 23.2. As can be seen in Figure 23.2, the ABH and Le antigens all share a common oligosaccharide core sequence, and the antigens appear to differ from each other by the sequential addition of individual sugars at the end or at branch points. Besides hapten inhibition, other biochemical data support this relationship among the different determinants. Enzymatic digestion of A, B, or H antigens yields a common core oligosaccharide from each. This product cross-reacts with antiserum specific for pneumococcal polysaccharide type XIV, which contains structural elements shared with blood group determinants, as shown at the bottom of Figure 23.2. In addition, this structure, known as precursor substance, has been isolated from ovarian cyst fluid.

Starting from precursor substance, the H determinant results from the addition of L-fucose to galactose, whereas Le^a determinant results from the addition of L-fucose to N-acetylglucosamine and Le^b from the addition of L-fucose to both sugars. Addition of N-acetylgalactosamine to H substance produces the A determinant, whereas addition of galactose produces the B determinant, in each case blocking reactivity of the H determinant.

The genetics of ABH and Le antigens is explained by this sequential addition of sugars via glycosyltransferases. The allelic nature of the AB antigens is explained by the addition of N-acetylgalactosamine, galactose, or nothing to the H antigen. The rare inherited trait of inability to synthesize the H determinants from precursor substance (Bombay phenotype) also blocks the expression of A and B antigens because the A and B transferases lack an acceptor substrate. However, the appearance of the Le^a antigen on red cells is independent of H antigen synthesis. Its structure, shown in Figure 23.2, can be derived directly from precursor substance without going through an H antigen intermediate. Comparing different individuals, the appearance of Le^a antigen on red blood cells correlates with its presence in

saliva, as the Le^a

antigen is not an intrinsic membrane component but must be absorbed from serum glycoproteins, which, in turn, depend on secretion. In addition to the independent synthetic pathway, the secretion of Le^a antigen is also independent of the secretory process for ABH antigens. Therefore, salivary nonsecretors of ABH antigens (which occur in 20% of individuals) may still secrete Le^a antigen if they have the fucosyl transferase encoded by the Le gene. In contrast, salivary secretion of ABH is required for red blood cells to express Le^b.

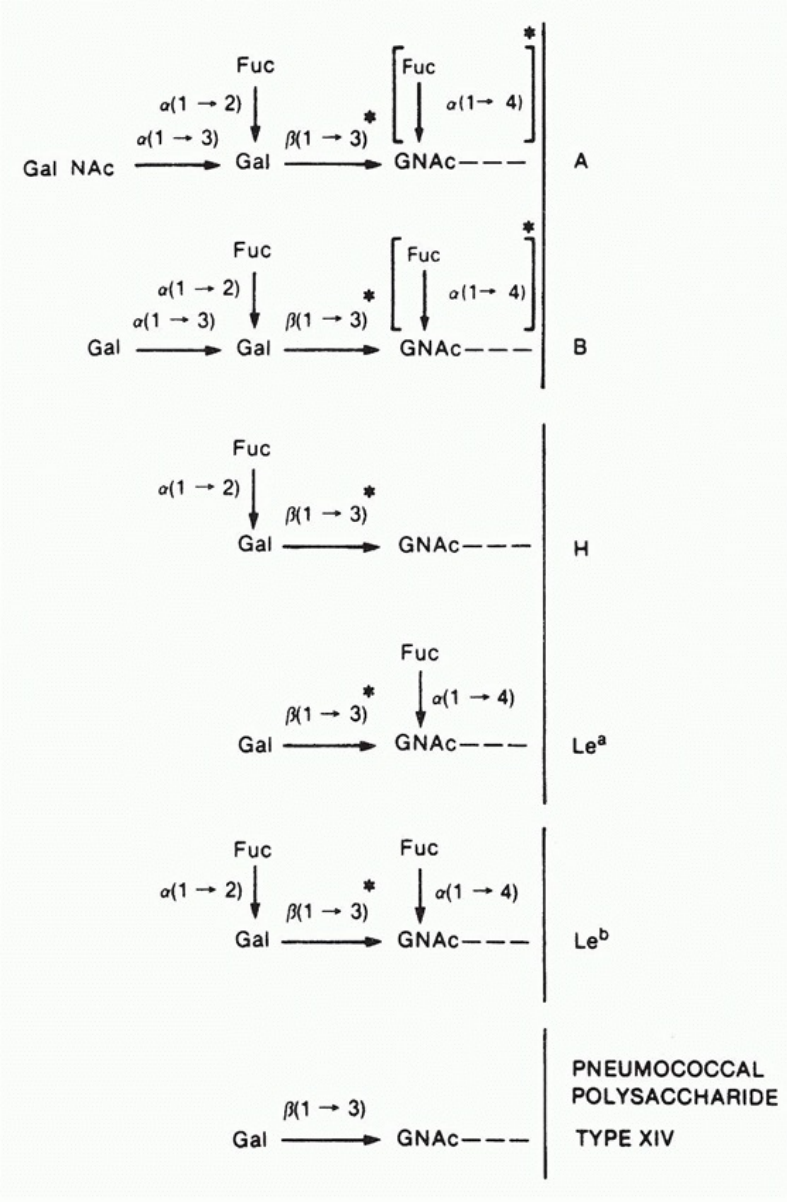

FIG. 23.2. Oligosaccharide Chain Specificity. Structure of the ABH and Le blood group antigens as determined by hapten inhibition studies.[8,11] There are two variants of each of these determinants. In type 1, the Gal-GNAc linkage is β(1 → 3), whereas in type 2, the Gal-GNAc linkage is β(1 → 4). In addition, there is heterogeneity in the A and B antigens with respect to the presence of the Le fucose attached to the GNAc. In the molecules that contain the extra fucose, when the Gal-GNAc linkage is β(1 → 3) (type 1), the fucose must be linked α(1 → 4), whereas the type 2 molecules, with the β(1 → 4)

Gal-GNAc linkage, contain α(1 → 3)-linked fucose. The *asterisks* indicate the sites of this variability in linkage.

Dextran-Binding Myeloma Proteins

Because polysaccharides are common environmental antigens, it is not surprising that randomly induced myeloma proteins were frequently found to have carbohydrate specificities. Careful studies of these monoclonal antibodies support the clonal expansion model of antibody diversity: heterogeneous antisera behave as the sum of many individual clones of antibody with respect to affinity and specificity. In the case of the Ig Aκ myeloma proteins W3129 and W3434, both antibodies were found to be specific for dextrans containing α-glu (1 → 6)glu bonds.[12] Hapten inhibition with a series of monosaccharide or oligosaccharides of increasing chain length indicated that the percentage of binding energy derived from the reaction with one glucose was 75%, two glucoses 95%, three glucoses 95% to 98%, and four glucoses 100%. This suggests that most binding energy between antidextran antibodies and dextran derives from the terminal monosaccharide, and that oligosaccharides of chain length four to six commonly fill the antibody-combining site. Human antidextran antisera behaved similarly, with tetrasaccharides contributing 95% of the binding energy. These experiments provided the first measure of the size of an antigenic determinant, four to six residues.[13,14] In addition, as was observed for antisera, binding affinity of myeloma proteins was highly sensitive to modifications of the terminal sugar and highly specific for α(1 → 6) versus α(1 → 3) glycosidic bonds. However, modification of the third or fourth sugar of an oligosaccharide had relatively less effect on hapten inhibition of either myeloma protein or of antisera reacting with dextran.

Studies with additional dextran-binding myeloma proteins[15] revealed that not all antipolysaccharide monoclonal antibodies are specific for the nonreducing end, as exemplified by QUPC 52. Competitive inhibition with monosaccharide and oligosaccharides revealed that <5% of binding energy derived from monosaccharides or disaccharides, 72% from trisaccharides, 88% from tetrasaccharides, and 100% from hexasaccharides, in marked contrast to other myeloma proteins. A second distinctive property of myeloma protein QUPC 52 was its ability to precipitate unbranched dextran of chain length 200. As the unbranched dextran has only one nonreducing end, and as the myeloma protein has only one specificity, lattice formation due to cross-linking between the nonreducing ends is impossible, and precipitation must be explained by binding some other determinant. Therefore, QUPC 52 appears to be specific for internal oligosaccharide units of three to seven chain length. The W3129 is specific for end determinants and will not precipitate unbranched dextran chains. Antibodies precipitating linear dextran were also detected in six antidextran human sera, comprising 48% to 90% of the total antibodies to branched chain dextran. Thus, antidextrans can be divided into those specific for terminal oligosaccharides and those specific for internal oligosaccharides; monoclonal examples of both types are available, and both types are present in human immune serum. Cisar et al.[15] speculated as to the different topology of the binding sites of W3129 or QUPC 52 necessary for terminal or internal oligosaccharide specificity. Both terminal and internal oligosaccharides have nearly identical chemical structures, differing at a single C-OH or glycoside bond. Perhaps the terminal oligosaccharide specificity of W3129 is due to the shape of the antibody-combining site—a cavity into which only the end can fit—whereas the

internal oligosaccharide-binding site of QUPC 52 could be a surface groove in the antibody, which would allow the rest of the polymer to protrude out at both ends. A more definitive

answer depends on x-ray crystallographic studies of the combining sites of monoclonal antibodies with precisely defined specificity, performed with antigen occupying the binding site.

With the advent of hybridoma technology, it became possible to produce monoclonal antibodies of any desired specificity. Immunizing mice with nearly linear dextran (the preferred antigen of QUPC 52), followed by fusion and screening (with linear dextran) for dextran-binding antibodies, yielded 12 hybridomas,[16] all with specificity similar to QUPC 52. First, oligosaccharide inhibition of all 12 monoclonals showed considerable increments in affinity up to hexasaccharides, with little affinity for disaccharides and only 49% to 77% of binding energy derived from trisaccharides.[17] Second, all 12 monoclonals had internal α(1 → 6) dextran specificity, as they could all precipitate linear dextran. Third,[9] out of 11 BALB/c monoclonals shared a cross-reactive idiotype with QUPC 52, whereas none shared idiotype with W3129.[18] These data support the hypothesis that different antibodies with similar specificity and similar groove-type sites may be derived from the same family of germline V_H genes bearing the QUPC 52 idiotype.[18]

The large number of environmental carbohydrate antigens and the high degree of specificity of antibodies elicited in response to each carbohydrate antigen suggest that a tremendous diversity of antibody molecules must be available, from which some antibodies can be selected for every possible antigenic structure. Studies of a series of 17 monoclonal anti-α(1 → 6) dextran hybridomas[19,20] have investigated whether the binding sites of closely related antibodies were derived from a small number of variable region genes, for both heavy and light chains, or whether antibodies of the same specificity could derive from variable region genes with highly divergent sequences. Each monoclonal had a groove-type site that could hold six or seven sugar residues (with one exception), based on inhibition of immunoprecipitation by different length oligosaccharides. Thus, unlike monoclonals to haptenated proteins, the precise epitope could be well characterized and was generally quite similar among the entire series.

Studies of the V_K sequences revealed that only three V_K groups were used in these hybridomas. Use of each V_K group correlated with the particular antigen used to immunize the animals, whether linear dextran or short oligosaccharides, so that 10 of the monoclonals from mice immunized the same way all used the same V_K.

In contrast, the 17 V_H chains were derived from at least five different germline genes from three different V_H gene families.[21] The two most frequently used germline V_H genes were found in seven and five monoclonals, respectively, with minor variations explainable by somatic mutations. The remarkable finding is that very different V_H chains (about 50% homologous) can combine with the same V_K to produce antibody-binding sites with nearly the same size, shape, antigen specificity, and affinity. Even when different V_H sequences combine with different V_K sequences, they can produce antibodies with very similar properties. Dextran binding depends on the antigen fitting into the groove and interacting favorably with the residues forming the sides and bottom of the groove. The results indicate that divergent variable region sequences, both in and out of the complementarity-determining regions, can be folded to form similar binding site contours, which result in similar immunochemical characteristics. Similar results have been reported in other antigen-antibody systems, such as phenyloxazolone.[22]

Additional studies of carbohydrate binding monoclonal antibodies have revealed significant

information about how the antibody variable regions can bind a carbohydrate structure with high affinity and specificity. Several examples are now available of crystal structures of carbohydrates bound to antibodies.

For example, monoclonal antibody Se155-4 is specific for the group B determinant of the salmonella O antigen, which consists of the sugars Gal-Abequose-Man.[23,24] The crystal structure of antibody bound to the polysaccharide shows that one hexose, abequose, fits into the binding pocket, while the rest of the interactions occur along the surface of the antibody, similar to the groove-type sites described previously. Binding energy depends on hydrogen bonds formed between the protein residues and the hydroxyl groups of the carbohydrate. The protein residues include aromatic amines, such as His 32, Trp 91, and Trp 96 of the light chain, as well as His 97 and His 35 of the heavy chain. In addition, one of the sugars is hydrogen bonded via a water molecule bridge to the amide bonds of the protein backbone. About three quarters of all sugar hydroxyl groups are involved in hydrogen bonds with the protein. Although each H-bond is relatively weak by itself, the combined effect of eight hydrogen bonds results in high-affinity binding. Antibody specificity derives from the fact that the carbohydrate fits into a binding pocket, where H-bond formation depends on precise interactions with amino acid residues that are oriented about the pocket. Surprisingly, most of these bonds are formed between sugar hydroxyls and aromatic amino acids that are neither charged nor very polar at neutral pH.

Similarly, monoclonal antibody BR96 and the humanized monoclonal hu3S193 are specific for the Le Y antigen, which resembles the Le B antigen described in Figure 23.2, except that the fucose-N-acetylglucosamine bond is β(1 → 3) instead of β(1 → 4). The Le Y antigen is commonly expressed on tumor cells of epithelial origin. The crystal structures have revealed the sources of the binding energy that results in affinity and specificity for this carbohydrate antigen.[25,26] These two monoclonals bind Le Y antigen in a large, deep pocket, which accommodates all four hexoses and correspond to the cavity type binding site predicted by Kabat.15 The terminal fucose goes in first while the other three sugars are hydrogen bonded to amino acid side chains lining the pocket, including Tyr 33, Tyr 35, and Gln 52 of the heavy chain and His 27 of the light chain. Once again, hydrogen bonds between hydroxyl groups of the sugars and aromatic amines (Trp and Tyr) of the protein play a dominant role in determining affinity and specificity of binding. A smaller number of H-bonds depend on amide groups of the protein backbone.

A third example is provided by human monoclonal 2G12, which has neutralizing activity against a broad spectrum of human immunodeficiency virus (HIV) isolates. This antibody binds the mannose-rich oligosaccharide side chains that form a protective surface, called a glycoshield, on the envelope glycoprotein gp120. The crystal structure shows that the two terminal mannose sugars of each oligosaccharide bind end on into a deep pocket of the antibody, in a cavity-type site.[27,28] Twelve hydrogen bonds form between the two terminal mannose residues and the protein, depending mainly on the amide groups of the protein backbone. Additional hydrogen bonds form between the third mannose residue and the side chain of Asp 100 of the heavy chain and between the fourth mannose residue and Tyr 94 of the light chain and Tyr 56 of the heavy chain. A unique feature of this antibody is the crossover of variable regions between heavy and light chains so that each binding site is made up of the V_H from one HL pair combining with the V_L chain of the opposite pair. This arrangement allows the antibody to bind one branch of an oligosaccharide and the opposite branch of a nearby oligosaccharide and makes it ideally suited for cross-linking the densely clustered oligosaccharides of gp120.

Immunogenicity of Polysaccharide Conjugates

Capsular polysaccharides are the main target of protective antibodies against bacterial infection, and, as such, are important vaccine antigens. In adults, the chain length of the polysaccharide is an important determinant of immunogenicity, and the polysaccharides induce a T-independent response that cannot be boosted on repeat exposure. In young children, whose maternal antibodies wane by 6 months of age and who most need immunity to pathogens such as *Haemophilus influenzae* type b and *Streptococcus pneumoniae* of multiple serotypes, the T-independent response to these polysaccharides is weak, regardless of chain length. To immunize children, the polysaccharides were coupled to a protein carrier to create a new T-dependent antigen that gained immunogenicity from T-cell help and boosted antibody titers with each successive dose. This strategy has produced highly successful conjugate vaccines against *H. influenzae* type b,[29] resulting in a markedly reduced incidence of meningitis caused by this agent in immunized children[30,31] and evidence of herd immunity even among unimmunized children. The same strategy has produced an effective vaccine against invasive disease[32] and otitis media[33] caused by the most prevalent serotypes of *S. pneumoniae*.

Protein and Polypeptide Antigenic Determinants

Like the proteins themselves, the antigen determinants of proteins consist of amino acid residues in a particular threedimensional array. The residues that make contact with complementary residues in the antibody-combining site are called contact residues. To make contact, of course, these residues must be exposed on the surface of the protein, not buried in the hydrophobic core. As the complementarity-determining residues in the hypervariable regions of antibodies have been found to span as much as 30 to 40 Å × 15 to 20 Å × 10 Å (D. R. Davies, personal communication), these contact residues comprising the antigenic determinant may cover a significant area of protein surface, as measured by x-ray crystallography of antibody-protein antigen complexes.[34,35,36,37] The size of the combining sites has also been estimated using simple synthetic oligopeptides of increasing length, such as oligolysine. In this case, a series of elegant studies[38,39,40] suggested that the maximum chain length a combining site could accommodate was six to eight residues, corresponding closely to that found earlier for oligosaccharides,[13,14] as discussed previously.

Several types of interactions contribute to the binding energy. Many of the amino acid residues exposed to solvent on the surface of a protein antigen will be hydrophilic. These are likely to interact with antibody contact residues via polar interactions. For instance, an anionic glutamic acid carboxyl group may bind to a complementary cationic lysine amino group on the antibody, or vice versa, or a glutamine amide side chain may form a hydrogen bond with the antibody. However, hydrophobic interactions can also play a major role. Proteins cannot exist in aqueous solution as stable monomers with too many hydrophobic residues on their surface. Those hydrophobic residues that are on the surface can contribute to binding to antibody for exactly the same reason. When a hydrophobic residue in a protein antigenic determinant or, similarly, in a carbohydrate determinant[8] interacts with a corresponding hydrophobic residue in the antibody-combining site, the water molecules previously in contact with each of them are excluded. The result is a significant stabilization of the interaction. A thorough review of these aspects of the chemistry of antigen-antibody binding is in Getzoff et al.[41]

Mapping Epitopes: Conformation versus Sequence

The other component that defines a protein antigenic determinant, besides the amino acid

residues involved, is the way these residues are arrayed in three dimensions. As the residues are on the surface of a protein, we can also think of this component as the topography of the antigenic determinant. Sela[42] divided protein antigenic determinants into two categories, sequential and conformational, depending on whether the primary sequence or the three-dimensional conformation appeared to contribute the most to binding. On the other hand, as the antibody-combining site has a preferred topography in the native antibody, it would seem a priori that some conformations of a particular polypeptide sequence would produce a better fit than others and therefore would be energetically favored in binding. Thus, conformation or topography must always play some role in the structure of an antigenic determinant.

Moreover, when one looks at the surface of a protein in a space-filling model, one cannot ascertain the direction of the backbone or the positions of the helices (contrast Figs. 23.3A and 23.3B).[43,44,45,46,47] It is hard to recognize whether two residues that are side by side on the surface are adjacent on the polypeptide backbone or whether they come from different parts of the sequence and are brought together by the folding of the molecule. If a protein maintains its native conformation when an antibody binds, then it must similarly

P.546

P.547

be hard for the antibody to discriminate between residues that are covalently connected directly and those connected only through a great deal of intervening polypeptide. Thus, the probability that an antigenic determinant on a native globular protein consists of only a consecutive sequence of amino acids in the primary structure is likely to be rather small. Even if most of the determinant were a continuous sequence, other nearby residues would probably play a role as well. Only if the protein were cleaved into fragments before the antibodies were made would there be any reason to favor connected sequences.

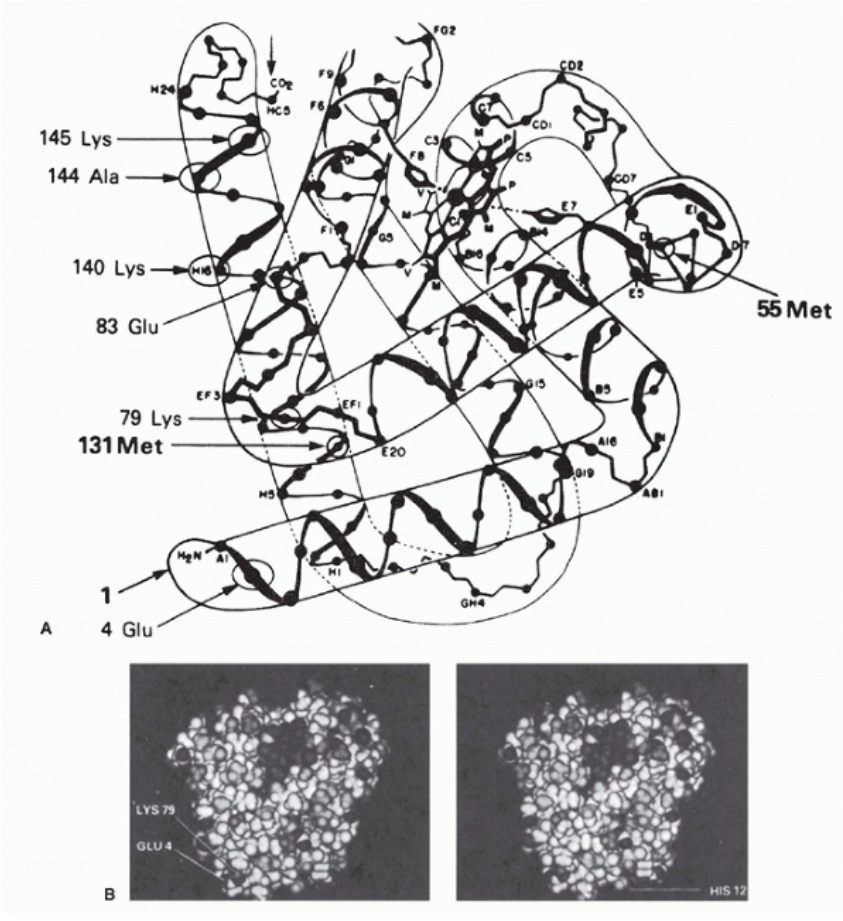

FIG. 23.3. A: Artist's representation of the polypeptide backbone of sperm whale myoglobin in its native three-dimensional conformation. The α helices are labeled A through H from the amino terminal to the carboxyl terminal. Side chains are omitted, except for the two histidine rings (F8 and E7) involved with the heme iron. Methionines at positions 55 and 131 are the sites of cleavage by cyanogen bromide (CNBr), allowing myoglobin to be cleaved into three fragments. Most of the helicity and other features of the native conformation are lost when the molecule is cleaved. A less drastic change in conformation is produced by removal of the heme to form apomyoglobin, as the heme interacts with several helices and stabilizes their positions relative to one another. The other labeled residues (Glu 4, Lys 49, Glu 83, Lys 140, Ala 144, and Lys 145) are residues that have been found to be involved in antigenic determinants recognized by monoclonal antibodies.[43] Note that cleavage by CNBr separates Lys 79 from Glu 4 and separates Glu 83 from Ala 144 and Lys 145. The "sequential" determinant of Koketsu and Atassi[44] (residues 15 to 22) is located at the elbow, lower right, from the end of the A helix to the beginning of the B helix. (Adapted from Dickerson.[45]) **B:** Stereoscopic views of a computer-generated space-filling molecular model of sperm whale myoglobin, based on the Takano[46] x-ray diffraction coordinates. This orientation, which corresponds to that in Panel A, is arbitrarily designated the "front view." The computer method was described by Feldmann et al.[47] The heme and aromatic carbons are *shaded darkest*, followed by carboxyl oxygens, then other oxygens, then primary amino groups, then other nitrogens, and finally side chains of aliphatic residues. The backbone and the side chains of nonaliphatic residues, except for the functional groups, are shown in *white*. Note that the direction of the helices is not apparent on the surface, in contrast to the backbone drawing in Panel A. The residues Glu 4, Lys 79, and His 12 are believed to be part of a topographic antigenic determinant recognized by a monoclonal antibody to myoglobin.[43] This stereo pair can be viewed in three dimensions using an inexpensive stereoviewer such as the "stereoscopes" sold by Abrams Instrument Corp. (Lansing, MI) or Hubbard Scientific Co. (Northbrook, IL). (Adapted from Berzofsky et al.[43])

This concept was analyzed and confirmed quantitatively by Barlow et al.,[48] who examined the atoms lying within spheres of different radii from a given surface atom on a protein. As the radius increases, the probability that all the atoms within the sphere will be from the same continuous segment of protein sequence decreases rapidly. Correspondingly, the fraction of surface atoms that would be located at the center of a sphere containing only residues from the same continuous segment falls dramatically as the radius of the sphere increases. For instance, for lysozyme, with a radius of 8 Å, fewer than 10% of the surface residues would lie in such a "continuous patch" of surface. These are primarily in regions that protrude from the surface. With a radius of 10 Å, almost none of the surface residues fall in the center of a continuous patch. Thus, for a contact area of about 20 Å × 25 Å, as found for a lysozyme-antibody complex studied by x-ray crystallography, none of the antigenic sites could be completely continuous segmental sites (see following discussion and Fig. 23.4). On the other hand, other analyses did not find a correlation of epitope residues with surface accessibility, suggesting that the situation is more complex.[49]

Antigenic sites consisting of amino acid residues that are widely separated in the primary protein sequence but brought together on the surface of the protein by the way it folds in its

native conformation have been called “assembled topographic” sites[50,51] because they are assembled from different parts of the sequence and exist only in the surface topography of the native molecule. By contrast, the sites that consist of only a single continuous segment of protein sequence have been called “segmental” antigenic sites.[50,51]

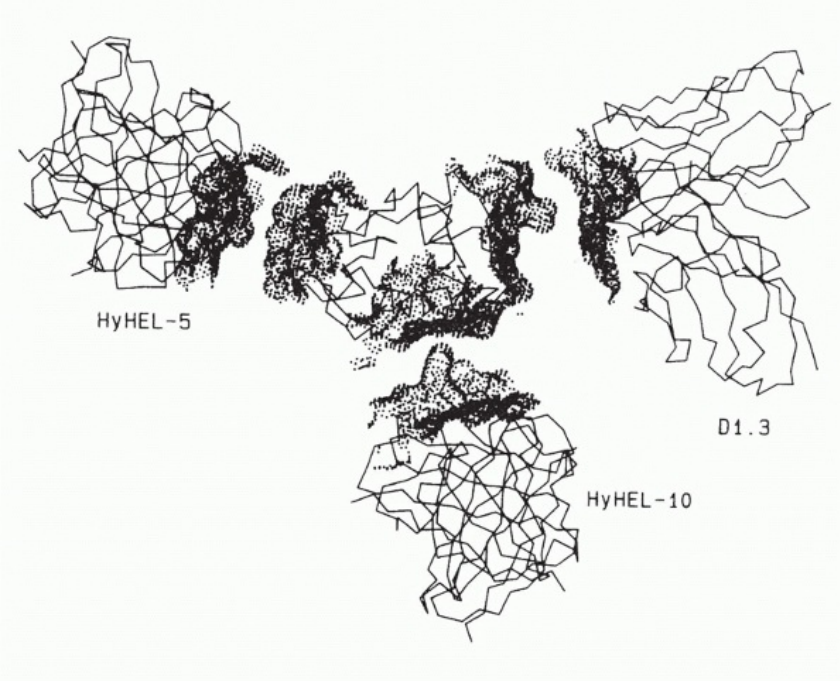

FIG. 23.4. Assembled Topographic Sites of Lysozyme Illustrated by the Footprints of Three Nonoverlapping Monoclonal Antibodies. Shown are the α-carbon backbones of lysozyme in the center and the Fv portions of three antilysozyme monoclonal antibodies D1.3, HyHEL-5, and HyHEL-10. The footprints of the antibodies on lysozyme and lysozyme on the antibodies (ie, their interacting surfaces) are shown by a *dotted representation*. Note that the three antibodies each contact more than one continuous loop of lysozyme and so define assembled topographic sites. Reproduced from Davies and Padlan[37] with permission.

In contrast to T-cell recognition of “processed” fragments retaining only primary and secondary structures, the evidence is overwhelming that most antibodies are made against the native conformation when the native protein is used as immunogen. For instance, antibodies to native staphylococcal nuclease were found to have about a 5000-fold higher affinity for the native protein than for the corresponding polypeptide on which they were isolated (by binding to the peptide attached to Sepharose).[52] An even more dramatic example is that demonstrated by Crumpton[53] for antibodies to native myoglobin or to apomyoglobin. Antibodies to native ferric myoglobin produced a brown precipitate with myoglobin but did not bind well to apomyoglobin, which, without the heme, has a slightly altered conformation. On the other hand, antibodies to the apomyoglobin, when mixed with native (brown) myoglobin, produced a white precipitate. These antibodies so strongly favored the conformation of apomyoglobin, from which the heme was excluded, that they trapped those molecules that vibrated toward that conformation and pulled the equilibrium state over to the apo form. One could almost say, figuratively, that the antibodies squeezed the heme out of the myoglobin. Looked at it thermodynamically, it is clear that the conformational

preference of the antibody for the apo versus native forms, in terms of free energy, had to be greater than the free energy of binding of the heme to myoglobin. Thus, in general, antibodies are made that are very specific for the conformation of the protein used as immunogen. Other more recent examples also show that antibodies can

enforce structures on disordered or denatured structures in proteins such as HIV-1 Tat[54] or influenza hemagglutinin.[55]

Synthetic peptides corresponding to segments of the protein antigen sequence can be used to identify the structures bound by antibodies specific for segmental antigenic sites. To identify assembled topographic sites, more complex approaches have been necessary. The earliest was the use of natural variants of the protein antigen with known amino acid substitutions, where such evolutionary variants exist.[50] Thus, substitution of different amino acids in proteins in the native conformation can be examined. The use of this method, which is illustrated later, is limited to studying the function of amino acids that vary among homologous proteins, that is, those that are polymorphic. It may now be extended to other residues by use of site-directed mutagenesis. A second method is to use the antibody that binds to the native protein to protect the antigenic site from modification[56] or proteolytic degradation.[57] A related but less sensitive approach makes use of competition with other antibodies.[58,59,60] A third approach, taking advantage of the capability of producing thousands of peptides on a solid-phase surface for direct binding assays,[61] is to study binding of a monoclonal antibody to every possible combination of six amino acids.[61] If the assembled topographic site can be mimicked by a combination of six amino acids not corresponding to any continuous segment of the protein sequence but structurally resembling a part of the surface, then one can produce a “mimotope” defining the specificity of that antibody.[61] Mimotopes have become widely used and can be combined with mutational analysis to map assembled topographic epitopes.[62] Mimetics have even been made for quaternary structural epitopes.[63] Many mimotope approaches use phase display peptide libraries to map epitopes of monoclonal antibodies.[64,65,66] However, other studies have been less optimistic about the ability to predict assembled topographic or discontinuous epitopes from mimotope binding[67] or random peptide libraries.[68]

Myoglobin also serves as a good model protein antigen for studying the range of variation of antigenic determinants from those that are more sequential in nature to those that do not even exist without the native conformation of the protein (see Fig. 23.3). A good example of the first more segmental type of determinant is that consisting of residues 15 to 22 in the amino terminal portion of the molecule. Crumpton and Wilkinson[69] first discovered that the chymotrypsin cleavage fragment consisting of residues 15 to 29 had antigenic activity for antibodies raised to either native or apomyoglobin. Two other groups[44,70] then found that synthetic peptides corresponding to residues 15 to 22 bind antibodies made to native sperm whale myoglobin, even though the synthetic peptides were only seven to eight residues long. Peptides of this length do not spend much time (in solution) in a conformation corresponding to that of the native protein. On the other hand, these synthetic peptides had a several hundred-fold lower affinity for the antibodies than did the native protein. Thus, even if most of the determinant was included in the consecutive sequence 15 to 22, the antibodies were still much more specific for the native conformation of this sequence than for the random conformation peptide. Moreover, there was no evidence to exclude the participation of other residues, nearby on the surface of myoglobin but not in this sequence, in the antigenic

determinant.[71,72,73,74*]

A good example of the importance of secondary structure is the case of the loop peptide (residues 64 to 80) of hen egg white lysozyme.[75] This loop in the protein sequence is created by the disulfide linkage between cysteine residues 64 and 80 and has been shown to be a major antigenic determinant for antibodies to lysozyme.[75] The isolated peptide 60 to 83, containing the loop, binds antibodies with high affinity, but opening of the loop by cleavage of the disulfide bond destroys most of the antigenic activity for antilysozyme antibodies.[75]

At the other end of the range of conformational requirements are those determinants involving residues far apart in the primary sequences that are brought close together on the surface of the native molecule by its folding in three dimensions, called assembled topographic determinants.[50,51] Of six monoclonal antibodies to sperm whale myoglobin studied by Berzofsky et al.,[43,76] none bound to any of the three cyanogen bromide (CNBr) cleavage fragments of myoglobin that together span the whole sequence of the molecule. Therefore, these monoclonal antibodies (all with affinities between 2×10^8 and 2×10^9 M^{-1}) were all highly specific for the native conformation. These were studied by comparing the relative affinities for a series of native myoglobins from different species with known amino acid sequences. This approach allowed the definition of some of the residues involved in binding to three of these antibodies. Two of these three monoclonal antibodies were found to recognize topographic determinants, as defined previously. One recognized a determinant including Glu 4 and Lys 79, which come within about 2 Å of each other to form a salt bridge in the native molecule (see Fig. 23.3A, B). The other antibody recognized a determinant involving Glu 83, Ala 144, and Lys 145 (see Fig. 23.3A). Again, these are far apart in the primary sequence but are brought within 12 Å of each other by the folding of the molecule in its native conformation. Similar examples have been reported for monoclonal antibodies to human myoglobin[77] and to lysozyme[37,58] as well as the HIV-1 envelope protein (neutralizing epitopes)[78,79] and the prion protein.[80] Other examples of such conformation-dependent antigenic determinants have been suggested using conventional antisera to such proteins as insulin,[81] hemoglobin,[82] tobacco mosaic virus,[83] and cytochrome c.[84] Moreover, the crystallographic structures of lysozyme-antibody[34,36,37] and neuraminidase-antibody[35] complexes, as well as HIV-1 envelope antibody complexes,[78,79] show clearly that, in both cases, the epitope bound is an assembled topographic site.

In the case of the three monoclonal antibodies binding to nonoverlapping sites of lysozyme (Fig. 23.4), it is clear that the footprints of all three antibody-combining sites cover more than one loop of polypeptide chain, and thus, each encompasses an assembled topographic site.[37] This result illustrates the concept that most antibody-combining sites must interact with more than a continuous loop of polypeptide chain and thus must define assembled topographic sites.[48] Another important example is represented by neutralizing antibodies to the HIV envelope protein that similarly bind assembled topographic sites[85,86] (see the end of this section).

How frequent are antibodies specific for topographic determinants compared to those that bind consecutive sequences when conventional antisera are examined? This question was studied by Lando et al.,[87] who passed goat, sheep, and rabbit antisera to sperm whale myoglobin over columns of myoglobin fragments, together spanning the whole sequence. After removal of all antibodies binding to the fragments, 30% to 40% of the antibodies

remained that still bound to the native myoglobin molecule with high affinity but did not bind to any of the fragments in solution by radioimmunoassay. Thus, in four of four antimyoglobin sera tested, 60% to 70% of the antibodies could bind peptides, and 30% to 40% could bind only native-conformation intact protein.

On the basis of studies such as these, it has been suggested that much of the surface of a protein molecule may be antigenic,[50,88] but that the surface can be divided up into antigenic domains.[43,73,74,77] Each of these domains consists of many overlapping determinants recognized by different antibodies.

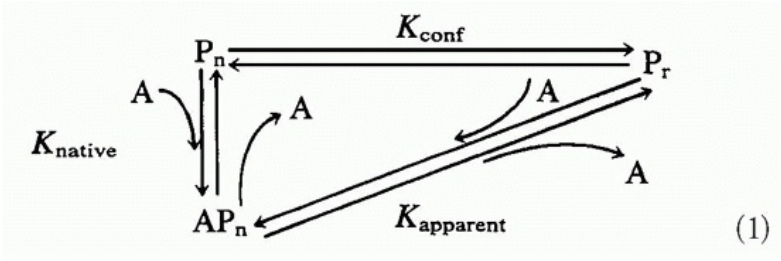
An additional interesting point is that in three published crystal structures of protein antigen-antibody complexes, the contact surfaces were broad, with local complementary pairs of concave and convex regions in both directions.[34,35,36,37] Thus, the concept of an antigen binding in the groove or pocket of an antibody may be oversimplified, and antibodies may sometimes bind by extending into pockets on an antigen.

Further information on the subjects discussed in this section is available in the reviews by Sela,[42] Crumpton,[53] Reichlin,[89] Kabat,[90] Benjamin et al.,[50] Berzofsky,[51] Getzoff et al.,[41] and Davis and Padlan.[37]

Conformational Equilibria of Protein and Peptide Antigenic Determinants

There are several possible mechanisms to explain why an antibody specific for a native protein will bind a peptide fragment in random conformation with lower affinity. Of course, the peptide may not contain all the contact residues of the antigenic determinant so that the binding energy would be lower. However, for cases in which all the residues in the determinant are present in the peptide, several mechanisms still remain. First, the affinity may be lower because the topography of the residues in the peptide may not produce as complementary a fit in the antibodycombining site as the native conformation would. Second, the apparent affinity may be reduced because only a small fraction of the peptide molecules are in a native-like conformation at any time, assuming that the antibody binds only to the native conformation. Because the concentration of peptide molecules in native conformation is lower than the total peptide concentration by a factor that corresponds to the conformational equilibrium constant of the peptide, the apparent affinity is also lower by this factor. This model is analogous to an allosteric model. A third, intermediate hypothesis would suggest that initial binding of the peptide in a nonnative conformation occurs with submaximal complementarity and is followed by an intramolecular conformational change in the peptide to achieve energy minimization by assuming a native-like conformation. This third hypothesis corresponds to an induced fit model. The loss of affinity is due to the energy required to change the conformation of the peptide, which in turn corresponds to the conformational equilibrium constant in the second hypothesis. To some extent, these models could be distinguished kinetically, as the first hypothesis predicts a faster “on” rate and a faster “off” rate than does the second hypothesis.[91] Such kinetic approaches have likewise been used to support an “encounter-docking” model related to this concept.[92]

Although not the only way to explain the data, the second hypothesis is useful because it provides a method to estimate the conformational equilibria of proteins and peptides.[52,93] The method assumes the second hypothesis, which can be expressed as follows:



where A = antibody, P_n = native peptide, and P_r = random conformation peptide so that

$$K_{apparent} = K_{conf}K_{native} \quad (2)$$

Thus, the ratio of the apparent association constant for peptide to the measured association constant for the native molecule should give the conformational equilibrium constant of the peptide. Note the implicit assumption that the total peptide concentration can be approximated by $[P_r]$. This will generally be true, as most peptide fragments of proteins demonstrate little native conformation, that is, $K_{conf} = [Pn] / [Pr]$ is much less than one. Also note that if the first hypothesis (or third) occurs to some extent, this method will overestimate K_{conf}. On the other hand, if the affinity for the peptide is lower because it lacks some of the contact residues of the determinant, this method will underestimate K_{conf} (by assuming that all the affinity difference is due to conformation). To some extent, the two errors may partially cancel out. When this method was used to determine the K_{conf} for a peptide from staphylococcal nuclease, a value of 2×10^{-4} (unitless because it is a ratio of two concentrations) was obtained.[52] Similarly, when antibodies raised to a peptide fragment were used, it was possible to estimate the fraction of time the native nuclease spends in nonnative

conformations.[93] In this case, the K_{conf} was found to be about 3000-fold in favor of the native conformation.

Antipeptide Antibodies that Bind to Native Proteins at a Specific Site

In light of the conformational differences between native proteins and peptides and the observed K_{conf} effects shown by antibodies to native proteins when tested on the corresponding peptides, it was somewhat surprising to find that antibodies to synthetic peptides show extensive cross-reactions with native proteins.[94,95] These two types of cross-reactions can be thought of as working in opposite directions: The binding of antiprotein antibodies to the peptide is inefficient, whereas the binding of antipeptide antibodies to the protein is quite efficient and commonly observed. This finding is quite useful, as automated solid-phase peptide synthesis has become readily available. This has been particularly useful in three areas: exploitation of protein sequences deduced by recombinant deoxyribonucleic acid (DNA) methods, preparation of site specific antibodies, and the attempt to focus the immune response on a single protein site that is biologically important but may not be particularly immunogenic. This section focuses on the explanation of the cross-reaction, uses of the cross-reaction, and the potential limitations regarding immunogenicity.

The basic assumption is that antibodies raised against peptides in an unfolded structure will bind the corresponding site on proteins folded into the native structure.[95] This is not immediately obvious, as antibody binding to antigen is the direct result of the antigen fitting into the binding site. Affinity is the direct consequence of “goodness of fit” between antibody and antigen, whereas antibody specificity is due to the inability of other antigens to occupy

the same site. How then can the antipeptide antibodies overcome the effect of K_{conf} and still bind native proteins with good affinity and specificity? The whole process depends on the antibodybinding site forming a three-dimensional space and the antigen filling it in an energetically favorable way.

Because the peptides are randomly folded, they rarely occupy the native conformation, so they are not likely to elicit antibodies against a conformation they do not maintain. If the antibodies are specific for a denatured structure, then, like the myoglobin molecules that were denatured to apomyoglobin by antibody binding,[53] the cross-reaction may depend on the native protein's ability to assume different conformational states. If the native protein is quite rigid, then the possibility of it assuming a random conformation is quite small; if it is a flexible three-dimensional spring, then local unfolding and refolding may occur all the time. Local unfolding of protein segments may permit the immunologic cross-reaction with antipeptide antibodies, as a flexible segment could assume many of the same conformations as the randomly folded peptide.[95] On the other hand, peptides with more stable conformations may be more likely to elicit antibodies that bind both the peptide and the native protein.[96] To this end, scaffolding has been used to maintain the conformation of peptides or protein fragments to be used as immunogens/vaccines, such as for respiratory syncytial virus[97] or HIV epitopes.[98,99]

In contrast, the ability of proteins to crystallize (a feature that allows the study of their structure by x-ray crystallography) has long been taken as evidence of protein rigidity.[100] In addition, the existence of discrete functional states of allosteric enzymes[101] provides additional evidence of stable structural states of a protein. Finally, the fact that antibodies can distinguish native from denatured forms of intact proteins is well known for proteins such as myoglobin.[53]

However, protein crystals are a somewhat artificial situation, as the formation of the crystal lattice imposes order on the components, each of which occupies a local energy minimum at the expense of considerable loss of randomness (entropy). Thus, the crystal structure may have artificial rigidity that exceeds the actual rigidity of protein molecules in solution. On the contrary, we may attribute some of the considerable difficulty in crystallizing proteins to disorder within the native conformation. Second, allosterism may be explained by two distinct conformations that are discrete without being particularly rigid. Finally, the ability to generate antiprotein antibodies that are conformation specific does not rule out the existence of antipeptide antibodies that are not. All antibodies are probably specific for some conformation of the antigen, but this need not be the crystallographic native conformation in order to achieve a significant affinity for those proteins or protein segments that have a “loose” native conformation.

Antipeptide antibodies have proved to be very powerful reagents when combined with recombinant DNA methods of gene sequencing.[95,102] From the DNA sequence, the protein sequence is predicted. A synthetic peptide is constructed, coupled to a suitable carrier molecule, and used to immunize animals. The resulting polyclonal antibodies can be detected with a peptide-coated enzyme-linked immunosorbent assay plate (see Chapter 7). They are used to immunoprecipitate the native protein from a ^{35}S-labeled cell lysate and thus confirm expression of the gene product in these cells. The antipeptide antibodies can also be used to isolate the previously unidentified gene product of a new gene. The site-specific antibodies are also useful in detecting posttranslational processing, as they bind all precursors and products that contain the site. In addition, because the antibodies bind only to the site

corresponding to the peptide, they are useful in probing structure-function relationships. They can be used to block the binding of a substrate to an enzyme or the binding of a virus to its cellular receptor.

Immunogenicity of Proteins and Peptides

Up to this point, we have considered the ability of antibodies to react with proteins or peptides as antigens. However, immunogenicity refers to the ability of these compounds to elicit antibodies following immunization. Several factors limit the immunogenicity of different regions of proteins, and these have been divided into those that are intrinsic to protein structure itself versus those extrinsic to the antigen that are related to the responder and vary from one animal or species to another.[51] In addition, we consider the special case of peptide immunogenicity, as it applies to vaccine development. The features of protein structure that have been suggested to explain the results include surface accessibility

of the site, hydrophilicity, flexibility, and proximity to a site recognized by helper T cells.

When the x-ray crystallographic structure and antigenic structure are known for the same protein, it is not surprising to find that a series of monoclonal antibodies binding to a molecule such as influenza neuraminidase choose an overlapping pattern of sites at the exposed head of the protein.[103]

The stalk of neuraminidase was not immunogenic apparently because it was almost entirely covered by carbohydrate. Beyond such things as carbohydrate, which may sterically interfere with antibody binding to protein, accessibility on the surface is clearly a sine qua non for an antigenic determinant to be bound by an antibody specific for the native conformation, without any requirement for unfolding of the structure.[51] Several measures of such accessibility have been suggested. All these require knowledge of the x-ray crystallographic three-dimensional structure. Some have measured accessibility to solvent by rolling a sphere with the radius of a water molecule over the surface of a protein.[104,105] Others have suggested that accessibility to water is not the best measure of accessibility to antibody and have demonstrated a better correlation by rolling a sphere with the radius of an antibody-combining domain.[106] Another approach to predicting antigenic sites on the basis of accessibility is to examine the degree of protrusion from the surface of the protein.[107] This was done by modeling the body of the protein as an ellipsoid and examining which amino acid residues remain outside ellipsoids of increasing dimensions. The most protruding residues were found to be part of antigenic sites bound by antibodies, but usually, these sites had been identified by using short synthetic peptides and so were segmental in nature. As noted previously, for an antigenic site to be contained completely within a single continuous segment of protein sequence, the site is likely to have to protrude from the surface, as otherwise residues from other parts of the sequence would fall within the area contacting the antibody.[48] However, inability of such surface or protrusion information to predict antigenic sites has also been encountered in some studies.[49]

Because the three-dimensional structure of most proteins is not known, other ways of predicting surface exposure have been proposed for the vast majority of antigens. For example, hydrophilic sites tend to be found on the water-exposed surface of proteins. Thus, hydrophilicity has been proposed as a second indication of immunogenicity.[108,109,110] This model has been used to analyze 12 proteins with known antigenic sites: The most hydrophilic site of each protein was indeed one of the antigenic sites. However, among the limitations are the facts that a significant fraction of surface residues can be nonpolar,[104,105] and that

several important examples of hydrophobic and aromatic amino acids involved in the antigenic sites are known.[42,83,111,112] Specificity of antibody binding likely depends on the complementarity of surfaces for hydrogen bonding and polar bonding as well as van der Waals contacts, whereas hydrophobic interactions and the exclusion of water from the interacting surfaces of proteins may contribute a large but nonspecific component to the energy of binding.[113] Another study suggested that amino acid pairs were better predictors of epitopes.[114]

A third factor suggested to play a role in immunogenicity of protein epitopes is mobility. Measurement of mobility in the native protein is largely dependent on the availability of a high-resolution crystal structure, so its applicability is limited to only a small subset of proteins. Furthermore, it has been studied only for antibodies specific for segmental antigenic sites; therefore, it may not apply to the large fraction of antibodies to assembled topographic sites. Studies of mobility have taken two directions. The case of antipeptide antibodies has already been discussed, in which antibodies made to peptides corresponding to more mobile segments of the native protein were more likely to bind to the native protein.[95,115] This is not considered just a consequence of the fact that more mobile segments are likely to be those on the surface and therefore more exposed because in the case of myohemerythrin (which was used as a model), two regions of the native protein that were equally exposed but less mobile did not bind nearly as well to the corresponding antipeptide antibodies.[116] However, as is clear from the previous discussion, this result applies to antibodies made against short peptides and therefore is not directly relevant to immunogenicity of parts of the native protein. Rather, it concerns the cross-reactivity of antipeptide antibodies with the native protein and therefore is of considerable practical importance for the purposes outlined in the section on antipeptide antibodies.

Studies in the other direction—that is, of antibodies raised against native proteins—would be by definition more relevant to the question of immunogenicity of parts of the native protein. Westhof et al.[117] used a series of hexapeptides to determine the specificity of antibodies raised against native tobacco mosaic virus protein and found that six of the seven peptides that bound antibodies to native protein corresponded to peaks of high mobility in the native protein. The correlation was better than could be accounted for just by accessibility because three peptides that corresponded to exposed regions of only average mobility did not bind antibodies to the native protein. However, when longer peptides—on the order of 20 amino acid residues—were used as probes, it was found that antibodies were present in the same antisera that bound to less mobile regions of the protein.[118] They simply had not been detected with the short hexapeptides with less conformational stability. Thus, it was not that the more mobile regions were necessarily more immunogenic but rather that antibodies to these were more easily detected with short peptides as probes. A similar good correlation of antigenic sites with mobile regions of the native protein in the case of myoglobin[117] may also be attributed to the fact that seven of the nine sites were defined with short peptides of six to eight residues.[71] Again, this result becomes a statement about cross-reactivity between peptides and native protein rather than about the immunogenicity of the native protein. For reviews, see Van Regenmortel[119] and Getzoff et al.[41]

To address the role of mobility in immunogenicity, an attempt was made to quantitate the relative fraction of antibodies specific for different sites on the antigen myohemerythrin.[120] The premise was that, although the entire surface of the protein may be immunogenic, certain regions may elicit significantly more antibodies than others and therefore may

be considered immunodominant or at least more immunogenic. Because this study was done with short synthetic peptides from 6 to 14 residues long based on the protein sequence, it was limited to the subset of antibodies specific for segmental antigenic sites. Among these, it was clear that the most immunogenic sites were in regions of the surface that were most mobile, convex in shape, and often of negative electrostatic potential. Other more recent studies corroborate the greater immunogenicity of more flexible segments of protein structures.[121] The role of these parameters has been reviewed.[41]

These results have important practical and theoretical implications. First, to use peptides to fractionate antiprotein antisera by affinity chromatography, peptides corresponding to more mobile segments of the native protein should be chosen when possible. If the crystal structure is not known, it may be possible to use peptides from amino or carboxyl termini or from exon-intron boundaries, as these are more likely to be mobile.[115] Second, these results may explain how a large but finite repertoire of antibody-producing B cells can respond to any antigen in nature or even artificial antigens never encountered in nature. Protein segments that are more flexible may be able to bind by induced fit in an antibody-combining site that is not perfectly complementary to the average native structure.[41,51] Indeed, evidence from the crystal structure of antigen-antibody complexes[122,123,124] suggests that mobility in the antibody-combining site as well as in the antigen may allow both reactants to adopt more complementary conformations on binding to each other, that is, a two-way induced fit. A nice example comes from the study of antibodies to myohemerythrin,[123] in which the data suggested that initial binding of exposed side chains of the antigen to the antibody promoted local displacements that allowed exposure and binding of other, previously buried residues that served as contact residues. The only way this could occur would be for such residues to become exposed during the course of an induced fit conformational change in the antigen.[41,123] In a second very clear example of induced fit, the contribution of antibody mobility to peptide binding was demonstrated for a monoclonal antibody to peptide 75 to 110 of influenza hemagglutinin, which was crystallized with or without peptide in the binding site and analyzed by x-ray crystallography for evidence of an induced fit.[124] Despite flexibility of the peptide, the antibody-binding site probably could not accommodate the peptide without a conformational change in the third complementarity determining region of the heavy chain, in which an asparagine residue of the antibody was rotated out of the way to allow a tyrosine residue of the peptide to fit in the binding pocket of the antibody.[124]

Regarding host-limited factors, immunogenicity is certainly limited by self-tolerance. Thus, the repertoire of potential antigenic sites on mammalian protein antigens such as myoglobin or cytochrome c can be thought of as greatly simplified by the sharing of numerous amino acids with the endogenous host protein. For mouse, guanaco, or horse cytochrome c injected into rabbits, each of the differences between the immunogen and rabbit cytochrome c is seen as an immunogenic site on a background of immunologically silent residues.[50,84,125] In another example, rabbit and dog antibodies to beef myoglobin bound almost equally well to beef or sheep myoglobin.[126] However, sheep antibodies bound beef but not sheep myoglobin, even though these two myoglobins differ by just six amino acids. Thus, the sheep immune system was able to screen out those clones that would be autoreactive with sheep myoglobin.

Ir genes of the host also play an important role in regulating the ability of an individual to make antibodies to a specific antigen.[127] These antigen-specific immune response genes are among the major histocompatibility complex (MHC) genes that code for transplantation

antigens. Structural mutations, gene transfer experiments, and biochemical studies[127] all indicate that Ir genes are actually the structural genes for MHC antigens. The mechanism of action of the MHC antigens works through their effect on helper T cells (described later in this chapter). There appear to be constraints on which B and T cells of a given specificity can help,[128,129] a process called T-B reciprocity.[130] Thus, if Ir genes control helper T-cell specificity, they will in turn limit which B cells are activated and which antibodies are made.

The immunogenicity of peptide antigens is also limited by intrinsic and extrinsic factors. With less structure to go on, each small peptide must presumably contain some non-self-structural feature in order to overcome self-tolerance. In addition, the same peptide must contain antigenic sites that can be recognized by helper T cells as well as by B cells. When no T-cell site is present, three approaches may be helpful: graft on a T-cell site, couple the peptide to a carrier protein, or overcome T-cell nonresponsiveness to the available structure with various immunologic agents, such as interleukin 2.

An example of a biologically relevant but poorly immunogenic peptide is the asparagine-alanine-asparagine-proline (NANP) repeat unit of the circumsporozoite (CS) protein of malaria sporozoites. A monoclonal antibody to the repeat unit of the CS protein can protect against murine malaria.[131] Thus, it would be desirable to make a malaria vaccine of the repeat unit of *Plasmodium falciparum* $(NANP)_n$. However, only mice of one MHC type ($H\text{-}2^b$) of all mouse strains tested were able to respond to $(NANP)_n$.[132,133] One approach to overcome this limitation is to couple $(NANP)_n$ to a site recognizable by T cells, perhaps a carrier protein such as tetanus toxoid.[134] In human trials, this conjugate was weakly immunogenic and only partially protective. Moreover, as helper T cells produced by this approach are specific for the unrelated carrier, a secondary or memory response would not be expected to be elicited by the pathogen itself.

Another choice might be to identify a T-cell site on the CS protein itself and couple the two synthetic peptides together to make one complete immunogen. The result with one such site, called Th2R, was to increase the range of responding mouse MHC types by one, to include $H\text{-}2^k$ as well as $H\text{-}2^b$.[135] This approach has the potential advantage of inducing a state of immunity that could be boosted by natural exposure to the sporozoite antigen. As CS-specific T and B cells are both elicited by the vaccine, natural exposure to the antigen could help maintain the level of immunity during the entire period of exposure.

Another strategy to improve the immunogenicity of peptide vaccines is to stimulate the T- and B-cell responses artificially by adding interleukin 2 to the vaccine. Results with myoglobin indicate that genetic nonresponsiveness can be overcome by appropriate doses of interleukin 2.[136] The same effect was found for peptides derived from malaria proteins.[137,137a]

One of the most important possible uses of peptide antigens is as synthetic vaccines. However, even though it is possible to elicit with synthetic peptides anti-influenza antibodies to nearly every part of the influenza hemagglutinin,[94] antibodies that neutralize viral infectivity have not been elicited by immunization with synthetic peptides. This may reflect the fact that antibody binding by itself often does not result in virus inactivation. Viral inactivation occurs only when antibody interferes with one of the steps in the life cycle of the virus, including binding to its cell surface receptor, internalization, and virus uncoating within the cell. Apparently, antibodies can bind to most of the exposed surface of the virus without affecting these functions. Only those antibodies that bind to certain “neutralizing” sites can

inactivate the virus. In addition, as in the case of the VP1 coat protein of poliovirus, certain neutralizing sites are found only on the native protein and not on the heat-denatured protein.[138] Thus, not only the site but also the conformation that is bound by the antibodies may be important for the antibody to inactivate the virus. These sites may often be assembled topographic sites not mimicked by peptide segments of the sequence. Perhaps binding of an antibody to such an assembled site can alter the relative positions of the component subsites so as to induce an allosteric neutralizing effect. Alternatively, antibodies to such an assembled site may prevent a conformational change necessary for activity of the viral protein.

One method of mapping neutralizing sites is based on the use of neutralizing monoclonal antibodies. The virus is grown in the presence of neutralizing concentrations of the monoclonal antibody, and virus mutants are selected for the ability to overcome antibody inhibition. These are sequenced, revealing the mutation that permits “escape” by altering the antigenic site for that antibody. This method has been used to map the neutralizing sites of influenza hemagglutinin[139] as well as poliovirus capsid protein VP1.[140] The influenza escaping mutations are clustered to form an assembled topographic site, with mutations distant from each other in the primary sequence of hemagglutinin but brought together by the three-dimensional folding of the native protein. At first, it was thought that neutralization was the result of steric hindrance of the hemagglutinin-binding site for the cell surface receptor of the virus.[141] However, similar work with poliovirus reveals that neutralizing antibodies that bind to assembled topographic sites may inactivate the virus at less than stoichiometric amounts, when at least half of the sites are unbound by antibody.[142] The neutralizing antibodies all cause a conformational change in the virus, which is reflected in a change in the isoelectric point of the particles from pH 7 to pH 4.[140,143] Antibodies that bind without neutralizing do not cause this shift. Thus, an alternative explanation for the mechanism of antibody-mediated neutralization is the triggering of the virus to self-destruct. Perhaps the reason that neutralizing sites are clustered near receptor-binding sites is that occupation of such sites by antibody mimics events normally caused by binding to the cellular receptor, causing the virus to prematurely trigger its cell entry mechanisms. However, in order to transmit a physiologic signal, the antibody may need to bind viral capsid proteins in the native conformation (especially assembled topographic sites), which antipeptide antibodies may fail to do. Antibodies of this specificity are similar to the viral receptors on the cell surface, some of which have been cloned and expressed without their transmembrane sequences as soluble proteins. The soluble recombinant receptors for poliovirus[144] and HIV-1[145,146,147] exhibit high-affinity binding to the virus and potent neutralizing activity in vitro. The HIV-1 receptor, cluster of differentiation (CD)4, has been combined with the human Ig heavy chain in a hybrid protein CD4-Ig,[148] which spontaneously assembles into dimers and resembles a monoclonal antibody, in which the binding site is the same as the receptor-binding site for HIV-1. In these recombinant constructs, high-affinity binding depends on the native conformation of the viral envelope glycoprotein gp120. Binding of CD4 to gp120 elicits a conformational change exposing a CD4-induced epitope, and fusions of CD4 domains to gp120 can be used as vaccines to elicit such antibodies.[149]

For HIV-1, two types of neutralizing antibodies have been identified. The first type binds a continuous or segmental determinant, such as the “V3 loop” sequence between amino acids 296 and 331 of gp120.[150,151,152] Antipeptide antibodies against this site can neutralize the virus.[150] However, because this site is located in a highly variable region of the envelope, these antibodies tend to neutralize a narrow range of viral variants with nearly the same

sequence as the immunogen. Even for this highly variable site, more broadly neutralizing antibodies can be obtained that recognize conserved conformations.[153,154,155] The second type of neutralizing antibody binds conserved sites on the native structure of gp120, allowing them to neutralize a broad spectrum of HIV-1 isolates. These antibodies are commonly found in the sera of infected patients,[156] and a panel of neutralizing monoclonals derived from these subjects has been analyzed.

These monoclonals can be divided into three types. One group, possibly the most common ones in human polyclonal sera, bind at or near the CD4 receptor-binding site of gp120.[79,157,158,159,160,161] A second type of monoclonal, called 2G12, binds a conformational site on gp120 that also depends on glycosylation, but has no direct effect on CD4 binding.[162] A third type, quite rare in human sera, is represented by monoclonal antibody 2F5[163] and binds a conserved site on the transmembrane protein gp41. Although this site is contained on a linear peptide ELDKWA, antibodies such as 2F5 cannot be elicited by immunizing with the peptide, again suggesting the conformational aspect of this site.[164,165] Indeed, the binding of antibodies to this membrane-proximal site has even been found to involve interaction of the antibody with the lipid membrane.[166] One might view this intriguing case as an example of a discontinuous or assembled topographic site created by the proximity of residues of the protein with structures in the lipid membrane, thus, spanning more than just different parts of the antigenic protein.

These monoclonals neutralize fresh isolates, as well as laboratory-adapted strains, and they neutralize viruses tropic for T cells or macrophages,[167] regardless of the use of CXCR4 or CCR5 as second receptor. These monoclonals, which target different sites, act synergistically. A cocktail combining all three types of monoclonals can protect monkeys against iv challenge or vaginal challenge with a simian immunodeficiency virus/HIV hybrid virus, indicating the potential for antibodies alone to prevent HIV infection.[168,169] Because each of the three conserved neutralizing determinants depends on the native conformation of the protein,[170] a prospective gp120 vaccine (or gp160 vaccine) would need to be in the native conformation to be able to elicit these antibodies.

ANTIGENIC DETERMINANTS RECOGNIZED BY T CELLS

Studies of T-cell specificity for antigen were motivated by the fact that the immune response to protein antigens is regulated at the T-cell level. A hapten, not immunogenic by itself, will elicit antibodies only when coupled to a protein that elicits a T-cell response in that animal. This ability of the protein component of the conjugate to confer immunogenicity on the hapten has been termed the “carrier effect.” Recognition of the carrier by specific helper T cells induces the B cells to make antibodies. Thus, the factors contributing to a good T-cell response appear to control the B-cell response as well.

“Nonresponder” animals display an antigen-specific failure to respond to a protein antigen, both for T cells and antibody responses. The “high responder” phenotype for each antigen is a genetically inheritable, usually dominant trait. Using inbred strains of mice, the genes controlling the immune response were found to be tightly linked to the MHC genes.[127,171] MHC-linked immune responsiveness has been shown to depend on the T-cell recognition of antigen bound within a groove of MHC antigens of the antigen-presenting cell (APC) (discussed herein below and see Chapters 21 and 22). The recognition of antigen in association with MHC molecules of the B cell is necessary for carrier-specific T cells to expand and provide helper signals to B cells.

In contrast to the range of antigens recognized by antibodies, the repertoire recognized by helper and cytotoxic T cells appears to be limited largely to protein and peptide antigens, although exceptions such as the small molecule tyrosine-azobenzene arsonate[172] exist. Once the antigenic determinants on proteins recognized by T cells are identified, it may be possible to better understand immunogenicity and perhaps even to manipulate the antibody response to biologically relevant antigens by altering the helper T-cell response to the antigen.

Defining Antigenic Structures

Polyclonal T-Cell Response

Significant progress in understanding T-cell specificity was made possible by focusing on T-cell proliferation in vitro, mimicking the clonal expansion of antigen specific clones in vivo. The proliferative response depends on only two cells: the antigen-specific T cell and an APC, usually a macrophage, dendritic cell, or B cell. The growth of T cells in culture is measured as the incorporation of [^{3}H]thymidine into newly formed DNA. Under appropriate conditions, thymidine incorporation increases with antigen concentration. This assay permits the substitution of different APCs and is highly useful in defining the MHC and antigen-processing requirements of the APCs.

Using primarily this assay, several different approaches have been taken to mapping T-cell epitopes. First, T cells immunized to one protein have been tested for a proliferative response in vitro to the identical protein or to a series of naturally occurring variants. By comparing the sequences of stimulatory and nonstimulatory variants, it was possible to identify potential epitopes recognized by T cells. For example, the T-cell response to myoglobin was analyzed by immunizing mice with sperm whale or horse myoglobin and testing the resulting T cells for proliferation in response to a series of myoglobins from different species with known amino acid substitutions.[173] Reciprocal patterns were observed in T cells from mice immunized with sperm whale or horse myoglobin. The response to the cross-stimulatory myoglobins was as strong as to the myoglobin used to immunize the mice. This suggested that a few shared amino acid residues formed an immunodominant epitope, and that most substitutions had no effect on the dominant epitope. A comparison of the sequences revealed that substitutions at a single residue could explain the pattern observed. All myoglobins that cross-stimulated sperm whale-immune T cells had Glu at position 109, whereas all that cross-stimulated horse-immune T cells had Asp at 109. No member of one group could stimulate T cells from donors immunized with a myoglobin of the other group. This suggested that an immunodominant epitope recognized by T cells was centered on position 109, regardless of which amino acid was substituted. Usually, this approach has led to correct localization of the antigenic site in the protein,[173,174,175] but the possibility of long-range effects on antigen processing must be kept in mind (see the section on “Antigen Processing”). Also, this approach using natural variants is limited in that it can focus on the correct region of the molecule but cannot define the boundaries of the site. Site-directed mutagenesis may therefore expand the capabilities of this approach.

A second approach is to use short peptide segments of the protein sequence, taking advantage of the fact that T cells specific for soluble protein antigens appear to see only segmental antigenic sites not assembled topographic ones.[127,176,177,178,179,180] These may be produced by chemical or enzymatic cleavage of the natural protein,[178,179,180,181,182,183,184,185,186] solid-phase peptide synthesis,[185,187,188,189,190] or recombinant DNA expression of cloned genes or gene

fragments.[191] In the case of class I MHC molecule-restricted cytotoxic T cells, viral gene deletion mutants expressing only part of the gene product have also been used.[192,193,194]

In the case of myoglobin-specific T cells, mapping of an epitope to residue Glu 109 was confirmed by use of a synthetic peptide 102 to 118, which stimulated the T cells.[189,195] The T cells elicited by a myoglobin with either Glu or Asp 109 could readily distinguish between synthetic peptides containing Glu or Asp at this position. Similar results were obtained with cytochrome c, where the predominant site recognized by T cells was localized with sequence variants to the region

around residue 100 at the carboxyl end of cytochrome.[174] Furthermore, the response to cytochrome c peptide 81 to 104 was as great as the response to the whole molecule. This indicated that a 24 amino acid peptide contained an entire antigenic site recognized by T cells. The T cells could distinguish between synthetic peptides with Lys or Gln at position 99, although both were immunogenic with the same MHC molecule.[196,197,198] This residue determined T-cell memory and specificity, and so presumably was interacting with the T-cell receptor (TCR). A similar conclusion could be drawn for residue 109 of myoglobin. However, this type of analysis must be used with caution. When multiple substitutions at position 109 were examined for T-cell recognition and MHC binding, residue 109 was found to affect both functions.[199] The ultimate use of synthetic peptides to analyze the segmental sites of a protein that are recognized by T cells was to synthesize a complete set of peptides, each staggered by just one amino acid from the previous peptide, corresponding to the entire sequence of hen egg lysozyme.[200] Around each immunodominant site, a cluster of several stimulatory peptides was found. The minimum "core" sequence consisted of just those residues shared by all antigenic peptides within a cluster, whereas the full extent of sequences spanning all stimulatory peptides within the same cluster defined the "determinant envelope." These two ways of defining an antigenic site differ, and one interpretation is that each core sequence corresponds to an MHC-binding site, whereas the determinant envelope includes the many ways for T cells to recognize the same peptide bound to the MHC.

In each case, the polyclonal T-cell response could be mapped to a single predominant antigenic site. These results are consistent with the idea that each protein antigen has a limited number of immunodominant sites (possibly one) recognized by T cells in association with MHC molecules of the high-responder type. If none of the antigenic sites could associate with MHC molecules on the APCs, then the strain would be a low responder, and the antigen would have little or no immunogenicity.

Monoclonal T Cells

Further progress in mapping T-cell sites depended on the analysis of cloned T-cell lines. These were either antigenspecific T-cell lines made by the method of Komoto and Fathman[201] or T-cell hybridomas made by the method of Kappler et al.[202] In the former method, T cells are allowed to proliferate in response to antigen and APCs, rested, and then restimulated again. After stimulation, the blasts can be cloned by limiting dilution and grown from a single cell in the presence of interleukin 2. In the second method, enriched populations of antigen-specific T cells are fused with a drug-sensitive T-cell tumor, and the fused cells are selected for their ability to grow in the presence of the drug. Then the antigen specificity of each fused cell line must be determined. The key to determining this in a tumor line is that antigen-specific stimulation of a T-cell hybridoma results in release of interleukin 2, even though proliferation is constitutive. T cells produced by either method are useful in defining epitopes, measuring their MHC associations and studying antigen-processing requirements.

Monoclonal T cells may be useful in identifying which of the many proteins from a pathogen are important for T-cell responses. For instance, Young and Lamb[203] have developed a way to screen proteins separated by SDS-polyacrylamide gel electrophoresis and blotted onto nitrocellulose for stimulation of T-cell clones and have used this to identify antigens of *Mycobacterium tuberculosis*.[204] Mustafa et al.[205] have even used T-cell clones to screen recombinant DNA expression libraries to identify relevant antigens of *Mycobacterium leprae*. Use of T cells to map epitopes has also been important in defining tumor antigens.[206,207,208,209,210,211]

Precise mapping of antigenic sites recognized by T cells was made possible by the fact that T cells would respond to peptide fragments of the antigen when they contain a complete antigenic determinant. A series of overlapping peptides can be used to walk along the protein sequence and find the antigenic site. Then, by truncating the peptide at either end, the minimum antigenic peptide can be determined. For example, in the case of myoglobin, a critical amino acid residue, such as Glu 109 or Lys 140, was found by comparing the sequences of stimulatory and nonstimulatory myoglobin variants and large CNBr cleavage fragments[212] as previously discussed, and then a series of truncated peptides containing the critical residue was synthesized with different overlapping lengths at either end.[185,189] Because solid-phase peptide synthesis starts from a fixed carboxyl end and proceeds toward the amino end, it can be stopped at various positions to produce a nested series of peptides that vary in length at the amino end. In this way, it was found that two of the Glu 109-specific T-cell clones responded to synthetic peptides 102 to 118 and 106 to 118 but not to peptide 109 to 118.[189] One clone responded to peptide 108 to 118, whereas the other did not. Thus, the amino end of the peptide recognized by one clone was Ser 108, whereas the other clone required Phe 106 and/or Ile 107. Similar fine specificity differences have been observed with T-cell clones specific for the peptides 52 to 61 and 74 to 96 of hen egg lysozyme,[182,213,214] the peptide 323 to 339 of chicken ovalbumin,[183] and the peptide 81 to 104 of pigeon cytochrome c[188]: The epitopes recognized by several T-cell clones overlap but are distinct. In addition, nine T-cell clones recognized a second T-cell determinant in myoglobin located around Lys 140, and each one responded to the CNBr cleavage fragment 132 to 153.[215] Further studies with a nested series of synthetic peptides showed that the stimulatory sequence is contained in peptide 136 to 145.[185]

These findings can be generalized to characterize a large number of epitopes recognized by T cells from a number of protein antigens (Table 23.4).[212,213,214,215,216,217,218,219,220,221,222,223,224,225,226,227] What these studies and others demonstrated about epitopes recognized by T cells is that in each case, the entire site is contained on a short peptide. MHC class I-restricted antigens also follow this rule,[228] even when the protein antigen is normally expressed on the surface of infected cells. This applies to viral glycoproteins, such as influenza hemagglutinin, which are recognized by cytolytic T cells after antigen processing[229] (see section on “Antigen Processing”). These peptides consist of no more than about 12 to 17 amino acid residues for class II MHC or 8 to 10 residues for class I. Within this size, they must contain all the information necessary to survive processing

within the APC, associate with the MHC antigen, and bind to the TCR, as discussed in the following sections.

TABLE 23.4 Examples of Immunodominant T-Cell Epitopes Recognized in Association with Class II MHC Molecules

Protein	T-Cell Antigenic Sites and Reference	Amphipathic Segments
Sperm whale myoglobin	69-78148	64-78
	102-118159	99-117

Sequential Steps that Focus the T-Cell Response on Immunodominant Determinants

In contrast to antibodies that bind all over the surface of a native protein[50] (see "Protein and Polypeptide Antigenic Determinants" section), it has been observed that T cells elicited by immunization with the native protein tend to be focused on one or a few immunodominant sites.[230,231,232] This is true whether one deals with model mammalian or avian proteins such as cytochrome c,[179] myoglobin,[178,180] lysozyme,[182,214,233,234] insulin,[187,219] and ovalbumin,[183] or with bacterial, viral, and parasitic proteins from pathogens, such as influenza hemagglutinin[217] or nucleoprotein (NP),[228] staphylococcal nuclease,[235] or malarial CS protein.[135,236] Because the latter category of proteins shares no obvious homology to mammalian proteins, the immunodominance of a few sites cannot be attributed simply to tolerance for the rest of the protein because of homologous host proteins. Moreover, immunodominance is not simply the preemption of the response by a single clone of predominant T cells because it has been observed that immunodominant sites tend to be the focus for a polyclonal response of a number of distinct T-cell clones recognizing overlapping subsites within the antigenic site or having different sensitivities to substitutions of amino acids within the site.[182,183,188,189,200,213,214,237]

Immunodominant antigenic sites appear to be qualitatively different from other sites. For example, in the case of myoglobin, when the number of clones responding to different epitopes after immunization with native protein was quantitated by limiting dilution, it was observed that the bulk of the response to the whole protein in association with the high-responder class II MHC molecules was focused on a single site within residues 102 to 118[195] (Fig. 23.5). When T cells in the (high × low responder) F1 hybrid restricted to each MHC haplotype were compared, there was little difference in the responses to nondominant epitopes, and all the overall difference in magnitude of response restricted by the high versus low responder MHC could be attributed to the high response to the immunodominant determinant in the former and the complete absence of this response in the latter (see Fig. 23.5). Similar results were found for two different high-responder and two different low-responder MHC haplotypes.[195] Why did the response to the other sites not compensate for the lack of response to the immunodominant site in the low responders?

The greater frequency of T cells specific for the immunodominant site may in part be attributed to the large number of ways this site can be recognized by different T-cell clones, as mentioned previously, but this only pushes the problem back one level. Why is an immunodominant site the focus for so many different T-cell clones? Because the answer

cannot depend on any particular T cell, it must depend on other factors primarily involved in the steps in antigen processing and presentation by MHC molecules.

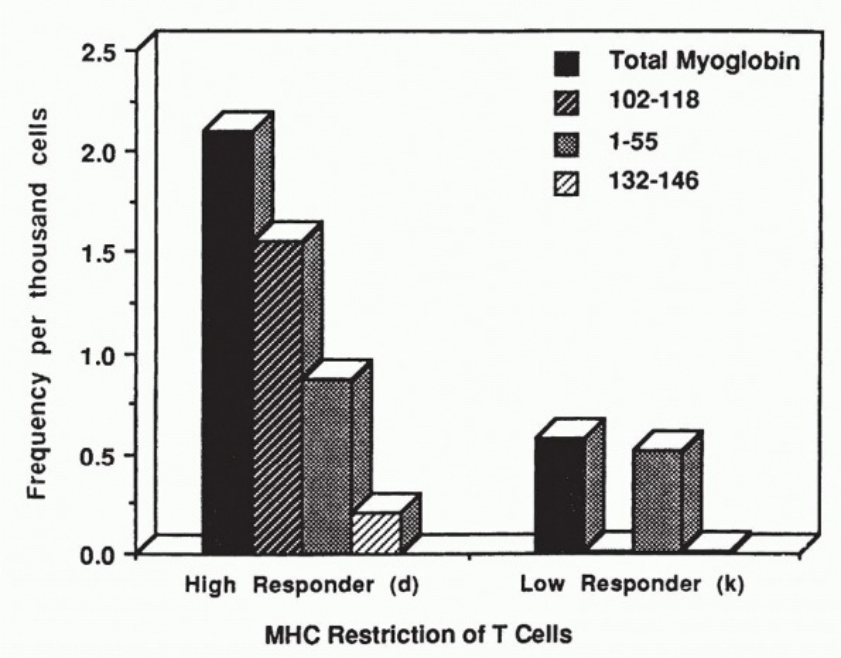

FIG. 23.5. Frequency of High- and Low-Responder Major Histocompatibility Complex (MHC)-Restricted T Cells in F1 Hybrid. High responsiveness may be accounted for by the response to a single immunodominant epitope. Lymph node T cells from (low-responder [H-2^k] × high-responder [H-2^d]) F1 hybrid mice immunized with whole myoglobin were plated at different limiting dilutions in microtiter wells with either high- or low-responder presenting cells and myoglobin as antigen. The cells growing in each well were tested for responsiveness to whole myoglobin and to various peptide epitopes of myoglobin. The frequency of T cells of each specificity and MHC restriction was calculated from Poisson statistics and is plotted on the ordinate. Most of the difference in T-cell frequency between high- and low-responder restriction types *(solid bars)* can be accounted for by the presence of T cells responding to the immunodominant site at residues 102 to 118, accounting for more than twothirds of the high-responder myoglobin-specific T cells, in contrast to the absence of such T cells restricted to the low-responder MHC type. (Based on the data in Kojima et al.[195].)

It has also been observed that some peptides may be immunogenic themselves, but the T-cell response they elicit is specific only for the peptide and does not cross-react with the native protein nor do T cells specific for the native protein recognize this site.[238,239,240] These are called cryptic determinants.[240] The reasons for these differences may involve the way the native protein is processed to produce fragments distinct from, but including or overlapping, the synthetic peptides used in experiments and also the competition among sites within the protein for binding to the same MHC molecules, as discussed further in the next section. To understand these factors that determine dominance or crypticity, one must understand the steps through which an antigen must go before it can stimulate a T-cell response.

Unlike B cells, T-cell recognition of antigen depends on the function of another cell, the

APC.[241] Antigen must pass through a number of intracellular compartments and survive processing and transport steps before it can be effectively presented to T cells. Following antigen synthesis in the cell (as in a virally infected cell) or antigen uptake via phagocytosis, pinocytosis, or, in some cases, receptor-mediated endocytosis, the subsequent steps include 1) partial degradation ("processing") into discrete antigenic fragments that can be recognized by T cells, 2) transport of these fragments into a cellular compartment where MHC binding can occur, 3) MHC binding and assembly of a stable peptide-MHC complex, and 4) recognition of that peptide-MHC complex by the expressed T-cell repertoire. At each step, a potential antigenic determinant runs the risk of being lost from the process, for example, by excessive degradation or failure to meet the binding requirements needed for transport to the next step. Only those peptides that surmount the four selective hurdles will prove to be antigenic for T cells. We will now consider each step in detail, for its contribution to the strength and specificity of the T-cell response to protein antigens.

Antigen Processing

Influence of Antigen Processing on the Expressed T-Cell Repertoire. Several lines of evidence indicate that antigen processing plays a critical role in determining which potential antigenic sites are recognized and, therefore, what part of the potential T-cell repertoire is expressed upon immunization with a protein antigen. Because the T cell does not see the native antigen but only the products of antigen processing, it is not unreasonable that the nature of these products would at least partly determine which potential epitopes could be recognized by T cells.

One line of evidence that processing plays a major role in T-cell repertoire expression came from comparisons that were made of the immunogenicity of peptide versus native molecule in the cases of myoglobin[238] or lysozyme.[239] In the case of myoglobin, a site of equine myoglobin (residues 102 to 118) that did not elicit a response when H-2^k mice were immunized with native myoglobin nevertheless was found to be immunogenic when such mice were immunized with the peptide.[238] Thus, the low responsiveness to this site in mice immunized with the native myoglobin was not due to either of the classical mechanisms of Ir gene defects—namely, a hole in the T-cell repertoire or a failure of the site to interact with MHC molecules of that strain. However, the peptide-immune T cells responded only poorly to native equine myoglobin in vitro. Thus, the peptide and the native molecule did not cross-react well in either direction. The problem was not simply a failure to process the native molecule to produce this epitope because (H-2^k × H-2^s) F1-presenting cells could present this epitope to H-2^s T cells when given native myoglobin but could not present it to H-2^k T cells. Also, because the same results applied to individual T-cell clones, the failure to respond to the native molecule was apparently not due to suppressor cells induced by the native molecule. Similar observations were made for the response to the peptide 74 to 96 of hen lysozyme in B10.A mice.[239] The peptide, not the native molecule, induced T cells specific for this site, and these T cells did not cross-react with the native molecule. With these alternative mechanisms excluded, we are left with the conclusion that an appropriate peptide was produced, but it differed from the synthetic peptide in such a way that a hindering site outside the minimal antigenic site interfered with presentation by presenting cells of certain MHC types. Further evidence consistent with this mechanism came from the work of Shastri et al.,[242] who found that different epitopes within the 74 to 96 region of lysozyme were immunodominant in H-2^b mice when different forms of the immunogen were used.

Another line of evidence came from fine specificity studies of individual T-cell clones. Shastri

et al.[243] observed that H-2^b T-cell clones specific for hen lysozymes were about 100-fold more sensitive to ring-necked pheasant lysozyme than to hen lysozyme. Nevertheless, they were equally sensitive to the CNBr cleavage fragments containing the antigenic sites from both lysozymes. Thus, regions outside the minimal antigenic site removable by CNBr cleavage presumably interfered with processing, presentation, or recognition of the corresponding site in hen lysozyme. Similarly, it was observed that a T-cell clone specific for sperm whale myoglobin, not equine myoglobin, responded equally well to the minimal epitope synthetic peptides from the two species.[238] Also, residues outside the actual site must be distinguishing equine from sperm whale myoglobin. Experiments using F1-presenting cells that can clearly produce this epitope for presentation to other T cells proved that the problem was not a failure to produce the appropriate fragment from hen lysozyme[239] or equine myoglobin.[238] Thus, these cases provide evidence that a structure outside the minimal site can hinder presentation in association with a particular MHC molecule.

Such a hindering structure was elegantly identified in a study by Grewal et al.[244] comparing hen egg lysozyme peptides presented by strains C57BL/6 and C3H.SW that share H-2^b but differ in non-MHC genes. After immunization with whole lysozyme, a strong T-cell response was seen to peptide 46 to 61 in C3H.SW mice but not at all in C57BL/6 mice. Because the F1 hybrids of these two strains responded, the lack of response in one strain was not due to a hole in

the T-cell repertoire produced by self-tolerance. It was found that peptide 46 to 60 bound directly to the I-A^b class II MHC molecule, whereas peptide 46 to 61 did not, indicating that the C-terminal Arg at position 61 hindered binding. Evidently, a non-MHC-linked difference in antigen processing allowed this Arg to be cleaved off the 46 to 61 peptide in C3H.SW mice, in which the peptide was dominant, but not in C57Bl/6 mice, in which the peptide was cryptic.

Even a small peptide that does not need processing may nevertheless be processed, and that processing may affect its interaction with MHC molecules. Fox et al.[245] found that substitution of a tyrosine for isoleucine at position 95 of cytochrome c peptide 93 to 103 enhanced presentation with Eβ^b but diminished presentation with Eβ^k when live APCs were used but not when the APCs were fixed and could not process antigen. Therefore, the tyrosine residue was not directly interacting with the different MHC molecule but was affecting the way the peptide was processed, which in turn affected MHC interaction.
