Dedication

For Charlotte, Gloria, Lucy, Jenna, Silvie, and Jake—and for Julien

Editors: **Paul, William E.**
Title: ***Fundamental Immunology, 7th Edition***

PREFACE

Immunology is the quintessential medical science. Indeed, no branch of the medical sciences has improved the health of people more than the application of immunologic principles to prevention of disease. Smallpox has been eliminated from the planet as a natural infection, as has poliomyelitis from the western hemisphere. Hepatitis B vaccine has prevented more cancers than any intervention other than smoking cessation. The human papilloma virus vaccine promises to cut strikingly the toll of cervical cancer.

The continued need for progress in immunology is clear. The epidemic of human immunodeficiency virus roars on. Glimmers of hope from vaccine trials have led to a redoubling of effort, and the struggle to design effective vaccines for the great infectious scourges goes on, with encouraging results but no breakthroughs yet. Highly effective therapeutic vaccines for cancers still elude us, but some immunologic therapies for cancer have met with encouraging results. We hope for much more as we marshal the tools coming from the study of the innate immune system, regulatory T cells, and lymphocyte differentiation and effector function.

Understanding the basis of inflammation and the cytokine world has given us effective drugs to treat rheumatoid arthritis and a growing number of other autoinflammatory/autoimmune diseases. The value of the interventions based on this knowledge, such as the use of tumor necrosis factor, interleukin-6, and interleukin -1 blockers, is now established. The application of anti-CD20 in the treatment of autoimmune disorders shows great promise. Even more promising strategies are on the horizon.

Fundamental Immunology has the goal of aiding in the education of a new generation of immunologists who can both probe more deeply into the organizing principles of the immune system and can translate this new information into effective treatments and preventatives that will extend and enlarge on the record of immunologic science in bettering the lot of human kind.

Were I beginning the task of preparing a comprehensive text of immunology today, I might have titled it *Immunology, Endless Fascination.* Certainly that describes my own view of this science over the 30 years that I have been working on the seven editions of *Fundamental Immunology.* I had believed that scientific progress was marked by periods of intense creativity, during which new concepts were established, followed by longer periods of consolidation, when work that made important but anticipated advances would dominate. Perhaps that will prove to be true of modern immunology as well when it is looked at by a disinterested observer, but for one in the midst, the pace of discovery seems to speed up with each passing year. *Endless fascination* certainly describes my experience of immunology.

I hope that this seventh edition will convey the dynamism and creativity of modern immunology and provide the reader with a solid introduction to our field and a picture of much

of the very latest that has been achieved. As with each of the previous editions, most of the chapters are entirely new and not simple reworkings of the chapter in the previous edition. In order to contain the seventh edition within one volume, a decision was made to cite references in the printed text but only to provide the detailed citations in the online version. However, the references will be linked to PubMed so cited information can be easily obtained. The electronic version can be accessed at www.fundamentalimmunology.com.

As before, this edition begins with an introductory section consisting of the chapters "The Immune System" and "History of Immunology." These give an overview of modern immunology and of its origins, and provide those new to the field with the basis to go on to the subsequent chapters. This is followed by an "expanded introduction" provided by the sections "Organization and Evolution of the Immune System," "Immunoglobulins and B-Lymphocytes," and "T-Lymphocytes." These are followed by the two core "basic" immunology sections: "The Intersection of Innate and Adaptive Immunity" and "Induction, Regulation, and Effector Functions of the Immune Response." The book concludes with sections devoted to the immune system's role in protection against pathogenic microorganisms, "Immunity to Infectious Agents," and to how the immune system is involved in a variety of human disorders, "Immunologic Mechanisms in Disease."

I repeat a word of caution that has been in the Preface to each edition. Immunology is moving very fast. Each of the chapters is written by an expert in the field, but in some areas there may be differences of opinion expressed by equally accomplished authors. I ask the reader to take note of the differences and to follow developments in the field.

William E. Paul

ACKNOWLEDGMENTS

The preparation of the seventh edition required the efforts of many individuals. I particularly wish to thank each of the authors. Their contributions, prepared in the midst of extremely busy schedules, are responsible for the value of this book. Leanne Vandetty of Lippincott Williams & Wilkins saw that the process of receiving, editing, and assembling the chapters went as smoothly as possible. Without her efforts, the completion of this edition would have been immeasurably more difficult. Frances DeStefano's counsel was of utmost importance in planning this edition and when she had to leave the project, Julie Goolsby took over and played a key role in making important publication decisions. I wish to gratefully acknowledge the efforts of each of the members of the editorial and production staffs of Lippincott Williams & Wilkins who participated in the preparation of this edition.

Front Matter

Nothing is as powerful as an idea whose time has come.

Paraphrased from Victor Hugo

Everything should be made as simple as possible, but not simpler.

ALBERT EINSTEIN

From my teachers I have learned much, from my colleagues still more, but from my students most of all.

The Talmud

Discovery consists of seeing what everybody has seen and thinking what nobody has thought.

ALBERT SZENT-GYORGYI

… the clonal selection hypothesis … assumes that … there exist clones of mesenchymal cells, each carrying immunologically reactive sites … complementary … to one (or possibly a small number) of potential antigenic determinants.

FRANK MACFARLANE BURNET

In the fields of observation, chance favors the prepared mind.

LOUIS PASTEUR

In all things of nature there is something of the marvelous.

ARISTOTLE

Chapter 1

The Immune System

William E. Paul

The immune system is a remarkable defense mechanism. It makes rapid, specific, and protective responses against the myriad potentially pathogenic microorganisms that inhabit the world in which we live. The tragic examples of acquired immunodeficiency syndrome (AIDS) and the inherited severe combined immunodeficiencies graphically illustrate the consequences of a nonfunctional adaptive immune system. Patients with AIDS and children with severe combined immunodeficiency often fall victim to infections that are of little or no consequence to those with normally functioning immune systems. The immune system also has a role in the rejection of tumors and, when dysregulated, may give rise to a series of autoimmune diseases, including insulin-dependent diabetes mellitus, multiple sclerosis, rheumatoid arthritis, systemic lupus erythematosus, inflammatory bowel disease, among others.

Fundamental Immunology has as its goal the authoritative presentation of the basic elements of the immune system, of the means through which the mechanisms of immunity act in a wide range of clinical conditions, including recovery from infectious diseases, rejection of tumors, transplantation of tissue and organs, autoimmunity and other immunopathologic conditions, and allergy, and how the mechanisms of immunity can be marshaled by vaccination to provide protection against microbial pathogens.

The purpose of the opening chapter is to provide readers with a general introduction to our current understanding of the immune system. It should be of particular importance for those with a limited background in immunology, providing them with the preparation needed for subsequent chapters of the book. Rather than providing extensive references in this chapter, each of the subject headings will indicate the chapters that deal in detail with the topic under discussion. Those chapters will not only provide an extended treatment of the topic but will also furnish the reader with a comprehensive reference list that can be found in the online version of *Fundamental Immunology*.

KEY CHARACTERISTICS OF THE IMMUNE SYSTEM

Innate Immunity (Chapters 15, 17, 19, and 20)

Powerful nonspecific defenses prevent or limit infections by most potentially pathogenic microorganisms. The epithelium provides both a physical barrier to the entry of microbes and produces a variety of antimicrobial factors. Agents that penetrate the epithelium are met with macrophages and related cells possessing “microbial sensors” that recognize key molecules characteristic of many microbial agents. These “pattern recognition receptors” include

several families of molecules, of which the most intensively studied are the toll-like receptors (TLRs) and the nucleotide oligomerization domain-like receptors. Each TLR recognizes a distinct substance (or set of substances) associated with microbial agents; for example, TLR4 recognizes lipopolysaccharides, TLR3, doublestranded ribonucleic acid, and TLR9, unmethylated CpG-containing DNA. Because the recognized substances are generally indispensable to the infectious agent, microbial sensors provide a highly efficient means to recognize potential pathogens.

The interaction of a TLR with its ligand induces a series of intracellular signaling events, of which activation of the NF-κB system is particularly important. Macrophage activation with enhancement of the cell's phagocytic activity and the induction of antimicrobial systems aid in the destruction of the pathogen. The induction of an inflammatory response as a result of the activation of the innate immune system recruits other cell types, including neutrophils, to the site. The innate system can provide an effective means to control or eliminate pathogens. Indeed, life forms other than vertebrates rely on the innate immune system to allow them to deal with microbial infection.

In vertebrates, the innate immune system also acts to recruit antigen-specific immune responses, not only by attracting cells of the immune system to the site of infection, but also through the uptake of antigen by dendritic cells (DCs) and its transport by these cells to lymphoid tissues where primary immune responses are initiated. Activated DCs express cell surface costimulatory molecules and produce cytokines that can regulate the quality of the immune response so that it is most appropriate to combating the particular infectious agent, be it a virus, bacterium, or parasite.

Primary Responses (Chapters 10 and 14)

Primary immune responses are initiated when a foreign antigenic substance interacts with antigen-specific lymphocytes under appropriate circumstances. The response generally consists of the production of antibody molecules specific for the antigenic determinants of the immunogen and of the expansion and differentiation of antigen-specific helper and effector T-lymphocytes. The latter include cytokine-producing cells and killer T cells, capable of lysing infected cells. Generally, the combination of the innate immune response and the primary adaptive response are sufficient to eradicate or to control the microbe. Indeed, the most effective function of the immune system is to mount a response that eliminates the infectious agent from the body, so-called sterilizing immunity.

Secondary Responses and Immunologic Memory (Chapters 10, 14, 29, and 31)

As a consequence of initial encounter with antigen, the immunized individual develops a state of immunologic memory. If the same (or a closely related) microorganism is encountered again, a secondary response is made. This generally consists of an antibody response that is more rapid, greater in magnitude, and composed of antibodies that bind to the antigen with greater affinity and are more effective in clearing the microbe from the body. A more rapid and more effective T-cell response also ensues. Thus, an initial infection with a microorganism often initiates a state of immunity in which the individual is protected against a second infection. In the majority of situations, protection is provided by high-affinity antibody

molecules that rapidly clear the re-introduced microbe. This is the basis of most licensed vaccines; the great power of vaccines is illustrated by the elimination of smallpox from the world and by the complete control of polio in the western hemisphere.

The Immune Response is Highly Specific and the Antigenic Universe is Vast

The immune response is highly specific. Primary immunization with a given microorganism evokes antibodies and T cells that are specific for the antigenic determinants found on that microorganism but that generally fail to recognize (or recognize only poorly) antigenic determinants expressed by unrelated microbes. Indeed, the range of antigenic specificities that can be discriminated by the immune system is enormous.

The Immune System is Tolerant of Self-Antigens (Chapters 32 and 33)

One of the most important features of the immune system is its ability to discriminate between antigenic determinants expressed on foreign substances, such as pathogenic microbes, and potential antigenic determinants expressed by the tissues of the host. The failure of the system to make full-blown immune responses to self-antigens is referred to as *immunologic tolerance*. Tolerance is a complex process that actually involves several distinct processes. One element, perhaps the most important, is an active process involving the elimination or inactivation of cells that can recognize self-antigens. In addition, there are mechanisms through which cells that encounter antigens (such as selfantigens) in the absence of cues from the innate immune system may fail to make a response, may make a minimal response, or may be inactivated through a process referred to as *anergy*. Finally, a specialized set of T cells exist designated regulatory cells that actively *suppress* responses against self-antigens. Indeed, individuals who have mutations in the key transcription factor *Foxp3* expressed by the regulatory cells develop severe multiorgan autoimmunity (Immunodysregulation polyendocrinopathy, enteropathy X-linked syndrome). The critical necessity to control selfreactivity is clearly shown by this multilayered system that involves elimination, inactivation, and suppression.

Immune Responses Against Self-Antigens can Result in Autoimmune Diseases (Chapter 44)

Failure in establishing immunologic tolerance or unusual presentations of self-antigens can give rise to tissuedamaging immune responses directed against antigenic determinants on host molecules. These can result in autoimmune diseases. As has already been mentioned, a group of extremely important diseases are caused by autoimmune responses or have major autoimmune components, including systemic lupus erythematosus, rheumatoid arthritis, insulin-dependent diabetes mellitus, multiple sclerosis, myasthenia gravis, and inflammatory bowel disease. Efforts to treat these diseases by modulating the autoimmune response are a major theme of contemporary medicine.

Acquired Immunodeficiency Syndrome is an Example of a Disease Caused by a Virus That the Immune System Generally Fails to Eliminate (Chapter 42)

Immune responses against infectious agents do not always lead to elimination of the pathogen. In some instances, a chronic infection ensues in which the immune system adopts a variety of strategies to limit damage caused by the organism or by the immune response. Indeed, herpes viruses, such as human cytomegalovirus, frequently are not eliminated by

immune responses and establish a chronic infection in which the virus is controlled by immune responses. One of the most notable infectious diseases in which the immune response generally fails to eliminate the organism is AIDS, caused by the human immunodeficiency virus (HIV). In this instance, the principal infected cells are those of the immune system

itself, leading to an eventual state in which the individual can no longer mount protective immune responses against other microbial pathogens. Indeed, under the assault of HIV, control of viruses such as cytomegalovirus is lost and they may cause major tissue damage.

Major Principles of Immunity

The major principles of the immune response are:

- Elimination of many microbial agents through the nonspecific protective mechanisms of the innate immune system
- Cues from the innate immune system inform the cells of the adaptive immune system as to whether it is appropriate to make a response and what type of response to make
- Cells of the adaptive immune system display exquisitely specific recognition of foreign antigens and mobilize potent mechanisms for elimination of microbes bearing such antigens
- The immune system displays memory of its previous responses
- Tolerance of self-antigens.

The remainder of this introductory chapter will describe briefly the molecular and cellular basis of the system and how these central characteristics of the immune response may be explained.

CELLS OF THE IMMUNE SYSTEM AND THEIR SPECIFIC RECEPTORS AND PRODUCTS

The immune system consists of several distinct cell types, each with important roles. The lymphocytes occupy central stage because they are the cells that determine the specificity of immunity. It is their response that orchestrates the effector limbs of the immune system. Cells that interact with lymphocytes play critical parts both in the presentation of antigen and in the mediation of immunologic functions. These cells include DCs and the closely related Langerhans cells, monocyte/macrophages, natural killer (NK) cells, neutrophils, mast cells, basophils, and eosinophils. In addition, a series of specialized epithelial and stromal cells provide the anatomic environment in which immunity occurs, often by secreting critical factors that regulate migration, growth and homeostasis, and gene activation in cells of the immune system. Such cells also play direct roles in the induction and effector phases of the response.

The cells of the immune system are found in peripheral organized tissues, such as the spleen, lymph nodes, Peyer's patches of the intestine, and tonsils, where primary immune responses generally occur (see Chapter 3). Many of the lymphocytes comprise a recirculating pool of cells found in the blood and lymph, as well as in the lymph nodes and spleen, providing the means to deliver immunocompetent cells to sites where they are needed and to allow immunity that is initiated locally to become generalized. Activated lymphocytes acquire the capacity to enter nonlymphoid tissues where they can express

effector functions and eradicate local infections. Some memory lymphocytes are “on patrol” in the tissues, scanning for reintroduction of their specific antigens. Lymphocytes are also found in the central lymphoid organs, the thymus, and bone marrow, where they undergo the developmental steps that equip them to mediate the responses of the mature immune system.

Individual lymphocytes are specialized in that they are committed to respond to a limited set of structurally related antigens. This commitment exists before the first contact of the immune system with a given antigen. It is expressed by the presence on the lymphocyte's surface of receptors specific for determinants (epitopes) of the antigen. Each lymphocyte possesses a population of receptors, all of which have identical combining sites (this is a slight oversimplification as occasionally T cells and less frequently B cells may express two populations of receptors). One set, or clone, of lymphocytes differs from another clone in the structure of the combining region of its receptors and thus in the epitopes that it can recognize. The ability of an organism to respond to virtually any non-self-antigen is achieved by the existence of a very large number of different lymphocytes, each bearing receptors specific for a distinct epitope. As a consequence, lymphocytes are an enormously heterogeneous group of cells. Based on reasonable assumptions as to the range of diversity that can be created in the genes encoding antigen-specific receptors, it is virtually certain that the number of distinct combining sites on lymphocyte receptors of an adult human can be measured in the millions.

Lymphocytes differ from each other not only in the specificity of their receptors but also in their functions. There are two broad classes of lymphocytes: the B-lymphocytes, which are precursors of antibody-secreting cells, and the T (thymus-derived)- lymphocytes. T-lymphocytes express important helper functions, such as the ability to aid in the development of specific types of immune responses, including the production of antibody by B cells, the increase in the microbicidal activity of macrophages, and the recruitment of granulocytes to sites of infection. Other T-lymphocytes are involved in direct effector functions, such as the lysis of virus-infected cells or certain neoplastic cells. Regulatory T-lymphocytes have the capacity to suppress immune responses.

B-LYMPHOCYTES AND ANTIBODY

B-Lymphocyte Development (Chapter 8)

B-lymphocytes derive from lymphoid progenitor cells, which in turn are derived from hematopoietic stem cells (Fig. 1.1). A detailed picture has been obtained of the molecular mechanisms through which committed early members of the B lineage develop into mature B-lymphocytes. These events occur in the fetal liver and, in adult life, in the bone marrow. Interaction with specialized stromal cells and their products, including cytokines such as interleukin (IL)-7 and BAFF, are critical to the normal regulation of this process.

The key events in B-cell development involve commitment to the B lineage and repression of the capacity to differentiate to cells of other lineages. In pro-B cells and pre-B cells, the genetic elements that encode the antigen-specific receptors are assembled. These receptors are im

munoglobulin (Ig) molecules specialized for expression on the cell surface. Igs are heterodimeric molecules consisting of heavy (H) and light (L) chains, both of which have

variable (V) regions, which are responsible for the binding of antigen and that differ in sequence from one Ig molecule to another (see Chapters 5, 6, and 7) (Fig. 1.2) and constant (C) regions.

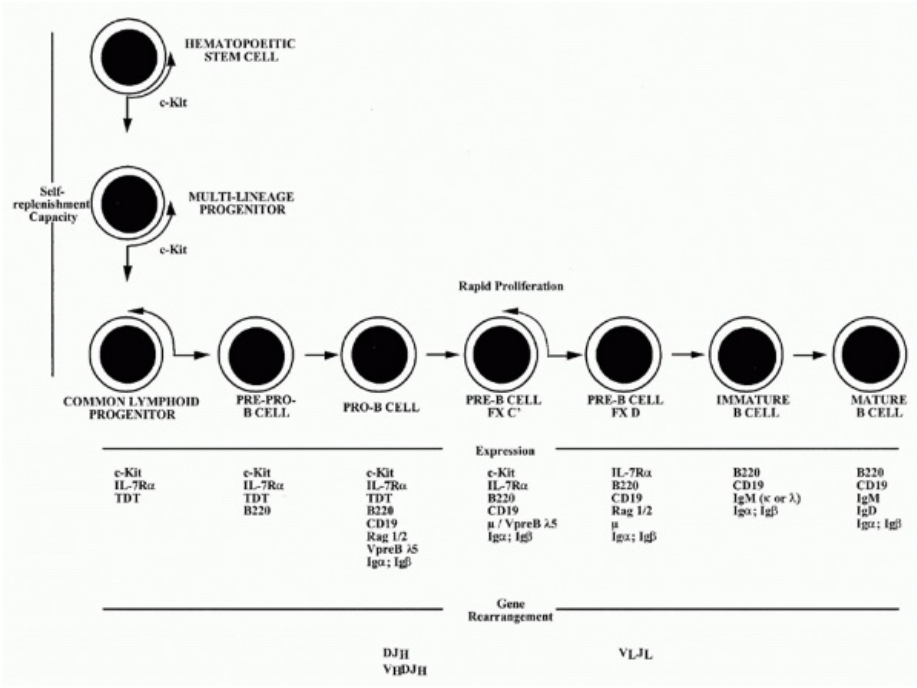

FIG. 1.1. The patterns of gene expression, timing of gene rearrangement events, and capacity for self-replenishment and for rapid proliferation of developing B lymphocytes are indicated. (Adapted from Hardy RR, Hayakawa K. B cell development pathways. *Ann Rev Immunol*. 2001;19:595-621.)

The genetic elements encoding the variable portions of Ig H and L chains are not contiguous in germline DNA or in the DNA of nonlymphoid cells (see Chapter 6) (Fig. 1.3). In pro- and pre-B cells, these genetic elements are translocated to construct an expressible V-region gene. This process involves a choice among a large set of potentially usable V, diversity (D), and joining (J) elements in a combinatorial manner and depends upon the recombinating activating gene (RAG) proteins, RAG1 and RAG2. Such combinatorial translocation, together with the addition of diversity in the course of the joining process, results in the generation of a very large number of distinct H and L chains. The pairing of H and L chains in a quasirandom manner further expands the number of distinct Ig molecules that can be formed.

The H-chain V region is initially expressed in association with the product of the μC-region gene. Together, these elements encode the μ IgH chain, which is used in Igs of the IgM class.

The successful completion of the process of Ig gene rearrangement and the expression of the resultant IgM on the cell surface marks the transition between the pre-B- and B-cell states (see Fig. 1.1). The newly differentiated B cell initially expresses surface Ig solely of the IgM class. The cell completes its maturation process by expressing on its surface a second class of Ig composed of the same L chain and the same H chain V (VDJ) region but of a different H chain C region; this second Ig H chain is designated δ, and the Ig to which it contributes is designated IgD, so that the mature naïve B cells express both IgM and IgD surface molecules

that share the same V region.

The differentiation process is controlled at several steps by a system of checks that determines whether prior steps have been successfully completed. These checks depend on the expression on the surface of the cell of appropriately constructed Ig or Ig-like molecules. For, example,

in the period after a μ chain has been successfully assembled but before an L chain has been assembled, the μ chain is expressed on the cell surface in association with a surrogate L chain, consisting of VpreB and λ5. Pre-B cells that fail to express this μ/VpreB λ5 complex do not move forward to future differentiation states or do so very inefficiently.

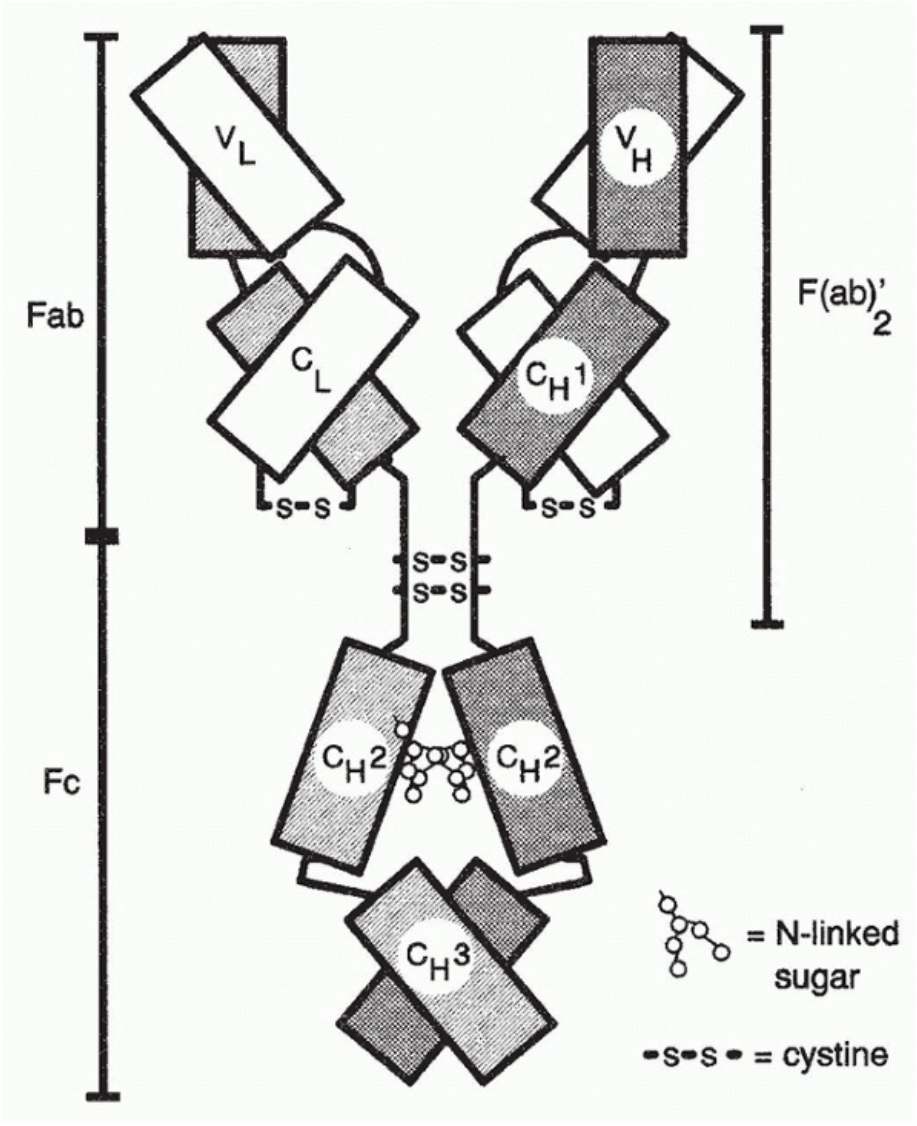

FIG. 1.2. A schematic representation of an immunoglobulin molecule indicating the means through the variable regions and the CH1 and CL regions of heavy and light chains pair with one another and how the CH2 and CH3 regions of the heavy chains pair.

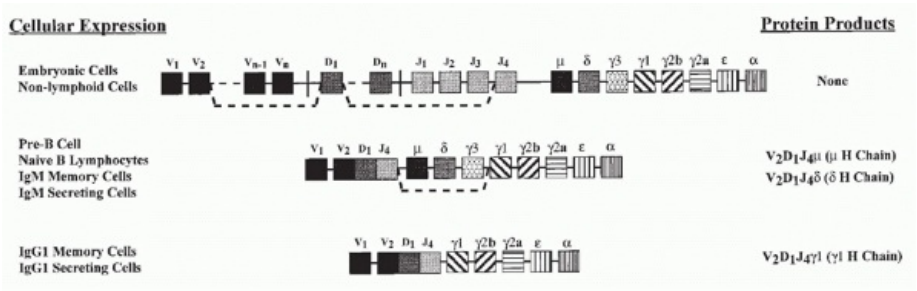

FIG. 1.3. Organization and translocation of mouse immunoglobulin (Ig)H genes. IgH chains are encoded by four distinct genetic elements: Igh-V (V), Igh-D (D), Igh-J (J) and Igh-C. The variable (V), diversity (D), and joining (J) genetic elements together specify the variable region of the heavy chain. The Igh-C element specifies the constant (C) region. The same V region can be expressed in association with each of the C regions (μ, δ, γ3,γ1,γ2b,γ2a, ε, and α). In the germline, the V, D, and J genes are far apart and there are multiple forms of each of these genes. In the course of lymphocyte development, a VDJ gene complex is formed by translocation of individual V and D genes so that they lie next to one of the J genes, with excision of the intervening genes. This VDJ complex is initially expressed with μ and δ C genes but may be subsequently translocated so that it lies near one of the other C genes (e.g., γ1) and in that case leads to the expression of a VDJ γ1 chain.

B-Lymphocyte Activation (Chapter 9)

A mature B cell can be activated by an encounter with antigen-expressing epitopes that are recognized by its cell surface Ig (Fig. 1.4). The activation process may be a direct one, dependent on cross-linkage of membrane Ig molecules by the antigen (*cross-linkage-dependent B-cell activation*), or an indirect one, occurring most efficiently in the context of an intimate interaction with a helper T cell, in a process often referred to as *cognate help*.

Because each B cell bears membrane Ig molecules with identical variable regions, cross-linkage of the cell surface receptors requires that the antigen express more than one copy of an epitope complementary to the binding site of the receptor. This requirement is fulfilled by antigens with repetitive epitopes. Among these antigens are the capsular polysaccharides of many medically important microorganisms such as pneumococci, streptococci, and meningococci. Similar expression of multiple identical epitopes on a single immunogenic particle is a property of many viruses because they express multiple copies of envelope proteins on their surface. Cross-linkage-dependent B-cell activation is a major protective immune response mounted against these microbes. The binding of complement components (see Chapter 36) to antigen or antigen/antibody complexes can increase the magnitude of the cross-linkage-dependent B-cell activation due to the action of a receptor for complement, which, together with other molecules, increases the magnitude of a B-cell response to limiting amounts of antigen.

Cognate help allows B cells to mount responses against antigens that cannot cross-link receptors and, at the same time, provides costimulatory signals that rescue B cells from

inactivation when they are stimulated by weak cross-linkage events. Cognate help is dependent on the binding of antigen by the B cell's membrane Ig, the endocytosis of the antigen, and its fragmentation into peptides within the endosomal/lysosomal compartment of the cell. Some of the resultant peptides are loaded into a groove in a specialized set of cell surface proteins, the class II major histocompatibility complex (MHC) molecules (Fig. 1.5). The resultant class II/

P.6

P.7

peptide complexes are expressed on the cell surface. As will be discussed subsequently, these complexes are the ligands for the antigen-specific receptors of a set of T cells designated CD4 T cells. CD4 T cells that have receptors specific for the class II/peptide complex expressed on the B-cell surface recognize and interact with that B cell. That interaction results in the activation of the B cell through the agency of cell surface molecules expressed by the T cells (e.g., the CD40 ligand [CD154]) and cytokines produced by the T cell (see Fig. 1.4). The role of the B-cell receptor for antigen is to create the T-cell ligand on the surface of antigen-specific B cells; activation of the B cell derives largely from the action of the T cell. However, in many physiologic situations, receptor cross-linkage stimuli and cognate help synergize to yield more vigorous B-cell responses. Recently, it has been shown that the association of ligands for TLRs with antigen will strikingly enhance B cell responses.

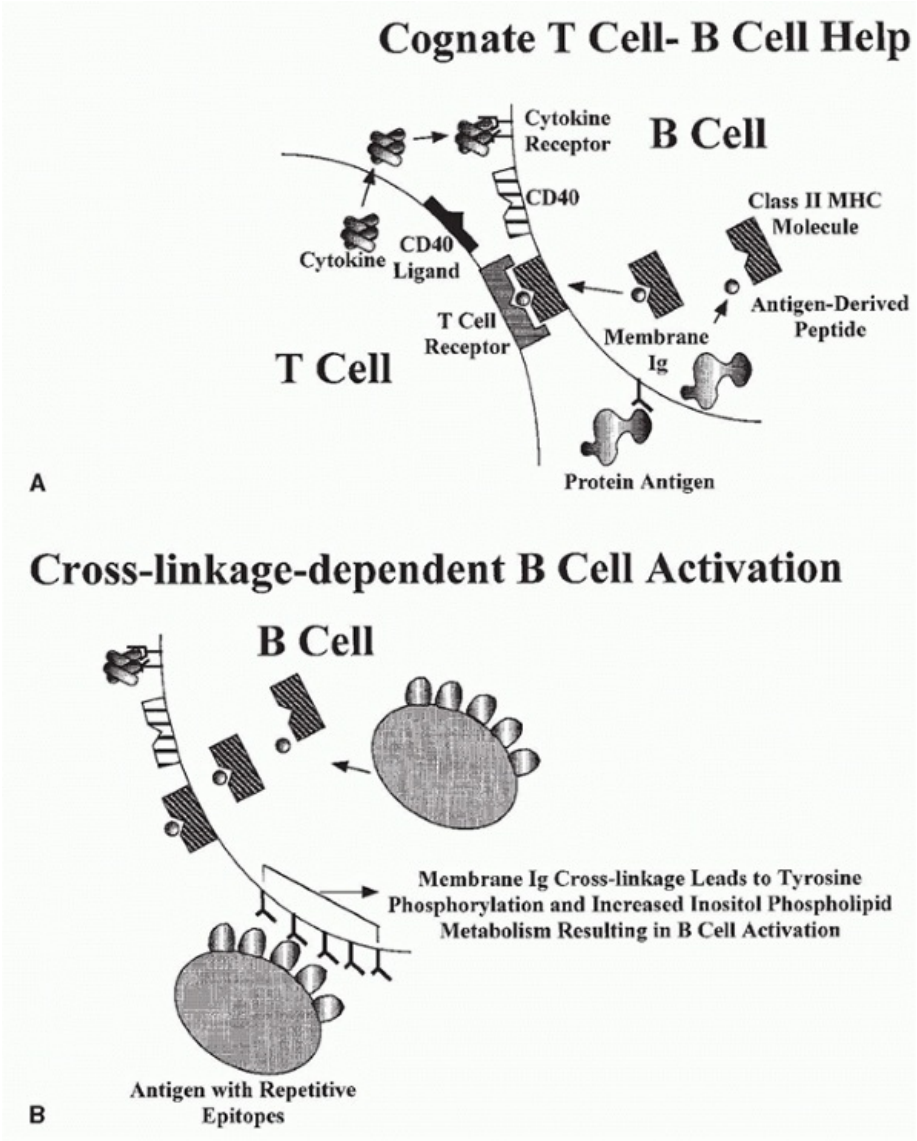

FIG. 1.4. Two Forms of B-Cell Activation. A: Cognate T cell/B cell help. Resting B cells can bind antigens that bear epitopes complementary to their cell surface Ig. Even if the antigen cannot cross-link the receptor, it will be endocytosed and enter late endosomes and lysosomes where it will be degraded to peptides. Some of these peptides will be loaded into class II major histocompatibility complex molecules and brought to the cell surface, where they can be recognized by CD4-positive T cells that bear receptors specific for that peptide/class II complex. This interaction allows an activation ligand on the T cells (CD40 ligand) to bind to its receptor on B cells (CD40) and to signal B-cell activation. In addition, the T cells secrete several cytokines that regulate the growth and differentiation of the stimulated B cell. **B:** Cross-linkage-dependent B cell activation. When B cells encounter antigens that bear multiple copies of an epitope that can bind to their surface immunoglobulin, the resultant crosslinkage stimulates biochemical signals within the cell leading to B-cell activation, growth, and differentiation. In many instances, B-cell activation events may result from both pathways of stimulation.

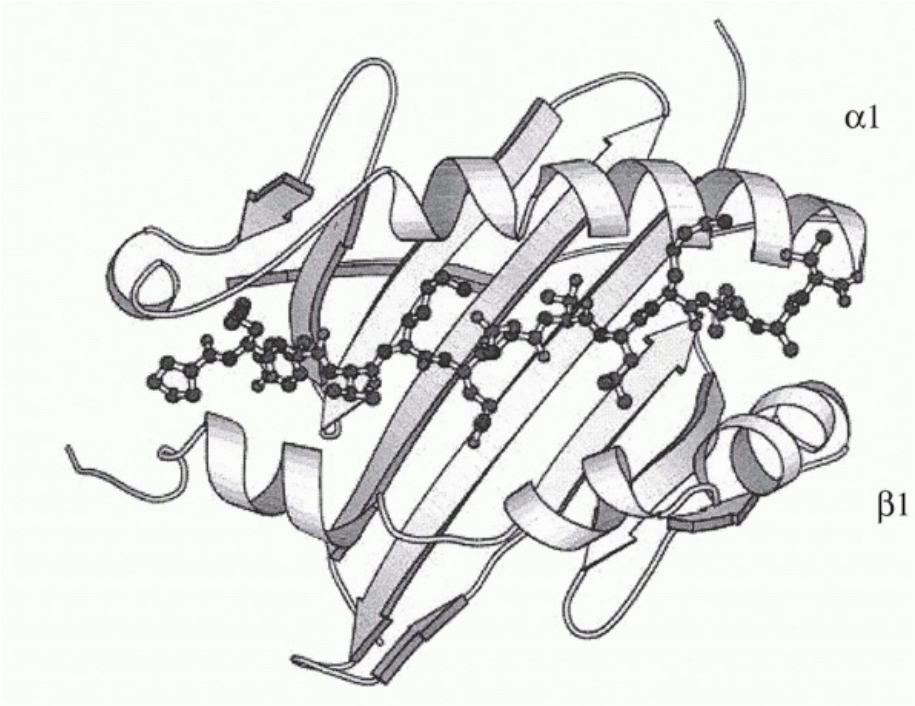

FIG. 1.5. Illustration of the structure of the peptide binding domain (α1 and β1) of a class II major histocompatibility complex molecule bound to an antigenic peptide from influenza hemagglutinin (adapted by D.H. Margulies from Stern LJ, Brown JH, Jardetzky TS, et al. Crystal structure of the human class II MHC protein HLA-DR1 complexed with an influenza virus peptide. *Nature*. 1994;68[6468]:215-221.)

B-Lymphocyte Differentiation (Chapters 9 and 10)

Activation of B cells prepares them to divide and to differentiate either into antibody-secreting cells or into memory cells, so that there are more cells specific for the antigen used for immunization. Those cells that differentiate into antibody-secreting cells account for primary antibody responses. Some of these antibody-secreting cells migrate to the bone marrow where they may continue to produce antibody for an extended period of time and may have lifetimes very long.

Memory B cells give rise to antibody-secreting cells upon rechallenge of the individual. The hallmark of the antibody response to rechallenge (a secondary response) is that it is of greater magnitude, occurs more promptly, is composed of antibodies with higher affinity for the antigen, and is dominated by Igs expressing γ, α, or ε C regions (IgG, IgA, or IgE) rather than by IgM, which is the dominant Ig of the primary response.

Division and differentiation of cells into antibody-secreting cells is largely controlled by the interaction of the activated B cells with T cells expressing CD154 and by their stimulation by T-cell-derived cytokines.

The differentiation of activated B cells into memory cells occurs in a specialized microenvironmental structure in the spleen and lymph nodes: the germinal center. The increase in antibody affinity also takes place within the germinal center. This process, designated *affinity maturation*, is dependent on somatic hypermutation. The survival of B

cells within the germinal center depends on their capacity to bind antigen so that as the amount of antigen diminishes, B cells that have higher affinity receptors, either naturally or as a result of the hypermutation process, have a selective survival and growth advantage. Thus, such cells come to dominate the population.

The process through which a single H-chain V region can become expressed with genes encoding C regions other than μ or δ is referred to as Ig class switching. It is dependent on a gene translocation event through which the C-region genes between the genetic elements encoding the V region and the newly expressed C gene are excised, resulting in the switched C gene being located in the position that the Cμ gene formerly occupied (see Fig. 1.3). This process also occurs mainly in germinal centers. Both somatic hypermutation and immunoglobulin class switching depend upon the action of activation-induced cytidine deaminase (AID) that plays an important role in the breakage and repair of DNA, which is essential for recombination events.

B1 and Marginal Zone B-Lymphocytes (Chapters 8 and 10)

B lymphocytes consist of at least three distinct populations: conventional B cells, B1 B cells, and marginal zone B cells. B1 B cells were initially recognized because some express a cell-surface protein, CD5, not generally found on other B cells. In the adult mouse, B1 B cells are found in relatively high frequency in the peritoneal cavity but are present at low frequency in the spleen and lymph nodes. B1 B cells are quite numerous in fetal and perinatal life and appear to be self-renewing, in contrast to conventional B cells, in which division and memory are antigen driven.

Marginal zone B cells are localized in a distinct anatomical region of the spleen (the marginal zone) that represents the major antigen filtering and scavenging area. Like B1 B cells, marginal zone B cells express a repertoire biased toward bacterial cell wall constituents and senescent self-components. Marginal zone and B1 B cells respond very rapidly to antigenic challenge, likely independently of T cells. Uniquely, among all populations of B cells, marginal zone B cells are dependent on Notch-2 signaling for their development.

B1 B cells and marginal zone B cells are responsible for the secretion of the serum IgM that exists in nonimmunized mice, often referred to as natural IgM. Among the antibodies found in such natural IgM are molecules that can combine with phosphatidylcholine (a component of pneumococcal cell walls) and with lipopolysaccharide and influenza virus. B1 B cells also produce autoantibodies, although they are generally of low affinity and in most cases not pathogenic. There is evidence that B1 B cells are important in resistance to several pathogens and may have a significant role in mucosal immunity.

B-Lymphocyte Tolerance (Chapter 32)

One of the central problems facing the immune system is that of being able to mount highly effective immune responses to the antigens of foreign, potentially pathogenic agents while ignoring antigens associated with the host's own tissues. The mechanisms ensuring this failure to respond to self-antigens are complex and involve a series of strategies. Chief among them is elimination of cells capable of self-reactivity or the inactivation of such cells. The encounter of immature, naïve B cells with antigens with repetitive epitopes capable of cross-linking membrane Ig can lead to elimination of the B cells, particularly if no T-cell help is provided at the time of the encounter. This elimination of potentially self-reactive cells is

often referred to as clonal elimination. Many selfreactive cells, rather than dying upon encounter with selfantigens, undergo a further round of Ig gene rearrangement. This *receptor editing* process allows a self-reactive cell to substitute a new receptor and therefore to avoid elimination.

There are many self-antigens that are not encountered by the developing B-cell population or that do not have the capacity to cross-link B-cell receptors to a sufficient degree to elicit the receptor editing /clonal elimination process. Such cells, even when mature, may nonetheless be inactivated through a process that involves cross-linkage of receptors without the receipt of critical costimulatory signals. These inactivated cells may be retained in the body but are unresponsive to antigen and are referred to as anergic. When removed from the presence of the anergy-inducing stimulus, anergic cells may regain responsiveness.

Immunoglobulins

Structure (Chapter 5)

Igs are the antigen-specific membrane receptors and secreted products of B cells. They are members of a large family of proteins designated the Ig supergene family. Members of the Ig supergene family have sequence homology, a common gene organization, and similarities in three-dimensional structure. The latter is characterized by a structural element referred to as the Ig fold, generally consisting of a set of seven β-pleated sheets organized into two opposing layers (Fig. 1.6). Many of the cell surface proteins that participate in immunologic recognition processes, including the T-cell receptor (TCR), the CD3 complex, and signaling molecules associated with the B-cell receptor (Igα and Igβ), are members of the Ig supergene family.

The Igs themselves are constructed of a unit that consists of two H chains and two L chains (see Fig. 1.2). The H and L chains are composed of a series of domains, each consisting of approximately 110 amino acids.

The L chains, of which there are two types (κ and λ), consist of two domains. The carboxy-terminal domain is essentially identical among L chains of a given type and is referred to as the C region. As already discussed, the amino terminal domain varies from L chain to L chain and contributes to the binding site of antibody. Because of its variability, it is referred to as the V region. The variability of this region is largely concentrated in three segments, designated the hypervariable or complementarity-determining regions (CDRs). The CDRs contain the amino acids that are the L chain's contribution to the lining of the antibody's combining site. The three CDRs are interspersed among four regions of much lower degree of variability, designated framework regions.

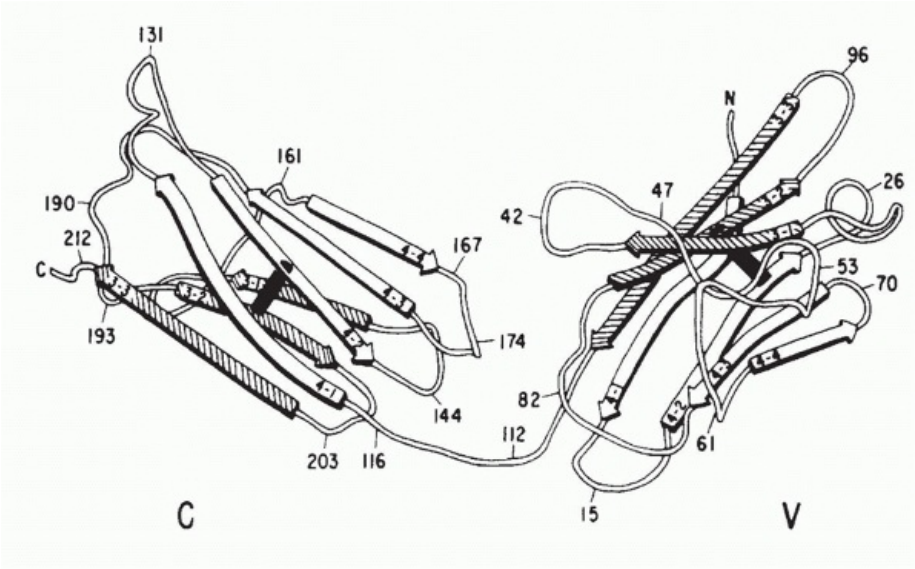

FIG. 1.6. Schematic Drawing of the Variable and Constant Domains of an Immunoglobulin Light Chain Illustrating the "Immunoglobulin Fold." The β strands participating in the antiparallel β-pleated sheets of each domain are represented as *arrows*. The β strands of the three-stranded sheets are *shaded*, whereas those in the four-stranded sheets are *white*. The intradomain disulfide bonds are represented as *black bars*. Selected amino acids are numbered with position 1 as the N terminus. (Reprinted with permission from Edmundson AB, Ely KR, Abola EE, Schiffer M, Panagiotopoulous N. Rotational allomerism and divergent evolution of domains in immunoglobulin light chains. *Biochemistry*. 1975;14:3953-3961).

The H chains of Ig molecules are of several classes determined by their constant regions (μ, δ, γ [of which there are several subclasses], α and ε). An assembled Ig molecule, consisting of one or more units of two identical H and L chains, derives its name from the constant region of the H chain that it possesses. Thus, there are IgM, IgD, IgG, IgA, and IgE antibodies. The H chains each consist of a single amino terminal V region and three or four C regions. In many H chains, a hinge region separates the first and second C regions and conveys flexibility to the molecule, allowing the two combining sites of a single unit to move in relation to one another so as to promote the binding of a single antibody molecule to an antigen that has more than one copy of the same epitope. Such divalent binding to a single antigenic structure results in a great gain in energy of interaction (see Chapter 7). The H-chain V region, like that of the L chain, contains three CDRs lining the combining site of the antibody and four framework regions.

The C region of each H-chain class conveys unique functional attributes to the antibodies that possess it. Among the distinct biologic functions of each class of antibody are the following:

- IgM antibodies are potent activators of the complement system (see Chapter 36).
- IgA antibodies are secreted into a variety of bodily fluids and are principally responsible for immunity at mucosal surfaces (see Chapter 34).
- IgE antibodies are bound by specific receptors (FcεRI) on basophils and mast cells. When

cross-linked by antigen, these IgE/FcεRI complexes cause the cells to release a set of mediators responsible for allergic inflammatory responses (see Chapter 45).

- IgD antibodies act virtually exclusively as membrane receptors for antigen.

- IgG antibodies, made up of four subclasses in both humans and mice, mediate a wide range of functions including transplacental passage and opsonization of antigens through binding of antigen/antibody complexes to specialized Fc receptors on macrophages and other cell types (see Chapters 19, 20, and 24).

IgD, IgG, and IgE antibodies consist of a single unit of two H and L chains. IgM antibodies are constructed of five or six such units, although they consist of a single unit when they act as membrane receptors. IgA antibodies may consist of one or more units. The antibodies that are made up of more than a single unit generally contain an additional polypeptide chain, the J chain, that appears to play a role in the polymerization process. In addition, secreted IgA expresses a chain, a secretory piece, that is derived from the receptor for polymeric IgA, which plays a role in the transport of IgA through the cells lining the lumen of the gut.

Each of the distinct Igs can exist as secreted antibodies and as membrane molecules. Antibodies and cell surface receptors of the same class made by a specific cell have identical structures except for differences in their carboxy-terminal regions. Membrane Igs possess a hydrophobic region, spanning the membrane, and a short intracytoplasmic tail, both of which are lacking in the secretory form.

Immunoglobulin Genetics (Chapter 6)

The components of the Ig H-chain gene have already been alluded to. To reiterate, the IgH chain gene of a mature lymphocyte is derived from a set of genetic elements that are separated from one another in the germline. The V region is composed of three types of genetic elements: V_H, D, and J_H. More than 100 V_H elements exist; there are more than 10 D elements and a small number of J_H elements (4 in the mouse). An H-chain V_HDJ_H gene is created by the translocation of one of the D elements on a given chromosome to one of the J_H elements on that chromosome, generally with the excision of the intervening DNA. This is followed by a second translocation event in which one of the V_H elements is brought into apposition with the assembled DJ_H element to create the V_HDJ_H (V region) gene (see Fig. 1.3). Although it is likely that the choice of the V_H, D, and J_H elements that are assembled is not entirely random, the combinatorial process allows the creation of a very large number of distinct H-chain V-region genes. Additional diversity is created by the imprecision of the joining events and by the deletion of nucleotides and addition of new, untemplated nucleotides between D and J_H and between V_H and D, forming N regions in these areas. This further increases the diversity of distinct IgH chains that can be generated from the relatively modest amount of genetic information present in the germline.

The assembly of L-chain genes follows generally similar rules. However, L chains are assembled from V_L and J_L elements only. Although there is junctional diversity, no N regions exist for L chains. Additional diversity is provided by the existence of two classes of L chains, κ and λ.

An Ig molecule is assembled by the pairing of an IgH-chain polypeptide with an IgL-chain

polypeptide. Although this process is almost certainly not completely random, it allows the formation of an exceedingly large number of distinct Ig molecules, the majority of which will have individual specificities.

The rearrangement events that result in the assembly of expressible IgH and IgL chains occur in the course of B-cell development in pro-B cells and pre-B cells, respectively (see Fig. 1.1). This process is regulated by the Ig products of the rearrangement events. The formation of a μ chain signals the termination of rearrangement of H-chain gene elements and the onset of rearrangement of L-chain gene elements, with κ rearrangements generally preceding λ rearrangements. One important consequence of this is that only a single expressible μ chain will be produced in a given cell, as the first expressible μ chain shuts off the possibility of producing an expressible μ chain on the alternative chromosome. Comparable mechanisms exist to ensure that only one L-chain gene is produced, leading to the phenomenon known as allelic exclusion. Thus, the product of only one of the two alternative allelic regions at both the H- and L-chain loci are expressed. The closely related phenomenon of L-chain isotype exclusion ensures the production of either κ or λ chains in an individual cell, but not both. An obvious but critical consequence of allelic exclusion is that in most cases an individual B cell makes antibodies, all of which have identical H- and L-chain V regions, a central prediction of the clonal selection theory of the immune response. During receptor editing, secondary rearrangements occur. Receptor editing is induced when the initial membrane Ig is capable of self-reactivity. As a consequence of the resultant secondary rearrangement, Ig of a different specificity is expressed, usually no longer self-reactive.

Class Switching (Chapter 6)

An individual B cell continues to express the same IgH-chain V region as it matures but it can switch the IgH-chain C region it uses (see Fig. 1.3). Thus, a cell that expresses receptors of the IgM and IgD classes may differentiate into a cell that expresses IgG, IgA, or IgE receptors and then into a cell secreting antibody of the same class as it expressed on the cell surface. This process allows the production of antibodies capable of mediating distinct biologic functions but that retain the same antigen-combining specificity. When linked with the process of affinity maturation of antibodies, Ig class switching provides antibodies of extremely high efficacy in preventing re-infection with microbial pathogens or in rapidly eliminating such pathogens. The associated phenomena of class switching and affinity maturation account for the high degree of effectiveness of antibodies produced in secondary immune responses.

The process of class switching is known to involve a genetic recombination event between specialized switch (S) regions, containing repetitive sequences, that are located upstream of each C region genetic element (with the exception of the δ C region). Thus, the S region upstream of the μ C_H region gene (Sμ) recombines with an S region upstream of a more 3′ isotype, such as Sγ1, to create a chimeric Sμ/Sγ1

region and in the deletion of the intervening DNA (Fig. 1.7). The genes encoding the C regions of the various γ chains (in the human γ1, γ2, γ3, and γ4; in the mouse γ1, γ2a, γ2b, and γ3), of the α chain, and of the ε chain are located 3′ of the Cμ and Cδ genes.

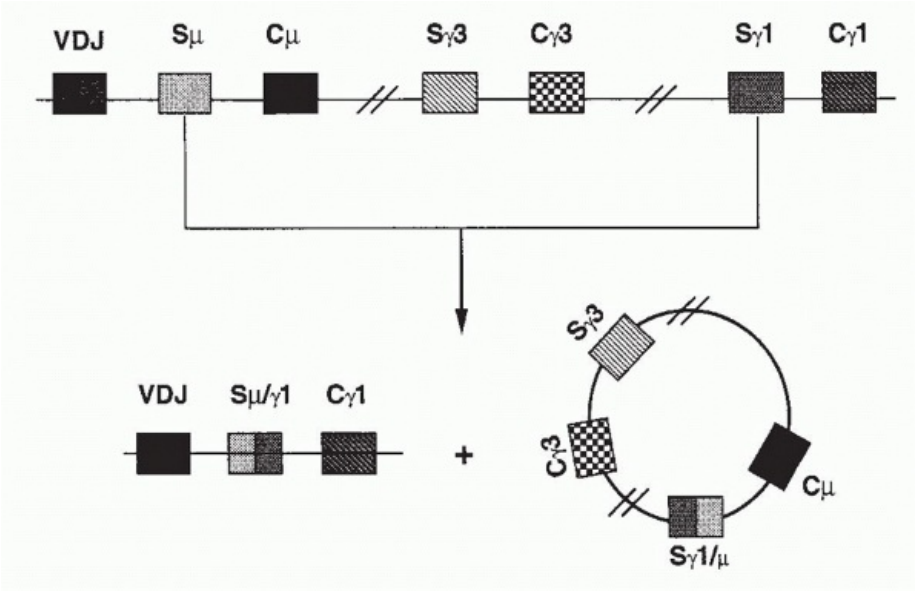

FIG. 1.7. Immunoglobulin Class Switching. The process through which a given VDJ gene in a stimulated B cell may switch the constant region gene with which it is associated from μ to another, such as γ1, is illustrated. A recombination event occurs in which DNA between a cleavage point in Sμ and one in Sγ1 forms a circular episome. This results in Cγ1 being located immediately downstream of the chimeric Sμ/γ1 region, in a position such that transcription initiating upstream of VDJ results in the formation of VDJCγ1 mRNA and γ1 H-chain protein.

The induction of the switching process is dependent on the action of a specialized set of B-cell stimulants. Of these, the most widely studied are CD154, expressed on the surface of activated T cells, and the TLR ligands such as bacterial lipopolysaccharide. The targeting of the C region that will be expressed as a result of switching is largely determined by cytokines. Thus, IL-4 determines that switch events in the human and mouse will be to the ε C region and to the γ4 (human) or γ1 (mouse) C regions. In the mouse, interferon-gamma (IFN-γ) determines switching to γ2a and transforming growth factor-beta (TGF-β) determines switching to α. A major goal is to understand the physiologic determination of the specificity of the switching process. Because cytokines are often the key controllers of which Ig classes will represent the switched isotype, this logically translates into asking what regulates the relative amounts of particular cytokines that are produced by different modes of immunization.

As already noted, both the switching process and somatic hypermutation depend upon the AID. Mice and humans that lack AID fail to undergo both immunoglobulin class switching and somatic hypermutation.

Affinity Maturation and Somatic Hypermutation (Chapters 6 and 10)

The process of generation of diversity embodied in the construction of the H- and L-chain V-region genes and of the pairing of H and L chains creates a large number of distinct antibody molecules, each expressed in an individual B cell. This primary repertoire is sufficiently large so that most epitopes on foreign antigens will encounter B cells with complementary receptors. Thus, if adequate T-cell help can be generated, antibody responses can be made

to a wide array of foreign substances. Nonetheless, the antibody that is initially produced usually has a relatively low affinity for the antigen. This is partially compensated for by the fact that IgM, the antibody initially made, is a pentamer. Through multivalent binding, high avidities can be achieved even if individual combining sites have only modest affinity (see Chapter 7). In the course of T-cell-dependent B-cell stimulation, particularly within the germinal center, a process of somatic hypermutation is initiated that leads to a large number of mutational events, largely confined to the H-chain and L-chain V-region genes and their immediately surrounding introns.

During the process of somatic hypermutation, mutational rates of 1 per 1,000 base pairs per generation may be achieved. This implies that with each cell division close to one mutation will occur in either the H- or L-chain V region of an individual cell. Such a high rate of mutation creates an enormous increase in antibody diversity. Although most of these mutations will either not affect the affinity with which the antibody binds its ligand or will lower that affinity, some will increase it. Thus, some B cells emerge that can bind antigen more avidly than the initial population of responding cells. Because there is an active process of apoptosis in the germinal center from which B cells can be rescued by the binding of antigen to their membrane receptors, cells with the most avid receptors should have an advantage over other antigen-specific B cells and should come to dominate the population of responding cells. Thus, upon rechallenge, the affinity of antibody produced will be greater than that in the initial response. As time after immunization elapses, the affinity of antibody produced will increase. This process leads to the presence in immunized individuals of high-affinity antibodies that are much more effective, on a weight basis, in protecting against microbial agents and other antigenbearing pathogens than was the antibody initially produced. Together with antibody class switching, affinity maturation results in the increased effectiveness of antibody in preventing reinfection with agents with which the individual has had a prior encounter.

T-LYMPHOCYTES

T-lymphocytes constitute the second major class of lymphocytes. They derive from precursors in hematopoietic tissue, undergo differentiation in the thymus (hence the name thymus-derived [T]-lymphocytes), and are then seeded to the peripheral lymphoid tissue and to the recirculating pool of lymphocytes (see Chapters 13 and 14). T cells are subdivided into two distinct classes based on the cell surface receptors they express. The majority of T cells express TCRs consisting of α and β chains. A second group of T cells express receptors made up of γ and δ chains. Among the α/β T cells are two important sublineages: those that express the coreceptor molecule CD4 (CD4 T cells) and those that express CD8 (CD8 T cells). These cells differ in how they recognize

antigen and mediate different types of regulatory and effector functions.

CD4 T cells are the major *helper* cells of the immune system (see Chapter 29). Their helper function depends both on cell surface molecules, such as CD154, induced upon these cells when they are activated and on the wide array of cytokines they secrete upon stimulation. CD4 T cells tend to differentiate, as a consequence of priming, into cells that principally secrete the cytokines IL-4, IL-13, IL-5 and IL-6 (T_{H2} cells) into cells that mainly produce IFN-γ and lymphotoxin (T_{H1} cells), or into cells that produce IL-17 and related cytokines (T_{H17}

cells). T_{H2} cells are very effective in immunity to helminthic parasites, T_{H1} cells are effective inducers of cellular immune responses, involving enhancement in the microbicidal activity of monocytes and macrophages and consequent increased efficiency in lysing microorganisms in intracellular vesicular compartments, while T_{H17} cells are efficient recruiters of granulocytes and other cells of the inflammatory system and play a major role in responses to extracellular bacterial pathogens. CD4 T cells can also acquire the capacity to enter B-cell follicles and help B cells develop into antibody-producing cells and undergo immunoglobulin class switching and affinity maturation; the cells are referred to as T follicular helper (T_{fh}) cells. Another possible fate of naïve CD4 T cells is to differentiate into induced regulatory T cells (iT_{regs}). However, most T_{regs} develop as a independent lineage of CD4 T cells. T_{regs} express the transcription factor Foxp3 and many express large amounts of the α chain of the IL-2 receptor (CD25).

T cells mediate important effector functions. Some of these are determined by the patterns of cytokines they secrete. These powerful molecules can be directly toxic to target cells and can mobilize potent inflammatory mechanisms. In addition, T cells, particularly CD8 T cells, can develop into cytotoxic T-lymphocytes (CTLs) capable of efficiently lysing target cells that express antigens recognized by the CTLs.

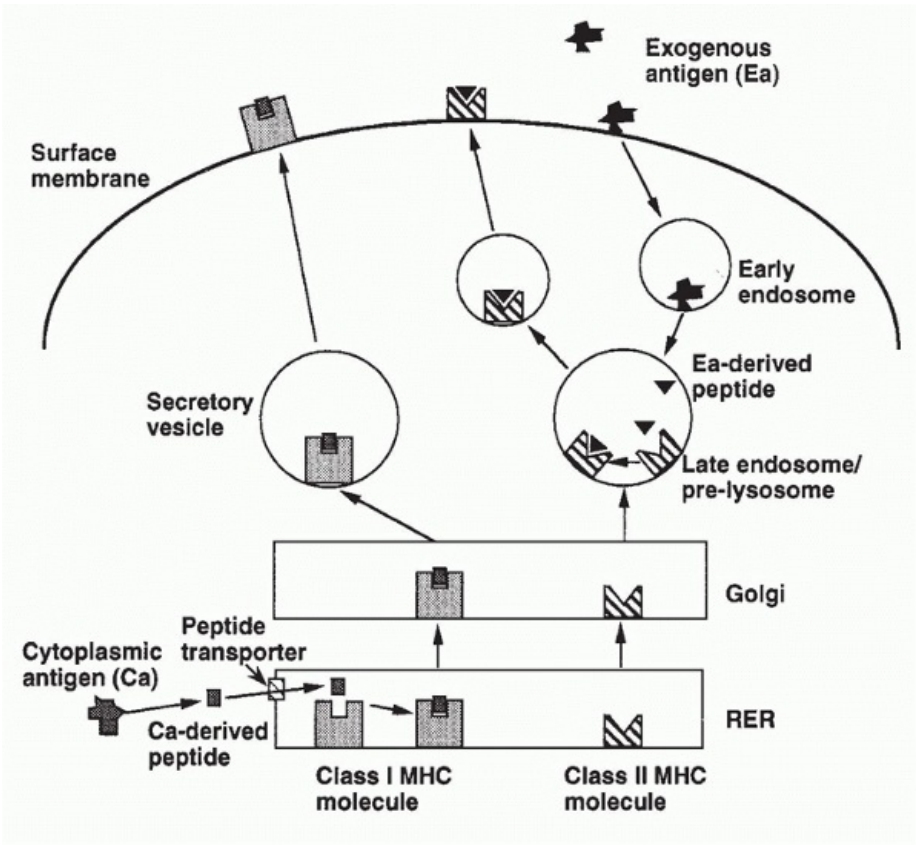

FIG. 1.8. Pathways of Antigen Processing. Exogenous antigen (Ea) enters the cell via endocytosis and is transported from early endosomes into late endosomes or prelysosomes, where it is fragmented and where resulting peptides (Ea-derived peptides) may be loaded into class II major histocompatibility complex (MHC) molecules. The latter have been transported from the rough endoplasmic reticulum (RER) through the Golgi apparatus to the peptide-containing vesicles. Class II MHC molecules/Ea-

derived peptide complexes are then transported to the cell surface, where they may be recognized by T-cell receptor expressed on CD4+ T cells. Cytoplasmic antigens (Ca) are degraded in the cytoplasm and then enter the RER through a peptide transporter. In the RER, Ca-derived peptides are loaded into class I MHC molecules that move through the Golgi apparatus into secretory vesicles and are then expressed on the cell surface where they may be recognized by CD8+ T cells (Reprinted with permission from Paul WE. In: Gallin JI, Goldstein, I, Snyderman, R, ed. *Inflammation*. New York: Raven,;1992:776.)

T-Lymphocyte Antigen Recognition (Chapters 11, 21, and 22)

T cells differ from B cells in their mechanism of antigen recognition. Ig, the B-cell's receptor, binds to individual antigenic epitopes on the surface of native molecules, be they on cell surfaces or in solution. Antibody and B-cell receptors evolved to bind to and to protect against microorganisms in extracellular fluids.

By contrast, T cells invariably recognize cell-associated molecules and mediate their functions by interacting with and altering the behavior of such *antigen-presenting cells* (APCs). Indeed, the TCR does not recognize antigenic determinants on intact, undenatured molecules. Rather, it recognizes a complex consisting of a peptide, derived by intracellular proteolysis of the antigen, bound into a specialized groove of a class II or class I MHC protein. Indeed, what differentiates a CD4 T cell from a CD8 T cell is that the CD4 T cells recognize peptide/class II complexes whereas the CD8 T cells recognize peptide/class I complexes.

The TCR's ligand (i.e., the peptide/MHC protein complex) is created within the APC. In general, class II MHC molecules bind peptides derived from proteins that have been taken up by the APC through an endocytic process (Fig. 1.8). These endocytosed proteins are fragmented by proteolytic enzymes within the endosomal/lysosomal compartment. The resulting peptides are loaded into class II MHC that traffic through this compartment. Peptide-loaded class II molecules are then expressed on the surface of the APC where they are available to be bound by CD4 T cells that have TCRs capable of recognizing

the expressed cell surface peptide/MHC protein complex. Thus, CD4 T cells are specialized to largely react with antigens derived from extracellular sources.

In contrast, class I MHC molecules are mainly loaded with peptides derived from internally synthesized proteins, such as viral gene products. These peptides are produced from cytosolic proteins by proteolysis within the proteasome and are translocated into the rough endoplasmic reticulum. Such peptides, generally nine amino acids in length, are bound by class I MHC molecules. The complex is brought to the cell surface, where it can be recognized by CD8 T cells expressing appropriate receptors. This property gives the T-cell system, particularly CD8 T cells, the ability to detect cells expressing proteins that are different from, or produced in much larger amounts than, those of cells of the remainder of the organism (e.g., viral antigens [whether internal, envelope, or cell surface] or mutant antigens [such as active oncogene products]), even if these proteins, in their intact form, are neither expressed on the cell surface nor secreted.

Although this division of class I-binding peptides being derived from internally synthesized proteins and class II-binding peptides from imported proteins is generally correct, there are important exceptions to this rule that are central for the function of the immune system. The most effective priming of naive CD8 T cells occurs in response to peptide/MHC-I complexes expressed by DCs and yet many viruses do not infect these cells but rather target other cell types. Viral antigens produced by infected cells can be taken up by specialized DCs and loaded into class I molecules in a process referred to as cross-presentation.

T-Lymphocyte Receptors (Chapter 11)

The TCR is a disulfide-linked heterodimer (Fig. 1.9). Its constituent chains (α and β, or γ and δ) are Ig supergene family members. The TCR is associated with a set of transmembrane proteins, collectively designated the CD3 complex, that play a critical role in signal transduction. The CD3 complex consists of γ, δ (note that the CD3 γ and δ chains and the TCR γ and δ chains are distinct polypeptides that, unfortunately, have similar designations) and ε chains and is associated with a homodimer of two ζ chains or a heterodimer of ζ and ε chains. CD3 γ, δ, and ε consist of extracellular domains that are Ig supergene family members. The cytosolic domains of CD3 γ, δ, and ε and of ζ and ε contain one or more copies of the immunoreceptor tyrosine-based activation motif (ITAM) (D/ExxYxxLxxxxxxYxxL/I) that is found in a variety of chains associated with immune recognition receptors. This motif appears to be important in the signal transduction process and provides a site through which protein tyrosine kinases can interact with these chains to propagate signaling events.

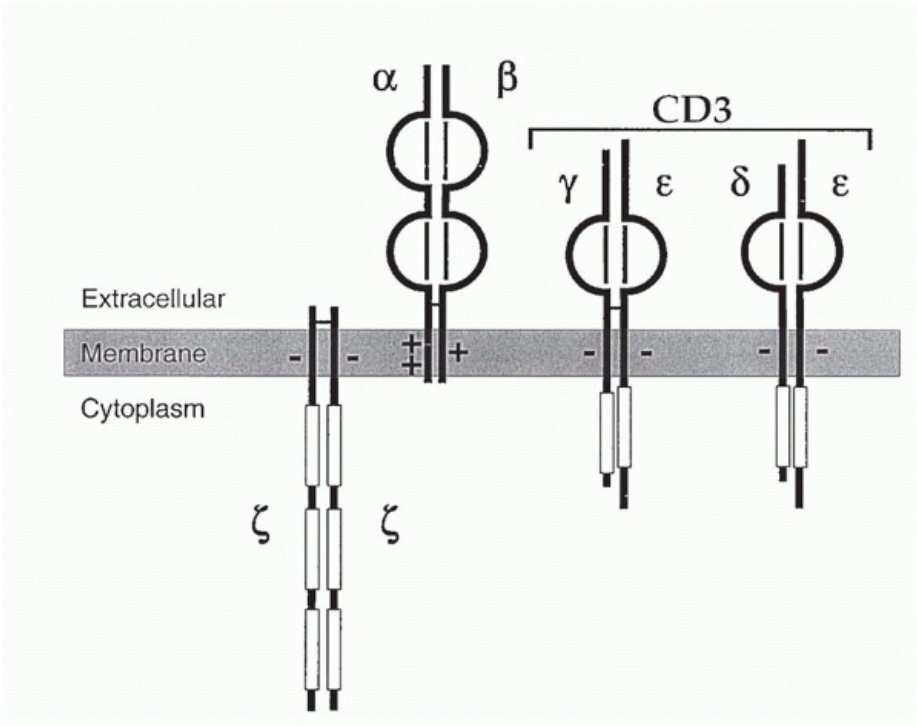

FIG. 1.9. The T-Cell Antigen Receptor. Illustrated schematically is the antigen binding subunit comprised of an αβ heterodimer and the associated invariant CD3 and ζ chains. Acidic (-) and basic (+) residues located within the plasma membrane are indicated. The *open rectangular boxes* indicate motifs within the cytoplasmic domains that interact with

protein tyrosine kinases.

The TCR chains are organized much like Ig chains. Their N-terminal portions are variable and their C-terminal portions are constant. Furthermore, similar recombinational mechanisms are used to assemble the V-region genes of the TCR chains. Thus, the V region of the TCR β chain is encoded by a gene constructed from three distinct genetic elements (*Vβ*, *D*, and *Jβ*) that are separated in the germline. Although the relative numbers of *Vβ*, *D*, and *Jβ* genes differ from that for the comparable Ig H variable region elements, the strategies for creation of a very large number of distinct genes by combinatorial assembly are the same. Both junctional diversity and N-region addition further diversify the genes and their encoded products. TCR β has fewer *V* genes than IgH but much more diversity centered on the *D/J* region, which encodes the equivalent of the third CDR of Igs. The α chain follows similar principles, except that it does not use a *D* gene.

The genes for TCR γ and δ chains are assembled in a similar manner except that they have many fewer V genes from which to choose. Indeed, γ/δ T cells in certain environments, such as the skin and specific mucosal surfaces, are exceptionally homogeneous. It has been suggested that the TCRs encoded by these essentially invariant γ and δ chains may be specific for some antigen that signals microbial invasion and that activation of γ/δ T cells through this mechanism constitutes an initial response that aids the development of the more sophisticated response of α/β T cells.

T-Lymphocyte Activation (Chapter 12)

T-cell activation is dependent on the interaction of the TCR/CD3 complex with its cognate ligand, a peptide bound in the groove of a class I or class II MHC molecule, on the surface of a competent APC. Through the use of chimeric cell surface molecules that possess cytosolic domains largely limited to the ITAM signaling motif alluded to previously, it is clear that cross-linkage of molecules containing such domains can generate some of the signals that result from TCR engagement. Nonetheless, the molecular events set in motion by receptor engagement are complex ones. Among the earliest steps is the activation of tyrosine kinases leading to the tyrosine phosphorylation of a set of substrates that control

several signaling pathways. Current evidence indicates that early events in this process involve the src family tyrosine kinases $p56^{lck}$, associated with the cytosolic domains of the CD4 and CD8 coreceptors, and $p59^{fyn}$, and ZAP-70, a Syk family tyrosine kinase, that binds to the phosphorylated ITAMs of the ζ chain. The protein tyrosine phosphatase CD45, found on the surface of all T cells, also plays a critical role in T-cell activation.

A series of important substrates are tyrosine phosphorylated as a result of the action of the kinases associated with the TCR complex. These include a 1) set of adapter proteins that link the TCR to the Ras pathway; 2) phospholipase Cγ1, the tyrosine phosphorylation of which increases its catalytic activity and engages the inositol phospholipid metabolic pathway, leading to elevation of intracellular free calcium concentration and activation protein kinase C; and 3) a series of other important enzymes that control cellular growth and differentiation. Particularly important is the phosphorylation of LAT, a molecule that acts as an organizing scaffold to which a series of signaling intermediates bind and upon which they

become activated and control downstream signaling.

The recognition and early activation events result in the reorganization of cell surface and cytosolic molecules on the T cell, and correspondingly, on the APC to produce a structure, the *immunological synapse*. The apposition of key interacting molecules involving a small segment of the membranes of the two cells concentrates these interacting molecules in a manner that both strengthens the interaction between the cells and intensifies the signaling events. It also creates a limited space into which cytokines may be secreted to influence the behavior of the interacting cells. The formation of the immunological synapse is one mechanism through which the recognition of relatively small numbers of ligands by TCRs on a specific T cell can be converted into a vigorous stimulatory process.

In general, normal T cells and cloned T-cell lines that are stimulated only by TCR cross-linkage fail to give complete responses. TCR engagement by itself may often lead to a response in which the key T-cell-derived growth factor, IL-2, is not produced and in which the cells enter a state of anergy such that they are unresponsive or poorly responsive to a subsequent competent stimulus (see Chapter 32). Full responsiveness of a T cell requires, in addition to receptor engagement, an accessory cell-delivered costimulatory signal. The engagement of CD28 on the T cell by CD80 and/or CD86 on the APC (or the engagement of comparable ligand/receptor pairs on the two cells) provides potent costimulatory activity. Inhibitors of this interaction markedly diminish antigen-specific T-cell activation in vivo and in vitro, indicating that the CD80/86-CD28 interaction is physiologically important in T-cell activation (see Chapters 12 and 14).

The interaction of CD80/86 with CD28 increases cytokine production by the responding T cells. For the production of IL-2, this increase appears to be mediated both by enhancing the transcription of the IL-2 gene and by stabilizing IL-2 mRNA. These dual consequences of the CD80/86-CD28 interaction cause a striking increase in the production of IL-2 by antigen-stimulated T cells.

CD80/86 has a second receptor on the T cell, CTLA-4, that is expressed later in the course of T-cell activation. The bulk of evidence indicates that the engagement of CTLA-4 by CD80/86 leads to a set of biochemical signals that terminate the T-cell response. Mice that are deficient in CTLA-4 expression develop fulminant autoimmune responses and anti-CTLA-4 antibodies are used as drugs to enhance antitumor immune responses.

T Lymphocyte Development (Chapter 13)

Upon entry into the thymus, T-cell precursors do not express TCR chains, the CD3 complex, or the CD4 or CD8 molecules (Fig. 1.10). Because these cells lack both CD4 and CD8, they are often referred to as double-negative cells. Thymocytes develop from this double-negative pool into cells that are both CD4+ and CD8+ (double-positive cells) and express low levels of TCR and CD3 on their surface. In turn, double-positive cells further differentiate into relatively mature thymocytes that express either CD4 or CD8 (single-positive cells) and high levels of the TCR/CD3 complex.

The expression of the TCR depends on complex rearrangement processes that generate TCR α and β (or γ and

δ) chains. Once TCR chains are expressed, these cells undergo two important selection processes within the thymus. One, termed *negative selection*, is the deletion of cells that

express receptors that bind with high affinity to complexes of self-peptides with self-MHC molecules. This is a major mechanism through which the T-cell compartment develops immunologic unresponsiveness to self antigens (see Chapters 13 and 32). In addition, a second major selection process is *positive selection*, in which T cells with receptors with "intermediate affinity" for self-peptides bound to self-MHC molecules are selected, thus forming the basis of the T-cell repertoire for foreign peptides associated with self-MHC molecules. T cells that are not positively selected are eliminated in the thymic cortex by apoptosis. Similarly, T cells that are negatively selected as a result of high-affinity binding to self-peptide/self-MHC complexes are also deleted through apoptotic death. These two selection processes result in the development of a population of T cells that are biased toward the recognition of peptides in association with self-MHC molecules from which those cells that are potentially autoreactive (capable of high-affinity binding of selfpeptide/self-MHC complexes) have been purged.

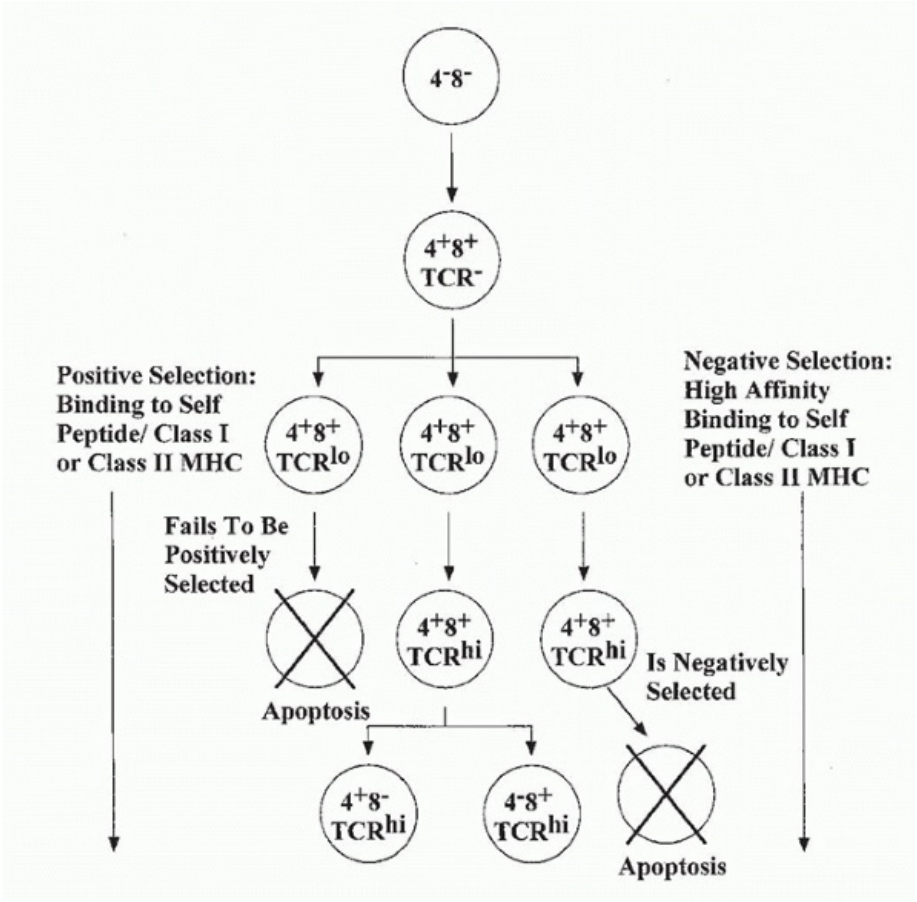

FIG. 1.10. Development of α/β T Cells in the Thymus. Doublenegative T cells (4^-8^-) acquire CD4 and CD8 (4^+8^+) and then express α/β TCRs, initially at low levels. Thereafter, the degree of expression of T-cell receptiors increases and the cells differentiate into CD4 or CD8 cells and are then exported to the periphery. Once the T cells have expressed receptors, their survival depends upon the recognition of peptide/major histocompatibility complex (MHC) class I or class II molecules with an affinity above some given threshold. Cells that fail to do so undergo apoptosis. These cells have failed to be *positively selected*. Positive selection is associated with the

differentiation of 4^+8^+ cells into CD4 or CD8 cells. Positive selection involving peptide/class I MHC molecules leads to the development of CD8 cells whereas positive selection involving peptide/class II MHC molecules leads to the development of CD4 cells. If a T cell recognizes a peptide/MHC complex with high affinity, it is also eliminated via apoptosis (it is *negatively selected*).

One important event in the development of T cells is their differentiation from double-positive cells into CD4+ or CD8+ single-positive cells. This process involves the interaction of double-positive thymocytes with peptide bound to class II or class I MHC molecules on accessory cells. Indeed, CD4 binds to monomorphic sites on class II molecules, whereas CD8 binds to comparable sites on class I molecules. The capacity of the TCR and CD4 (or of the TCR and CD8) to bind to a class II MHC (or a class I MHC) molecule on an accessory cell leads either to the differentiation of doublepositive thymocytes into CD4+ (or CD8+) single-positive T cells or to the selection of cells that have "stochastically" differentiated down the CD4 (or CD8) pathway.

Less is understood about the differentiation of thymocytes that express TCRs composed of γ/δ chains. These cells fail to express either CD4 or CD8. However, γ/δ cells are relatively numerous early in fetal life; this, together with their limited degree of heterogeneity, suggests that they may comprise a relatively primitive T-cell compartment.

T-Lymphocyte Functions (Chapters 14, 29, and 33)

T cells mediate a wide range of immunologic functions. These include the capacity to help B cells develop into antibody-producing cells, the capacity to increase the microbicidal action of monocytes/macrophages, the inhibition of certain types of immune responses, direct killing of target cells, and mobilization of the inflammatory response. In general, these effects depend on their expression of specific cellsurface molecules and the secretion of cytokines.

T Cells that Help Antibody Responses (Chapter 13)

Helper T cells, T_{FH} cells, can stimulate B cells to make antibody responses to proteins and other T-cell-dependent antigens. T-cell-dependent antigens are immunogens in which individual epitopes appear only once or only a limited number of times so that they are unable to cross-link the membrane Ig of B cells or do so inefficiently. B cells bind the antigen through their membrane Ig, and the complex undergoes endocytosis. Within the endosomal and lysosomal compartments, the antigen is fragmented into peptides by proteolytic enzymes and one or more of the generated peptides are loaded into class II MHC molecules, which traffic through this vesicular compartment. The resulting complex of class II MHC molecule and bound peptide is exported to the B-cell surface membrane. T cells with receptors specific for the peptide/class II molecular complex recognize that complex on the B cell.

B-cell activation depends not only on the binding of peptide/class II MHC complexes on the B cell surface by the TCR but also on the interaction of T-cell CD154 with CD40 on the B cell. T cells do not constitutively express CD154; rather, it is induced as a result of an interaction with an activated APC that expresses a cognate antigen recognized by the TCR of the T cell. Furthermore, CD80/86 are generally expressed by activated but not resting B cells so that interactions involving resting B cells and naïve T cells generally do not lead to efficient antibody production. By contrast, a T cell already activated and expressing CD154 can

interact with a resting B cell, leading to its upregulation of CD80/86 and to a more productive T-cell/B-cell interaction with the delivery of cognate help and the development of the B cell into an antibody-producing cell. Similarly, activated B cells expressing large amounts of class II molecules and CD80/86 can act as effective APCs and can participate with T cells in efficient cognate help interactions. Cross-linkage of membrane Ig on the B cell, even if inefficient, may synergize with the CD154/CD40 interaction to yield vigorous B-cell activation.

The subsequent events in the B-cell response program, including proliferation, Ig secretion, and class switching, either depend on or are enhanced by the actions of T-cell-derived cytokines. Thus, B-cell proliferation and Ig secretion are enhanced by the actions of several type I cytokines including IL-2 and IL-4. Ig class switching is dependent both on the initiation of competence for switching, which can be induced by the CD154/CD40 interaction, and on the targeting of particular C regions for switching, which is determined, in many instances, by cytokines. The best studied example of this is the role of IL-4 in determining switching to IgG1 and IgE in the mouse and to IgG4 and IgE in the human. Indeed, the central role of IL-4 in the production of IgE is demonstrated by the fact that mice that lack the IL-4 gene or the gene for the IL-4 receptor α chain, as a result of gene knockouts, have a marked defect in IgE production. Similarly, IFN-γ determines switching to IgG_{2a} in the mouse. The relationship between T_{FH} cells that produce IL-4 and T_{H2} cells and those that produce IFN-γ and T_{H1} cells is still uncertain.

Induction of Cellular Immunity (Chapters 14 and 19)

T cells also may act to enhance the capacity of monocytes and macrophages to destroy intracellular microorganisms. In particular, IFN-γ enhances several mechanisms through which mononuclear phagocytes destroy intracellular bacteria and parasites, including the generation of nitric oxide and induction of TNF. T_{H1} cells are particularly effective in

enhancing microbicidal action because they produce IFN-γ. By contrast, three of the major cytokines produced by T_{H2} cells, IL-4, IL-13, and IL-10, block these activities; IL-4 and IL-13 induce an alternative gene activation program in macrophages resulting in *alternatively activated macrophages*, characterized (in the mouse) by the expression of arginase 1 and chitinase. Thus, T_{H2} cells often oppose the action of T_{H1} cells in inducing cellular immunity and in certain infections with microorganisms that are intracellular pathogens of macrophages; a T_{H2}-dominated response may be associated with failure to control the infection.

Regulatory T Cells (Chapter 33)

There has been a longstanding interest in the capacity of T cells to diminish as well as to help immune responses. Cells that mediate such effects are referred to as T_{regs}. T_{regs} may be identified by their expression of Foxp3 and of CD25, the IL-2 receptor alpha chain. These cells inhibit the capacity of both CD4 and CD8 T cells to respond to their cognate antigens. The mechanisms through which their suppressor function is mediated are still somewhat controversial. In some instances, it appears that cell/cell contact is essential for suppression, whereas in other circumstances production of cytokines by T_{regs} has been implicated in their ability to inhibit responses. Evidence has been presented for both IL-10 and TGF-β as mediators of inhibition.

T_{regs} have been particularly studied in the context of various autoimmune conditions. In the absence of T_{regs}, conventional T cells cause several types of autoimmune responses, including autoimmune gastritis and inflammatory bowel disease. T_{regs} express cell surface receptors allowing them to recognize autoantigens; their responses to such recognition results in the suppression of responses by conventional T cells. Whether the receptor repertoire of T_{regs} and the conventional T cells are the same has not been fully determined, although there is increasing evidence that T_{regs} derive from a thymic CD4 T-cell population with relatively high affinity for selfantigen. As noted previously, iT_{regs} can be derived in the periphery from naive CD4 T-cell populations. This is seen when naive cells are stimulated by their cognate ligands in the presence of TGF-β and IL-2.

Cytotoxic T Cells (Chapter 37)

One of the most striking actions of T cells is the lysis of cells expressing specific antigens. Most cells with such cytotoxic activity are CD8 T cells that recognize peptides derived from proteins produced within the target cell and bound to class I MHC molecules expressed on the surface of the target cell. However, CD4 T cells can express CTL activity, although in such cases the antigen recognized is a peptide associated with a class II MHC molecule; often, such peptides derive from exogenous antigens.

There are two major mechanisms of cytotoxicity. One involves the production by the CTL of perforin, a molecule that can insert into the membrane of target cells and promote the lysis of that cell. Perforin-mediated lysis is mediated a series of enzymes produced by activated CTLs, referred to as granzymes. Many active CTLs also express large amounts of fas ligand on their surface. The interaction of fas ligand on the surface of the CTL with fas on the surface of the target cell initiates apoptosis in the target cell.

CTL-mediated lysis is a major mechanism for the destruction of virus-infected cells. If activated during the period in which the virus is in its eclipse phase, CTLs may be capable of eliminating virus and curing the host with relatively limited cell destruction. On the other hand, vigorous CTL activity after a virus has been widely disseminated may lead to substantial tissue injury because of the large number of cells that are killed by the action of the CTLs. Thus, in many infections, the disease is caused by the destruction of tissue by CTLs rather than by the virus itself. One example is hepatitis B, in which much of the liver damage represents the attack of hepatitis B virus-specific CTLs on infected liver cells.

It is usually observed that CTLs that have been induced as a result of a viral infection or intentional immunization must be reactivated in vitro through the recognition of antigen on the target cell. This is particularly true if some interval has elapsed between the time of infection or immunization and the time of test. This has led to some question being raised as to the importance of CTL immunity in protection against re-infection and how important CTL generation is in the long-term immunity induced by protective vaccines. On the other hand, in active infections, such as seen in individuals with HIV, CTL that can kill their target cells immediately are often seen. There is much evidence to suggest that these cells play an active role in controlling the number of HIV-positive T cells.

CYTOKINES (CHAPTERS 25, 26, 27, 28)

Many of the functions of cells of the immune system are mediated through the production of

a set of small proteins referred to as cytokines. These proteins can now be divided into several families. They include the type I cytokines or hematopoeitins that encompass many of the interleukins (i.e., IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-11, IL-12, IL-13, IL-15, IL-21, IL-23, and IL-27), as well as several hematopoietic growth factors; the type II cytokines, including the interferons and IL-10; the TNF-related molecules, including TNF, lymphotoxin, and Fas ligand; Ig superfamily members, including IL-1, IL-18, IL-33, IL-36, and IL-37; and the chemokines, a large family of molecules playing critical roles in a wide variety of immune and inflammatory functions. IL-17 and its congeners, including IL-25, constitute a structurally unique set of cytokines.

Many of the cytokines are T-cell products; their production represents one of the means through which the wide variety of functions of T cells are mediated. Most cytokines are not constitutive products of the T cell. Rather, they are produced in response to T-cell activation, usually resulting from presentation of antigen to T cells by APCs in concert with the action of a costimulatory molecule, such as the interaction of CD80/86 with CD28. Although cytokines are produced in small quantities, they are potent, binding to their receptors with equilibrium constants of approximately 10^{10} M^{-1}. In some instances, cytokines are directionally secreted into the immunological synapse formed between a T cell and an APC. In such cases, the cytokine acts in a paracrine manner. Indeed, many cytokines

have limited action at a distance from the cell that produced them. This appears to be particularly true of many of the type I cytokines. However, other cytokines act by diffusion through extracellular fluids and blood to target cells that are distant from the producers. Among these are cytokines that have proinflammatory effects, such as IL-1, IL-6, and TNF, and the chemokines, that play important roles in regulating the migration of lymphocytes and other cell types.

Chemokines (Chapter 28)

A large family of small proteins that are *chemotactic cytokines* (chemokines) have been described. While members of this family have a variety of functions, perhaps the most dramatic is their capacity to regulate leukocyte migration and thus to act as critical dynamic organizers of cell distribution in the immune and inflammatory responses. The receptors for chemokines are seven transmembrane-spanning, G-protein coupled receptors.

The chemokines are subdivided based on the number and positioning of their highly conserved cysteines. Among chemokines with four conserved cysteines, the cysteines are adjacent in one large group (the CC chemokines), whereas in a second large group they are separated by one amino acid (CXC chemokines). There are also rare chemokines in which the cysteines are separated by three amino acids (CX3C) or in which there are only two conserved cysteines (C chemokines).

Individual chemokines may signal through more than one chemokine receptor, and individual receptors may interact with more than one chemokine, producing a complex set of chemokine/chemokine receptor pairs and providing opportunities for exceedingly fine regulation of cellular functions.

THE MAJOR HISTOCOMPATIBILITY COMPLEX AND ANTIGEN PRESENTATION (CHAPTERS 21 AND 22)

The MHC has already been introduced in this chapter in the discussion of T-cell recognition of antigen-derived peptides bound to specialized grooves in class I and class II MHC proteins. Indeed, the class I and class II MHC molecules are essential to the process of T-cell recognition and response. Nonetheless, they were first recognized not for this reason but because of the dominant role that MHC class I and class II proteins play in transplantation immunity (see Chapter 46).

When the genetic basis of transplantation rejection between mice of distinct inbred strains was sought, it was recognized that although multiple genetic regions contributed to the rejection process, one region played a dominant role. Differences at this region alone would cause prompt graft rejection, whereas any other individual difference usually resulted in a slow rejection of foreign tissue. For this reason, the genetic region responsible for prompt graft rejection was termed the *major* histocompatibility complex.

In all higher vertebrates that have been thoroughly studied, a comparable MHC exists. The defining features of the MHC are the transplantation antigens that it encodes. These are the class I and class II MHC molecules. The genes encoding these molecules show an unprecedented degree of polymorphism. This, together with their critical role in antigen presentation, explains their central role as the target of the immune responses leading to the rejection of organ and tissue allografts.

The MHC also includes other genes, particularly genes for certain complement components. In addition, genes for the cytokines TNF-α and lymphotoxin (also designated TNF-β) are found in the MHC.

Class I MHC Molecules (Chapter 21)

Class I MHC molecules are membrane glycoproteins expressed on most cells. They consist of an α chain of approximately 45,000 daltons noncovalently associated with α2-microglobulin, a 12,000-dalton molecule (Fig. 1.11). The gene for the α chain is encoded in the MHC, whereas that for β2-microglobulin is not. Both the α chain and β2-microglobulin are Ig supergene family members. The α chain is highly polymorphic, with the polymorphisms found mainly in the regions that constitute the binding sites for antigenderived peptides and that are contact sites for the TCR.

The class I α chain consists of three extracellular regions or domains, each of similar length, designated α1, α2, and α3. In addition, α chains have a membrane-spanning domain and a short carboxy-terminal cytoplasmic tail. The

crystal structure of class I molecules indicates that the α1 and α2 domains form a site for the binding of peptides derived from antigens. This site is defined by a floor consisting of β sheets and bounded by α-helical walls. The polymorphisms of the class I molecule are mainly in these areas.

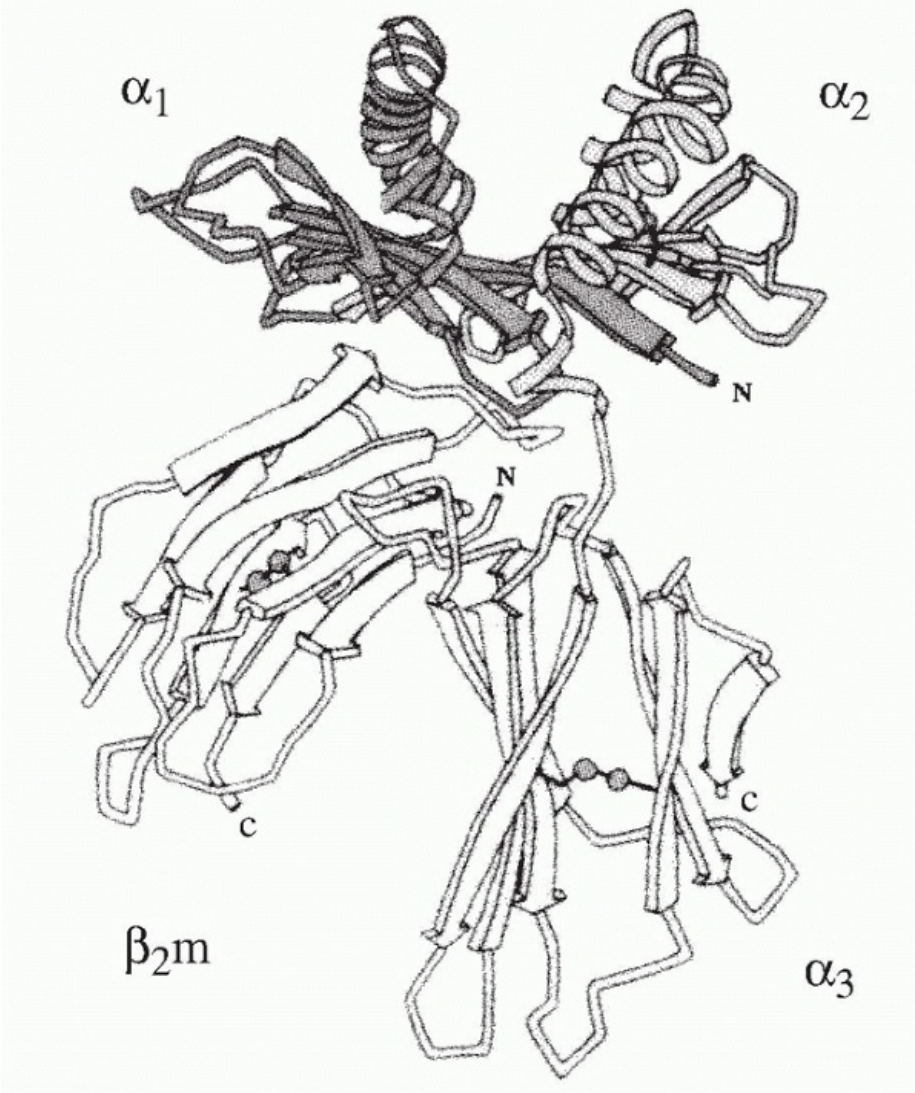

FIG. 1.11. Model of the Class I HLA-A2 Molecule. A schematic representation of the structure of the HLA-A2 class I major histocom-patibility complex (MHC) molecule. The polymorphic α1 and α2 domains are at the top. They form a groove into which antigen-derived peptides fit to form the peptide/MHC class I complex that is recognized by T-cell receptors of CD8 T cells. (Reprinted from Bjorkman PJ, Saper MA, Samraoui B, Bennett WS, Strominger JL, Wiley DC. Structure of the human class II histocompatibility antigen, HLA-A2. *Nature*. 1987;329:506-512).

In the human, three loci encoding classical class I molecules have been defined; these are designated human leukocyte antigen (HLA)-A, HLA-B, and HLA-C. All display high degrees of polymorphism. A similar situation exists in the mouse. In addition, there are a series of genes that encode class I-like molecules (class Ib molecules). Some of these have been shown to have antigen-presenting activity for formylated peptides, suggesting that they may be specialized to present certain prokaryotic antigens. The class Ib molecule CD1 has been shown to have antigen-presenting function for mycobacterial lipids, providing a mechanism through which T cells specific for such molecules can be generated. CD1d, presenting certain endogenous or exogenous phospholipids, is recognized by a novel class of T cells (NK T cells) that produce large amounts of cytokines upon immediate stimulation.

Class II MHC Molecules (Chapter 21)

Class II MHC molecules are heterodimeric membrane glycoproteins. Their constituent chains are designated α and β; both chains are immunoglobulin supergene family members, and both are encoded within the MHC. Each chain consists of two extracellular domains (α1 and α2; β1 and β2, respectively), a hydrophobic domain, and a short cytoplasmic segment. The overall conformation of class II MHC molecules appears to be quite similar to that of class I molecules. The peptide-binding site of the class II molecules is contributed to by the α1 and β1 domains (see Fig. 1.5); it is within these domains that the majority of the polymorphic residues of class II molecules are found.

A comparison of the three-dimensional structures of class I and class II molecules indicates certain distinctive features that explain differences in the length of peptides that the two types of MHC molecules can bind. Class I molecules generally bind peptides with a mean length of nine amino acids, whereas class II molecules can bind substantially larger peptides.

In the mouse, class II MHC molecules are encoded by genes within the I region of the MHC. These molecules are often referred to as I region-associated (Ia) antigens. Two sets of class II molecules exist, designated I-A and I-E, respectively. The α and β chains of the I-A molecules (Aα and Aβ) pair with one another, as do the α and β chains of I-E (Eα and Eβ).

In the human, there are three major sets of class II molecules, encoded in the DR, DQ, and DP regions of the HLA complex.

Class II molecules have a more restricted tissue distribution than class I molecules. Class II molecules are found on B cells, DCs, epidermal Langerhans cells, macrophages, thymic epithelial cells, and, in the human, activated T cells. Levels of class II molecule expression are regulated in many cell types by interferons and in B cells by IL-4. Indeed, interferons can cause expression of class II molecules on many cell types that normally lack these cell surface molecules. Interferons also can cause striking upregulation in the expression of class I MHC molecules. Thus, immunologically mediated inflammation may result in aberrant expression of class II MHC molecules and heightened expression of class I molecules. Such altered expression of MHC molecules can allow cells that do not normally function as APCs for CD4 T cells to do so and enhances the sensitivity of such cells to CD8 T cells. This has important consequences for immunopathologic responses and for autoimmunity.

Antigen Presentation (Chapter 22)

As already discussed, the function of class I and class II MHC molecules is to bind and present antigen-derived peptides to T cells whose receptors can recognize the peptide/MHC complex that is generated. There are two major types of antigen-processing pathways, specialized to deal with distinct classes of pathogens that the T cell system must confront (see Fig. 1.8).

Extracellular bacteria and extracellular proteins may enter APCs by endocytosis or phagocytosis. Their antigens and the antigens of bacteria that live within endosomes or lysosomes are fragmented in these organelles, and peptides derived from the antigen are loaded into class II MHC molecules as these proteins traverse the vesicular compartments in which the peptides are found. The loading of peptide is important in stabilizing the structure of the class II MHC molecule. The acidic pH of the compartments in which loading occurs facilitates the loading process. Once the peptide-loaded class II molecules reaches neutral

pH, such as at the cell surface, the peptide/MHC complex is stable. Peptide dissociation from such class II molecules is very slow, with a half-time measured in hours. The peptide/class II complex is recognized by those CD4 T cells that have complementary receptors. As already pointed out, the specialization of CD4 T cells to recognize peptide/class II complexes is partly due to the affinity of the CD4 molecule for monomorphic determinants on class II molecules. Obviously, this form of antigen processing can only apply to cells that express class II MHC molecules. Indeed, APCs for CD4 T cells principally include cells that normally express class II MHC molecules, namely DCs, B cells, and macrophages.

T cells also can recognize proteins that are produced within the cell that presents the antigen. The major pathogens recognized by this means are viruses and other obligate intracellular (nonendosomal/nonlysosomal) microbes that have infected cells. In addition, proteins that are unique to tumors, such as mutant oncogenes, or are overexpressed in tumors also can be recognized by T cells. Endogenously produced proteins are fragmented in the cytosol by proteases in the proteasome. The resultant peptides are transported into the rough endoplasmic reticulum through the action of a specialized transport system. These peptides are then available for loading into class I molecules. In contrast to the loading of class II molecules, which is facilitated by the acid pH of the loading environment, the loading of class I molecules is controlled by interaction of the class I α chain

with β2-microglobulin. Thus, the bond between peptide and class I molecule is generally weak in the absence of β2-microglobulin, and the binding of β2-microglobulin strikingly stabilizes the complex. (Similarly, the binding of β2-microglobulin to the α chain is markedly enhanced by the presence of peptide in the α chain groove.) The peptide-loaded class I molecule is then brought to the cell surface. In contrast to peptide-loaded class II molecules that are recognized by CD4 T cells, peptide-loaded class I molecules are recognized by CD8 T cells. This form of antigen processing and presentation can be performed by virtually all cells because, with a few exceptions, class I MHC molecules are universally expressed.

Although the specialization of class I molecules to bind and present endogenously produced peptides and of class II molecules to bind and present peptides derived from exogenous antigens is generally correct, there are exceptions, many of which have physiologic importance. Particularly important is the capacity of some DCs to load peptides from exogenous antigens into class I MHC molecules, allowing sensitization of CD8 T cells to the antigens of pathogens that infect cells other than DCs.

T-Lymphocyte Recognition of Peptide/MHC Complexes Results in MHC-Restricted Recognition (Chapter 11)

Before the biochemical nature of the interaction between antigen-derived peptides and MHC molecules was recognized, it was observed that T-cell responses displayed *MHC-restricted antigen recognition*. Thus, if individual animals were primed to a given antigen, their T cells would be able to recognize and respond to that antigen only if the APCs that presented the antigen shared MHC molecules with the animal that had been immunized. The antigen would not be recognized when presented by APCs of an allogeneic MHC type. This can now be explained by the fact that the TCR recognizes peptide bound to an MHC molecule. MHC molecules display high degrees of polymorphism, and this polymorphism is concentrated in the regions of the class I and class II molecules that interact with the peptide and that can bind to the TCR. Differences in structure of the MHC molecules derived from different

individuals (or different inbred strains of mice) profoundly affect the recognition process. Two obvious explanations exist to account for this. First, the structure of the grooves in different class I or class II MHC molecules may determine that a different range of peptides are bound or, even if the same peptide is bound, may change the conformation of the surface of the peptide presented to the TCR. Second, polymorphic sites on the walls of the α-helices that are exposed to the TCR can either enhance or diminish binding of the whole complex, depending on their structure. Thus, priming an individual with a given antigen on APCs that are syngeneic to the individual will elicit a response by T cells whose TCRs are specific for a complex consisting of a peptide derived from the antigen and the exposed polymorphic residues of the MHC molecule. When the same antigen is used with APCs of different MHC type, it is unlikely that the same peptide/MHC surface can be formed, and thus the primed T cells are not likely to bind and respond to such stimulation.

Indeed, this process also occurs within the thymus in the generation of the T-cell repertoire, as already discussed. T cells developing within the thymus undergo a positive selection event in which those T cells capable of recognizing MHC molecules displayed within the thymus are selected (and the remainder undergo programmed cell death). This leads to the skewing of the population of T cells that emerges from the thymus so that the cells are specialized to respond to peptides on self-MHC molecules. One of the unsolved enigmas of positive selection within the thymus is how the vast array of T cells with receptors capable of reacting with a very large set of foreign peptides associated with self-MHC molecules are chosen by self-MHC molecules that can only display self-peptides. It is believed that a high degree of cross-reactivity may exist so that T cells selected to bind a given class I (or class II) molecule plus a particular self-peptide can also bind a set of other (foreign) peptides bound to the same MHC molecule.

Furthermore, the affinity of an interaction required for positive selection in the thymus appears to be considerably lower that that required for full activation of peripheral T cells. Thus, thymocytes selected by a given self-peptide/self-MHC complex will generally not mount a full response when they encounter the same peptide/MHC complex in the periphery, although they will respond to a set of foreign peptide/MHC complexes to which they bind with higher affinity. Recognition of the self-peptide/self-MHC complex in the periphery nonetheless is important in sustaining the viability of resting T-lymphocytes.

Our modern understanding of T-cell recognition also aids in explaining the phenomenon of immune response gene control of specific responses. In many situations, the capacity to recognize simple antigens can be found in only some members of a species. In most such cases, the genes that determine the capacity to make these responses have been mapped to the MHC. Such immune response gene control of immune responses is based on the capacity of different class II MHC molecules (or class I MHC molecules) to bind different sets of peptides. Thus, for simple molecules, it is likely that peptides can be generated that are only capable of binding to some of the polymorphic MHC molecules of the species. Only individuals that possess those allelic forms of the MHC will be able to respond to those antigens. Based on this, some individuals are nonresponders because of the failure to generate a peptide/MHC molecule complex that can be recognized by the T-cell system.

This mechanism also may explain the linkage of MHC type with susceptibility to various diseases. Many diseases show a greater incidence in individuals of a given MHC type. These include reactive arthritides, gluten-sensitive enteropathy, insulin-dependent diabetes

mellitus, and rheumatoid arthritis (see Chapter 44). One explanation is that the MHC type that is associated with increased incidence may convey altered responsiveness to antigens of agents that cause or exacerbate the disease. Indeed, it appears that many of these diseases are due to enhanced or inappropriate immune responses.

Antigen-Presenting Cells (Chapter 16)

T cells recognize peptide/MHC complexes on the surface of other cells. Such cells are often referred to as APCs. Although

effector cells can mediate their functions by recognizing such complexes on virtually any cell type, naïve cells are most efficiently activated by a set of specialized APC, the DCs. DCs are a multimember family with distinctive locations and functions. Among them are the plasmacytoid DCs that are the principal source of type I interferons in viral infections.

In general, in their immature form, DCs are resident in the tissues where they are efficient at capturing and endocytosing antigen. Their antigen capture activity is dependent upon expression of several surface receptors including Fc receptors, receptors for heat shock proteins, and C-type lectins. If they receive signals, such as various inflammatory stimuli, often mediated by TLRs, they downregulate the expression of these molecules but increase their expression of surface MHC molecules and various costimualtory molecules such as CD80/86. In addition, such stimulation induces expression of chemokine receptors such as CCR2 and CCR7. The latter allow stimulated DCs to follow signals from the chemokines SLC and ELC, and to migrate into the T-cell zone of lymph nodes. As part of the maturation process, they may also acquire the capacity to produce cytokines and express surface molecules that can aid in determining the polarization of T-cell priming. This includes the production of IL-12, IL-23, IL-6, and IL-10, and the expression of inducible costimulator ligand and of Notch ligands. Interaction of naïve T cells with immature DCs may induce a state of peripheral tolerance.

EFFECTOR MECHANISMS OF IMMUNITY

The ultimate purpose of the immune system is to mount responses that protect the individual against infections with pathogenic microorganisms by eliminating these microbes or, where it is not possible to eliminate infection, to control their spread and virulence. In addition, the immune system may play an important role in the control of the development and spread of some malignant tumors. The responses that actually cause the destruction of the agents that initiate these pathogenic states (e.g., bacteria, viruses, parasites, tumor cells) are collectively the effector mechanisms of the immune system. Several have already been alluded to. Among them are the cytotoxic action of CTLs, which leads to the destruction of cells harboring viruses and, in some circumstances, expressing tumor antigens. In some cases, antibody can be directly protective by neutralizing determinants essential to a critical step through which the pathogen establishes or spreads an infectious process. However, in most cases, the immune system mobilizes powerful nonspecific mechanisms to mediate its effector function.

Effector Cells of the Immune Response

Among the cells that mediate important functions in the immune system are cells of the monocyte/macrophage lineage, NK cells, mast cells, basophils, eosinophils, and neutrophils.

It is beyond the scope of this introductory chapter to present an extended discussion of each of these important cell types. However, a brief mention of some of their actions will help in understanding their critical functions in the immune response.

Monocytes and Macrophages (Chapter 19)

Cells of the monocyte/macrophage lineage play a central role in immunity. One of the key goals of cellular immunity is to aid the macrophages in eliminating organisms that have established intracellular infections. In general, non-activated macrophages are inefficient in destroying intracellular microbes. However, the production of IFN-γ and other mediators by T cells can enhance the capacity of macrophages to eliminate such microorganisms. Several mechanisms exist for this purpose, including the development of reactive forms of oxygen, the development of nitric oxide, and the induction of a series of proteolytic enzymes, as well as the induction of cytokine production. Macrophages can act as APCs and thus can enlist the "help" of activated, cytokineproducing CD4+ T cells in regulating their function.

Although macrophages function as APCs for attracting activated T cells, they do not appear to be particularly effective in the activation of naïve CD4 T cells. In instances in which they are the site of infection or have phagocytosed infectious agents or their proteins, antigens from these agents may be transferred to DCs. In such cases, the DCs would be the principal APCs that activate naïve or possibly resting memory CD4 T cells. Such activated T cells would then be available to help infected macrophages.

Natural Killer Cells (Chapter 17)

NK cells play an important role in the immune system. Indeed, in mice that lack mature T and B cells due to the *scid* mutation, the NK system appears to be highly active and to provide these animals a substantial measure of protection against infection. NK cells are closely related to T cells. They lack conventional TCR (or Ig) but express two classes of receptors. They have a set of activating receptors that allow them to recognize features associated with virally infected cells or tumor cells. They also express receptors for MHC molecules that shut off their lytic activity. Thus, virally infected cells or tumor cells that escape the surveillance of cytotoxic T cells by downregulating or shutting off expression of MHC molecules then become targets for efficient killing by NK cells because the cytotoxic activity of the latter cells is no longer shut off by the recognition of particular alleles of MHC class I molecules.

In addition, NK cells express a receptor for the Fc portion of IgG (FcγRIII). Antibody-coated cells can be recognized by NK cells, and such cells can then be lysed. This process is referred to as antibody-dependent cellular cytotoxicity.

NK cells are efficient producers of IFN-γ. A variety of stimuli, including recognition of virally infected cells and tumor cells, cross-linkage of FcγRIII, and stimulation by the cytokines IL-12 and IL-18, cause striking induction of IFN-γ production by NK cells.

Mast Cells and Basophils (Chapters 20 and 45)

Mast cells and basophils play important roles in the induction of allergic inflammatory responses. They express cell surface receptors for the Fc portions of IgE (FcεRI) and for certain classes of IgG (FcγR). This enables them to bind antibody to

their surfaces, and when antigens capable of reacting with that antibody are introduced, the

resultant cross-linkage of FcεRI and/or FcγR results in the prompt release of a series of potent mediators such as histamine, serotonin, and a variety of enzymes that play critical roles in initiating allergic and anaphylactic-type responses. In addition, such stimulation also causes these cells to produce a set of cytokines, including IL-3, IL-4, IL-13, IL-5, IL-6, granulocyte-macrophage colony-stimulating factor, and TNFα, that have important late consequences in allergic inflammatory responses.

Granulocytes (Chapter 20)

Granulocytes have critical roles to play in a wide range of inflammatory situations. Rather than attempting an extended discussion of these potent cells, it may be sufficient to say that in their absence it is exceedingly difficult to clear infections with extracellular bacteria and that the immune response plays an important role in orchestrating the growth, differentiation, and mobilization of these crucial cells. Recent work indicates that T_{H17} cells are particularly important because of their role in recruiting granulocytes to sites of immune responses.

Eosinophils (Chapters 20 and 45)

Eosinophils are bone marrow-derived myeloid cells that complete their late differentiation under the influence of IL-5. They migrate to tissue sites in response to the chemokine eotaxin and as a result of their adhesion receptors. Because T_{H2} cells can produce IL-5 and stimulate the production of eotaxin, eosinophil accumulation is often associated with T_{H2}-mediated inflammation. Eosinophils store a series of proteins in their secondary granules including major basic protein, eosinophil cationic protein, and eosionphil peroxidase. When released, these proteins are responsible for much of the damage that eosinophils mediate both to helminthic parasites and to the epithelium. Eosinophils have been implicated as important in protective responses to helminths and in the tissue damage seen in allergic inflammation in conditions such as asthma.

The Complement System (Chapter 36)

The complement system is a complex system of proteolytic enzymes, regulatory and inflammatory proteins and peptides, cell surface receptors, and proteins capable of causing the lysis of cells. The system can be thought of as consisting of three arrays of proteins. Two of these sets of proteins, when engaged, lead to the activation of the third component of complement (C3) (Fig. 1.12). The activation of C3 releases proteins that are critical for opsonization (preparation for phagocytosis) of bacteria and other particles, and engages the third set of proteins that insert into biologic membranes and produce cell death through osmotic lysis. In addition, fragments generated from some of the complement components (e.g., C3a and C5a) have potent inflammatory activities.

The Classical Pathway of Complement Activation

The two activation systems for C3 are referred to as the classical pathway and the alternative pathway. The classical pathway is initiated by the formation of complexes of antigen with IgM or IgG antibody. This leads to the binding of the first component of complement, C1, and its activation, creating the C1 esterase that can cleave the next two components of the complement system, C4 and C2.

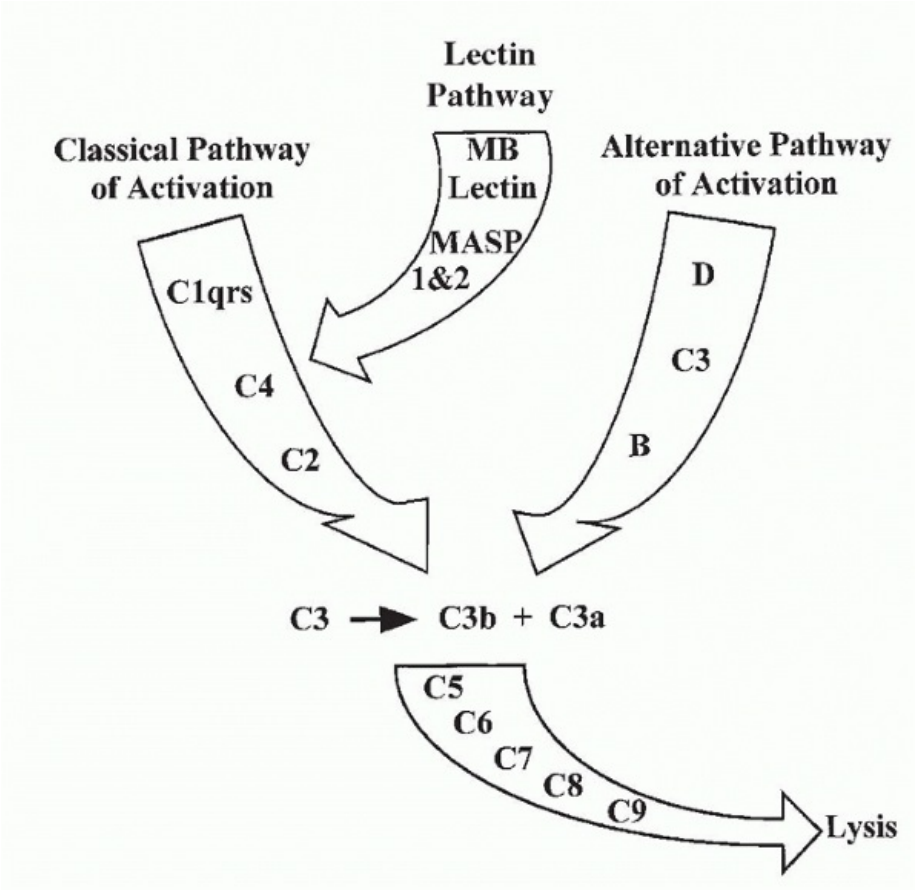

FIG. 1.12. The Complement System. The classical pathway of complement activation, usually initiated by the aggregation of C1 by binding to antigen/antibody complexes, resulting in the formation of an enzyme, a C3 convertase, that cleaves C3 into two fragments, C3b and C3a. The classical pathway can also be initiated by the aggregation of mannan-binding lectin as a result of binding sugars expressed in the capsules of many pathogenic microbes. The components of the lectin pathway appear to mimic the function of C1qrs. The alternative pathway of complement activation provides a potent means of activating complement without requiring antibody recognition of antigen. It results in the formation of a distinct C3 convertase. The fragments formed by cleaving C3 have important biologic activities. In addition, C3b, together with elements of the classical pathway (C4b, C2a) or the alternative pathway (Bb, properdin), form enzymes (C5 convertases) that cleave C5, the initial member of the terminal family of proteins. Cleavage of C5 leads to the formation of the membrane attack complex that can result in the osmotic lysis of cells.

C4 is a trimeric molecule, consisting of α, β, and γ chains. C1 esterase cleaves the α chain, releasing C4b, which binds to surfaces in the immediate vicinity of the antigen/antibody/C1 esterase complex. A single C1 esterase molecule will cause the deposition of multiple C4b molecules.

C2 is a single polypeptide chain that binds to C4b and is then proteolytically cleaved by C1 esterase, releasing C2b. The resulting complex of the residual portion of C2 (C2a) with C4b (C4b2a) is a serine protease whose substrate is C3. Cleavage of C3 by C4b2a (also referred to as the classical pathway C3 convertase) results in the release of C3a and C3b. A single

antigen/antibody complex and its associated C1 esterase can lead to the production of a large number of C3 convertases (i.e., C4b2a complexes) and thus to cleavage of a large number of C3 molecules.

The components of the classical pathway can be activated by a distinct, non-antibody-dependent mechanism, termed the lectin pathway. The mannose-binding lectin (MBL) is

activated by binding to (and being cross-linked by) repetitive sugar residues such as N-acetylglucosamine or mannose. The activation of MBL recruits the MBL-associated serine proteases MASP-1 and MASP-2, which cleave C4 and C2 and lead to the formation of the classical pathway C3 convertase. Because the capsules of several pathogenic microbes can be bound by MBL, the lectin pathway provides an antibody-independent mechanism through which the complement system can be activated by foreign microorganisms.

The Alternative Pathway of Complement Activation

Although discovered more recently, the alternative pathway is the evolutionarily more ancient system of complement activation. Indeed, it, and the MBL activation of the classical pathway, can be regarded as important components of the innate immune system. The alternative pathway can be activated by a variety of agents such as insoluble yeast cell wall preparations and bacterial lipopolysaccharide. Antigen/antibody complexes also can activate the alternative pathway. The C3 convertase of the alternative pathway consists of a complex of C3b (itself a product of cleavage of C3) bound to the b fragment of the molecule factor B. C3bBb is produced by the action of the hydrolytic enzyme, factor D, that cleaves factor B; this cleavage only occurs when factor B has been bound by C3b.

Apart from the importance of the alternative pathway in activating the complement system in response to nonspecific stimulants, it also can act to amplify the activity of the classical pathway because the C3 convertase of the classical system (C4b2a) provides a source of C3b that can strikingly enhance formation of the alternative pathway convertase (C3bBb) in the presence of factor D.

The Terminal Components of the Complement System

C3b, formed from C3 by the action of the C3 convertases, possesses an internal thioester bond that can be cleaved to form a free sulfhydryl group. The latter can form a covalent bond with a variety of surface structures. C3b is recognized by receptors on various types of cells, including macrophages and B cells. The binding of C3b to antibody-coated bacteria is often an essential step for the phagocytosis of these microbes by macrophages.

C3b is also essential to the engagement of the terminal components of the complement system (C5 through C9) to form the membrane attack complex that causes cellular lysis. This process is initiated by the cleavage of C5, a 200,000-dalton two-chain molecule. The C5 convertases that catalyze this reaction are C4b2a3b (the classical pathway C5 convertase) or a complex of C3bBb with a protein designated properdin (the alternative pathway C5 convertase). Cleaved C5, C5b, forms a complex with C6 and then with C7, C8, and C9. This C5b/C9 complex behaves as an integral membrane protein that is responsible for the formation of complement-induced lesions in cell membranes. Such lesions have a donut-like appearance, with C9 molecules forming the ring of the donut.

In addition to the role of the complement system in opsonization and in cell lysis, several of

the fragments of complement components formed during activation are potent mediators of inflammation. C3a, the 9,000-dalton fragment released by the action of the C3 convertases, binds to receptors on mast cells and basophils, resulting in the release of histamine and other mediators of anaphylaxis. C3a is thus termed an anaphylotoxin, as is C5a, the 11,000-dalton fragment released as a result of the action of the C5 convertases. C5a is also a chemoattractant for neutrophils and monocytes.

Finally, it is important to note that the process of activation of the complement cascade is highly regulated. Several regulatory proteins (e.g., C1 esterase inhibitor, decay accelerator factor, membrane cofactor protein) exist that function to prevent uncontrolled complement activation. Abnormalities in these regulatory proteins are often associated with clinical disorders such as hereditary angioedema and paroxysmal nocturnal hemoglobinuria.

CONCLUSION

This introductory chapter should provide the reader with an appreciation of the overall organization of the immune system and of the properties of its key cellular and molecular components. It should be obvious that the immune system is highly complex, that it is capable of a wide range of effector functions, and that its activities are subject to potent, but only partially understood, regulatory processes. As the most versatile and powerful defense of higher organisms, the immune system may provide the key to the development of effective means to treat and prevent a broad range of diseases. Indeed, the last two sections of this book deal with immunity to infectious agents and immunologic mechanisms in disease. The introductory material provided here should be of aid to the uninitiated reader in understanding the immunologic mechanisms brought into play in a wide range of clinical conditions in which immune processes play a major role either in pathogenesis or in recovery.

Chapter 2

History of Immunology

Steven Greenberg

INTRODUCTION

There comes a time during every argument at which the two opposing parties reach a critical juncture: either resolution or impasse. Variations on this essentially Socratic theme have played out in all spheres of human intellectual activity. The dialectic of science ranges from incremental and relatively harmonious shifts in key, to a few abruptly dissonant ones, taking the form of what Thomas Kuhn would refer to as "paradigm shifts."[1] Such is the case with immunology, a field distinguished by more than its fair share of paradigm shifts. Arguably, its first dialectic, between the "cellularists" and the "humoralists," did not result in an early synthesis, but was characterized by partisan and often entrenched positions. Ultimately, the two parallel paths of cellular and chemical immunology converged, but it was not until the latter half of the 20th century that the two paths became one. How the paths were forged in the first place was an amalgam of the cultural institutions of the time, the creative output of the scientists themselves, and the imperatives of devising effective strategies to combat infection and contagion.

ANTECEDENTS TO THE GERM THEORY OF DISEASE

Ancient Theories of Disease Causation

Religious beliefs in ancient Greece drew contrasts between the sacred or the pure (*katharos*) and the polluted (*miaros*).[2] Pollution, or *miasma*, was blamed for many ancient transgressions, from the petty and personal, to the gravest, most famously embodied in the Oedipus myth. To remove the stain of *miasma*, the transgressor must undergo rites of purification (*catharsis*). To the ancient Greeks in the age of Homer, these were deeply ingrained beliefs that were essentially religious in nature. Because *miasma* was viewed as a source of suffering, it is not surprising that *miasma* was implicated in disease, as described by Hippocrates in his treatise "On Air, Water, and Places" in which *miasma* was associated with "unhealthy vapors."[3,4] Hippocrates is credited with being the first to recognize the potential of disease to arise from the environment and not as a result of religious superstition. *Mal aria*, which is Old Italian for "bad air," was one of many diseases thought to be caused by *miasma*. The concept that *miasma* was the source of disease persisted through the millennia and was a leading theory of how contagious diseases were transmitted up until the time of Pasteur.

Much of what we know about the medicine of ancient Greece is codified in *The Hippocratic*

Corpus, a collection of more than 60 volumes of text. Its authorship is disputed, but it is generally recognized as a compilation of works by Hippocrates himself as well as his students and intellectual heirs. One of his students, as well as son-in-law, Polybus, was credited as the author of *De Natura Hominis* (*On the Nature of Man*), the earliest known text describing the ancient Greek conceptual basis for disease pathogenesis, as embodied in the four humors: black bile, yellow bile, phlegm, and blood.[5]

> The body of man has in itself blood, phlegm, yellow bile and black bile; these make up the nature of his body, although these he feels pain or enjoys health. Now he enjoys the most perfect health when these elements are duly proportioned to one another in respect of compounding, power and bulk, and when they are perfectly mingled. Pain is felt when one of these elements is in defect or excess, or is isolated in the body without being compounded with all the others.

The Greek view that disease arose from an imbalance of the four humors did not supersede the *miasma* theory of disease, but was rather a more general view of disease causation, compared with the subset of apparently communicable diseases best explained by *miasma*.

The Romans developed and refined Greek concepts of disease. Marcus Terentius Varro (116 to 27 bce), referred to as “the most learned of all Romans” by the Roman rhetorician Quintilian,[6] was a prolific Roman scholar, estimated to have written more than 600 volumes. During the civil war of the first century, he served as Pompey's legate in Spain and fought at Pharsalus against Caesar but ultimately reconciled with Caesar, who appointed him director of the public library in 47 bce. Varro is perhaps best known for his only complete extant work, *Rerum Rusticarum Libri Tres* (*On Agricultural Topics*), in which he so presciently anticipated the existence of disease-causing microbes that seemed to Varro to be the immediate cause of diseases[7]:

> Precautions must also be taken in the neighbourhood of swamps, both for the reasons given, and because there are bred certain minute creatures which cannot be seen by the eyes, which float in the air and enter the body through the mouth and nose and there cause serious diseases.

Thus, Varro provided a mechanistic basis for disease that was consistent with the prevailing belief of *miasma* as the source of illness.

The Greek medical tradition was carried on for generations and was ultimately passed on to Claudius Galinus

(Galen), the Greek expatriate who was its greatest explicator. Galen was born in Pergamum in Asia Minor in 130 ce. After beginning his medical training in Pergamum at the behest of his father, he traveled widely in pursuit of “postgraduate” medical training in Smyrna, Corinth, and Alexandria. He returned to Pergamum and practiced surgery on gladiators, which provided a unique opportunity to deepen his knowledge of human anatomy and perfect his surgical technique.[8] Following an outbreak of plague among the Roman troops in Aquileia in

168 ce, he was summoned by the Emperor Marcus Aurelius and was appointed personal physician to his son, Commodus.[8] Galen's view of medicine was based on Hippocrates' *Corpus*. His output was prodigious more than any other ancient author of medical texts. He distinguished symptoms from diseases and offered explanations of the former that were consistent with his interpretations of disease pathogenesis; thus, tertian fever was the result of an "imbalance of yellow bile," quartan was caused by "too much black bile," and quotidian by "an excess of phlegm." Vomiting was viewed as the body's attempt to expel poisons, and the prescription of bleeding was to rid the body of "corrupt humors."[9] Galen's view of medicine remained the dominant one until the 17th century.

Early Concepts of Immunity

The term "immunity" itself is derived from the Latin practice of "exemption" from taxes or public service that normal citizens had to discharge, a favor bestowed by the emperor to meritorious individuals or entire communities.[10] However, the concept of immunity dates back at least as far as Thucydides, who described the plague of Athens of 430 bce that was responsible for the death of more than a quarter of the Athenian population[11]:

> Yet it was with those who had recovered from the disease that the sick and the dying found most compassion. These knew what I had from experience and had now no fear for themselves; the same man was never attacked twice-never at least fatally.

The traditional, religious view of the plague was that it is the work of Apollo who was held responsible for earlier plagues (eg, the plague on the Greek army in Troy because the Greek general Agamemnon abducted the daughter of Apollo's priest, Chryses). The religiously inclined could take some refuge in appealing to Apollo's son, Asklepios, who was revered as the god of healing, as were his daughters Hygeia (Hygiene), Iaso (Remedy), Akæso (Healing), Aglæa (Healthy glow), and Panakeia (Cure-all). In contrast, Thucydides characteristically did not offer facile religious explanations for sickness or recovery. In fact, he described the futility of the Athenians' plight in stark terms[11]:

> Neither the fear of the gods nor laws of men awed any man, not the former because they concluded it was alike to worship or not worship from seeing that alike they all perished, nor the latter because no man expected that lives would last till he received punishment of his crimes by judgment.

It seemed inevitable that in seeking an explanation for why some developed disease and others did not, many others would rely on a moralistic or religious view. In a remarkable passage from Galen's *On the Different Types of Fever* , not only does he set forth an explanation of how disease is transmitted through the air, and using the same term as Fracastoro would, "seeds," some 1300 years later, but he also blames a licentious lifestyle for susceptibility to the plague:

> Suppose, for example, that the circumambient air carries certain seeds

> of plague, and that of the bodies which share [breathe] it, some are full of various residues which are soon to become putrefied in themselves, while others are clean and free of such residues. Assume also that in the former there is a general blockage of their pores, a so-called plethora, and a life of ease devoted to gluttony, drink and sex, with all their necessarily concomitant digestive disorders. The others, which are clean and lack these residues, as well as being fine in themselves, have all a wholesome transpiration through pores that are neither blocked nor constricted; they take appropriate exercise and lead a temperate life. Assuming all this, which of these bodies is most likely to be affected by the rotting air they inspire?

This passage has been analyzed extensively by Nutton, who questioned the extent to which "seed" is used metaphorically[12]; if so, it is particularly apt.

Religious explanations for disease and immunity persisted throughout history. Particularly during the growth of Christianity during the Middle Ages, disease and sin were linked, though not inextricably; the great theologian Thomas Aquinas provided this distinction between sin and other causes of diseases[13]:

> … we need to consider that sin consists of a disorder of the soul, just as physical disease consists of a disorder of the body. And so sin is a disease of the soul, as it were, and pardon is for sin what healing is for disease.

Yet for many, a disease as dire as the plague would continue to be viewed as divine retribution for sin; for others, it was the result of astrological phenomena, while for still others, it was the result of a "conspiracy plotted by Jews to poison wells."[14] With the exception of the latter, which at least offered a proximate physical cause of disease, regardless of the lack of evidence, there was an abstract quality to these explanations that were shrouded in belief and superstition but lacking in substance. Further theories of disease pathogenesis would have to await the 16th century.

Fracastoro's Seeds

Girolamo Fracastoro (1478 to 1553) was an Italian who would have met most definitions of a Renaissance scholar: an accomplished physician, poet, mathematician, botanist, and astronomer. Educated by his father in Verona, and later at the University of Padua, he became an instructor in logic at the University of Padua in 1501 and in anatomy in 1502. He left Padua in 1508 and returned to Verona, where he

dedicated himself to his studies and his medical practice. In 1546, he proposed that disease was caused by *seminaria* ("seeds") that could be transmitted by three ways: direct contact from one person to another; through "fomites," or articles of clothing or dirty linen; and through the air. Although Nutton[12] has pointed out that Galen and Lucretius also used the term "seeds" to describe the transmission of illness through the air (see previous discussion), Fracastoro was the first to make them the focal point for disease transmission and to describe

their predilection for certain organs. Like the 10th century Arab physician Rhazes, who believed smallpox to have an affinity for blood, and specifically for the traces of menstrual blood that were believed to taint everyone in utero, as later suggested by Avicenna, Fracastoro offered the following explanation for immunity to smallpox: Following infection by smallpox seminaria, the menstrual blood would putrefy, rise to the surface, and force its way out via the smallpox pustules.[15] "Hence when this process has taken place, the malady usually does not recur because the infection has already been secreted in the previous attack."

Fracastoro's *seminaria* theory remained influential for nearly three centuries, in many ways serving as an early template for the germ theory of disease.

THE GERM THEORY OF DISEASE AND DEVELOPMENT OF VACCINES

Until the mid-19th century, the Galenic view of disease origins was the dominant one. Not only was the etiology of diseases misunderstood but also was the origin of life itself. The theory of spontaneous generation, which arose from Aristotle, held that life originated spontaneously from inanimate matter. The first experimental evidence against spontaneous generation came from Franceso Redi, the head physician in the Medici court, who in 1668 provided early evidence against the theory.[16*] Nevertheless, no overarching theory was proposed to replace it. Neither the mindset nor the necessary technology were available until the latter part of the 17th century, when an apprentice in a dry goods store, Anton van Leeuwenhoek, began a lifelong obsession with grinding the perfect lens. Leeuwenhoek's lenses were tiny but were ground with high degree of curvature, enabling him to visualize the hitherto undiscovered word of microbes. On September 17, 1683, Leeuwenhoek wrote a letter to the Royal Society, which was the first description of living, motile bacteria obtained from the plaque of his own teeth.[17] Leeuwenhoek was not the first to build a microscope (which was used by, among others, Redi), but his was far superior to existing multilensed or compound microscopes. Other scientists of the time, notably Robert Hooke, also observed microorganisms, and it was Hooke who was the first to publish the first image of a microorganism (the fungus *Mucor*) in 1665.[18] Some 150 years later, Dutrochet and then later Schwann, Schleiden, and Virchow, taking advantage of the microscopes of the their time, advanced the concept that "all living things are composed of cells and cell products."[19] Virchow took this one step further by declaring *omnis cellula e cellula* or "all cells develop only from existing cells." Whether Virchow rejected the germ theory or not is a matter of debate, but it is more likely that Virchow's underlying emphasis was not on external causes, but disease mechanisms, as he wrote in 1885: "First the discovery of the parasite, then the investigation of its etiology, then the question: how does it give rise to the disease."[20] Although it is hard to escape the possibility that a certain degree of professional jealousy may have played a role in Virchow's refusal to embrace the germ theory of disease, his viewpoint is one of but many examples of apparently strict dichotomies in science that would ultimately undergo revision and later synthesis. This is a theme that was to be recapitulated many times in the history of immunology.

The Conceptual Basis for the Germ Theory of Disease

Between Leeuwenhoek's technical breakthroughs in lens design in the late 17th century and the work of Pasteur and Koch in the late 19th century, several individuals endorsed

Fracastoro's “seed” theory, which gained new relevance when bacteria were first visualized. Among these was Jacob Henle, a German pathologist who was later to become Koch's teacher. Henle wrote a treatise that not only laid out the germ theory of disease in great detail but also arguably articulated an early version of what would later be known as “Koch's postulates”[21]: “Before microscopic forms can be regarded as the cause of contagion in man, they must be constantly found in contagious material. They must be isolated from it and their strength tested.” However, Henle's essay was a theoretical one and Henle himself never provided any experimental evidence in support of it. In the same year, decades before Pasteur and Koch would even begin to describe the germ theory of disease, Henry Holland, a Scottish-trained physician to Queen Caroline, who traveled extensively and was acquainted with the scientific luminaries of the time, including Davie, Gay Lussac, Berthollet, and Laplace, wrote a treatise in which he stated,[22]

> The question is, what weight we may attach to the opinion that certain diseases, and especially some of epidemic and contagious kind, are derived from minute forms of animal life, existing in the atmosphere under particular circumstances; and capable, by application to the lining membranes or other parts, of acting as a virus on the human body.

In a footnote, he cited others, including Kircher, and particularly Johannes Nyander, who wrote nearly a century earlier[23]:

> … it may be an easy matter for very minute insects to be the causes of diverse contagious diseases,” of which he included plague, measles, smallpox, and syphilis.

Nyander himself credits Lynceus Leuwenhoekius (“lynx-eyed” or “keen-eyed” Leuwenhoek) as the first to have seen such

“animalcules.” Thus, it is fair to say that the germ theory of disease itself had been “germinating” for some time prior to its scientific proof by Pasteur and Koch.

Experimental Evidence for the Germ Theory of Disease

The honor of the first experimental demonstration for the germ theory of disease may belong to two students of Francesco Redi. In 1687, soon after Redi had offered proof against spontaneous generation, two of his students, Bonomo and Cestoni, went on to observe the causative agent of scabies using the newly developed microscope and were able to transfer disease from person to person.[24] Perhaps the first demonstration of the bacterial pathogenesis of diseases in animals and humans was by Casimir Davaine, a French scientist who provided essentially the same evidence that Pasteur and Koch would years later that anthrax was caused by *bacteridies*. In 1865, Davaine was awarded the Prix Bréant by the Académie des Science for his work.[25]

Davaine's compatriot, Louis Pasteur, was the consummate experimentalist. A chemist by

training, his interest in infectious disease began with his study of fermentation. He made important contributions to the science of fermentation and his work led to many practical benefits to the beer and wine industry of France. His interest in microbes began with his speculation that the same type of microbe required for fermentation was likely responsible for transmitting disease. In 1865, he was asked to investigate a disease called pébrine that affected the silk worm industry. Within a year, Pasteur had established that pébrine was caused by a microbe, which provided further proof for the germ theory of disease. Some 14 years later, his expertise was again sought out of economic interests, in this case by farmers whose poultry stocks were diminished by chicken cholera. In a famous example of scientific serendipity, his assistant, Charles Chamberland, failed to inoculate chickens with cultures of chicken cholera bacilli, as instructed by Pasteur, but instead went on vacation. Upon returning several weeks later, he inoculated chickens with the old bacterial cultures, but the chickens didn't die as expected. Rather than disregard the experiment as a failure, “chance had favored the prepared mind” of Pasteur, who had his assistants inject fresh cholera into the same hens that had previously been injected; now none of the hens became ill. Pasteur had surmised that the bacterial cultures had become weakened by extended culture.[26] Thus began the use of attenuated strains of microbes to immunize against disease,[27] and the birth of the science of vaccination. The term “vaccine,” derived from the Latin *vaccus* for cow, was, coined by Pasteur in honor of Jenner. Attenuation as a strategy of developing vaccines would prove to be enormously valuable, leading to development of the first rabies vaccine by Pasteur himself, a vaccine against the viral causative agent of yellow fever by Theiler,[28] and the Bacillus Calmette-Guérin vaccine at Pasteur's institute.[29]

Although Robert Koch is credited as the originator of “Koch's Postulates,” it may come as a surprise that the essence of the postulates were first formulated by Koch's teacher, Jacob Henle (see previous discussion) and his contemporary, Edwin Klebs.[30] However, neither Henle nor Klebs applied their theories to any practical benefit, which is why Koch received credit for the postulates. Koch was the first to articulate then systematically apply them to prove that *Bacillus anthracis* was the causative agent of anthrax. Koch was a country physician living in Prussia, whose scientific career began unceremoniously with a gift of a microscope from his wife.[31] His first series of investigations began with observing the blood of a dead cow that succumbed to anthrax. Confirming the observation of Davaine and others before him, he observed filamentous bacteria in the blood. Not content merely with the observation, he began a series of technically challenging experiments, necessitating the development of many novel techniques used in microbiology laboratories even today, such as the use of solid medium to grow individual clones or colonies of bacteria. He proved that the filamentous bacteria were present only in infected animals and were capable of reproducing the disease when injected into healthy animals. This was the first systematic application of the eponymous postulates, which has since become the *sine qua non* of disease causation by infectious agents. His work was published in 1876,[32] the first of many groundbreaking publications. Koch's most profoundly important contribution to medicine was the discovery of the causative agent of tuberculosis. The lecture at which he announced his findings, on March 24, 1882, described later by Ehrlich as “the most important experience of his scientific life,” is considered by many to be the single most important lecture in medical history. Koch described the invention of novel staining methods to detect the tubercle bacillus and presented tissue dissections from guinea pigs that were infected with tuberculous material

from the lungs of infected apes and humans who had died from the disease.[33] For “his investigations and discoveries in regard to tuberculosis,” Koch was awarded the Nobel Prize in 1905.

The Unhealthy Rivalry Between Pasteur and Koch, and its Lasting Effects

The Franco-Prusssian war of 1870, the culmination of years of tension between France and Prussia, resulted in a Prussian victory and unity among the German states under King Wilhelm of Prussia. The Treaty of Frankfurt left a unified Germany the city of Strasbourg as well as possession of Alsace and the northern part of Lorraine, which was thought to contribute to further resentment of the Germans by the French and public support for World War I. It is against this backdrop that the relationship between Pasteur and Koch must be viewed. Koch had served in the Prussian army, and Pasteur's son was a conscript fighting for the French. Furthermore, there was intense professional rivalry between the two, especially over their work on anthrax pathogenesis. According to a letter from Charles Ruel, former *privat docent* at the University of Geneva, Koch was in the audience when Pasteur spoke on attenuation and vaccination at the fourth International Congress of Hygiene and Demography held in Geneva in September 1882. Pasteur spoke repeatedly about

German collected works (*recueil Allemand*). According to the letter[34]:

> Koch and his friend Prof. Lichtheim, were sitting side by side; they knew French only imperfectly and both mistook the word pride (orgueil) for collection (recueil). They felt their self-respect profoundly wounded and interpreted the words German pride as a grave insult.

This is but one ironic example of the level of rancor and misunderstanding between the two great men. It is said that Pasteur and Koch underwent some form of reconciliation later in their lives. Regardless, the aftermath of their rivalry, in many ways personifying the bitter relations between France and Germany, had a lasting effect on the evolution of the nascent field of immunology. In the years to come, the intellectual heirs of Pasteur and Koch would reenact the lifelong competitive tensions that characterized their relationship.

The Germ Theory of Disease: A Summation

In many ways, the “germ theory of disease” really did not begin with Pasteur and Koch, but rather by their predecessors, Henle, Klebs, and Davaine, who in turn owed credit to Fracastoro, and ultimately to Galen and Varro, some 1,600 years earlier. What enabled Pasteur and Koch to firmly establish the germ theory of disease began as a thought process that over time became distilled to something tangible: First, the idea that invisible “seeds” might propagate disease; second, the advent of an optically superior microscope, by Leuwenhoek, which enabled scientists their first glimpses at the “minute creatures” postulated by Varro; third, the growing evidence against spontaneous generation that began with Redi, thus opening the door for a new theory of disease; and finally, the inductive genius and careful experimental techniques of Pasteur and Koch.

The Long History of Vaccination: Success and the Unprepared Mind

Vaccination did not originate with Pasteur; its practice had been carried out for centuries without any fundamental understanding of its basis. Probably the earliest recorded example of intentionally inducing immunity to an infectious disease was in the 10th century in China, where smallpox was endemic.[35] The process of "variolation" involved exposing healthy people to material from the lesions caused by the disease, either by putting it under the skin, or, more often, inserting powdered scabs from smallpox pustules into the nose. Variolation was known and practiced frequently in the Ottoman Empire, where it had been introduced by Circassian traders in the 17th century.[35] Unfortunately, because there was no standardization of the inoculum, variolation occasionally resulted in death or disfigurement from smallpox, thus limiting its acceptance. Variolation later became popular in England, mainly due to the efforts of Lady Mary Wortley Montague. Lady Montague was the wife of the British ambassador to the Ottoman court who herself had contracted a severe case of smallpox. While in Istanbul, Lady Montague observed the practice of variolation. Determined not to have her family suffer as she had, she directed the surgeon of the embassy to learn the technique and, in March 1718, to variolate her 5-year-old son. After her return to England, she promoted the technique and had her surgeon variolate her 4-year-old daughter in the presence of the king's physician. The surgeon, Charles Maitland, was given leave to perform what came to be known as the "Royal Experiment," in which he variolated six condemned prisoners who later survived. By these and other experiments, the safety of the procedure was established, and two of the king's grandchildren were variolated on April 17, 1722. After this, the practice of variolation spread rapidly throughout England in the 1740s and then to the American colonies.[35,36]

It is difficult to say what influence the English country physician Edward Jenner (1749 to 1823) had on Pasteur's later discovery of attenuation of bacterial cultures and its application to vaccination. Regardless, it is fair to say that Jenner had a major influence on public health, as he was the first to publish the development and use of a safe alternative to variolation.[37] Although Jenner is rightly celebrated for his development of cowpox as a safe vaccine for smallpox, he was not the first to make use of a relatively nonpathogenic virus to induce immunity. Twenty years earlier, Benjamin Jesty, an English farmer, inoculated his wife and two sons with material taken from the cowpox lesion of the udder of a cow in his neighbor's herd.[36] In 1796, Jenner inoculated James Phipps, an 8-year-old boy, with material obtained from a cowpox lesion that appeared on the hand of a dairymaid (Fig. 2.1). Six weeks later, he inoculated the experimental subject with smallpox without producing disease. Further studies by Jenner established the efficacy of his vaccination procedure. For this feat, Jenner received a cash prize of £30,000 and election to nearly all of the learned societies throughout Europe.[38]

EMERGENCE OF IMMUNOLOGY AS A DISCIPLINE

The Cellularists versus the Humoralists

The international renown of Pasteur and Koch led to the establishment of research institutes that bore their names. Many talented young scientists were drawn to these institutes whose research missions should have been complementary, but were not, and the partisan battle that began with Pasteur and Koch would soon be reenacted on a larger scale.

Metchnikoff and the Birth of Cellular Immunology

Elie Metchnikoff (1845 to 1916), an ambitious student at the University of Kharkoff ("I have zeal and ability, I am naturally talented—I am ambitious to become a distinguished investigator"),[31] borrowed a professor's microscope and began a lifelong quest to understand the cellular basis for immunity. A comparative zoologist by training, his early academic focus was on understanding the development of metazoans. Heavily influenced by Darwin's publication of *The Origin of Species* in 1859,[39] he viewed early embryologic development as a competition among specialized cell

types.[40] Ontogeny was seen as a set of "interactions of cell lineages with each other to limit self-replication by any one component in favour of the interests of the organism as a whole. "[40] He focused his interest on an amoeboid marker cell of the mesoderm, which was dubbed "phagocyte" (devouring cell) by a contemporary of Metchnikoff's, the Viennese zoologist, Carl Claus. In a justly famous passage from Olga Metchnikoff's biography of her husband, she describes the observation that became the defining moment of his scientific career[41]:

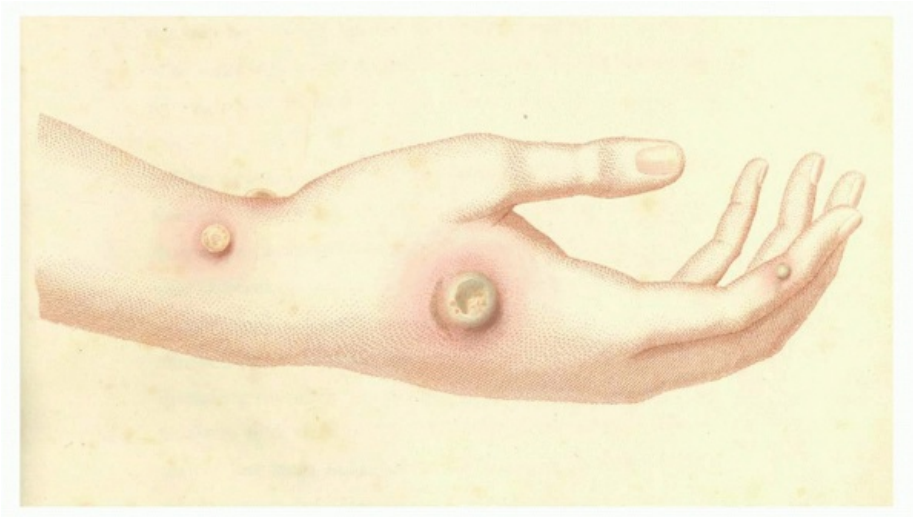

FIG. 2.1. Cowpox Pustule on the Arm of Sarah Nelmes. Reprinted with permission from Jenner37; courtesy of Dr Jenner's House: Birthplace of Vaccination, Gloucestershire, UK.

> One day when the whole family had gone to a circus to see some extraordinary performing apes, I remained alone with my microscope, observing the life in the mobile cells of a transparent star-fish larva, when a new thought suddenly flashed across my brain. It struck me that similar cells might serve in the defense of the organism against intruders. Feeling that there was in this something of surpassing interest, I felt so excited that I began striding up and down the room and even went to the seashore in order to collect my thoughts. I said to myself that, if my supposition was true, a splinter introduced into the

> body of a star-fish larva, devoid of blood-vessels or of a nervous system, should soon be surrounded by mobile cells as is to be observed in a man who runs a splinter into his finger. This was no sooner said than done. There was a small garden to our dwelling, in which we had a few days previously organised a “Christmas tree” for the children on a little tangerine tree; I fetched from it a few rose thorns and introduced them at once under the skin of some beautiful star-fish larvae as transparent as water. I was too excited to sleep that night in the expectation of the result of my experiment, and very early the next morning I ascertained that it had fully succeeded. That experiment formed the basis of the phagocyte theory, to the development of which I devoted the next twenty-five years of my life.

Contrary to popular belief, Metchnikoff was not the first to visualize and describe phagocytosis, nor was he the first to suggest that it played a role in host defense. In a historical recount of the history of phagocytosis,[42] Stossel argues that a Lutheran pastor, Johann August Ephraim Goeze, was the first to describe phagocytosis by microscopic observations of cells derived from hay infusoria in 1777. Much later, German pathologists of the mid-19th century, including Lieberkühn, Henle, and Vogel, drew connections between “pus corpuscles” of wounds and blood corpuscles.[42] Others at the time, particularly the English physicians William Addison and Augustus Waller, observed leukocyte migration through capillaries in response to local injury, and Ernst Haeckel, a German marine biologist who was later to oppose Metchnikoff in an early theory of gastrulation, described molluscan leukocytes ingesting India ink particles in 1862.[43]

A handful of scientists of the time made the conceptual link between phagocytosis and host defense, and Metchnikoff himself cites a few: “When (the phagocytosis theory) is once firmly established, it will be time enough to determine each part taken in its foundation by workers such as Panum, Gaule, Roser, etc…”[44] However, it seems that none of these workers seized upon this concept and appreciated its importance to the degree that Metchnikoff had; certainly, none had further developed and tested what in retrospect was the correct interpretation of the defensive function of phagocytosis.

Following the key experiment in 1882, described previously, Metchnikoff performed many others to test the “phagocytosis theory,” such as the observation of infection in water fleas, which he viewed as a Darwinian struggle between pathogen and host[45]:

> Once they have insinuated themselves into the organism's inmost part, the spores cause an accumulation of the mobile cells round them, which correspond to the white corpuscles in human blood. A battle takes place between the two elements.

Drawing the analogy with host defense in higher organisms, Metchnikoff described the killing of the spores by “mobile cells,” thus ensuring immunity for the organism. His view of phagocytosis expanded to encompass not only host defense but also organismal development, which he viewed in a teleologic context; he cited the dissolution of the tadpole's

tail by the “pervasion of phagocytes.”[46] By the time he moved to Paris to become *Chef de Service* at the Pasteur Institute in

1888, Metchnikoff had already formulated and tested what had become, according to his view, a cornerstone of the science of immune system. Perhaps what he had not appreciated at the time was that his move to Paris would come to signify to the Germans a complicit alliance with the French. He thus had unwittingly entered a battle that not only had been fought in the political arena but in the laboratory as well.

The Ascendance of Humoral Immunity

Several related developments in the new field of immunology occurred at the end of the 19th century that would seal the fate of cellular immunology for at least 50 years: The discovery by Roux and Yersin[47] that toxins alone derived from diphtheria bacilli could reproduce the symptoms of diphtheria; the discovery by von Behring and Kitasato in 1890[48] of humoral immunity to diphtheria and tetanus and the passive transfer of immunity to diphtheria in animals by von Behring and Wernicke in 1892[49]; and the discovery of alexins (Greek for “without a name”) by Hans Buchner in 1899[50] and Jules Bordet at about the same time.[51] Alexin was renamed “complement” by Ehrlich, as it “complemented” the activity of antibodies. Indeed, the ability of humoral components alone to lyse bacteria (the Pfeiffer phenomenon) or erythrocytes in the absence of phagocytosis[51] provided strong independent evidence supporting the humoralists' claims. The discovery of complement also had practical uses, as complement fixation became the basis of a widely used serologic test for the diagnosis of syphilis, the so-called Wasserman test.[52] The collective discoveries of the “humoralists” would lead to the successful treatment of a number of previously intractable diseases, such as diphtheria. Indeed, the first Nobel Prize in physiology of medicine was awarded to von Behring in 1901, “For his work on serum therapy, especially its application against diphtheria, by which he has opened a new road in the domain of medical science and thereby placed in the hands of the physician a victorious weapon against illness and death.” Bordet himself would later be awarded the Nobel Prize “for his studies in regard to immunity.” Among Bordet's contributions was the development of the complement fixation test together with his brother-in-law, Octave Gengou. This formed the basis of what Bordet termed “serodiagnosis.”

Although the lines in the sand had already been drawn by the mostly Prussian humoralists led by Ehrlich on the one hand and the cellularists led by Metchnikoff on the other, it was Metchnikoff who wrote a letter to von Behring, proposing a scientific “truce”[53]:

> I now believe … we can calmly work side by side. We can mutually support one another, just like the phagocytes and antitoxins, since … the phagocytes receive considerable assistance from the antitoxic property, just as the phagocytes … render great assistance to the organism or respectively its antitoxic powers, since they capture and destroy … bacteria.

In fact, von Behring did not seem rigidly against the cellular school, and Metchnikoff viewed

him as supporting the view that "active immunity requires some type of cellular basis."[53,54] It is difficult to know what to make of this passage; it sounds vague and seems to state the obvious, yet it does suggest a degree of flexibility that more intransigent proponents of the humoralist camp seemed to lack at the time. Regardless, scientific reconciliation would not be forthcoming until many years later, although phagocytosis theory was granted a temporary reprieve by the British physician Almoth Wright, who demonstrated the phenomenon of opsonization of bacteria. Wright was the first to describe a mechanism by which humoral and cellular components of immunity cooperate to kill bacteria.[55] Wright is possibly best known in his incarnation as Sir Colenso Ridgeon in Shaw's "The Doctor's Dilemma." Ridgeon defined "opsonin" as "…what you butter the disease germs with to make your white blood corpuscles eat them."[56] In what was viewed as a well-deserved but partly symbolic gesture, nevertheless, Metchnikoff and Ehrlich, two exemplars of the opposing schools of immunity, were awarded the Nobel Prize in 1908 "in recognition for their work on immunity." It would not be until 40 years later that another cell type of the immune system would be first identified as being the source of antibody[57] and 70 years later when dendritic cells (DCs) would be first identified as being the key phagocytic leukocyte responsible for initiating the immune response.[58]

Paul Ehrlich: The Cellularist's Humoralist

Paul Ehrlich embodies a pivotal figure in the history of immunology. Although he would make many practical discoveries in his long research career, his greatest contribution to immunology, like Jerne's over a half century later, was a conceptual breakthrough that served to stimulate the field of immunology for years to come. Although I am tempted to consider his "side chain theory" of antibody formation a paradigm shift, that would presume that there was a preexisting paradigm to shift from, when in fact there was no paradigm of antibody specificity to begin with.

Ehrlich began his research career as a medical student. One of his professors was the pathologist Wilhelm von Waldeyer, who introduced the young Ehrlich, who already showed a strong interest in chemistry, to histologic methods for staining cells and tissues. Following further training in several medical schools, he was influenced by the chemist von Bayer and the pathologists Cohnheim, Haidenhain, and Weigert (his cousin). He presented his thesis on histologic staining in Leipzig at the age of 24, in which he was the first to describe mast cells. As noted by Silverstein, the opening sentence of the thesis gave an inkling of his approach to science[59]:

> While in the modern histological literature, directions on tintorial method are already so numerous, and still increase from day to day, yet their theoretical basis has had only a very negligible consideration.

The same year, he was appointed senior physician in the Department of Internal Medicine at the Charité-Hospital in Berlin. The head of the clinic, Friedrich Frerichs, encouraged Ehrlich to continue his histochemical investigations, which led to the identification of neutrophils, eosinophils,

and basophils as well as the diagnosis of his own case of pulmonary tuberculosis.[60]

It is notable that the term “side-chain” (*seitenketten* in German) was a chemical term in use at Ehrlich's time meaning much the same as it does today. It is inescapable to conclude that Ehrlich's focus and interest in chemistry would be the driving force behind his thinking about how antibody is formed, and “selected for,” by antigen. The essence of Ehrlich's side chain theory, first proposed in 1897 (Fig. 2.2) is well articulated in Ehrlich's Nobel lecture and is paraphrased here[61]:

1. “The relationship between toxin and antitoxin are *strictly specific*—tetanus antitoxin neutralizes exclusively tetanus toxin, diphtheria serum only diphtheria toxin …”
2. “For this reason it must be assumed that the (toxin and antitoxin) enter into a *chemical bond* … fitting each other ‘like lock and key.’”
3. “The group in the protoplasm, the *cell receptor* , must be identical with the *antitoxin* which is contained in solution in the serum of immunized animals.”
4. “As these receptors, which may be regarded as *lateral chains* (“seitenketten”) of the protoplasm…become occupied by the toxin, the relevant normal function of this group is eliminated…the deficiency is not merely *exactly compensated*, but *made up to excess* (hyperregeneration).”

What Ehrlich proposed purely on theoretical grounds is a brilliant argument based on a combination of inductive and deductive reasoning. Characteristic of Ehrlich, it is lucid, logical, and profound. Beginning with a consideration of a simple chemical bond, Ehrlich somehow ends up with an antibody-producing cell; hence, “the cellularist's humoralist.”

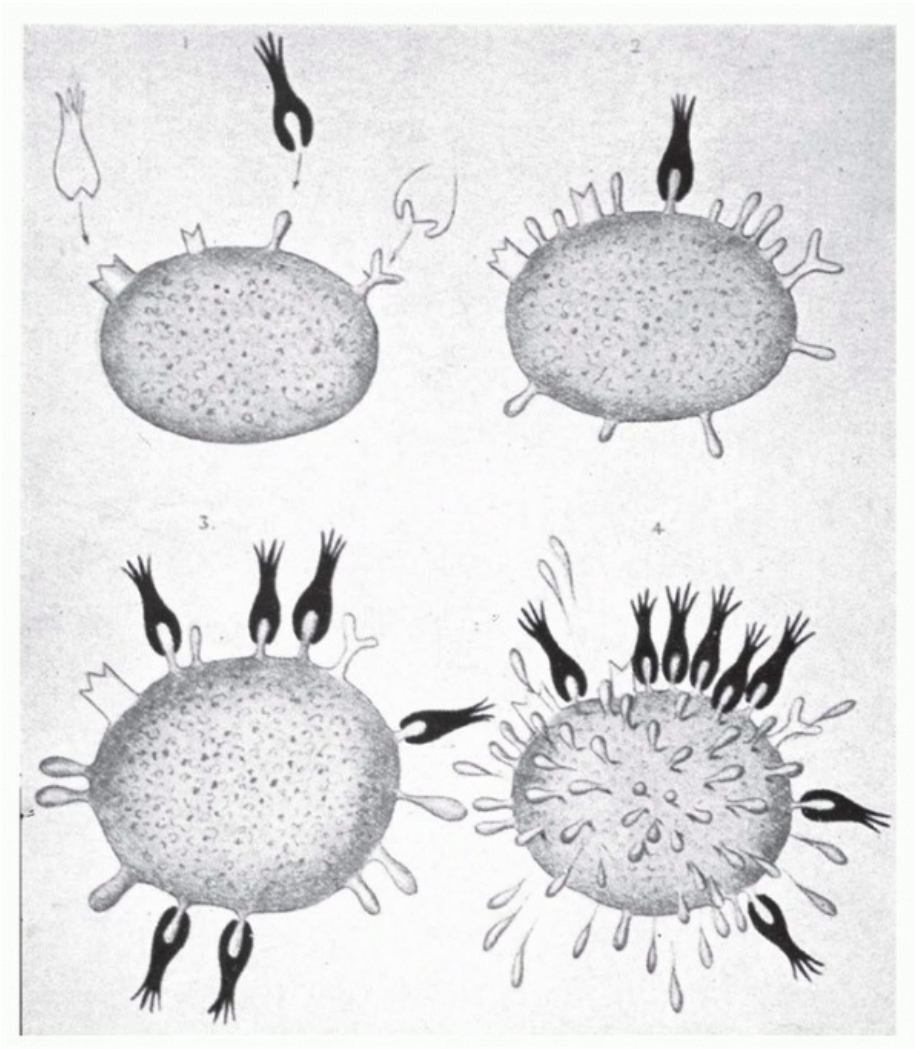

FIG. 2.2. Ehrlich's "Seitenkette" (Side Chains). From Ehrlich.[171]

Not every biologist was enamored of Ehrlich's model, and soon after he proposed it, it came under attack, most notably by Jules Bordet. Bordet objected to Ehrlich's insistence that the specificity of the antigen-antibody reaction required an irreversible bond, whereas Bordet, whose views seemed to be more deductively grounded in his immediate line of investigation (eg, precipitin reactions and complement fixation) thought that adsorptive interactions between antigen and antibody were sufficient to account for specificity.[15,60] Although Ehrlich's side-chain theory provided a logically consistent mechanism to account for antibody specificity, it would later be criticized for failing to account for antibody diversity. That problem would not be conquered for another 60 years in yet another "paradigm shift" when Talmage, Burnet, and Lederberg proposed the clonal selection theory. However, the concept of clonality was not yet conceived of in 1897, and in any case, it is hard to envision how a clonal selection theory could have been developed without the prior description by Ehrlich of antibody selection itself.

IMMUNOLOGY BRANCHES OUT: BENEFICIARIES OF THE EARLY FOCUS ON HUMORAL IMMUNITY

"Man built most nobly when limitations were at their greatest."

Immunology during the early part of the 20th century was heavily influenced by the early victories of the humoralists. Aside from the spectacular practical implications of the work of von Behring, Bordet, and Ehrlich, among others, the immunologist's toolkit of the early 20th century immunologist was very limited. Advanced microscopic techniques were not yet available, and cell fractionation techniques had not yet been invented. Given these limitations, it is hard to envision how the gap between antibody and cell could have been bridged any closer than Ehrlich had managed, at least on a theoretical level. However, the focus on humoral immunity did allow for the rapid development of several fields, most notably immunochemistry as well as hematology and allergy. It would be some time before cellular immunology would catch up.

Karl Landsteiner and the Birth of Transfusion Medicine and Autoimmunity

As described by Silverstein, “No single individual contributed as importantly to so many different areas of immunology as did Karl Landsteiner.”[15] Landsteiner was born in Baden in 1868 and attended Vienna Medical School. He began his training in internal medicine and studied chemistry with Emil Fischer, who would receive the Nobel Prize in chemistry in 1902. He transferred to the Department of Pathological Anatomy, home to Erdheim, Billroth, Escherich, and other accomplished scientists, where he remained until

1907.[62] Landsteiner's first major accomplishment was the discovery of the human ABO blood group antigens at the turn of the century.[63,64] His motivation was succinctly described in his Nobel lecture speech[65]:

> … proteins in individual animal and plant species differ and are characteristic of each species … The problem raised by the discovery of biochemical specificity peculiar to a species … was to establish whether the differentiation extends beyond the species and whether the individuals within a species show similar though smaller differences.

His experiment was a simple one, in which he applied the sera of six heathy men, including himself, to red blood cells of each, and noted that the sera of the men reacted differently with each other—no serum reacted with that same individual's red blood cells. At the end of the paper, Landsteiner noted that the results could account for the variable clinical consequences of human blood transfusion —and thus was borne the discovery of the ABO red blood cell antigens that would later become useful in blood typing prior to transfusions. Many years later, Landsteiner would discover the M, N, P isoantigens in 1927[66] and the Rh system in 1940[67]).

Landsteiner's next major contribution was the codiscovery with Donath of the first autoimmune disease, paroxysmal cold hemoglobinurea,[68] which challenged Ehrlich's dictum that such a situation could not occur.[69]

> The organism possesses certain contrivances by means of which the immunity reaction … is prevented from acting against the organism's own elements and so giving rise to autotoxins … so that one might be justified in speaking of a "horror autotoxicus" of the organism.

The nature of the contrivances was thought to be of "the greatest importance" by Ehrlich, who later stated[70]: "According to our present investigations either the disappearance of receptors or the presence of autoantitoxin is foremost among these contrivances." Depending on how this statement is interpreted, it could be viewed as Ehrlich's formulation of either clonal deletion or anti-idiotypes. Two years after the discovery of paroxysmal cold hemoglobinurea, an Italian ophthalmologist, who observed sympathetic ophthalmia, a disease in which damage to one eye leads to inflammation of the opposite eye, speculated that this disease was due to "autocytotoxins."[71] Autoimmunity research was taken up by a few others, but perhaps owing to either a misinterpretation of Ehrlich, or possibly due to deference to his authority in the field, progress was slow. It would not be years later, until the discovery of the role of sensitization of the newly discovered Rh antigen as an etiology of erythroblastosis fetalis,[72,73] that autoimmunity became an active area of research for immunologists. The first time that autoimmunity was first associated specifically with arthritis was 1957, when Kunkel and colleagues discovered what came to be called "rheumatoid factor," large complexes of immunoglobulin (Ig)M directed against IgG in the sera of some patients with rheumatoid arthritis.[74] This observation fundamentally changed the field of rheumatology.[75]

Landsteiner received the Nobel Prize in 1930 "for his discovery of the human blood groups." Ironically, upon receiving the prize, it is said that he felt the prize should have been awarded for his work on haptens, which would play a great role in the development of the growing field of immunochemistry.

Discovery of Hypersensitivity: The "Other Work"

In 1901 to 1902, Paul Portier and Charles Richet were attempting to raise tolerance in laboratory animals to actinotoxin, an uncharacterized toxin derived from tentacles of sea anemones. Their experiments appeared to be unsuccessful, and, in some cases, it appeared that the animals actually became sensitized to the antigen. They repeated their studies using dogs and obtained completely unanticipated results: All eight dogs collapsed and died within minutes after receiving a relatively small dose. First thinking the results were due to experimental error, they later realized that the sensitized animals had all been exposed to antigen 14 to 23 days previously.[76] They proposed the name "aphylaxis" (against protection), a term later changed to "anaphylaxis."[77] Richet continued his investigations on anaphylaxis and was awarded the Nobel Prize in 1913 for his work. Soon after Portier and Richet made their seminal discovery, Maurice Arthus was able to induce a localized form of anaphylaxis (swelling and ultimately gangrene) by repeated subcutaneous injections of horse serum, considered fairly nontoxic.[76] Yet, a third type of hypersensitivity was described by the pediatricians von Pirquet and Schick,[78] who noted that vaccinated children occasionally developed fever, joint pains, rash, diarrhea, and hypotension. They concluded that the clinical features of what is now called "serum sickness" were not a direct result of the injection of antiserum, but the outcome of "when antigen and antibody meet." As von Pirquet

later explained,[79]

> We are able to observe the effects of the toxic body formed when antigen and antibody meet, that is, the serum disease. We see that at the time when the antibody arises, and therefore the antigen disappears, symptoms of general disease occur. The supposed connection is that these symptoms are due to toxic bodies formed by this digestion of the allergen through the antibody.

Although von Pirquet does not precisely define what he meant by “toxic body,” some have interpreted this to mean antigen-antibody complexes. It is possible that he was reluctant to be more specific as he did not actually have a way of observing or quantifying the complexes; it is also possible that he did not have a ready explanation for how such a complex, if formed, could lead to the symptoms and signs of serum sickness. It would not be until many years later that Frank Dixon and colleagues would precisely delineate the nature of the immune complexes.[80] Nevertheless, it is clear that von Pirquet and Schick viewed this phenomenon as

lying along a continuum with the normal immune response, or rather being a necessary component of it. As they later stated,[81]

> The conception that the antibodies, which should protect against disease, are also responsible for the disease, sounds at first absurd… One forgets too easily that the disease represents only a stage in the development of immunity, and that the organism often attains the advantage of immunity only by means of disease.

It is von Pirquet and Schick who coined the term “ allergy” (from the Greek *allos*, other, and *ergon*, work).[79] By highlighting the role of tissue injury in promoting immunity, they closed the loop that Metchnikoff had begun at the end of the 19th century. This theme would be revisited and expanded upon in the latter part of the 20th century when it was discovered that the inflammation that accompanied the innate immune response was a necessary prequel to the acquired immune response.

THE LONG JOURNEY FROM THE DAWN OF IMMUNOCHEMISTRY TO THE STRUCTURE OF IMMUNOGLOBULINS

Challenges to Ehrlich: The Problem with the “Keys”

One of the difficulties that Ehrlich faced was bridging the gap between the conceptual basis of antibody specificity and the actual basis of antibody specificity. If his side-chain theory was correct, then every cell involved in antibody production would be capable of reacting against every possible antigen it might encounter. Even without considering the cellular origins of antibodies, Ehrlich's critics, such as the Viennese Max von Gruber, raised the question of how the astonishingly large number of different specificities of the antibody molecules themselves could be generated.[15] The size of the repertoire seemed impossibly large if

every “lock” had a unique “key.” Landsteiner became von Gruber's assistant at the University of Vienna in 1896, and he inherited von Gruber's critical view of Ehrlich's theory. Landsteiner's early approach to this problem was to adopt Bordet's “colloid” explanation of the antigen-antibody interaction,[15] which rejected covalent interactions in favor of multiple weaker interactions, a theme that was later taken up by Pauling, with some interesting consequences. Later, stimulated by the work by Obermeyer and Pick, who described chemical modifications of proteins,[82] Landsteiner used structurally related reactive chemicals to derivatize proteins. He showed that antisera raised against one of the chemically modified proteins would react to varying degrees with proteins modified by structurally similar, but not identical, reactive molecules. These results were interpreted as being incompatible with Ehrlich's “lock and key” specificity but called for a more nuanced view of antigen-antibody specificity. It became immediately apparent that the size of the repertoire could be greatly enhanced if one allowed for such graded degrees of binding affinities.

Immunoglobulin Structure: The “Keys” to the Problem

It was clear that further progress on defining the physicochemical nature of the antigen-antibody reaction required the development of specific tools that were unavailable at the turn of the century. Antibodies, whose chemical structures were unknown at the time, were considered “colloids” (from Greek *kolla*, glue), a suspension of particles suspended in a continuous phase of another component. In 1924, the Swedish chemist Svedberg designed a centrifuge based on a modified milk separator. The centrifuge could develop a centrifugal field of up to 5000 g and enabled Svedberg to measure the molecular mass of hemoglobin[83]; he was the first to determine the molecular mass of macroglobulins, derived from a patient with Waldenström macroglobulinemia, which we now know as IgM. A student in Svendberg's laboratory, Arne Tiselius, developed gel electrophoresis,[84] which allowed for the separation of molecules based on charge and size. These tools enabled Michael Heidelberger to establish the field of “immunochemistry.” Heidelberger devoted nearly his entire research career pursuing the implications of a simple but profound discovery he made with Oswald Avery in 1923 that type-specific antigens of pneumococcus bacteria are complex polysaccharides. Over the next three decades, this discovery enabled him to determine, for the first time, the exact weight and chemical composition of antibodies, antigens, and complement. He showed that antibodies are multivalent proteins and used these insights to devise a simple vaccine against pneumonia whose effectiveness was first proven in soldiers who fought in World War II.[85]

The Chemical Nature of Immunoglobulin Molecules

By 1950, it was appreciated that antibodies were proteins of 150,000 molecular mass containing bivalent antigencombining sites. Based on Porter's observation that Igs could be split into smaller products by enzymes such as papain, yielding Fab fragments that bind antigen and Fc (crystallizable) portions that do not, Edelman and Poulik further defined Ig structure by hypothesizing that Bence-Jones proteins, derived from myeloma cells, were free light chains of Ig molecules.[86] As this hypothesis appeared to be correct, this provided a means of obtaining a ready supply of homogeneous Ig subunits. Reduction of disulfide bonds led to still different products, enabling them to propose that the Ig molecule consists of two light chains and two heavy chains, and that the antigen-binding site consisted of

contributions from both heavy and light chains.[86] Further refinement of techniques in protein chemistry allowed Edelman and Porter to work out the primary structure of Ig molecules, for which they received the Nobel Prize in 1972.

CONFRONTING THE SIZE OF THE REPERTOIRE

The value of a large repertoire from which to select is appreciated by any performing musician. Yet in the 1950s, the repertoire problem was unsolved, leading to competing theories of how a large repertoire of diverse antibodies are generated. There were two mutually exclusive leading schools of thought: “instruction” theories and “selection” theories.

Instruction Theories of Antibody Diversity

As noted by Silverstein,[15] the first description of antigen as template was by Bail and Tsuda, who proposed in 1909 that antigen persists after its encounter with antibody, and that by so doing, it leaves an impression on the antibody.[87] This concept was further refined by Breinl and Haurowitz, who suggested that antigen is carried to the site of protein formation, where it would serve as a template to instruct antibody formation.[88] Finally, in 1940, Linus Pauling provided a chemical explanation for antigen-directed instruction: that “antibodies differ from normal serum globulin only the way the ends of the polypeptide chain is coiled” as a result of their amino acid sequence, and that “they have accessible a very great many configurations with nearly the same stability.” Under the “influence” of antigen, they “assume configurations complementary to surface regions of the antigen,” forming two active ends, and that after “freeing one end and the liberation of the central part of the chain, it folds up to form the central part of the antibody molecule, with two oppositely directed ends able to attach themselves to two antigen molecules.” This interaction would be further stabilized by weak interactions between antigen and antibody.[89] Assuming a degree of degeneracy in the initial antigen-antibody interaction, these theories were consistent with the findings of Landsteiner, who showed that antigen-antibody interactions were not absolutely specific, as envisioned by Ehrlich (Fig. 2.3). In retrospect, these theories had great chemical appeal; however, a central weakness is that if the initial interactions between antigen and antibody are degenerate, that implies that the interactions cannot be of high affinity (otherwise they would not be degenerate). Yet, if the initial interactions are weak, how would they occur in the first place? At some level, there has to be a certain degree of preexisting antibody specificity, which implies a preexisting repertoire. Although the instruction theories of antibody selectivity helped explain some of the specificity of the antigen-antibody interactions, they could not account for all of them. It is notable that the underlying basic principles have been since invoked for other encounters in the immune system. For example, a “bar code model” of interactions between the T-cell receptor (TcR) and peptide-major histocompatibility complex (MHC) (pMHC) has recently been proposed, in which the initial encounter between TcR and pMHC is governed by strong interactions, followed by “scanning” the epitope and modest changes in conformation of the TcR, leading to strengthening of the TcR-pMHC association.[90]

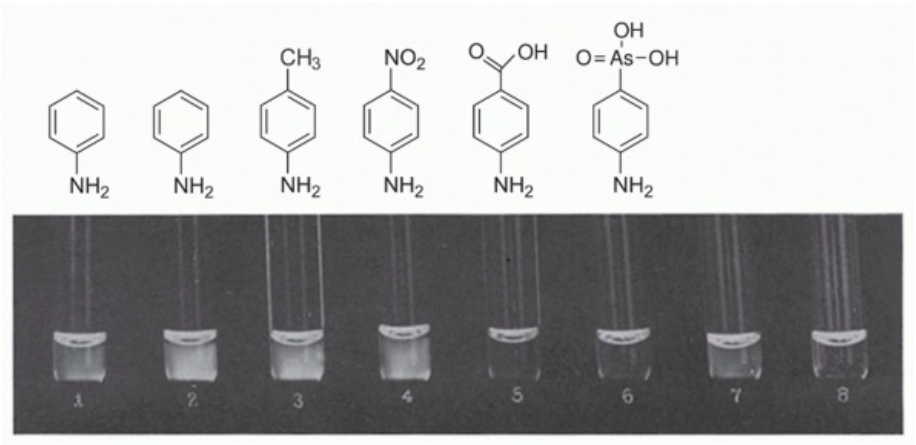

FIG. 2.3. Demonstration of Serologic Specificity by Landsteiner and Scheer. Reactions from immune serum for aniline with various azoproteins and with unchanged horse serum reading after 15 minutes. *(1)* azoprotein from chicken serum and aniline, *(2)* azoprotein from horse serum and aniline, *(3)* azoprotein from horse serum and para-toluidine, *(4)* azoprotein from horse serum and para-nitroaniline, *(5)* azoprotein from horse serum and para-aminobenzoic acid, *(6)* azoprotein from horse serum and para-arsanilic acid, *(7)* unchanged horse serum, *(8)* saline control. Modified from Landsteiner and van der Scheer.[486]

Jerne's Natural Selection Theory of Antibody Formation

Instruction theories of antibody specificity persisted through the 1950s, when they were modified to include participation of enzymes to act as intermediaries between antigen and antibody as well as the newly discovered structure of deoxyribonucleic acid (DNA). In 1955, Niels Jerne published a highly influential paper in which he proposed a new theory of antibody formation that he described as the “natural selection theory of antibody formation.„91

> The antigen is solely a selective carrier of spontaneously circulating antibody to a system of cells which can reproduce this antibody. Globulin molecules are continuously being synthesized in an enormous variety of different configurations…among which… will be fractions possessing affinity toward any antigen to which the animal can respond.

Jerne referred to these preexisting antibodies “natural antibodies,” and went on to state that antigens selectively attach to those globulin molecules that happen to have a complementary configuration. According to Jerne, once the interaction occurs, the antigen-antibody complexes may be engulfed by a “phagocytic cell,” at which point the antigen is eliminated. The antibody within the phagocytic cell can remain or be transferred to another cell, which is the signal for reproduction of the same specific antibodies. More antibody is released into the circulation, resulting in a larger percentage of specific circulating antibody. Jerne states that “the reproduction need not be highly faithful; copying mistakes will be harmless and may

occasionally produce an improved fit."[91] These are remarkable concepts, as Jerne appeared to have invoked Metchnikoff, a Darwinian interpretation of antibody selectivity at the organismic level, as well

as to have anticipated affinity maturation. It is easy to see why Jerne's ideas were so influential. However, the central problem, the lack of an explanation for the huge existing repertoire, which hampered the instruction theories of antibody diversity, as well as Ehrlich's side-chain theory was still unanswered. Jerne admitted this weakness and speculated that the "spontaneous production of globulin molecules of a great variety of random specificities" may reside in a "… specialized lymphoid tissue, such as that of the thymus."[91] Perhaps a more existential problem was that the flow of information was from the existing preformed antibody to more antibody without any genetic intermediary. What was lacking was a specific mechanism to transfer information between a specific antibody and the specific synthesis of that same antibody. Jerne admitted to this problem and nominated ribonucleic acid (RNA) as a key template; he then stated " … a protein molecule may determine the order of the nucleotides in the synthesis of RNA," citing a paper that does not actually make this assertion.[91]

What accounted for this conceptual block that had persisted for more than half a century? On one level, it was ignorance of the "fundamental dogma of molecular biology," which had not yet been articulated.[92] But on another level, it perhaps can be traced back to the decisive victory of the humoralists over the cellularists. So long as the focus was on the antigen-antibody interaction, there was no way to invoke a biologically plausible mechanism of generating a preexisting Ig repertoire and of selectively expanding a specific portion of that repertoire.

Development of the Clonal Selection Theory

In 1957, the American immunologist David Talmage published a review whose focus was allergy; however, in the review, Talmage drew an analogy between natural selection, in which there is "selective multiplication of a few species out of a diverse population" and antibody production. In a very succinct but remarkably insightful passage, he lays out the essence of the clonal selection theory[93]:

> As a working hypothesis it is tempting to consider that one of the multiplying units in the antibody response is the cell itself. According to this hypothesis, only those cells are selected for multiplication whose synthesized product has affinity for the antigen injected.

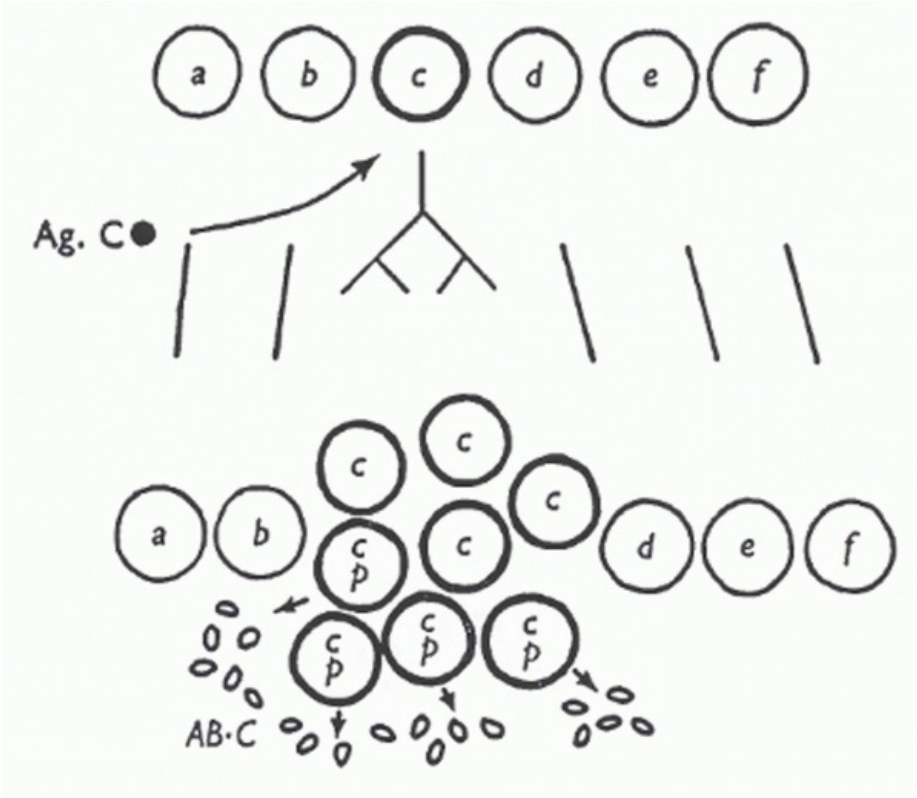

FIG. 2.4. In this diagram, antigen C (Ag.C) is recognized by clone "c," triggering this clone, but not others, to proliferate. Antibody against Ag.C (AB.C) is indicated at the bottom. From Burnet.[246] Copyright ©1959 Sir MacFarlane Burnet. Reprinted with the permission of Cambridge University Press.

At about the same time, Burnet published his own paper outlining the key aspects of the clonal selection theory[94] (Fig. 2.4). In a later interview, Talmage discussed how he provided a preprint of his review to Burnet before he published his landmark paper on the clonal selection theory, but both he and Nossal stated that Burnet developed the theory independently. Talmage thought that the two papers were similar in substance, but that "Burnet had the good fortune to make an analogy of the idea to the clones that grow in bacteria and he gave it a very catchy name, 'clonal selection.'"[95] Among the ideas that led both immunologists to propose the clonal selection theory was the known logarithmic rise in antibody titer during the primary immune response "as if it is a product of some multiplying substance."[95] Other experiments demonstrated that lymphoid cells obtained from previously immunized rabbits that were then transferred to x-radiated recipients were sufficient to induce a recall response in the recipients.[96]

Although we now know that the clonal selection theory is correct, it took more than 10 years for clonal selection to be widely accepted, according to Talmage.[95] Among the key pieces of evidence to prove the theory was the demonstration of antibody production from single cells, by Nossal and Lederberg,[97] and the later finding that cognate antigen was capable of aggregating all surface Ig on individual cells,[98]

which corroborated Nossal and Lederberg's results. Finally, in 1975, Köhler and Milstein demonstrated the production of monoclonal antibodies from single clones of immortalized plasma cells.[99] Along with Jerne, they shared the Nobel Prize in 1984.

The Structural Basis of Antibody Diversity: The Dialectic Revisited

By the mid-1970s, the puzzle of antibody diversity was far from solved—many of the pieces were still missing. The conceptual basis for the clonal selection theory was laid in 1957 by redirecting the focus of investigation from immunochemistry to cell biology. However, what was needed to actually prove the theory was a delineation of the molecular basis for the enormous size of the repertoire. Two lines of investigation converged to provide this evidence: the sequencing of Ig proteins followed by the sequencing of Ig genes. In 1965, Hischmann and Craig sequenced two Bence-Jones proteins and found that there was conservation of the amino acid sequence at the C-termini but considerable diversity at the N-termini.[100] In the ensuing years, sequence data on a number of myeloma proteins became available, and in 1970, Kabat and Wu applied statistical criteria to analyze sequencing data from 77 Ig chains. They identified three regions within the 107 residues comprising the light chain variable region that demonstrated a still further degree of variability (ie, hypervariability). They hypothesized that these regions of extreme diversity represented the complementarity-determining residues and suggested by analogy with prokaryotes that they arose through episomal incorporation into the light chain locus by a recombination event.[101] If this, indeed, was the underlying explanation for antibody diversity, then there would have to be a very large number of episomal elements to account for a diverse repertoire. This was a different view than the one taken by Dreyer and Bennet 5 years earlier, who proposed that variable region genes that had undergone duplication and spontaneous mutation throughout evolution underwent a “genetic scrambling” event, resulting in their juxtaposition to the constant regions of the Ig genes. They even suggested the involvement of enzymes involved in DNA repair as contributing to such an event.[102] Thus, two opposing viewpoints began to emerge to account for the generation of diversity (or GOD, as playfully described by Richard Gershon): somatic mutation of a few genes, as suggested originally by Burnet,[94] and supported by Weigert and Cohn's sequencing data of the mouse λ light chain locus,[103] or somatic recombination among many duplicated genes within the germline, as proposed by Dreyer and Bennet[102] and later refined by Edelman and Gally[104] and Hood and Talmage.[105] In the years that followed, various teleologic arguments were proposed to support one theory over the other. In 1976, at least a partial resolution was provided by Hozumi and Tonegawa, who provided evidence that the V_K and C_K loci from embryonic DNA rearrange to form a contiguous polypeptide in mature lymphocytes.[106] The advent of molecular cloning led to direct proof that the variable and constant regions of the light chain gene had undergone rearrangement at the DNA level.[107,108] This was followed by the demonstration by Weigert et al.[109] that the Ig V_K region in the mouse is encoded by multiple V, J, and C regions joined at the DNA level during differentiation of individual lymphocytes. Finally, in 1980, Early et al.[110] demonstrated how V, D, and J regions of the Ig locus could recombine to generate a virtually unlimited combination of antibody specificities.

In the ensuing years, the molecular mechanisms governing VDJ recombination were

uncovered. These involved recognition of conserved sequences flanking germline V, D, and J segments, introduction of double-strand breaks, potential loss or gain of nucleotides at the coding junctions, and polymerization and ligation to complete the joining process. Many talented scientists contributed to these discoveries, including Alt, Yancopoulos, Blackwell, and Gellert.[111] This culminated in the isolation of the recombinase activating genes (RAG) by Baltimore's group.[112, 113] The dominant view that emerged from these studies largely favored the “germline-ists,” reinforced by Tonegawa's receiving the Nobel Prize in 1984. However, in yet another example of a synthesis of two apparently contradictory approximations of the truth, evidence for somatic hypermutation began to emerge.[114,115] Its importance was established when it was causally linked to the generation of B cells with very high affinity antibodies,[116] a phenomenon termed “affinity maturation.”[117]

SPECIALIZATION WITHIN THE IMMUNE SYSTEM

Division of Labor: Discovery of T and B Cells

The first person to demonstrate delayed type hypersensitivity may have been Robert Koch in 1882. On his quixotic pursuit of developing a vaccination against tuberculosis, he injected himself with spent medium from cultures of human tubercle bacilli and noted a particularly severe reaction, including systemic effects.[118] Although he was not successful in developing a vaccine against tuberculosis, he recognized the diagnostic potential of this procedure. It was not until 1942, and then later in 1945, that Landsteiner and Chase demonstrated that cells from guinea pigs previously immunized with *Mycobacterium tuberculosis* or hapten would transfer reactivity to a naïve recipient when challenged with the immunogen.[119,120] This was the first demonstration that cells, rather than antibody, transmitted specific immunity, a finding that in some ways vindicated Metchnikoff's cellular focus.

The identity of the cells mediating the transferred hypersensitivity was unknown. Based on experiments performed decades earlier, as Silverstein has noted,[121] James Murphy at the Rockefeller Institute argued that lymphocytes were important in the host resistance to tuberculous infection. Murphy used mice exposed to x-rays or splenectomized to manipulate lymphocyte numbers and showed that conditions that would have been predicted to deplete lymphocytes resulted in early death of the mice due to disseminated tuberculosis.[122] In earlier papers, Murphy also showed more directly that lymphocytes were important in graft rejection in transplanted chick embryos. Why were these seemingly important observations ignored? Was it because the

experiments relied to a certain extent on inference, rather than direct proof that lymphocytes were key mediators of tuberculous immunity? Most likely, it was a combination of events: The lingering vestiges of the confrontation between the cellularists and the humoralists and the fact that there was little conceptual basis for understanding how a small innocuous-appearing cell type could participate in immunity.

In a completely independent line of investigation, it was known for some time that certain strains of mice had a high spontaneous rate of developing lymphocytic leukemia. In attempting to explain the finding that thymectomy of 2-month-old mice failed to develop leukemia, Jacques Miller found that neonatally thymectomized mice appeared ill and revealed

a marked deficiency of lymphocytes in blood and lymphoid tissues. Furthermore, these mice failed to reject allografts or xenografts.[123] However, not all areas within lymphoid organs were depleted of lymphocytes, consistent with “thymic-dependent” (paracortical areas of the lymph nodes and periarteriolar sheaths of the spleen) and “thymic-independent” regions (follicles and medullary cords). Miller concluded that the thymus was important for the development of a subset of lymphocytes important in allograft rejection.

The involvement of lymphoid cells in antibody production was considered likely in the 1940s, mainly due to “guilt by association.” For example, Erich and Harris injected antigens, such as typhoid vaccine and sheep erythrocytes, into the feet of rabbits, and then compared the formation of antibody to histologic changes in the draining lymph nodes.[124] Similar experiments were performed using intravenous injection of antigen, and the appearance of antibody and plasma cells in the spleen appeared to be correlated.[125] However, actual proof for the involvement of B cells in antibody production was quite accidental.[126] In 1952, Bruce Glick, a young doctorate student at Ohio State University, was investigating the function of an obscure avian organ, the “bursa of Fabricius.” He removed the organ, which did not result in a discernable phenotype. A fellow graduate student asked to use one of Glick's birds to develop an antibody against *Salmonella* and found that the bursectomized chicken failed to make antibodies. This led to the publication that eventually appeared in *Poultry Science* describing the role of the organ in the generation of bursa-derived or “B” cells.[127] As there was no anatomic equivalent of the bursa in mammals, an exhaustive search finally revealed the bone marrow origin of these cells. It was also found that thymusderived cells, later named “T cells,” were needed to “help” B cells produce antibody.[128,129,130] These distinctions were further clarified when Cooper et al.[131,132] showed that T cells were required for delayed-type hypersensitivity and graft versus host reaction. Thus was borne one of many central dichotomies that Mazumdar[133] has argued drives the field of immunology.

In 1957, Gowans[134] cannulated the thoracic duct of rats and measured the rate of flow of the lymph. He suggested that “the continuous entry of living lymphocytes into the blood may be essential for maintaining the output of lymphocytes from the thoracic duct.” He later showed that intravenous transfusion of radiolabeled lymphocytes resulted in appearance of the radiolabeled cells into the thoracic duct, thus defining the continuous recirculation of lymphocytes from the lymphatics to the blood.[135] In retrospect, these experiments were critically important in understanding how lymphocytes are constantly patrolling the lymphatics, vigilantly on the lookout for antigen.

TRANSPLANTATION BIOLOGY AND THE PURSUIT OF IMMUNOLOGIC TOLERANCE

The history of transplantation began many hundreds of years ago and was vigorously pursued by surgeons and tumor researchers during the early part of the 20th century. These events are well summarized in several texts, notably Brent's *A History of Transplantation Immunology* and Silverstein's *A History of Immunology* . The influence of these early workers, particularly Carrel's, on the surgical aspects of transplantation is clear, but their impact on the field of transplantation immunology was limited because the conceptual framework of immunology was still rudimentary. Analogous to the role that smallpox had in

catalyzing early vaccine development, large-scale bombing campaigns in World War II resulted in many civilian and military burn victims who required skin grafting, compelling surgeons to develop better techniques to avoid homograft rejection. The British zoologist Peter Medawar was assigned to the War Wounds Committee of the Medical Research Council. In 1943, Medawar and Gibson[136] published “The fate of skin homografts in man” based on a single burn victim who received multiple “pinch grafts” of skin. The authors concluded that autografts succeed, whereas allografts fail after an initial take, and that the destruction of the foreign epidermis is brought about by a mechanism of active immunization. Medawar returned to Oxford University to study homograft rejection in laboratory animals and proved that this was an immunologic phenomenon. Medawar[137] concluded that the mechanism by which foreign skin is eliminated belongs to the category of “actively acquired immune reactions.” Shortly after this publication, Ray Owen[138] published the provocative finding that dizygotic twin calves, who share a common circulatory system in utero, exhibit chimaerism with respect to their twin's erythrocytes and fail to produce antibodies against each other's erythrocytes. This led Burnet and Fenner[139] to predict that introduction of a foreign antigen early enough in life would fail to elicit an immune response. Medawar reasoned that the successful exchange of skin grafts between dizygotic calves would verify this hypothesis. Together with his postdoctoral fellow Rupert Billingham, he performed a series of grafting experiments that provided direct support for this model.[140]

> Mammals and birds never develop, or develop to only a limited degree, the power to react immunologically against foreign homologous tissue cells to which they have been exposed sufficiently early in fœtal life … this phenomenon is the exact inverse of “actively acquired immunity”, and we therefore propose to describe it as “actively acquired tolerance.”

At the same time, Milan Hašek[141] in Prague demonstrated successful parabiosis of chick embryos derived from two

different strains. Hašek's stated motivation to perform the experiment was to determine whether exchange of blood in the different chick strains induced a “mutual metabolic assimilation between parabionts,” rather than to induce a state of immune tolerance. It has been suggested that Hašek's real motivation for the experiment was to advance the Lysenkoist genetic doctrine to appease the local communist regime in Czechoslovakia.[142] Regardless, the result has been reinterpreted as an example of the induction of immunologic tolerance. In 1960, Medawar shared the Nobel Prize with Burnet “for the discovery of acquired immunologic tolerance.”

Mechanism versus Metaphor: “Self/Nonself” Discrimination

Medawar's experiments and Burnet's formulation of the clonal selection theory occurred at a critical juncture in the history of the evolving field of immunology. Had their development been dyssynchronous, it is doubtful that much progress would have been made on either front. Indeed, transplantation experiments had been performed earlier in the century with little insight as to why allografts failed. The viewpoint that Burnet espoused, that the function of

the immune system is to distinguish “self” from “nonself,” has proved to have enormous heuristic value ever since its formulation more than 60 years ago. Is this distinction mostly metaphorical, as suggested by Tauber,[143] or does it reflect a more concrete generative reality? To begin to address this question, it is necessary to briefly review a parallel development in immunology, the discovery of the components of the immune system that define molecular self-hood.

Looking Under the Hood: The Discovery of the Major Histocompatibility Complex

The clonal selection theory represented a conceptual breakthrough in the history of immunology, but it did not explain how lymphocytes actually recognize antigen. These insights would eventually come from three sources over the span of 20 years: studies of the genetics of graft rejection in inbred strains of mice by George Snell in the 1940s, studies of the agglutination of white blood cells by sera from transfused patients by Jean Dausset in the 1950s, and studies of the immune response to simple antigens in guinea pigs by Baruj Benacerraf in the 1960s. Snell was interested in identifying genes that controlled the ability of mice to resist tumor transplants. He pioneered the use of congenic mice, which are genetically identical except for a single region or locus. Snell observed that tumor grafts were accepted between inbred mice but not between mice of different strains. The same was true for normal tissues. Snell termed the underlying genes “histocompatibility” genes. In collaboration with Peter Gorer, who had prepared antisera that reacted with cells from one mouse strain but not another, Snell established that the major histocompatibility locus corresponded to a reactivity that Gorer had designated antigen II, renamed locus histocompatibility 2 or H-2.[144] Two loci within this region, designated K and D, carried genes specifying antigens involved in triggering graft rejection. In the 1950s, Dausset observed that patients who had received many blood transfusions produced antibodies that could agglutinate white blood cells from donors but not the patient's own cells. Several of the patients produced antibodies against the same antigen.[145] Subsequent family studies indicated that a genetically determined system, named “human leukocyte antigen” (HLA) system, was found to be the ortholog of H-2 in the mouse. Dissection of the human system would take many years, during which time transplantation surgeons made use of the emerging findings to assist in tissue typing. In the 1960s, Baruj Benacerraf, an immunologist working at New York University, noticed that some outbred guinea pigs responded to simple antigens by developing delayed hypersensitivity reactions upon challenge while others did not, and that this was under genetic control. He termed these genes “immune response genes.” McDevitt and Sela observed similar genes in mice, and McDevitt showed that they are encoded in the MHC.[146] In 1980, Benacerraf, Snell, and Dausset shared the Nobel Prize “for their work on genetically determined structures of the cell surface that regulated immunologic reactions.”

Of course, the identification of the HLA region and the subsequent cloning of the genes encoded in this region proved to be landmarks in the history of immunology. Besides providing a molecular identity to the key orchestrators of antigen presentation to T cells, the identification of specific MHC alleles with autoimmune diseases has led to important insights into their pathogenesis. Ironically, the first recognized HLA association with human disease, HLA-B27, which was associated with the disease ankylosing spondylitis,[144,147] has

generated perhaps more heat than light, as there is no definitive mechanism that explains how HLA-B27 is linked to disease pathogenesis, underscoring that the HLA locus, which took so many years to uncover at the genetic level, still has much to teach us.

The Discovery of Major Histocompatibility Complex Restriction as the Molecular Basis for "Self/Nonself" Discrimination

It was known for several years that cooperation between T and B cells occurred in syngeneic or H-2-compatible animals.[148,149,150] In 1972, Kindred and Shreffler[151] showed that even in nude mice, cooperation between T and B cells required H-2 compatibility; however, the exact role of that H-2 molecules played in this process and the nature of the T- and B-cell interactions remained a mystery. A valuable clue was provided by experiments by Rosenthal and Shevach,[152] who demonstrated that efficient presentation of antigen by antigenpulsed macrophages to T cells also required histocompatibility matching. In 1974, Doherty and Zinkernagel sought to understand the role of T cells in the immune response to viral meningitis. They theorized that it was the strength of the immune response that caused the fatal destruction of brain cells infected with this virus. To test this theory, they mixed virusinfected mouse cells with T lymphocytes from other infected mice. The T lymphocytes did destroy the virus-infected cells, but only if the infected cells and the lymphocytes came from a genetically identical strain of mice. T lymphocytes would

ignore virus-infected cells that had been taken from another strain of mice.[153] Further experiments strongly suggested that the same TcR that recognizes viral antigen also recognizes the MHC molecule.[154] The implications of the Zinkernagel-Doherty experiment were profound. First, it established the principle of MHC restriction: T cells recognize antigen only in the context of MHC molecules. Second, the experiment established that cytotoxic TcR-bearing cells must recognize two separate signals on an infected cell before they can destroy it. One signal is a fragment of the invading virus that the cell displays on its surface and the other is a self-identifying tag from the cell's MHC molecules; it was felt likely that the same TcR probably recognizes both. Thus, the experiment pointed to the identity of the molecular structure that constituted immunologic "self"—it is the MHC molecule—and therefore a virus-infected cell bearing MHC molecules was likely to constitute "altered" or "nonself." Finally, the fact that MHC is highly polymorphic implies that any given allelic product will be capable of forming a different altered self from other MHC allelic products; thus, the specific identity of the MHC molecule itself determines the strength of the immune response.

Although the Zinkernagel-Doherty experiment answered many questions, the steps between encounter of antigen by an antigen-presenting cell (APC) and presentation of that antigen to a T cell was somewhat of a "black box." It had long been thought that intact antigen was presented to T cells, but it was not until 1981 that Ziegler and Unanue[155] showed that an antigen processing event was necessary for I-region (MHC class II)-restricted antigen presentation to T cells. This appeared to require antigen processing in a lysosomal-like compartment.[156] Peptide loading is a complicated affair, involving prior binding of MHC class II by an "invariant chain" to prevent premature loading of incompletely folded proteins in the endoplasmic reticulum.[157,158] Peptide loading requires proteolysis of the invariant chain.[159,160] Mellman and colleagues would go on to show that the actual compartment in

which antigen loading occurred is uniquely specialized for antigen presentation in B cells[161] and DCs.[162] In a landmark paper, Unanue and colleagues purified MHC class II molecules from 10^{11} B cells and showed a 1:1 binding with peptide and MHC class II I-A^d, but not I-A^k,[163] thus demonstrating MHC restriction at the biochemical level.

The processing events required for MHC class I restriction seemed more elusive, as some of the molecular components required for this were not known at the time. It was suspected that an intracellular proteolytic event was needed to process antigen, but that was not proven until 1994 when Rock et al.[164] showed that proteasomal inhibitors blocked degradation of most cell proteins and subsequent generation of peptides presented on MHC class I molecules. The actual mechanism by which peptides generated in the cytosol gained entry into the secretory compartment was provided in 1990, when four groups announced the identification of a member of a family of ABC transporters, called "TAP," which provided this function.[165,166,167,168] Finally, in 1987, Bjorkman et al.[169,170] demonstrated that the antigen in question was a peptide actually bound to the groove of the MHC class I molecule.

SPECIALIZATION WITHIN THE IMMUNE SYSTEM II.

Discovery of B- and T-Cell Antigen Receptors

The discovery of the B-cell receptor (BcR) for antigen began with Ehrlich,[171] when he proposed that cells that produced "amboceptors" expressed them at their surfaces; in fact, Ehrlich's drawings of amboceptor-producing cells emphasized this point (see Fig. 2.2). Evidence for the existence of surface Ig was provided by indirect immunofluorescence and autoradiography, in which immunoreactivity against a single class, IgM, was observed in 1970.[172,173,174,175] The function of the BcR was uncovered by Rock and Lanzavecchia, who showed that MHC class II-restricted antigen presentation by hapten-specific B cells was enhanced 10^3- to 10^4- fold by specific binding, endocytosis, and loading of peptide antigen onto MHC class II molecules.[176,177] In 1952, Colonel Ogden Bruton at the Walter Reed Army Hospital was caring for the 8-year-old son of a general. The boy had had recurrent pneumococcal infections, including bacteremia, but he recovered with antibiotics. Bruton noted that the boy did not mount an antibody response to pneumococcal vaccination and upon testing his serum using Tiselius apparatus, the electrophoretic pattern revealed a complete absence of γ-globulins.[178] Other cases appeared, and it was soon clear that the defect was X-linked. This is often cited as the first description of a primary immunodeficiency. It was not until 1993 that the molecular defect of agammaglobulinemia was uncovered. It was due to deficient expression of a tyrosine kinase, named *Bruton tyrosine kinase*.[179,180] This discovery highlights another function of the BcR, which is to help provide signals for B-cell maturation. Without its expression, B-cell development is blocked beyond the pre-B-cell to immature B-cell stage.[181]

The discovery of the TcR for antigen was likened to the hunt of the apocryphal Snark,[182] according to Mak,[183] except the TcR was finally captured after a hunt that lasted over 20 years or more, depending on one's perspective. The hunt was characterized by extended periods of uncertainty, when it was not clear whether the same receptor bound to antigen and

MHC simultaneously, whether two separate TcR proteins bound MHC and antigen separately (the “intimacy model”), or whether one TcR molecule bound MHC molecules altered by antigen. It was also not known what form the antigen would actually take, and many considered it likely that the binding was strictly analogous to the binding of antibody and antigen, amounting to an “IgT-antigen” interaction.[184] The existence of the TcR was deemed within reach when a clone-specific monoclonal antibody (mAb) against a murine lymphoma was isolated.[185] Finally, in 1984, using differential hybridization approaches, Davis and Mak independently announced the cloning of the β-subunit of the mouse and human TcR, respectively.[186,187] This was soon followed by the cloning of the α-subunits of the mouse and human TcRs,[188,189,190,191] and the identification of other subunits of a different type of TcR, the γδ TcR.[192] Eventually, the crystal structures of pMHC combinations demonstrated that contact between TcR and pMHC was dominated by direct TcR-MHC contacts, rather than TcR-peptide interactions.[193,194,195] Beyond the initial recognition stage, signaling through the

TcR, as in the BcR, is a highly regulated process tuned to recognize cues from pMHC that govern positive and negative selection.[196] There is little doubt that had Medawar survived, he would have appreciated how the clonal selection theory has remained a driving force underlying the molecular details of antigen receptor signaling.

Discovery of Distinct Immunoglobulin Classes

Ehrlich's terminology for antibodies changed depending on the context; he sometimes referred to “amboceptors,” or immune bodies, and at other times he used the more familiar term “antikörper.” Regardless, he did not know the chemical makeup of antibodies, though he recognized that they must contain separate binding sites for antigen and complement. Elucidation of the actual structure of antibodies would have to await the seminal work of Porter and Edelman in the 1960s; however, the actual discovery of specific antibody classes, or isotypes, took place over many years. The first class of antibodies to be discovered was IgG. In 1939, Tiselius and Kabat immunized rabbits with ovalbumin, then absorbed a portion of the resulting antiserum with ovalbumin. When they applied samples of the unabsorbed and antigen-absorbed antisera to electrophoresis, they observed a marked decrease in the amount of protein that migrated in the γ region of electrophoretic mobility, farthest away from the fast-migrating albumin peak. They called the antibody that corresponded to this fraction “γ-globulin.”[197]

The next antibody class to be discovered was a result of an observation by the Swedish oncologist Jan Waldenström. He described two patients with oronasal bleeding, lymphadenopathy, low serum fibrinogen, and increased lymphoid cells in the bone marrow.[198] With the help of a colleague in Svedberg's laboratory, he noted that serum from these patients contained an abnormally large amount of homogeneous globulin with sedimentation coefficients corresponding to a molecular weight of more than one million. Waldenström thought this corresponded to a preformed large molecule, which became known as macroglobulin. Proof that a macroglobulin possessed antibody activity was finally provided in 1967,[199] which ultimately led to its current name, IgM.

IgA was discovered by Gugler et al.[200] who isolated IgA from human milk, and Heremans et al.[201] who isolated IgA from human serum. It was later found in high concentrations in all exocrine secretions[202] and further characterized by Tomasi and Zigelbaum,[203] who suggested that IgA plays an essential role in mucosal immunity. It was not until 1984 that the mechanism of secretion of IgA and IgM across epithelial barriers was uncovered; it was shown to depend on interactions of an Ig-associated polypeptide, the J chain, with a glycoprotein on the surface of epithelial cells, referred to as the "polymeric IgA receptor."[204] This receptor mediated transcytosis of secretory IgA and IgM.

The discovery of IgE had a particularly long gestation period and is well summarized in a review.[205] It began with a report by Prausnitz, in 1921, who injected his forearm with serum from a coworker allergic to fish (and coauthor on the ensuing paper); this was followed by a wheal and flare upon further injection of fish extract.[206] This property was expected for a class of antibodies termed "reagins" (from German *reagieren*, to react). IgE was identified as a specific immunoglobulin class by Teruka and Kimishige Ishizaka in 1966[207,208] and was shown to be increased in sera from asthmatics.[209] In 1993, Kinet and colleagues demonstrated that its high affinity receptor, FcεRI, was required for anaphylaxis.[210]

IgD is the most recent Ig subclass to be recognized. It was discovered from a patient with multiple myeloma.[211] Surface IgD is coexpressed with IgM on mature B cells. The function of IgD is not well understood, although the abundance of IgM- IgD+ B cells in the human upper respiratory mucosa suggests that it is likely involved in mucosal immunity.[212]

Because IgA and IgE were isolated based on their predominant location (IgA) or function (IgE), their role in the immune response was relatively easy to decode, but the relationships between the different Ig classes was unknown. It was discovered in 1963 that the early immune response was initiated by the rapidly sedimenting (19S) antibody, later shown to be IgM, followed by the production of a more slowly sedimenting (7S) antibody, now known to be IgG.[213,214] Although production of the different Ig classes was initially interpreted as being due to the participation of different cells, it was later shown that single clones of B cells were capable of producing multiple isotypes[215,216,217] in a process called class switch recombination (CSR). The enzymology of CSR was worked out much later by Alt, Nussenzweig, Honjo, and others, who showed that it required DNA repair enzymes[218,219] and activation-induced cytidine deaminase (AID). AID is mutated in an autosomal recessive form of the primary immunodeficiency, hyper-IgM type 2, in which afflicted patients are deficient in CSR and somatic hypermutation, consistent with an important role for AID in both processes.[220,221,222]

Discovery of Antibody Effector Functions: Fc Receptors

Almoth Wright was the first to recognize the importance of antibody-mediated effector functions other than neutralization or complement-mediated lysis. His studies were ignored for a long time, and it would take many years to appreciate the importance of the "other end" of the antibody molecule. Since the 1970s, studies on the effector functions of the Fc portion of IgG made extensive use of several in vitro model systems, often involving

phagocytosis.[223,224,225,226,227,228,229,230,231,232] The eventual cloning of receptors for the Fc portion of IgG (FcγRs) by Ravetch and et al.[233] revealed many similarities and some differences, but these early studies did not reveal how the receptors transduced signaling events, such as phagocytosis. It was not until 1989 that Michael Reth[234] noted a short tyrosine-containing sequence in common with several antigen receptors, including subunits of the TcR, the BcR,[235] and Fcγ and Fcε receptors[236] that the signaling function of FcγRs was understood in a larger context. Following receptor engagement, tyrosine residues within this consensus sequence, subsequently named "immunoreceptor tyrosine-based activation motif" (ITAM), become phosphorylated

by Src family tyrosine kinases and serve as docking sites for Syk tyrosine kinase,[237] or ZAP-70, in the case of the TcR. The membrane-associated tyrosine kinases become activated and phosphorylate substrates that further convey downstream signals. Absence of ZAP-70 leads to a severe combined immunodeficiency disease (SCID).[238] These studies uncovered the central role of nonreceptor tyrosine kinases in the immune system, which appeared to explain in large part how antigen and Fc receptors evoke calcium signaling,[239] degranulation,[240] phagocytosis,[229,241,242] and antibody-mediated cellular cytotoxicity.[243] Furthermore, the ITAM-containing γ-chain[244] that is associated with FcγRs is required for immune complex-mediated glomerulonephritis in mice.[245] Thus, it is likely that the hypersensitivity phenomena originally observed by von Pirquet at the beginning of the 20th century, and later attributed to immune complexes by Dixon et al.,[80] has a similar pathophysiology, at least in part.

THE HERMENEUTICS OF LYMPHOCYTE ACTIVATION

Evolution of Early Lymphocyte Activation Models

By the late 1950s, it became clear that lymphocytes were highly adept at interpreting or translating environmental cues and responding by maintaining a state of activation or tolerance. The focus of immunology had shifted from identifying the relevant cell types involved in the immune response to discovering what can be viewed as the "hermeneutics" (a term derived from the Greek ἑρμηνεύω, "translate" or "interpret") of lymphocyte activation. Based on the clonal selection theory, Burnet[246] proposed that activation or tolerance was the result of an antigen stimulating a single cell, depending on the age of the organism. This was in keeping with experiments in which tolerance was induced by exposing antigen during fetal life or shortly thereafter.[138,140,141] In 1959, Lederberg[247] modified this model to describe activation or tolerance as occuring depending on the age of the cell rather than the organism.

> If an antigen is introduced prior to the maturation of any antibody-forming cell, the hypersensitivity of such cells, while still immature, to an antigen-antibody reaction will eliminate specific cell types as the arise by mutation, thereby inducing apparent tolerance to that antigen.

However, the model could not account for several observations, among which were that the

dosage and specific form of the immunogen, such as a hapten, could also influence the outcome of the encounter. This led Talmage and Pearlman[248] to propose an alternative model in which antigen alone would induce tolerance, but aggregated antigen, perhaps associated with complement, could induce an additional nonspecific stimulus to trigger clonal expansion. The suggestion of the need for a second "nonspecific" stimulus, and particularly complement, was remarkably prescient in light of the finding that complement can provide exactly such a stimulus to amplify immunogenicity by 10^3- to 10^4- fold.[249] In 1968, and later revised in 1970, Bretscher and Cohn[250,251] provided a variation on this model, in which a thymus-derived antigen-sensitive cell-bound antigen containing at two separate sites, one for a receptor on the "antiantigen-sensitive" cell and another bound to a "carrier" antibody. If the second site on the antigen was occupied by antibody, then that would deliver a signal to the "antiantigen-sensitive" cell to induce immunity. In contrast, if the site remained unbound, the antigen would induce tolerance. In this model, two cells were involved, but they were separated in time and space. Among the problems with the model was its circularity: What would provide the stimulus for the production of the carrier antibody in the first place? Other theories were proposed to explain the phenomenon of alloreactivity. The most intriguing of these was provided by Lafferty and Cunningham,[252] who proposed the existence of an "antigen bridge," which was now provided by another cell to provide "Signal 2." When MHC restriction was described in 1977, this model was modified somewhat to include the provision that the second signal was triggered by MHC on the stimulator cell[253] (Table 2.1).

Discovery of Costimulation: T Cells as Beneficiaries

By 1975, models for lymphocyte activation had matured, but many details remained sketchy, particularly the identity of the elusive Signal 2. In 1987, Jenkins and Schwartz utilized a system designed to "convert" Ag-specific T-cell clones into suppressor cells. They used a model system in which T-cell clones against a pigeon cytochrome peptide were incubated with ethylene carbodiimide-fixed Ag-pulsed splenocytes as APCs. They obtained the surprising result that the T-cell clones became unresponsive to subsequent restimulation with untreated APCs plus peptide, although they remained viable and proliferated in response to interleukin (IL)-2.[254] This showed that Ag-specific unresponsiveness could be induced in the absence of suppressor cells and that stimulation with cognate antigen alone was insufficient to induce proliferation; the missing Signal 2 was defined as "costimulation" and ultimately identified as cluster of differentiation (CD)28-mediated signaling by Allison and colleagues.[255] Since this seminal discovery, an entire family of CD28-like molecules in T cells and their cognate ligands on APCs has been identified,[256,257] which includes an inhibitory member of the family, cytotoxic T-lymphocyte antigen-4.[258] This has led to the clinical development of cytotoxic T-lymphocyte antigen-4-Ig, an inhibitor of CD28,[259] which was approved for the treatment of rheumatoid arthritis by the U.S. Food and Drug Administration in 2006 and by the European Medicines Agency in 2007.

Discovery of the Mechanism of B-Cell Help

It was known since the 1960s that T cells were needed to "help" B cells produce antibody, but the molecular nature of that help was unknown.[129,260] Experiments had suggested that T-cell help required cell-to-cell contact, implying the existence of the involvement of cell

surface receptor-ligand interactions. Agonistic antibodies against CD40 drove B cells into cell cycle, raising the possibility that a cognate ligand on T helper cells participates in the mechanism of

T-cell help. Using a CD40-Ig fusion protein, murine CD40L was cloned.[261,262] Use of a mAb against the human CD40L confirmed that expression was restricted to mantle and centrocytic zones of lymphoid follicles and the spleen periarteriolar lymphoid sheath in association with CD40+ B cells,[263] which is the distribution that might be expected for a highly localized signal to provide T-cell help to B cells. Indeed, in 2000, the specific type of T cell that provided CD40L-mediated help to B cells, now called a T follicular helper cell, was identified by its unique anatomic location and expression of a homing receptor, CXCR5.[264,265] In 1993, four groups independently announced that defects in the CD40 ligand gene are responsible for X-linked hyper-IgM syndrome in which affected adults express elevated levels of IgM and defects in class switching.[266,267,268,269]

TABLE 2.1 Different Models of Lymphocyte Activation

Basis of Immune Recognition	Signals	Components	Conditions for Tolerance	Authors
Self versus nonself	1	B cell/Ag	Immature organism	Burnet, 1959230
	1	B cell/Ag	Immature Ab-forming cell	Lederberg, 1959231
	2	B cell/Ag-Ab + complement	Absence of bound Ab/complement	Talmage and Pearlman, 1963232
	2	Humoral Ag-sensitive responder cell/bivalent Ag/carrier antigen-sensitive thymusdependent cell	Absence of carrier Ab or lack of	Bretscher and Cohn, 1968,234 1970235
	2	Signal 1: Ab-bound responder cells + Ag	Absence of Signal 2	Lafferty and Cunningham, 1975236

		Signal 2: Stimulator cell + Ag		
Noninfectious self versus infected nonself	2	Signal 1: Lymphocyte + MHC/Ag Signal 2: PAMP+ APC	Absence of Signal 2	Janeway, 1989390
Danger	3+	“Signal 0”: Alarm Signal 1: (Th cell-APC-Ag; Tc-infected cells; B cell/Ag; Signal 2: Help (Th to B) or costimulation (APC to T)	Absence of “Signal 0”	Matzinger, 1994451

Abbreviations: Ag, antigen; Ab, antibody; APC, antigen-presenting cells; MHC, major histocompatibility complex; PAMP, pathogen-associated molecular pattern; Th, T helper.

T-Cell Subsets and T-Cell Signaling Paradigms

The widespread use of mAbs since their discovery by Köhler and Milstein resulted in the production of many antibodies directed against T cells that had nonoverlapping patterns of expression. Much of this early work was done by Schlossman, Reinherz, and colleagues.[270,271,272,273,274,275] In most cases, the antibodies themselves identified T cells with specific functions; and in 1987 and 1988, two groups found that the molecules recognized by two of these mAbs, denoted by their cluster designations, CD8 and CD4, mediated adhesion to MHC class I and II, respectively.[276,277] CD4 and CD8 were shown to bind to nonpolymorphic regions of MHC molecules,[277] suggesting that they might stabilize otherwise weak interactions between TcR and pMHC. Later experiments demonstrated that the cytosolic domains of these coreceptors were able to bind, and recruit, the nonreceptor Src family tyrosine kinase Lck.[278,279] It was not known at the time what the relevant substrates of Lck might be, but in 1989, at about the same time that the ITAM consensus sequence was identified, two groups showed that Lck was capable of phosphorylating subunits of the CD3 complex and the ζ subunits of the TcR.[280,281] Following the discovery of another key tyrosine kinase associated with the ζ subunit of the TcR, ZAP-70, by Chan and Weiss,[238] a complicated cell signaling paradigm began to emerge in which “Signal 1,” delivered by pMHC expressed on either APCs or virus-infected cells, is conveyed by a series of phosphorylation events, leading to phosphorylation of phospholipase C-γ, triggering increases in cytosolic calcium and dephosphorylation of a key transcription factor, NFAT. The elusive machinery of “store-operated calcium channels” required for calcium-based

signaling[282] was finally elucidated in 2006.[283,284,285,286] Defects in this pathway in lymphocytes lead to a form of SCID.[286] Dephosphorylated NFAT, alone or in conjunction with AP-1, translocates to the nucleus where it binds to sites on the promoters of key genes such as IL-2, culminating in T-cell proliferation.[287] The initial interaction between TcR-bearing T cells and pMHC-bearing APCs induces a cooperative series of protein-protein interactions in a spatially delimited fashion (the "immunologic synapse") that facilitates signaling events.[288] We now know that signal transduction by the TcR shares common elements, and in some cases identical kinases and substrates, with signaling by other ITAM-containing receptors, such as the BcR, and Fc receptors or IgG and IgE.[289,290,291] Recent data suggest that similar mechanisms governing "immunologic synapses" in T cells may also be characteristic of "phagocytic synapses,"[292] underscoring a further degree of conservation of ITAM-based pathways. It is ironic that lymphocytes, which had appeared morphologically uninteresting to so many biologists until the latter part of the 20th century, would share so many characteristics in common with their visually more intriguing cousins.

Cell to Cell Communication: Mice Have a Tale to Tell

The first cytokine to be characterized is credited to Isaacs and Lindenmann,[293] who studied an influenza virus-induced factor from chick chorioallantoic membranes that blocked a second viral infection; this factor was called "interferon" (IFN). It was not purified to homogeneity until 20 years later.[294,295] Type I IFNs, which include IFNα and IFN-β, and type II IFN, IFNγ, bind to distinct receptors. A major advance in our understanding of cytokine signaling occurred in 1992, when Schindler et al.[296] demonstrated the tyrosine phosphorylation and nuclear translocation of a complex of four proteins, named IFNα stimulated gene factor 3. IFNα stimulated gene factor proteins were isolated from nuclear extracts derived from over 10^{10} cells, followed by sequencing and cloning of their genes; two of these proteins are members of what are now known as STAT proteins, which were shown to be substrates for members of the Janus-associated kinase family.[297,298,299,300,301,302,303] The most common severe immunodeficiency attributable to defective cytokine signaling is X-linked SCID, which is due to mutation in the common γ_C gene that is shared by receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21.[304] Mutations in Janus-associated kinase 3 were found in two patients with a severe form of SCID indistinguishable from X-linked SCID.[305,306] Dominant-negative mutations in STAT3, which is important in the signal transduction of IL-6 and IL-10, were found to be responsible for hyper-IgE syndrome, a disease associated with highly elevated serum IgE, recurrent staphylococcal skin infections and pneumonia, and skeletal abnormalities.[307,308]

Much of our knowledge of this pathway, as well as many other components of the immune system, is due to the use of gene targeting in mice. In 1985, Smithies et al.[309] introduced a short DNA sequence from the human beta-globin locus into an erythroleukemia cell line and were able to detect a specific exchange of the beta-globin gene with the homologous sequence in about 1 in 10^3, demonstrating the feasibility of gene targeting. At the same time, Capecchi introduced DNA directly into the nucleus of a cell using a microelectrode. Capecchi

noted that multiple copies of the introduced gene were integrated into the host cell's chromosome through homologous recombination. These studies established the potential for homologous recombination in somatic cells. The next major step was based on the ability of using blastocyst-derived embryonic stem cells to introduce genes into the germline of the mouse.[310,311] By injecting blastocysts with cultured embryonic stem cells that were infected with a retrovirus, Evans and colleagues generated chimeric mice in which retroviral DNA was detectable in both somatic and germ-line cells.[311] Eventually, Evans, Smithies, and Capecchi refined these techniques, which led to the first knockout mouse, in which the gene encoding hypoxanthine guanine phosphoribosyl transferase was deleted. The resultant phenotypic resembled that of the Lesch-Nyhan syndrome, which is characterized by mental retardation and self-mutilation.[312,313] Today, gene targeting techniques are used worldwide to study the effects of deletion or overexpression of genes important in immunity and any disease that can be reproduced in the mouse and in other species in which the technique has been used. In 2007, Smithies, Capecchi, and Evans shared the Nobel Prize "for their discoveries of principles for introducing specific gene modifications in mice by the use of embryonic stem cells."

Chemokines

If cytokines determine what cells do, then chemokines determine where cells go. The first chemokines purified were derived from platelets, although neither protein (platelet factor 4 [CXCL4][314,315] and β-thromboglobulin [CXCL7][316]) was recognized to be chemotactic when first identified. IL-8 (CXCL8) was the first chemokine to be purified and sequenced based on its chemotactic function for neutrophils,[317] and its receptors were cloned in 1991.[318,319] The word "chemotaxis" was coined by Pfeffer in 1884, who observed spermatids migrating toward a pipette containing maleic acid salts.[320] It is not clear who first explicitly observed chemotaxis of leukocytes, although several scientists, notably Schultze, Lieberkühn, Davaine, and Wharton Jones described amoeboid movement in leukocytes in the middle of the 19th century.[321] Since then, chemotaxis has been studied in vitro using various techniques, including specialized chambers that facilitate this process.[322]

The effects of chemokines on cells are complex, but a major function is to orchestrate the process of diapedesis, the process of transendothelial migration first described by Dutrochet in 1824.[323] In 1979, Hayward et al.[324] described six infants from two families whose umbilical cords were still attached at 3 weeks of age. Five of these developed severe local and disseminated infections from which four died. The molecular defect was identified by Springer et al.[325] in 1984, who showed that leukocytes from patients with the disease lacked all known β2 integrin adhesion receptors. This was eventually traced to absent or abnormal β2 subunits (CD18). Marlin and Springer[326] later described the requirement of the β2 integrin, LFA-1, to bind its counter-receptor, ICAM-1, on endothelial surfaces for diapedesis to occur normally. The function of chemokines is to provide chemotactic gradients as well as activate the integrins for tight adhesion prior to the active participation in endothelial cells in diapedesis.[327,328] Interestingly, LFA-1 was shown to be required as an accessory molecule during interaction of T cells with their cognate targets.[329]

Chemokines are critical for initiating the primary immune response as APCs, such as DCs. DCs and naïve T cells both share a common chemokine receptor, CCR7. T cells migrate through high endothelial venules, which secrete the chemokine SLC (CCL21). SLC is needed for integrin-mediated adhesion of the T cells.[330] Mice lacking expression of SLC have defects in lymphocyte and DC localization to the T-cell zone of secondary lymphoid organs.[331] The chemokine-directed "patrolling" of naïve T cells in the lymph nodes is probably the major mechanism by which the very few lymphocytes with the relevant TcR specificity remain there to interact with the antigen-loaded APCs during an immune response. Thus, chemokines are essential components of the "clonal selection" of lymphocytes.

T-Cell Polarization: The Power of Dichotomy

In 1986, Coffman and Mosmann at DNAX Research Institute were interested in determining factors that differentiated different types of T helper cell lines. One such line was capable of inducing a 100-fold increase in IgE secretion from mouse splenocytes, which was potently blocked by IFNγ.[332] When the team characterized other cloned T-cell lines, it became clear that there were very specific patterns of secretion: Some clones, which they called T_H1 cells, produced IL-2 and IFNγ, while other clones, which they called T_H2 cells, produced factors that stimulated B cells (B-cell-stimulating factor-1), mast cells, other T cells, and IgE and IgG1 secretion. All clones produced IL-3.[333] Further work, in collaboration with Paul, who first identified B-cell-stimulating factor-1,[334,335,336] clarified that B-cell-stimulating factor-1 was the same factor that stimulated mast cells and T cells, later renamed IL-4. Coffman and Mosmann[337] defined the now well-established paradigm of polarized T helper cell secretion; they demonstrated that IL-4 and IFNγ reciprocally inhibit the outgrowth of T_H1 and T_H2 cells, respectively. The later identification of transcription factors that are selectively expressed in these cells (GATA-3 and T-bet, respectively) and can even reprogram the cells to transdifferentiate toward the "opposite" phenotype further substantiated this dichotomy.[338,339] These findings had profound implications for immunologists, who began to classify diseases according to their predominant T_H cytokine profiles. Thus, tuberculosis and most bacterial and fungal infections produced a T_H1 pattern of cytokines, whereas asthma and other allergic diseases produced a T_H2 pattern of cytokines. While this reductionist view of cytokine production is no doubt an oversimplification, this simple dichotomy has proved quite robust and has helped guide the development of novel therapeutics for various diseases.

There is, however, a danger to oversimplification[340]—sometimes it is necessary to be a "fox" rather than a "hedgehog."[341] Some diseases, such as Crohn disease, an inflammatory bowel disease that was thought to be driven by the T_H1-polarizing cytokine, IL-12, is more likely driven by a related cytokine, IL-23, with which IL-12 shares a common subunit; indeed, a genome-wide association study in 2006 revealed a highly significant association of the gene encoding a subunit of the IL-23 receptor and early-onset Crohn disease.[342] Ustekinumab, a mAb against the IL-12/IL-23 p40 common subunit was approved by the U.S. Food and Drug Administration for the treatment of moderate-to-severe Crohn disease in 2006 and for moderate-to-severe plaque psoriasis in 2009.

The Language of Immunoregulation: Explaining the "Contrivances"

The concept of immunoregulation is implicit in the term "immunity" (exempt), and the history of how different immunologists have viewed immunoregulation, depending on their perspectives, is worthy of a chapter in itself. Jerne[343] hypothesized that antibodies can act as antigens and elicit an immune response against their idiotypes, which would then serve to regulate the immune response. While appealing, efforts to prove the importance of this concept have achieved limited success. In 1970, Gershon and Kondo[344] found that thymus-derived cells could specifically induce tolerance, and they and others spent many years trying to isolate antigen-specific T suppressor cells but were unable to do so. In the 1990s, the field shifted away from clonotypic suppressor cells toward T cells secreting specific tolerogenic factors, such as IL-10-secreting "Tr1 cells" and transforming growth factor-β-secreting "Th3 cells."[340,345] This was followed by the identification of cell surface markers of a subset of CD4+ cells that were required to suppress autoimmunity in mice. These turned out to be CD25 and CD5 in a CD4+ population of cells in the mouse, cells which were later called regulatory T cells. In 2001, the *FoxP3* gene was identified as the gene that was mutated in Scurfy mice, which develop severe autoimmunity as a result of a single gene mutation.[346] Similarly, mutations in the human homolog of *FoxP3* were found to be associated with the disease called IPEX (*i*mmune dysregulation, *p*olyendocrinophathy *e*nteropathy, *X*-linked syndrome).[347,348,349] Analogous to the capacity for T-bet and GATA3 to drive T_H1 and T_H2 differentiation, respectively, expression of FoxP3 was sufficient to drive the differentiation of T helper cells to a CD4+ CD25+ regulatory T phenotype.[350,351]

Central tolerance, sometimes referred to as "negative selection," is a means of shaping the repertoire that was thought likely to exist following the discovery of the thymus as an immune organ by Miller in 1961; however, proof for this was lacking. How could one prove the existence of a phenomenon that predicted the absence of a cell, rather than its presence? It was not until 1987 that Kappler et al.[352] used a mAb against a specific TcR Vβ segment to show that the mAb recognized immature thymocytes but not mature thymocytes or T cells, thus proving that negative selection occurs. Von Boehmer demonstrated a similar phenomenon using a TcR transgenic mouse model.[353] Negative selection of immature B cells was also demonstrated in the classic experiments of Nossal and Pike,[354] Sidman and Unanue,[355] and Raff et al.[356]

Clearly, the field of immunoregulation is still evolving. Novel mechanisms of immunoregulation will surely be discovered, and novel regulatory interactions will be uncovered. The role of tolerogenic DCs,[357,358] CD8+ T cells,[359,360] and myeloid-derived suppressor cells[361,362,363] are likely to play important roles and some of these will likely find their way to the clinic. Perhaps, however, we have made some progress in support of Ehrlich's contention[364]:

> The organism possesses certain contrivances by means of which the immunity reaction, so easily produced by all kinds of cells, is prevented from working against the organism's own elements.

Immune Subversion: The Case of Tumors

The idea that the immune system is capable of responding to tumors dates back to Ehrlich,[365] who predicted that cancer would occur at a high frequency in the absence of

an immune response. This theme was recapitulated by others, notably Burnet,[366] who argued that T cells would be prominent in what he termed “immune surveillance.” The field enjoyed a resurgence in 1994 when Schreiber and colleagues demonstrated that tumors expressing dominantnegative IFNγ receptors demonstrated enhanced tumorigenicity in syngeneic mice.[367] This was supported by studies using lFNγ receptor-deficient or STAT1-deficient mice.[368] Additional evidence for an active immune response against tumors is the spontaneous development of autoimmunity in some individuals with tumors; for example, paraneoplastic cerebellar degeneration occurs in individuals with a cytotoxic T-cell response to a shared antigen on tumor cells and neuronal cells.[369] The immune response to tumors is complex, with participation from cytotoxic T cells, natural killer (NK) cells, DCs, and myeloid cells.[370] The “counterresponse” by the tumors, which has been termed “escape” or “evasion,” is equally complex.[370] While it is beyond the scope of this chapter to discuss any of these in detail, several relevant points of historical interest should be noted. In 1976, a postdoctoral fellow named Mike Bevan was studying alloreactive cytotoxic T-cell responses and was able to demonstrate that spleen cells from an H-2^b/H-2^d-restricted mouse primed with H-2^b cells that differed in minor histocompatibility loci contained increased numbers of both H-2^b- and H-2^d-restricted cytotoxic CD8 T cells.[371,372] Bevan interpreted this as evidence of “cross-priming,” in which ingestion of cell-associated antigens by phagocytosis led to cytosolic entry of antigens and loading onto MHC class I molecules and then presentation to cytotoxic T cells. It was completely novel and counterintuitive, but subsequent studies validated this interpretation.[373] Recent progress has been made in our understanding mechanisms by which antigens gain entry into the cytosol from phagosomes.[374] These studies were based on key findings by Desjardins and colleagues who first demonstrated recruitment of endoplasmic reticulum membrane to nascent phagosomes.[375,376] Mice that lack CD8α+ DCs, a cell type that is adept at cross-priming, were unable to demonstrate cross-priming and were incapable of generating a cytotoxic response against West Nile virus and a highly immunogenic fibrosarcoma tumor.[377] Thus, crosspriming is important in tumor immunity.

Tumor cells are capable of circumventing the host immune response in various ways, including downregulation of MHC class I molecules, although this would potentially render them susceptible to NK-mediated killing, according to the “missing self” hypothesis.[378] Tumors elaborate a host of cytokines and growth factors that directly inhibit various components of the immune system.[370] An additional means of tumor evasion specifically bears on the meaning of “immunologic self.” Most cells in the body express a cell surface protein, CD47, which is a ligand for a receptor present on macrophages and DCs, SIRPα.[379] SIRPα interacts with tyrosine phosphatases via its cytosolic domain[380]; therefore,

corecruitment of SIRPα to tyrosine kinase-coupled signaling scaffolds is predicted to inhibit kinase-mediated signaling events. Lindberg and colleagues showed in 2000 that CD47 on erythrocytes in mice prevented their phagocytosis until levels fell below a certain level, thus CD47 served as an aging "clock" that signified a "don't eat me" signal.[381] In 2010, in a remarkable study, expression levels of CD47 on non-Hodgkin lymphoma (NHL) cells were negatively correlated with survival. Blocking anti-CD47 antibodies preferentially enabled phagocytosis of NHL cells and synergized with rituximab. Treatment of human NHL-engrafted mice with an anti-CD47 antibody reduced lymphoma burden and improved survival, while combination treatment with rituximab (anti-CD20) led to elimination of lymphoma and cure.[382] In these settings, CD47, rather than MHC proteins, serve as a marker of "self." It is somewhat counterintuitive that, at least in the case of NHL, tumor masquerading as self is one mechanism by which tumors evade the immune system. Ironically, downregulation of MHC class I molecules, the classic marker of self, is yet another mechanism of how tumor evasion of immunity.[370]

Immune Hijacking: The Discovery of Human Immunodeficiency Virus

The first description of what would come to be known as the "acquired immunodeficiency syndrome" appeared in 1981.[383] Initially described in five homosexual men, the disease soon was apparent in Haitians, transfusion recipients, infants, Africans, and female sexual contacts of infected men.[384] In just 2 years, Montagnier's team published the first paper demonstrating the presence of retroviral particles from diseased patients,[385] and a year later, Gallo's group published five papers in *Science* providing convincing evidence that this retrovirus was the cause of acquired immunodeficiency syndrome.[386,387,388,389,390] Barré-Sinoussi and Montagnier won the Nobel Prize for their discovery of human immunodeficiency virus (HIV), along with zur Hausen, for demonstrating that human papillomavirus can cause cervical cancer. Many felt that Gallo should have been awarded the prize as well.

Pneumonia due to *Pneumocystis carinii* (later re-named *P. jerovici*) was common in initial cases of acquired immunodeficiency syndrome, but patients soon presented with an array of opportunistic infectious diseases, malignancies (eg, Kaposi sarcoma and lymphoma), and even autoimmune diseases. In 1986, Maddon et al.[391] demonstrated that CD4 is an essential receptor that mediates HIV-1 entry into lymphocytes; this was followed in 1996 by the demonstration of CXCR4 and CCR5 as coreceptors for HIV-1 entry.[392] Since then, many laboratories worldwide have dedicated their efforts to uncovering HIV pathogenesis.[393,394] One of the major challenges to the immune system as well as the development of an HIV-1 vaccine is the enormous plasticity of the viral sequence due to the high error rate of reverse transcription.[393]

Intensive efforts in academia and the pharmaceutical industry have resulted in highly active antiretroviral therapy based on targeting multiple steps of viral replication, mostly focusing on reverse transcriptase and protease. A disease that was once virtually 100% fatal is now manageable, resulting in an 80% to 90% decrease in mortality rates in the United States and Europe.[393] Among the major

challenges facing immunologists and virologists is eliminating the latent reservoir of virus in resting memory CD4+ lymphocytes, developing an effective HIV-1 vaccine, and providing treatment for the 90% of infected individuals worldwide who reside in developing countries and have poor access to antiretroviral therapy.

METCHNIKOFF'S LEGACY

The Rediscovery of Innate Immunity

Arguably, the most important advance in immunology in the last 15 years has been the "rediscovery" of innate immunity. The closest term to "innate immunity" that was used at the turn of the century was "natural immunity." When the cellularists and the humoralists were debating the relative importance of cells and soluble antikörper at the turn of the century, much of the phenomena that Metchnikoff observed under the microscope represented different aspects of innate immunity. However, Metchnikoff distinguished enhanced immunity due to vaccination as a result of what we would call today an acquired immune response: "an agglutinative substance…in the…fluids of the body becomes much more developed in those of immunised animals."[395] He thought that infections could lead to an acquired immune response, but the nature of that response was to foster an enhanced response in phagocytic cells.[395]

> In certain infective diseases terminating fatally a very marked phagocytosis is observed even in susceptible animals … The acquisition of immunity against microorganisms is, therefore, due not only to the change from negative to positive chemiotaxis, but also to the perfecting of the phagocytic and digestive powers of the leucocytes.

In 1932, Fleming[396] recounted the discovery of lysozyme, which he made in 1921, "because its importance in connection with natural immunity does not seem to be generally appreciated." Although the discovery has been cited to represent another example of scientific serendipity, resulting from accidental dripping of nasal secretions from Fleming himself onto a culture plate,[397] Fleming wrote that "cultures of nasal mucus were made from a person suffering an acute cold" when the bacterolytic phenomenon due to lysozyme was observed.[396] Fleming would go on to discover penicillin, which was a bona fide example of scientific serendipity, and receive the Nobel Prize for his discovery.

Of course, lysozyme is but one of many innate immune molecules important in the early phase of host defense. Other cationic proteins include defensins, which are secreted by leukocytes and epithelial cells, and chemokines, whose tertiary but not primary structures are related to defensins. Some members of both classes have the dual role of recruiting inflammatory cells to sites of infection and killing bacteria.[398,399,400,401] Other examples of components of innate immunity include "innate immune lymphocytes," such as NK cells, NK T cells, and γδ T cells. Although it is beyond the scope of this chapter to describe these cell types except in passing, the discovery of NK cells in 1975[402,403,404] provided a cellular mechanism to account for the observation that some host immune cells recognize and kill

virus-infected or neoplastic cells lacking expression of MHC class I molecules. NK cells also provide an early, immediate source of cytokines, allowing them to rapidly respond to injury prior to maturation of the primary immune response.[405]

The "modern era" of the study of innate immunity began in 1989. In a characteristic example of his remarkable insight, Janeway[406] published an article in which he described a new model for immune recognition. Janeway argued that rather than distinguish "self" from "nonself," the immune system had evolved to distinguish "noninfectious self from infected nonself" (see Table 2.1). Janeway compared the innate and acquired immune systems. He emphasized that the former evolved to respond rapidly to "pathogen associated molecular patterns" by as yet unidentified receptors in a nonclonal fashion. Janeway was acutely aware of the significance of Freund's discovery of adjuvant[407] and the implications this had for the primary immune response. What was remarkable about Janeway's hypothesis is its intuitive appeal and its Darwinian flavor, in some ways analogous to Metchnikoff's view of phagocytosis. In addition, it had great predictive power. In a completely independent line of investigation, Jules Hoffmann became interested in exploring inflammatory pathways in *Drosophila*. Hoffman was aware of Baltimore's discovery of nuclear factor κ-light-chain-enhancer of activated B cells (NF-κB), a transcription factor, originally identified as a lipopolysaccharide (LPS)-inducible transcription factor in B cells in 1986.[408] Mice rendered deficient in NF-κB demonstrated multifocal defects in immune responses, including those to LPS.[409,410] Based on his observation of similarities between the cytokine-induced activation cascade of NF-κB in mammals and the activation of the morphogen dorsal in *Drosophila* embryos, Hoffmann demonstrated that the dorsoventral signaling pathway and an extracellular toll ligand control expression of antifungal peptide gene expression. Mutations in the toll signaling pathway dramatically reduced survival after fungal infection.[411] Until that time, there was only a limited understanding of pathogen recognition in eukaryotes; the only receptor that was known to participate in the recognition of LPS was CD14, a molecule that is expressed predominantly on macrophages.[412] Shortly after publication of Hoffmann's landmark study, Janeway and Medzhitov published an article in *Nature* that described the cloning of a human homolog of *Drosophila* toll. A constitutively active mutant of human toll transfected into human cell lines induced the activation of NF-κB and the expression of the inflammatory cytokines IL-1, IL-6, and IL-8 as well as the expression of the costimulatory molecule B7.1 "which is required for the activation of naïve T cells."[413] The choice of these proteins was not accidental, and it was clear that Medzhitov and Janeway had Janeway's hypothesis of 1989 in mind. Meanwhile, Beutler et al.[414] were zeroing in on the genetic identification of a mutation in a mouse strain that was incapable of responding to LPS, a component of the cell walls of all gram-negative bacteria. Beutler and Cerami were the first to show that immunization against tumor necrosis factor, the prototypic cytokine

that is produced following administration of LPS, protected mice from lethal shock.[414] Beutler demonstrated that the codominant Lpsd allele of C3H/HeJ mice corresponded to a missense mutation in the toll-like receptor-4 gene.[415] Since these publications, a family of innate immune receptors has been defined, each responding to different ligands encountered by hosts during infection.[416] Initial interactions of innate immune receptors on APCs with

their ligands encounters are necessary for the upregulation of costimulatory molecules, without which tolerance would occur.[417] Janeway's prediction in 1989 was borne out, providing strong empirical evidence in support of his model for immune recognition (see Table. 2.1). In 2012, Beutler and Hoffman, together with Steinman, received the Nobel Prize.

The field of innate immunity has exploded since the key observations of Hoffman, Beutler, Janeway, and Medzhitov. Many other receptors and components of the innate immune system have been discovered. These include components of the complement system,[418] cell surface lectins,[419] collectins such as lung surfactant proteins[420] and mannosebinding proteins,[421] scavenger receptors,[422,423] and pentraxins.[424] Most of these participate in recognition of pathogens, including fungi,[425] bacteria,[426] and viruses such as HIV.[427] In some instances, the phagocytic cells themselves serve as the source of opsonins, such as complement.[428] A variety of innate immune receptors also recognize apoptotic and necrotic cells.[429,430] Secretion of opsonins, such as milk fat globule-EGF factor 8, can enhance uptake of targets such as apoptotic cells,[431] and the absence of this protein has been linked to autoimmunity in mice.[432] Similar results were found in other mouse strains engineered to be deficient in clearance of apoptotic cells.[433,434] The conceptual basis of these experiments was built on earlier work of Savill, Henson, and others who showed that the immunologically “silent” disposal of apoptotic debris is an active process serving to divert self-antigens toward a nonphlogistic mode of phagocytosis.[435,436,437] In the context of resolution of acute infections, a similar function is provided by the production of omega-3 polyunsaturated fatty-acid-derived “anti-inflammatory” lipids (“resolvins”), first identified by Serhan et al. in 2000.[438,439]

Cytosolic Components of Innate Immunity: Discovery of the Nicotinamide Adenine Dinucleotide Phosphate-Oxidase

In 1957, Good and colleagues described an X-linked disease in which children succumbed to chronic suppurative and granulomatous infiltrations and chronic infections.[440] Neutrophils isolated from these children showed decreased bactericidal activity, although they demonstrated normal phagocytosis.[441] However, they showed decreased hydrogen peroxide production and hexose monophosphate shunt activity.[442] In 1974, Curnutte et al.[443] identified defective superoxide anion production in children with this syndrome who also failed to reduce the dye, nitroblue tetrazolium.[444] This simple test has been widely used to diagnose what came to be called “chronic granulomatous disease.” In 1978, Segal et al.[445,446] identified the molecular defect in X-linked chronic granulomatous disease as the absence of cytochrome b. Since then, all the components of this multiprotein enzyme complex have been identified.[447,448,449,450,451,452] Of note is that the oxidase responsible for X-linked chronic granulomatous disease, now referred to as NOX2, is but one of a family of oxidases that are widely expressed and have been implicated in various disease.[453] We now know that there are multiple reactive oxygen species, many of which combine with other reactive molecules, such as nitric oxide, to generate reactive nitrogen species. Nathan and colleagues demonstrated that mice deficient in inducible nitric oxide

synthase proved highly susceptible *Mycobacterium tuberculosis*, resembling wild-type littermates immunosuppressed by high-dose glucocorticoids.[454]

In addition to its role in microbial killing, NOX2 is recruited to early phagosomes in DCs and mediates the sustained production of low levels of reactive oxygen species, causing active and maintained alkalinization of the phagosomal lumen. DCs lacking NOX2 show enhanced phagosomal acidification and increased antigen degradation, resulting in impaired cross-priming.[455]

Cytosolic Components of Innate Immunity Signal Danger

There are many additional cytosolic proteins important in innate immunity. Of particular interest is the discovery of a family of pattern recognition receptors, most commonly referred to as nucleotide oligomerization domain-like receptors.[456] In 2000 and 2001, a number of genetic studies linked defects in *NLR* genes to inflammatory diseases, including Crohn disease,[457] Blau syndrome,[458] Muckle-Wells syndrome,[459] and familial Mediterranean fever.[460] In 2002, Tschopp and colleagues described a multiprotein complex that they called the "inflammasome," which included members of the nucleotide oligomerization domain-like receptors family and caspase-1.[461] They showed that activation of the inflammasome leads to generation of IL-1β, a cytokine that was first cloned by Dinarello and colleagues in 1984,[462] representing one of the key "endogenous pyrogens" first detected in 1953.[463,464] In 2006, Tschopp showed that the NLRP3 inflammasome was activated by monosodium urate crystals, implicating this pathway in gout.[465] From a historical perspective, gout is among the earliest diseases to be described. It was identified by the Egyptians in 2640 bce and was later recognized by Hippocrates in the fifth century bc, who referred to it as "the unwalkable disease." Leeuwenhoek was the first to observe urate crystals from a tophus.[466] Recently, an advisory panel of the U.S. Food and Drug Administration recommended against approval of canakinumab, a humanized mAb against IL-1, for the treatment of gout; although it was effective, it was not deemed safe due to increased risk of serious infections.

In 1994, Matzinger[467] proposed a new model of immune recognition. She proposed that APCs are activated by danger/alarm signals from injured cells (see Table 2.1). Although this was a purely theoretical model, since then, there have been numerous instances in which injured or

damaged components of the host have been recognized to trigger inflammation. As Matzinger explains,[468]

> Although this may seem to be just one more step down the pathway of slowly increasingly complex cellular interaction, this small step drops us off a cliff … in which the "foreignness" of a pathogen is not the important feature that triggers a response, and "selfness" is no guarantee of tolerance.

Thus, release of uric acid crystals can be viewed as an example of a "danger signal." Similarly, release of intracellular stores of adenosine triphosphate from dying cells as a

trigger for signaling cellular injury, predicted in 1988,[469] was shown to be capable of activating the NLRP3 inflammasome.[470] Although Matzinger's model shares features in common with Janeway's, the emphasis on endogenous danger signals rather than direct engagement of pattern recognition receptors by pathogens is novel. The fact that pathogens and “endogenous danger signals” share common receptors and signaling pathways is consistent with the idea that either exogenous or endogenous triggers of innate immune receptors accomplish the same thing: to facilitate the primary immune response.

Cytosolic Components Maintain Safety: The Role of Autophagy

There are numerous examples of microbes that are ingested by phagocytosis but either remain viable within acidic organelles or escape into the host cytoplasm. Macroautophagy is an evolutionarily conserved process in which cytoplasmic components are sequestered by a double membrane sac, eventually acquiring endosomal and lysosomal characteristics.[471] In 2004, Deretic and colleagues showed that IFNγ induced autophagy in macrophages, which contributed to suppression of intracellular survival of mycobacteria.[472] In the same year, Nakagawa et al.[473] demonstrated that autophagy was necessary for killing of group A *Streptococcus*, which had escaped into the host cytoplasm. Since then, many publications have confirmed the importance of autophagy in both innate and acquired immunity.[471]

The Renaissance of Cellular Immunology: Discovery of Dendritic Cells

Although we tend to take for granted the concept that APCs are necessary to process antigen, this was not firmly established until 1967. Mosier used a method pioneered by Mishell and Dutton for measuring in vitro antibody production with sheep erythrocytes as antigen.[474] Mosier separated mouse spleen cells into an adherent fraction and a nonadherent fraction. The adherent cells, which were phagocytic, were deemed “macrophage rich,” and the nonadherent cells were deemed “lymphocyte rich.” Both populations together, but neither alone, were needed for an antibody response, and Mosier[475] concluded that antibody production required “antigen phagocytosis by macrophages and macrophage lymphocyte interactions,” although he did not know the nature of the interactions. Further experiments established that exceedingly few adherent cells were needed for antibody production, perhaps as few as 1 in 10^4 adherent cells.[476] In the mid-1970s, Zanvil Cohn and a postdoctorate in his laboratory at Rockefeller University, Ralph Steinman, were characterizing a novel adherent population of cells from spleen.[477,478,479] The cells had an unusual “tree-like” morphology, prompting the name “dendritic cell.”[477] These cells proved difficult to purify, necessitating Steinman and Cohn to develop a rather laborious density gradient technique for cell purification.[480] In 1978, they used this technique to show that DCs could stimulate a primary mixed leukocyte reaction —an index of lymphocyte proliferation—and showed that DCs are at least 100 times more effective than B cells and macrophages for this function.[58] This landmark paper was the first demonstration of the unique capability of DCs to efficiently present antigen. Since then, many DC subsets have been described with critical functions in shaping the immune response. For example, Banchereau and colleagues showed that one subtype of DC, a “plasmacytoid” DC, is the principal IFNα-secreting cell in systemic lupus erythematosus with the capacity to

induce plasma cell differentiation.[481,482] Other DC subsets can respond to cues from epithelial cells, which secrete the cytokine TSLP, and shape T-cell polarization toward a T_H2 phenotype.[483,484] This may be a critical pathway in promoting allergic inflammation in asthma.[485] Since the initial discovery of DCs in 1973, Steinman and his many colleagues and collaborators have uncovered novel functions of DCs in triggering and shaping immunity as well as inducing tolerance. Many laboratories worldwide are using DCs in both capacities, and Steinman himself was the recipient of a DC-based vaccine against his own pancreatic cancer. Steinman was awarded the Nobel Prize, posthumously, in 2012—tragically, just days after he succumbed to cancer. The Nobel was a fitting tribute to a consummate cellular immunologist whose scientific curiosity and pedigree could be traced to Metchnikoff.

ACKNOWLEDGMENTS

I would like to acknowledge my appreciation of my former mentor and good friend, Sam Silverstein, my former teachers, Ben Pernis and Len Chess, and to my colleagues who helped make teaching a great source of joy to me: Ned Braunstein, Vinnie Butler, Mitch Cairo, Kathryn Calame, Steve Canfield, Raph Clynes, Kathy Nickerson, Paul Rothman, Ale Pernis, Chris Schindler, and Bob Winchester. I am also indebted to Arthur Silverstein, whom I have come to know only from his scholarship, but in whom I feel a kindred spirit.

INTRODUCTION

The mammalian immune system defends against invading pathogens, by both the innate and adaptive mechanisms. Although cells that can respond to pathogens are scattered in tissues throughout the body, the optimal structures for the response to antigens are organized, compartmentalized cellular aggregates that facilitate antigen concentration and presentation to a large repertoire of antigen-specific lymphocytes. The primary lymphoid organs, the fetal liver, thymus, and bone marrow, are the sites where diverse populations of naïve lymphocytes mature to disperse throughout the body to await foreign invaders. This remarkable differentiation process occurs in a foreign antigen-independent fashion. The secondary lymphoid organs, including the lymph nodes, spleen, Peyer's patches, and other mucosal-associated lymphoid tissues (MALTs), are discrete sites in which naïve, antigen-specific T- and B-lymphocytes encounter invaders to generate an adaptive response. The lymph nodes and spleen have been considered to be somewhat static structures, while, in fact, they are responsive to environmental influences and undergo remarkable changes in the course of antigenic challenge. Precise programs control the development of the spleen, lymph nodes, Peyer's patches, tonsils and adenoids, and (in the mouse and rat) the nasal-associated lymphoid tissue (NALT). Somewhat less anatomically restricted tissues that are even more sensitive to the environment facilitate and include accumulations of lymphoid cells are organized, but less discretely defined: the bronchus-associated lymphoid tissues (BALTs) and inducible lymphoid follicles (ILFs). Tertiary lymphoid organs, or more accurately, tertiary lymphoid tissues, are accumulations of lymphoid cells that arise ectopically in sites that are not anatomically restricted and are not regulated by developmental programs. Tertiary lymphoid tissues respond to environmental stimuli and arise during chronic inflammation subsequent to microbial infection, graft rejection, autoimmunity, or cancer by the process of lymphoid neogenesis.[1,2] In this chapter, the structure, function, trafficking patterns, and developmental signals that regulate the hierarchy of lymphoid organs will be described.

PRIMARY LYMPHOID ORGANS

The primary lymphoid organs are the sites where pre-B- and pre-T-lymphocytes mature into naïve B and T cells in the absence of foreign antigen. Each T cell or B cell expresses a

unique receptor that can recognize and respond to exogenous antigen and, in most cases, discriminate between self-and foreign antigens. Naïve cells leave the primary lymphoid organs having received and responded to developmental cues that result in the rearrangement of their genetic material to generate a repertoire capable of recognizing and responding to a wide variety of foreign antigens. In the course of maturation in the primary lymphoid organs, the naïve lymphocytes express various chemokine receptors and adhesion molecules that direct them to secondary lymphoid organs.

Fetal Liver

The earliest lymphoid cell precursors derive from self-renewing hematopoietic precursors called hematopoietic stem cells (HSCs). During ontogeny, these cells occupy several niches. In the fetal mouse, the first wave of hematopoiesis occurs in the yolk sac and aorta-gonad-mesonephros region at E10.5.[3] The placenta also contains HSC activity.[4,5,6] Cells leave these tissues and migrate to the fetal liver, and then the bone marrow and thymus and spleen under the influence of chemokines and adhesion molecules (Fig. 3.1). The cells in the fetal liver respond to CXCL12 (stromal cell derived factor) and, in contrast to those in the bone marrow, also respond to Steel factor[7] (Table 3.1). The fetal liver is also the source of CD4+CD3- lymphoid tissue inducer cells that express lymphotoxin (LT)α (also called tumor necrosis factor [TNF] β) and LTβ. The requirement of inducer cells for the

development of secondary lymphoid organs is described in the following. Differentiation of HSCs to B cells occurs in the fetal liver, but does not require interleukin (IL)-7. B-cell development is described in detail elsewhere in this volume. Of the several different subsets of B cells, those generated by the fetal liver HSCs are somewhat limited and are of the B-1 subset.[8] They do not give rise to cluster of differentiation (CD)5 B cells, predominately B1-B cells, and do not express terminal deoxynucleotidyl transferase and myosin-like light chain.[8,9] It is not known whether these differences are intrinsic to the cells or are due to differences in the cytokine environment of fetal liver and bone marrow. The ligands for P-selectin, E-selectin, and vascular cell adhesion molecule (VCAM)-1 are required for the cells to leave the fetal liver and home to the bone marrow.[10,11]

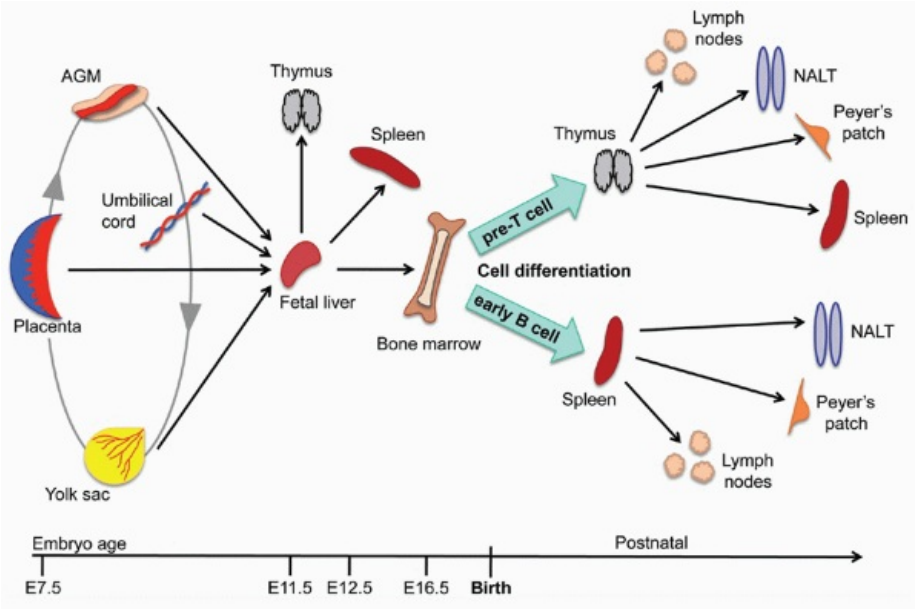

FIG. 3.1. Embryonic and Postnatal Development of T and B Cells in Mouse Primary and Secondary Lymphoid Organs. Embryonic diagram based on information summarized in Medvinsky et al.[6]

TABLE 3.1 Chemokines Implicated in Lymphoid Organ Development and Maintenance

Standard Name	Common Names	Receptor
CXCL12	SDF-1	CXCR4
CXCL13	BCA-1, BLC	CXCR5
CCL17	TARC	CCR4
CCL19	ELC, MIP-3β	CCR7
CCL20	MIP-3α	CCR6
CCL21	SLC, 6Ckine	CCR7
CCL25	TECK	CCR9
CCL28	MEC	CCR10

BCA, B-cell chemoattractant; BLC, B lymphocyte chemoattractant; ELC, EBI-1 ligand

chemokine; MEC, mucosae as-associated epithelial chemokine; MIP, macrophage inflammatory protein; SDF-1, stromal cell derived factor; SLC, secondary lymphoid tissue chemokine; TARC, thymus and activation regulatory chemokine; TECK, thymus-expressed chemokine.

Bone Marrow

Functions

The bone marrow is the source of self-renewing populations of stem cells. These cells include hematopoietic precurscor cells, HSCs, and endothelial progenitor cells, which may derive from a single precursor.[12] The adult bone marrow contains stem cells that can differentiate into adipocytes, chondrocytes, osteocytes, and myoblasts.[13] Collectively, these cells are called hematopoietic/stem progenitor cells. In the adult, cells leave the leave the bone marrow and seed the thymus where they undergo differentiation to naïve T cells. Additional factors enable the differentiation of immature B cells from HSCs.

In addition to serving as a primary lymphoid organ where B-cell differentiation and development occur, the bone marrow is also a home for antibody secreting cells.[14] After B cells

have interacted with antigen in the secondary lymphoid organs, such as the lymph nodes, spleen, and Peyer's patches, they enter the bloodstream and travel to the marrow. Thus, this organ not only serves as a primary lymphoid organ, but also as a reservoir for fully differentiated plasma cells.

Architecture: Cellular and Functional Niches

The microenvironment of the bone marrow, contained in the central cavity of bone, is a complex three-dimensional structure, with cellular niches that influence B cells during their development and later, as plasma cells, as they return to the bone marrow. The bone marrow has a rich blood supply with a nutrient artery that branches into ascending and descending arteries further dividing into cortical capillaries, periosteal capillaries, and endosteal capillaries, finally merging into a sinus.[15] Previously, the prevailing understanding of B-cell differentiation in the bone marrow was that primitive HSCs were located in close contact with the endosteum near osteoblasts (the “endosteal niche”). During the course of differentiation into mature B cells, they moved into the central region of the bone marrow cavity (the “vascular niche”).[16] The former niche was identified as the location of HSC; the latter, as the site of B-cell differentiation.[17] This anatomic concept has been challenged, as it has been reported that HSCs are found throughout the bone marrow. More recently, a reticular niche has been described that includes CXCL12 abundant reticular cells.[18] Growth factors and cytokines produced by different stromal cells influence cells at different stages in their differentiation. Thus, it is more appropriate to consider functional or cellular, rather than anatomical, niches.[15,19] Once the HSCs differentiate into immature B cells expressing cell surface immunoglobulin (Ig) M, they undergo processes of negative selection and receptor editing, leave the bone marrow, and travel through the blood stream to the secondary

lymphoid organs where they complete their differentiation.

Several cytokines and chemokines influence B-cell differentiation in the bone marrow. Flt-3 ligand (also called Flk-2L) signals B-cell differentiation and growth and synergizes with several other hematopoietic growth factors.[20] Its receptor, Flt-3 (also known as Flk-2), expressed by primitive HSCs, is a member of the class II tyrosine kinase family. In contrast to fetal liver, HSCs from adult bone marrow do not respond to Steel factor. Chemokines contribute to B-cell differentiation in the bone marrow and define the functional niches. For excellent reviews of this topic, see Nagasawa,[15] Heissig et al.,[18] and Mazo et al.[21] Many of these factors affect other lymphoid cells, such as dendritic cells (DCs) and T cells. Several of these factors, whose functions have been identified in gene deletion studies in mice, in morphologic analysis, and in cell culture studies, play roles in multiple aspects of lymphoid organ development; their activities, though important in the bone marrow, are not limited to that organ. CXCL12, also known as stromal cell derived factor, is a chemokine that is crucial for recruitment of HSCs to the bone marrow. It is widely expressed by osteoblasts, reticular cells,[19] and endothelial cells.[22] In fact, the interaction of HSCs expressing CXCR4, the receptor for CXCL12, with that chemokine on the endothelial surface is the first step in the HSC's exit from the circulation into the marrow.[23] CXCL12 is also essential for the earliest stage of B-cell development (pre-pro-B cells). Its receptor, CXCR4, is expressed on early B cells and is downregulated in pre-B cells. CXCR4 remains at low levels in immature B cells and mature B cells in secondary lymphoid organs, but is upregulated after B cells interact with antigen and differentiate into plasma cells.[14] This explains the propensity of antibody-secreting cells to return to the bone marrow. Once a pre-pro-B cell has interacted with CXCL12, it moves on to a different cell expressing IL-7. In B-cell development, IL-7 acts later than CXCL12 in a narrow window between pro-B cells and immature B cells in the scheme proposed by Nagasawa.[15]

Traffic In and Out: Chemokines and Adhesion Molecules

The extensive vascularization of the bone marrow allows entrance of hematopoietic precursors and plasma cells and egress of mature cells. Hematopoietic progenitor recruitment to the bone marrow in the mouse is dependent on the interaction of a variety of chemokines, integrins, and selectins, and their receptors, counter receptors, and vascular cell adhesion molecules. These include α_4 integrin (VLA4 or $\alpha_4\beta_1$), VCAM-1,[24] P-selectin glycoprotein ligand-1, E-selectin,[25] $\alpha_4\beta_7$, and mucosal addressin cell adhesion molecule (MAdCAM-1).[26] A small subpopulation of newly formed B cells in the bone marrow that expresses L-selectin has been described,[27] suggesting a mechanism for entrance into lymph nodes (see subsequent discussion).

In addition to the acquisition of Ig expression that occurs in the bone marrow under the control of stromal cells, B cells express various chemokine receptors and adhesion molecules in the process of differentiation. In a study of human bone marrow B cells, it was determined that pro-B and pre-B cells migrate toward CXCL12, but not toward a wide range of other chemokines, including CCL19 and CCL21, though they do express low levels of CCR7, the receptor for those ligands. However, mature bone marrow B cells do respond to CCL 19 and CCL 21,[28] CXCL13 (indicating a functional CXCR5), and CCL20 (MIP3α). On the other hand,

CCR6 expression and responsiveness to CCL20 are only seen in mouse B cells after they have migrated into the periphery during the process of maturation and are in the circulating B cell pool.[29]

Thymus

Functions

The thymus is defined as a primary lymphoid organ due to its inimitable role in T-cell development. Indeed, a mutant known as the “nude” (*nu/nu*) mouse, which lacks a normal thymus, is completely devoid of mature T cells.[30] Although some studies suggest that T cells can develop extrathymically in organs such as the “cervical thymus”[31] and the gut epithelium,[32] the thymus remains the main site for T-cell maturation, education, and selection. T-cell precursors represent more than 95% of total cells in the thymus and give rise to mature T cells. These cells are crucial components of the adaptive immune system in that they are highly specific in their ability to recognize a nearly infinite number of antigens owing to their diverse repertoire.[30,33]

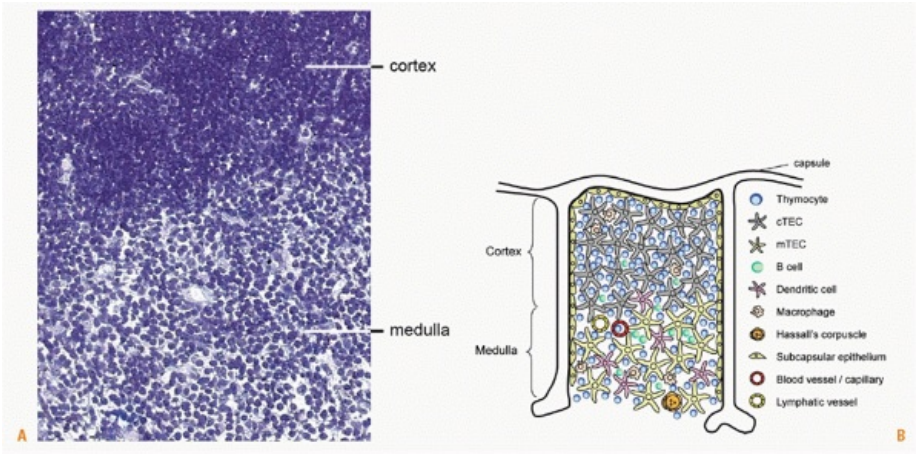

FIG. 3.2. A: Thymic structure. Low power magnification of a hematoxylin-stained frozen section of a mouse thymus. The cortex is well populated with lymphocytes; the medulla is less tightly packed and thus stains less intensely. **B:** Diagram of mouse thymic cellular populations. Precursor T cells enter through blood vessels at the corticomedullary junction. They progress to the medulla where they undergo differentiation from double negative to double positive (DP) cells expressing T-cell receptors. Thymic stromal cells provide growth factors. DP cells undergo positive selection, under the influence of cortical thymic epithelial cells. Single positive (SP) cluster of differentiation (CD)4 or CD8 cells migrate into the medulla where they undergo negative selection, mainly through autoimmune regulator expressing medullary thymic epithelial cells and dendritic cells. SP cells, having undergone differentiation, exit through blood vessels (not shown) to the periphery.

The T-cell repertoire is shaped during development in the thymus by the processes of

positive and negative selection. Negative and positive selection are so stringent that nearly 95% of all T-cell precursors are deleted in the thymus.[34] Negative selection ensures that T cells, which are capable of recognizing the organism's self-antigens presented on major histocompatibility complex (MHC) class I or II molecules with high affinity, are eliminated prior to their export to the periphery. In contrast, positive selection, which requires a higher degree of T-cell receptor (TCR) avidity than negative selection,[35] allows for T cells recognizing self-antigen with low to medium affinity to leave the thymus and eventually protect the organism against invading pathogens.

While negative selection is highly efficient in eliminating the majority of self-reactive T cells, some of these cells do escape the thymus and exit to the periphery. These autoreactive cells impose a threat to various organs as their activation may result in the development of autoimmune diseases. The immune system has evolved several ways to prevent the activation of autoreactive T cells in the periphery. One mechanism that protects against autoimmunity is the generation of a T-cell population capable of suppressing activation of self-reactive T cells. These thymus-derived protective T cells, known as regulatory cells (T_{reg}), recognize self-antigens with relatively high affinity.

Architecture

The thymus in the mouse consists of two symmetric lobes located above the heart, while in humans the thymus is multilobed. Each lobe can be divided into three distinct regions: capsule, cortex, and medulla. The latter two regions harbor thymocytes at various maturation stages. Although maturing T cells constitute the majority of cells in the thymus, other cell types such as macrophages, DCs, B cells, and epithelial cells are also present.[36] Histologic analysis of the thymus reveals a clear distinction between the thymic cortex and medulla, which are separated by a corticomedullary border. The thymic cortex appears darker and more densely populated with T-cell precursors, whereas, the medulla appears considerably lighter and contains smaller numbers of T cells relative to other cell types (Fig. 3.2A). Blood vessels and small blood capillaries are found throughout the thymus. The fact that T-cell progenitors are found in the more highly vascularized corticomedullary border suggests that blood vessels in this region facilitate the entry of T-cell progenitors into the thymic parenchyma.[37] In the thymic medulla, the close association between medullary thymic epithelial cells and thymic blood vessels[38] suggests that these vessels may act as organizers of the medullary thymic compartment. Lymphatic vessel distribution coincides with that of blood vessels and capillaries.[39] The majority of lymphatic vessels are located in the thymic medulla, though some can also be found in the cortex. The role of lymphatic vessels in thymic function is unclear, although it has been proposed that these vessels deliver extrathymic antigens into the thymus or export mature T cells from the thymus into the circulation.

Cellular Composition and Functions

T-cell precursors at various stages of differentiation represent the majority of cells in the thymus. Antigen-presenting cells (APCs) of either hematopoietic or stromal origin mediate the education and selection of T cells in the thymus. The different stages in T-cell selection and maturation that take place in distinct regions of the thymus (Fig. 3.2B) are discussed at length

elsewhere in this volume. Briefly, lymphoid progenitors enter the thymus at the corticomedullary border.[37] Following their entry, these cells, identified as double negative (DN) T cells due to a lack of expression of the cell surface molecules CD4 and CD8, undergo four maturation steps termed DN1 to DN4, which are distinguished by the expression of two additional cell surface molecules: CD25 and CD44.[40,41] DN3 cells migrate to the subcapsular zone while rearranging their TCRβ chain and expressing it in combination with a surrogate α chain. Those cells that have successfully rearranged the genes for α and β chains of the TCR become double positive (DP) cells, and express both CD4 and CD8 surface markers. In the cortex, DP cells undergo negative and positive selection.[42,43] Positively selected DP cells further differentiate into single positive (SP) cells expressing either CD4 or CD8. Following their differentiation, SP cells relocate to the medulla where they mature and undergo further rounds of deletion. SP cells that do survive are then exported out of the thymus.[44] DN precursors can give rise to an additional T-cell population expressing the γδTCR. These T cells are distinct from TCRαβ T cells in their tissue distribution and recognition of antigens. TCRαβ DP cells control the development of TCRγδ cells via the production of LTβ.[45] T_{reg} development in the human thymus occurs at the DP stage allowing for the production of CD4 and CD8 positive T_{reg}s.[46]

The thymic parenchyma consists of a complex threedimensional structure supported by thymic epithelial cells (TECs). TECs in the thymic cortex and thymic medulla are phenotypically and functionally distinct and support different stages of T-cell maturation. Several cell surface markers are used to distinguish medullary TECs (mTECs) from cortical TECs (cTECs) in the mouse. Among these markers are the cytokeratins K5 and K8, the adhesion molecule Ep-CAM, and the glycoprotein Ly-51. K8 and Ly-51 are expressed by cTECs, while K5 and Ep-CAM are expressed by mTECs.[47,48] TECs are unique in that they express MHC II constitutively, similarly to professional APCs. The role of TECs in T-cell selection was recently elucidated by their expression of the transcription factor, autoimmune regulator (AIRE). This transcription factor plays an important role in T-cell selection and prevention of autoimmunity, as illustrated by the fact that humans with a mutated form of the *AIRE* gene exhibit polyendocrine autoimmunity due to inadequate T-cell selection.[49,50] It has become clear that AIRE controls the expression of certain tissue-restricted antigens in the thymus, such as insulin, a protein that is unique to the β cells of the islets of Langerhans in the pancreas.[48,51] The expression of tissue-restricted antigens in the thymus facilitates the negative selection of maturing T cells, which would otherwise be allowed to leave the thymus. The thymic medulla includes distinct structures also known as Hassall corpuscles. Originally described by Arthur Hill Hassall in 1849, this structure consists of concentric stratified keratinizing epithelium. Hassall corpuscles are implicated in several processes of the thymus,[52] including the expression of tissue-restricted antigens, such as insulin (a key antigen in type 1 diabetes),[53] Igs, and filaggrin (key antigens in rheumatoid arthritis),[54,55] and serving as a prominent site for T-cell apoptosis.[56]

DCs are professional APCs that are found in the thymus. Thymic DCs can be divided into two distinct populations. The first population originates from a thymocyte precursor,[57,58] whereas the second population is derived from partially mature peripheral DCs that

continuously enter the thymus from the circulation.[59] DCs do not appear to be involved in positive selection, but do contribute to negative selection.[60,61,62,63] They have also been implicated in the selection of T_{reg}s in humans,[64] and recent reports in the mouse suggest that peripheral DCs can migrate to the thymus and serve as efficient inducers of T_{reg}s.[65] Activation of thymic DCs can be mediated in part by the IL-7-like cytokine, thymic stromal lymphopoietin. In the human thymus, Hassall corpuscles produce thymic stromal lymphopoietin, and thymic stromal lymphopoietin-activated DCs can alter the fate of self-reactive T cells from deletion to positive selection of T_{reg}s.[66] More specifically, thymic stromal lymphopoietin expression in a subset of DCs, plasmacytoid DCs, can induce the generation of particularly potent T_{reg}s from CD4+CD8- CD25- thymocytes.[67] These findings highlight the heterogeneity of DCs and emphasize their ability to fulfill different roles during T-cell development in the thymus.

Macrophages and B cells are additional hematopoieticderived professional APCs in the thymus. In contrast to DCs, thymic macrophages are located throughout the thymus and do not play a significant role in T-cell selection.[68] B cells are detected in human and mouse thymus at relatively low numbers[69,70] and are characterized by the expression of the cell surface molecule CD5. They are capable of producing antibodies of several different isotypes.[71] It has been suggested that thymic B cells induce negative selection in developing thymocytes,[69] although B cell-deficient mice show a limited T-cell repertoire when compared with normal mice, also suggesting a role in positive selection.[72] Recent data consistent with a role for B cells in thymic negative selection have emerged. Mice whose B cells were experimentally manipulated to express a myelin oligodendrocyte glycoprotein peptide show deletion of myelin oligodendrocyte glycoprotein-specific T effector cells.[73] One mechanism for the effect of B cells on T-cell selection is suggested by the observation that B cells play a role in the control of tissue-restricted antigens. Studies done in mice deficient in B cells showed fewer thymic epithelial cells with reduced expression of insulin and myelin oligodendrocyte glycoprotein, native antigens of the pancreas and brain, respectively.[74]

Traffic In and Out: Adhesion Molecules and Chemokines

Adhesion molecules mediate the extravasation of leukocytes from blood and lymphatic vessels into the thymus. These molecules also play an important role in facilitating lymphocyte homing into various regions of the thymus. Indeed,

thymic blood vessels express the adhesion molecules intercellular adhesion molecule (ICAM)-1, VCAM-1, CD34, peripheral node addressin (PNAd) and vascular adhesion protein-1.[75] The expression of high levels of ICAM-1, VCAM-1, and vascular adhesion protein-1 on venules near the corticomedullary border suggests that these molecules may play a role in the recruitment of thymocyte progenitors. More specifically, vascular adhesion protein-1, which is restricted to the venules surrounding the sites of progenitor homing, can mediate the extravasation of leukocytes. The regional distribution of these adhesion molecules further illustrates the importance of a distinct anatomical separation between cortex and medulla and represents their individual functions.

Chemokine-mediated T-cell migration and traffic to and within the thymus is crucial for normal T-cell selection. The compartmentalization of the thymus is orchestrated by a milieu of chemokines. The thymic cortex is involved in the maturation of DN cells to DP cells and by positively selecting DP T cells capable of recognizing MHC:peptide complexes and eliminating the cells that are not. The thymic medulla acts as a site of negative selection of SP T cells based on TCR recognition avidity to self-antigens and possibly positive selection of T_{reg}. Various chemokines that are produced by the thymic cortex and medulla allow T cells expressing different chemokine receptors to home to specific regions of the thymus. This differential expression of chemokines is complemented by the fact that T cells at different maturation states express different chemokine receptors. During development, the entry of lymphoid progenitors into the thymus is highly dependent on CCL21 and CCL25, which bind the chemokine receptors CCR7 and CCR9, respectively. Mice lacking CCR7 or CCL21[76,77] show a transient delay in thymus colonization by lymphocytes (day 14.5), and this delay is further extended (day 17.5) in mice lacking CCR9.[78] Lymphoid progenitors enter the thymus at the corticomedullary border and commence their migration outwards toward the subcapsular region of the cortex as DN3 cells. The expression of the chemokine receptors CXCR4 and CCR7 by DN cells is important in directing cell migration.[79,80] In the subcapsular region, DN thymocytes that have successfully rearranged their TCRαβ chains progress to the DP cell stage. Positively selected DP cells move inwards toward the thymic medulla for further differentiation into SP cells. The ligands for CCR7 are crucial in mediating the migration of positively selected DP cells into the medulla as illustrated by the fact that a deficiency in CCR7 or its ligands, CCL19 or CCL21, prevents DP cell relocation from the cortex to the medulla resulting in abnormal central tolerance.[81,82] This abnormal tolerance is associated with a reduction in thymic B-cell numbers and reduced expression of tissue-restricted antigens.[74] Interestingly, antigen itself can control T-cell migration speed from the cortex to the medulla. In the presence of a negative selection ligand, T cells slow down considerably and are limited to a confined zone 30 μ in diameter allowing for a more prolonged selection and induction of developmental arrest.[83]

The export of positively selected SP T cells out of the thymus is also dependent on chemokines. Chemokines involved in T-cell emigration are CXCL12 and its receptor CXCR4, which repel SP cells out of thymus,[84] and CCL19, which promotes T-cell emigration from the thymus of newborn mice.[85] The chemoattractant, sphingosine 1-phosphate (S1P), is an additional mediator of T-cell emigration. SP T cell express a S1P receptor ($S1P_1$) and are attracted to the high levels of S1P present in the serum promoting their egress.[86,87]

While the role of different thymic compartments and chemokines in the maturation of naïve SP T cells has been extensively studied, the thymic regions and chemokines that control the selection of regulatory T cells remain largely unknown. It may be that chemokines produced by both cTECs and thymic DCs play a role in regulatory T-cell selection, albeit during different stages of maturation.

Development

The initial development of the thymus at midgestation in the mouse is independent of vascularization or bone marrow-derived cells. In the mouse, the thymus rudiment is first

evident on day 11 of gestation as it evolves from the endoderm of the third pharyngeal pouch.[88] This gives rise to the thymic lobes as well as to the parathyroid gland. On day 12.5 of gestation, a separation of the primordium is observed and by day 13.5 a distinct thymus is apparent. Evidence has suggested that not only the pharyngeal pouch endoderm but also the ectoderm may also be involved in thymic development.[89,90] More specifically, it was suggested that the pharyngeal pouch ectoderm contributes to the development of cTECs whereas the endoderm contributes solely to the development of mTECs. This “dual origin” model was mainly supported by histological data as well as data collected from thymi of *nu/nu* mice.[91,92,93] More recently, it was shown that both thymic cortex and medulla are derived solely from the pharyngeal pouch endoderm[94]; although the endoderm and ectoderm are found in close proximity between gestational day 10.5 and 11, only the endoderm actively contributes to thymic development.[95] These findings support the so-called single origin model of thymus development.

The contribution of lymphocytes to the normal development of thymic cortex and medulla is well recognized. In models of T-cell deficiency, cTEC and mTEC development is halted at different stages depending on the stage of T-cell arrest. If T-cell development is arrested at the DN stage, as in the recombination activating gene-deficient mouse, the thymic medulla is greatly reduced while the thymic cortex remains unaffected.[96,97] A more severe phenotype is observed in transgenic mice that overexpress the human CD3 signaling molecule. In these mice, T-cell arrest occurs earlier than in recombination activating gene knockout mice, leading to a loss of both cortex and medulla and to a shift from a three-dimensional to a two-dimensional structure of the thymic epithelia.[97]

Recently, LTα and LTβ have been identified as master regulators of mTEC development and expression of tissue-restricted antigens. LTα and LTβ are members of the TNF superfamily and mediate the processes of secondary lymphoid organ development and inflammation.[1,98] In the absence of LT, tissue-restricted antigen and AIRE expression are reduced and certain mTEC subpopulations fail to develop.[99,100] T cells, owing to their vast numbers, appear

to be the main source for LT production in the thymus[45]; however, additional resident cells also serve as a source of LT. Recently, resident thymic B cells were identified as the highest source of LTα and LTβ on a per cell basis,[74] revealing yet another aspect of thymic B cells in thymus development and function.

The development of the thymus in humans closely follows the model of thymic development in the mouse and bird. Similar to the mouse, human thymic colonization by hematopoietic stem cells occurs relatively early, at week 8.2 of gestation. During this stage, the thymic medulla and cortex are organized, suggesting that thymocytes are required for normal thymic development. Between gestation week 9.5 and 10, the first signs of thymocyte negative selection are evident, and by gestation week 10 to 12.75 the gradual onset of positive selection is detected.[101]

SECONDARY LYMPHOID ORGANS

Naïve cells express their receptors for specific antigen, leave primary lymphoid organs,

circulate through the bloodstream, migrate into the tissues, and lodge in secondary lymphoid organs. The frequency of naïve cells specific for an individual antigen is quite low (estimates range from 1 in 10^5 to 1 in 10^6). Thus, the chance that an individual T or B cell will encounter its specific antigen in the circulation is rather low. Secondary lymphoid organs are strategically located in anatomically distinct sites where foreign antigen and APCs efficiently concentrate and activate rare antigen-specific lymphocytes, thus leading to the initiation of adaptive immune responses and generation of long-lived protective immunity. These organs include highly organized, compartmentalized, and mostly encapsulated tissues such as lymph nodes, spleen, appendix, tonsils, murine NALTs, and Peyer's patches. Naïve cells are also primed in less discrete tissues throughout the body, including the BALTs, cryptopatches, and ILF.

Lymph Nodes

Lymph nodes are bean-shaped structures dispersed along lymphatic vessels. The lymphatic vessel system plays important roles in tissue fluid balance, fat transport, and the immune response. In contradistinction to blood vessels, which form a closed recirculating system, lymphatic vessels comprise a blind-end, unidirectional transportation system. The absorbing lymphatic vessels, or lymphatic capillaries, remove interstitial fluid and macromolecules from extracellular spaces and transport the collected lymph through the primary collector. The collected lymph and its cellular contents are transported into the thoracic duct and returned back to blood circulation. In humans, lymph collected from the entire lower body region, the left head, and left arm region accumulates in the thoracic duct and returns to blood circulation via the left subclavian vein; lymph collected from right head and right arm region returns to blood via the right subclavian vein.

Lymph nodes, usually embedded in fat, are located at vascular junctions, and are served by lymphatic vessels that bring in antigen, and connect them to other lymph nodes. Though most lymph nodes are classified as peripheral lymph nodes, a few (cervical, mesenteric, and sacral), termed mucosal nodes, express a slightly different complement of endothelial adhesion molecules, cooperate with the mucosal system, and are regulated somewhat differently in development (see following discussion). Although all lymph nodes are vascularized, and thus can receive antigens from the bloodstream, they are also served by a rich lymphatic vessel system and are thus particularly effective in mounting responses to antigens that are present in tissues. These antigens may be derived from foreign invaders that are transported by APCs or can be derived from self-antigens. Thus, lymph nodes extend the role of the primary lymphoid organs and discriminate between dangerous foreign antigens and benign self-antigens. This capacity relies on the APCs and their state of activation in the lymph node, and the recognition capacity of the naïve T and B cells.

Lymph nodes can also function as niches for generating peripheral tolerance, an additional mechanism to minimize the effects of those self-reactive T-cells that escape central tolerance in the thymus.[102] DCs constitutively sample selfantigens and migrate to draining lymph nodes even in the steady state.[103,104,105] Because most self-antigen-bearing DCs in lymph nodes are immature[106] and have low levels of costimulatory molecules, they are not effective at activating naïve cells. They regulate self-reactive T cells by inducing anergy, clonal deletion, and/or expanding T_{reg}s.[105,106,107,108,109] Several groups have recently

described populations of cells in secondary lymphoid organs that can present tissue-restricted antigens to CD8 cells.[110,111,112,113,114] These include two different populations of AIRE-expressing stromal cells, DCs, and AIRE-negative lymphatic endothelial cells. These cells may play a role in self-tolerance, or perhaps they can prime for autoimmunity in inflammatory conditions.

Structure and Organization

A collagen capsule surrounds the highly compartmentalized lymph node (Fig. 3.3). The cortical region includes discrete clusters called primary follicles consisting of densely packed naïve B cells and follicular DCs (FDCs). After B cells encounter their cognate antigen, they are activated. They then proliferate secondary follicles and germinal centers develop. T cells and DCs distribute in the paracortex. Macrophages reside in the subcapsular zone and in the medullary area, and those in the subcapsular zone appear to be particularly adept at presenting antigen-antibody complexes to B cells.[115] Follicular DCs, a population of mesenchymal origin, support B-cell follicles or germinal centers under stimulation.[1] Plasma cells are also concentrated in the medulla as they prepare to leave the lymph node and circulate to the bone marrow. A network composed of reticular fibers, fibrous extracellular matrix bundles, and another mesenchymal cell population, the fibroblastic reticular cells, supports the entire lymph node.[116] Compartmentalization of cells in the lymph node is orchestrated by lymphoid chemokines CCL19, CCL21, and CXCL13. Stromal cells in the paracortical region produce CCL19 and the protein is transported to the surface of high endothelial venules (HEVs).[117] CCL21 is encoded by several genes[118]; CCL21-leu is expressed by lymphatic vessels

outside the lymph node[119]; CCL21-ser is made by stromal cells and HEVs in the lymph node. CCL19 and CCL21 recruit CCR7-expressing cells across the HEVs to the paracortical region. CXCL13, produced by stromal cells in the B-cell follicles, attracts CXCR5 expressing B cells.[120] After naïve T and B cells encounter antigen, they undergo extensive changes in expression of chemokine receptors and adhesion molecules that result in their movement to different areas of the lymph node or leaving it all together.[121,122] $S1P_1$ facilitates lymphocyte egress from lymph nodes as they move toward the ligand S1P in the lymph,[123,124] as discussed in more detail subsequently.

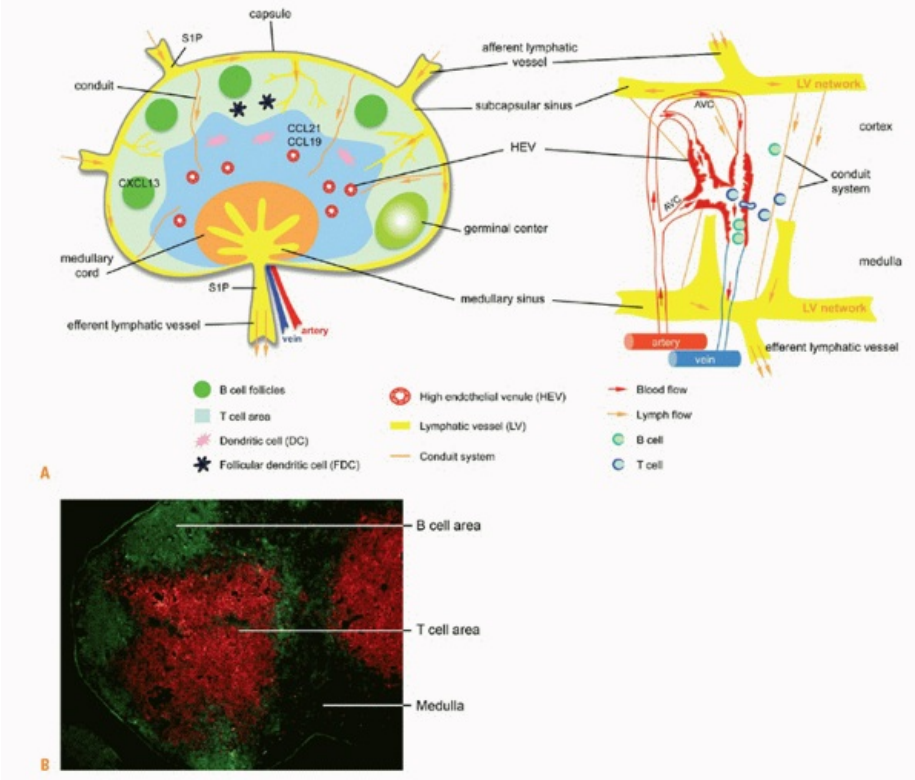

FIG. 3.3. A: Lymph node structure and functional regions. The lymph node is divided into an outer cortex and inner medulla surrounded by a capsule and lymphatic sinus. The cortex includes B cells and follicular dendritic cells. The paracortical region includes T cells and dendritic cells. Macrophages are found in the subcapsular sinus and medullary cord. Lymphocytes enter into the lymph node through an artery at the hilus region, and into the parenchyma through high endothelial venules (HEVs) expressing peripheral node addressin and CCL19 and CCL21. Stromal cells also produce these chemokines. T cells and dendritic cells (DCs) are directed to the paracortical region by CCL19 and CCL21. B cells are directed to the cortex by CXCL13. After interaction with antigen and T cells, germinal centers develop. Antigen and DCs drain into the lymph node from the tissues through afferent lymphatic vessels. Antigen continues to percolate through the node via a conduit system. Activated cells leave through efferent lymphatic vessels. Diagram of the blood network of a rat lymph node (*right*) is adapted from Anderson and Anderson.[125] Note the arteriovenous communications, the venous sphincters, and cells leaving the HEVs into the parenchyma. **B:** Lymph node compartmentalization. Immunofluorescent staining of B cells (anti-B220, *green*) in follicles in the cortex and T cells (anti-cluster of differentiation 3, *red*) in the paracortical area. The medulla is unstained.

Lymph Node Vasculature: Blood Vessels and Lymphatic Vessels

Soluble antigen and APCs enter into lymph nodes via afferent lymphatic vessels. After surveying antigens in the lymph

nodes, lymphocytes leave those organs via efferent lymphatic vessels that can connect to the

next lymph node in the chain and finally return to blood circulation.[125,126,127] In this manner, HEVs and lymphatic vessels maintain lymphocyte homeostasis during the steady state.

Blood endothelial cells play a crucial role in lymphocyte trafficking in the lymph node. One or two arteries enter the lymph node at the hilus. These arteries branch and pass through the medulla area, enter the cortex, and sometimes continue in the subcapsular area. Beneath the subcapsular sinus, the branching capillaries form loops and some of them become arteriovenous communications. Arteriovenous communications become HEVs in the cortex area and occasionally extend from the subcapsular sinus to the medulla. HEVs constitute a specialized postcapillary network in the lymph node, playing a critical role in lymphocyte recirculation. Each main HEV trunk receives three to five branches lined with high endothelial cells and two or three branches lined with flat endothelial cells. The luminal diameters of HEVs progressively increase from cortex to medulla. Finally, HEVs merge into segmental veins in the medulla area and join larger veins in the hilus[125] (see Fig. 3.3A). Intravital microscopy has revealed that the entire venular tree consists of five branching orders with the higher orders in the paracortex and the lower orders located in the medulla and hilus areas. Only the higher order venules, located in the T-cell area, are specialized into HEVs and are recognized by the monoclonal antibody MECA-79.[126,127] Recirculating naive lymphocytes leave the bloodstream via HEVs, specialized vessels with a high cuboidal endothelium, and migrate into the lymph node parenchyma. PNAd, defined by the MECA-79 antigen, is an L-selectin ligand, and is a characteristic HEV adhesion molecule. PNAd is composed of a variety of core glycoproteins, including GlyCAM-1, CD34, Sgp200, and podocalyxin; these proteins must be sialylated, sulfated, and fucosylated to become functional L-selectin ligands. The several enzymes that mediate these posttranslational modification events include FucT-IV, FucT-VII, and GlcNAc6ST2 (also called HEC-6ST, LSST, GST-3, HECGlcNAc6ST, gene name *Chst4*),[128,129,130,131,132] which with the exception of a population of cells in the intestine[133,134] is uniquely expressed in high endothelial cells. Together with another sulfotransferase, GlcNAC6ST1, that is expressed at sites in addition to HEVs, it sulfates glycoproteins in the Golgi apparatus[135] to generate the MECA-79 epitope. PNAd, expressed on the endothelial surface, slows down (tethers) naïve L-selectin^{hi} lymphocytes in their progress through the blood vessels. After this initial interaction, CCL19 and CCL21 on the HEVs are instrumental in activating the lymphocyte integrin lymphocyte function-associated antigen (LFA)-1. This results in tight binding of LFA-1 to ICAM-1 on the HEV, facilitating diapedesis of lymphocytes that migrate between or through the endothelial cells toward the chemokines located in the paracortical region (T cells, DCs) or cortex (B cells). Data suggest that the HEV-lymphocyte interaction is not random in different lymphoid tissues in the mouse.[136,137] T-lymphocytes adhere preferentially to peripheral lymph node HEVs, B cells prefer to adhere to HEVs in Peyer's patches, and T and B cells exhibit an intermediate pattern of adhesion to mesenteric lymph node HEVs.[34,136,138] The selective adhesion of naïve lymphocytes to HEVs is at least partially controlled by the differentially expressed adhesion molecules in different lymphoid organs. PNAd rapidly replaces MAdCAM-1 after birth in mouse peripheral lymph nodes,[139] but is expressed in mucosal lymph nodes together with MAdCAM-1, the ligand for the integrin $\alpha_4\beta_7$.

Lymphatic vessels also play critical roles in the immune response. The collected lymph and cell contents enter the lymph node via several afferent lymphatic vessels and filter through the node where they again are concentrated in the medullary sinus. Lymphatic vessels are concentrated in the subcapsular sinus and medullary area.[125] Factors from afferent lymph can be either transported deep into the lymph node cortex or move via the subcapsular sinus and leave the lymph node through efferent lymphatic vessels.[116] In this manner, soluble antigen and APCs from peripheral tissues are efficiently concentrated in the draining lymph node and initiate an adaptive immune response. Lymphocytes can also enter lymph nodes through afferent lymphatic vessels and leave via efferent vessels and move to the next lymph node in the chain. This is accomplished in part through a gradient of S1P, which is at a high concentration in the lymph and low concentration in the lymph node. Lymphocytes in the lymph node downregulate this receptor ($S1P_1$) and then upregulate it as they prepare to leave and migrate toward the higher concentration in the efferent lymph.[123,124] Human and murine lymphatic vessels express several characteristic markers: lymphatic vessel endothelial hyaluronan receptor-1 (LYVE-1), Prox-1, podoplanin, CCL21, the vascular endothelial growth factor receptor-3 (VEGFR-3), and neuropilin-2.[140]

Conduit System

A conduit system in the lymph nodes physically connects the lymphatic sinus with the walls of blood vessels and enables the incoming factor(s) from lymph to move rapidly deep into the paracortical area.[116,125] The conduit system consists of four layers: 1) a core of type I and type III collagen bundles; 2) a microfibrillar zone composed largely of fibrillins; 3) a basement membrane abundant with laminins 8 and 10, perlecan, and type IV collagen that provides a supportive structure; and 4) fibroblastic reticular cells that embrace the entire conduit system.[141,142] This conduit system enables incoming lymph to penetrate deep into the T-cell area. A special subset of immature DCs, called conduit-associated DCs, can take up and process antigens moving along the conduit.[142] In this manner, the conduit system probably provides a physical support for rapid initiation of adaptive immune responses after immunization.

The Intimate Relationship Between Lymph and High Endothelial Venules

Incoming lymph is necessary for the maintenance of HEV phenotype and function. After afferent lymphatic vessels are severed, dramatic changes occur in HEVs. These include flattening of the endothelium, a decrease in the uptake of ^{35}S-sulphate[143,144] (a functional marker of GlcNAC6ST-2), a reduction of lymphocyte adherence to the vessels,[145,146,147]

and decreased expression of PNAd and the HEV genes, *Glycam-1* and *Fuc-TVII*.[146,147,148] An increase in MAdCAM-1 expression[146] suggests that these events are not simply due to a general downregulation of blood vessel gene expression and indicates that continual accumulation of afferent lymph factor(s) in lymph nodes is necessary for HEV maintenance. The nature of such lymph factor(s) is unknown.

Topographic relations between HEVs and the lymphatic sinus have been described in the rat mesenteric lymph nodes. Some HEVs are located in the medulla area and positioned closely

in relation to the lymphatic sinus.[125] Occasionally, HEVs are separated from an adjacent lymphatic sinus by only a thin layer of collagen bundles. The closely apposed HEV and lymphatic sinus in the medulla provide the physical support for the intimate relationship between lymph and HEV. However, most HEVs are located in the paracortical area and are separated from the lymphatic sinus by lymphocytes. The conduit system physically connects the subcapsular sinus and HEVs and allows incoming lymph factor(s) to migrate rapidly to the wall of HEVs.[125,149,150] Low-molecular-weight fluorescent tracers (below 70 kD) move rapidly via the conduit system and lead directly to the wall of HEVs. In this manner, low-molecular-weight tracers can migrate with lymph within minutes to HEVs and enter the HEV lumen.[116] Lymph-borne chemokines likely adopt this route to regulate HEV function. IL-8 administration via afferent lymph increases lymphocyte HEV transmigration within minutes.[125,151] In addition, lymph-borne chemokines, such as MIP-1α, also enter the conduit system and move rapidly to HEVs.[116] These data suggest that lymph factor(s) can quickly access and regulate HEVs.

Development

Despite their distinctions in the adult with regard to morphology and expressed genes, a close association of blood vessels and lymphatic vessels is seen during embryogenesis. The generation of embryonic lymphatic vessels from preexisting veins in pig embryos was first described in the early 1900s by Sabin and has recently been molecularly defined.[140] A variety of transcription factors have been identified that contribute to the lymphatic specification and maintenance of the lymphatic vessels phenotype.[152] As early as mouse E9, expression of Sox18 and CoupTFII is apparent in the cardinal vein. These induce Prox1 in the dorsolateral side of the vein resulting in polarization and lymphatic-biased endothelial cells. Prox1 generates a feedback signal for the further maintenance of budding and migration of endothelial cells. Targets of Prox1 include Prox1 itself, podoplanin, VEGFR3, integrin-α, and Nrp-2. Prox1 expression in blood endothelial cells also represses expression of markers of those cells. NfatC1, Foxc2, and Tbx1 are additional transcription factors that are expressed later in lymphatic vessel development and contribute to patterning, pericyte covering of lymphatic vessels, lymphatic vessel valves, and lymphatic vessel maturation. At E11.5-12.0, CCL21 is expressed in these lymphatic-biased endothelial cells, as is VEGFR-3, which is reduced in blood endothelial cells. The endothelial cells expressing LYVE-1, Prox1, VEGFR-3, and CCL21 become irreversibly committed toward a lymphatic pathway.[153,154] The separation of lymphatic endothelial cells from venous endothelium requires a Syk/SLP-76 signal[155] that is provided by platelets.[156,157] Thus, during early lymphangiogenesis, some endothelial cells express both blood vessel and lymphatic vessel markers, indicating the close association of these two vascular systems. Mesenchymal lymphangioblasts may also contribute to early lymphangiogenesis.[158] The lymphatic venous junction remains in adults in only limited regions but plays an essential role in connecting the function of the two vascular systems.

Studies in the mouse have taken advantage of transgenic, knockout, and imaging studies to provide a mechanistic understanding of the process of lymph node development. Although lymph sacs per se do not appear to be essential for the initiation of lymph nodes, a lymphatic vessel system is necessary for the later development and cellular population of lymph

nodes.[159] Furthermore, an interaction between mesenchymal cells and primitive endothelial cells is apparent in the early lymph node anlage.[160]

Cytokines, Chemokines, and Transcription Factors in Lymphoid Organogenesis

The TNF-/LT-receptor family members play key roles in secondary lymphoid organ development. $LT_{\alpha 3}$, signaling through TNFRI and TNFRII, and membrane bound $LT_{\alpha 1\beta 2}$, signaling through the LTβ receptor (LTβR) have been implicated. Mice deficient in LTα lack all lymph nodes and Peyer's patches, and exhibit a disorganized spleen and severely disorganized NALT (see subsequent discussion).[161,162,163] Mice deficient in LTβ lack peripheral lymph nodes but retain mesenteric, sacral, and cervical lymph nodes.[164,165,166] *Ltβr -/-* mice have a phenotype similar to that of Lt^{α}*-/-* mice.[167] LTβR is also recognized by LTβ-related ligand, LIGHT, which also binds to the herpes virus entry mediator. LIGHT-LTβR signaling does not appear to play an essential role during lymphoid organogenesis, as no significant defect is observed in *Light-/-* mice[168]; however, mice doubly deficient in LIGHT and LTβ have fewer mesenteric lymph nodes than mice deficient in LTβ alone, indicating a cooperative effect of the two LTβR ligands. Treatment of pregnant females with an inhibitory soluble protein of LTβR (LTβR and human IgG Fc fusion protein, LTβR-Ig) inhibits most lymph nodes in the developing embryos, depending on the time of administration. Mesenteric lymph nodes are not inhibited by this treatment. These studies indicate that individual lymph nodes differ in the nature and time of cytokine signaling during development.[169] Several additional cytokine and chemokinereceptor pairs are crucial for lymphoid organogenesis. Mice deficient in IL-7 or IL-7R,[170,171] or TRANCE or TRANCER, also called RANKL and RANK,[172,173] exhibit defects in lymph node development. CXCR5- or CXCL13-deficient mice[174,175] lack some lymph nodes and almost all Peyer's patches.[98] The relative importance of the different cytokines in the development of individual lymphoid organs has been recently summarized.[176]

The NF-κB signaling pathways, downstream of the TNF family receptors, play important roles in lymphoid organ development.[177] The alternative pathway, characterized by NF-κB-inducing kinase (NIK) and IKKα is particularly

important. *aly/aly* mice, which have a point mutation in *Nik*, lack all lymph nodes and Peyer's patches.[178,179] In these mice, LTβR, but not TNFR, mediated signaling between NIK and members of the TRAF family appears to be disrupted.[179,180,181] LTβR signaling induces gene expression via both the classical and alternative NF-κB pathways in mouse embryo fibroblasts. The classical pathway mediated by p50:p65 heterodimers induces expression of proinflammatory genes (*Vcam-1*, *Mip1b*, *Mip2*). Intraperitoneal injection of an agonistic LTβR antibody induces splenic chemokines (CCL19, CCL21, and CXCL13) and requires NIK activity and subsequent p100 processing.[182] IKKα is a critical component in alternative NF-κB pathway. Mice with a mutated form of the *Ikka* gene have reduced HEV expression of HEC-6ST (GlcNAc6ST2) and GlyCAM-1, further confirming that the LTβR signal regulates HEVs through the alternative NFκB pathway.[183] Several other signaling pathways that contribute to lymphoid organogenesis include the helix-loop-helix transcription factor inhibitor

(Id2) and retinoid acid-related orphan receptors (RORs) RORγ and RORγt.[184,185,186]

Studies of lymph node anlage formation reveal the mechanisms by which cytokines trigger and coordinate lymphoid organogenesis. There is likely an initiating factor, though this has not been definitively identified. In the case of Peyer's patches, a cell producing the receptor tyrosine kinase has been implicated.[187,188] Recent data indicate that the earliest stages of lymph node development appear to be dependent on retinoic acid that may be produced by nerves in the vicinity of the developing node.[189] Circulating CD4+CD3-CD45+ RORγt+ hematopoietic progenitor cells called lymphoid tissue-inducer cells, derived from fetal liver progenitors,[98,185,190,191,192] provide crucial signals in lymph node organogenesis. These lymphoid tissue-inducer cells accumulate in the developing lymph node, forming clusters with resident stromal organizer cells, to initiate a cascade of intracellular and intercellular events that lead to the maturation of the primordial lymph node.[1,98] During this early step, a positive feedback loop involves several signaling pathways, including LTαβ/LTβR, IL-7R/IL-7, CXCR5/CXCL13, and RANK/RANKL, are expressed on the lymphoid tissue-inducer cells and the stromal organizer cells. The prolonged interaction between lymphoid tissue-inducer cells and stromal organizer cells promotes the development of HEVs, which support the entry of naïve lymphocytes.[193] It is unclear how HEVs differentiate from the flat blood vessels during early lymphoid organogenesis. At birth, HEVs of all lymph nodes express MAdCAM-1, which is replaced in the first few days in peripheral lymph nodes by PNAd.[194] Both MAdCAM-1 and PNAd are expressed in mucosal lymph nodes. LTα alone can induce MAdCAM-1, but PNAd requires LTαβ.[2,195,196] In the remaining mesenteric lymph nodes of *Ltβ-/-* mice, PNAd expression is impaired,[196] indicating that optimal lymph node HEV PNAd expression requires $LT\alpha_1\beta_2$ signaling through the LTβR and the alternative NF-κB pathway.[183] Because the maturation of HEVs is coincident with further development of the lymph node,[139,197] the homing of LT-expressing lymphocytes most likely contributes to HEV maturation. Continual signaling through the LTβR is necessary for maintenance of HEV gene expression.[198,199] Recent data suggest that the actual physical presence of lymphocytes in the close vicinity of HEVs contributes in important ways to the physical cobblestone appearance of these vessels.[200]

Changes in Lymph Nodes after Immunization

Lymph nodes undergo dramatic changes and remodeling after immunization. Early after a variety of immunogenic exposures, such as skin painting with oxazolone, injection of ovalbumin or sheep red blood cells in adjuvant, or bacterial or viral infection, remodeling occurs. This remodeling is apparent as a complex kinetics of changes in lymph flow, lymph cell content, blood flow, HEV gene expression, and lymphatic vessels.[199] Afferent lymph flow and lymph cell content increase soon after initial inflammation, and eventually return to preimmunization levels.[201,202,203,204,205] Lymph node lymphangiogenesis occurs, which eventually resolves.[199,206] Blood flow and lymphocyte migration into lymph nodes peak at 72 to 96 hours,[166,204,207,208] accompanied by an increase in HEV number and dilation,[209,210] accounting for the significant lymph node enlargement apparent at 72 to 96

hours.[207] Efferent lymph flow also increases soon after immunization, but lymph cell content in the efferent lymph drops during the first several hours, indicating the first wave of accumulation of lymphocytes in the draining lymph node. The cell content of the efferent lymph later increases and peaks at 72 to 96 hours.[211] These events, taken together, contribute to the significant enlargement of the draining lymph node at day 4 after immunization. During the early times after immunization, despite the increase in the number of HEVs, the expression of genes that contribute to L-selectin ligand, including *Fuct-vii*, *Glycam-1*, *Sgp200*, and *Chst4*, is initially downregulated followed by a recovery.[148,199,212] However, despite the downregulation of chemokines CCL21 and CXCL12, some genes such as those encoding CXCL9, CCL3, and E-selectin are upregulated,[213] as is MAdCAM-1,[199] suggesting a reversion to an immature phenotype before the eventual recovery of the mature phenotype.

In rodents, HEV maturation is coincident with the continuing development of the lymph node and population of lymphocytes after birth, indicating that the mature HEV phenotype relies on the lymph node microenvironment.[139,197] Plasticity of the mature lymph node is also seen after injection of LTβR-Ig. LTβR-Ig treatment reduces lymph node cellularity, reverts the HEV phenotype to the immature state, inhibits FDC function, and disrupts immune responses to foreign antigens.[198,199,214]

Spleen

Function

The spleen is a large reddish organ located beneath the diaphragm close to the stomach and the pancreas. It is the main filter of the blood and integrates the innate and adaptive responses. Its structure in well-defined different compartments, red pulp and white pulp, determines a variety of functions. The red pulp is a source of hematopoiesis in the embryo that can continue in adult life under stress. Clearance of blood-borne damaged platelets, aged

erythrocytes, and dead cells also occurs in that region. An important function, consequent to its destruction of effete erythrocytes, is its role in iron recycling. In some species, such as horses or dogs, the spleen stores erythrocytes that can be released after stress. The white pulp and marginal zone constitute the highly organized lymphoid compartment of the spleen. Due to this organized lymphoid structure and the special vasculature and circulation, the spleen is a crucial site for blood-borne antigen clearance and presentation to T and B cells. The spleen is crucial in defense against blood-borne pathogens and contributes most significantly to defense against bacterial and fungi infections.[215]

Architecture and Cellular Composition

A fibrous capsule and trabeculae of fibrous connective tissue maintain the structure of the spleen. The general principles of splenic organization are similar across species, though specifics may differ.[216,217,218,219,220] Classically, the spleen can be divided into two areas: red pulp and white pulp. A transit area, the marginal zone (MZ), surrounds the white pulp (Fig. 3.4). These compartments are anatomically and functionally distinct. The red pulp,

in its activities as a hematogenous organ, removes damaged cells and acts as a site for iron storage and turnover. The white pulp is an organized lymphoid structure. The complex structure of the spleen is directly related to the complexity of the vasculature of this organ. The afferent splenic artery branches into central arterioles, surrounded by white pulp areas, and end in cords in the red pulp. Blood then collects in venous sinuses that determine the engulfment of erythrocytes by red pulp macrophages. Finally, the sinuses empty into the efferent splenic vein. Some small arterial branches end in the MZ, which demarcates the red and white pulp. The MZ structure differs somewhat between humans and rodents. A perifollicular zone surrounds the human MZ, which consists of inner and outer marginal zones, whereas the rodent MZ is

a single structure and has no perifollicular zone. The MZ is the transition between the innate and acquired immune systems and is an important transit area for cells reaching the white pulp. It also contains a large number of resident cells. There are two specialized macrophage populations: the MZ macrophages and MZ metallophilic macrophages. MZ macrophages have a high phagocytic activity and are phenotypically different from other macrophage populations in the spleen as exemplified by the expression of SIGNR1 and macrophage-associated receptor (MARCO) with collagenous structure, molecules implicated in the recognition of pathogens. SIGNR1, a C-type lectin in the mouse that is a homologue of human DC-specific intercellular adhesion molecule,[221] is also found in medullary and subcapsular macrophages in the lymph node. MZ macrophages are crucial Marco for the capture of a wide variety of pathogens, including yeast, bacteria, and viruses.[222,223] MARCO, expressed constitutively on MZ macrophages,[224] is a class A scavenger pattern recognition receptor. In addition to the recognition of blood-borne pathogens, MARCO interplays with MZ B cells, modulating their migration to the white pulp.[225] MZ metallophilic macrophages are located at the inner border of the MZ, in contact with marginal sinus lining cells, stromal cells that express MadCAM-1.[226] MZ metallophilic macrophages differ from the MZ macrophages and red pulp macrophages in that they express the sialic acid-binding Ig-like lectin sialoadhesin (Siglec-1), which binds to oligosaccharide ligands present on many cells.[227] Little is known about the specific roles of this population of macrophages during the immune response; however, the phenotype of mice deficient in sialoadhesin implies a role of MZ metallophilic macrophages in T-cell activation.[228,229] Recent studies confirm that MZ metallophilic macrophages are essential for cross-presentation of blood-borne adenovirus antigens to splenic CD8 DCs, activating cytotoxic T-lymphocytes.[230] The MZ also contains a specialized subset of B cells that differ phenotypically and functionally from follicular B cells; they can be considered as a bridge between the innate and adaptive immune systems. They express higher levels of IgM low levels of IgD and the molecule CD1d. These B cells bind antigen in the MZ directly and/or through interactions with MZ macrophages[231] and migrate to the white pulp, where they present blood-borne antigens.[232] The organization of the remainder of the white pulp of the spleen is similar to that of the other secondary lymphoid organs with compartmentalized B- and T-cell areas. The white pulp consists of a central arteriole that is surrounded by T cells, also known as the periarteriolar lymphoid sheath, which is surrounded by B-cell follicles (see Fig. 3.4). T cells interact with DCs and B cells. B cells migrate to the follicles where they interact with FDCs. At the T:B-cell border, T cells,

especially T follicular helper cells,[233] interact with B cells. Germinal centers are the site of somatic hypermutation and Ig class switching. Plasma cells are found mainly in the red pulp.

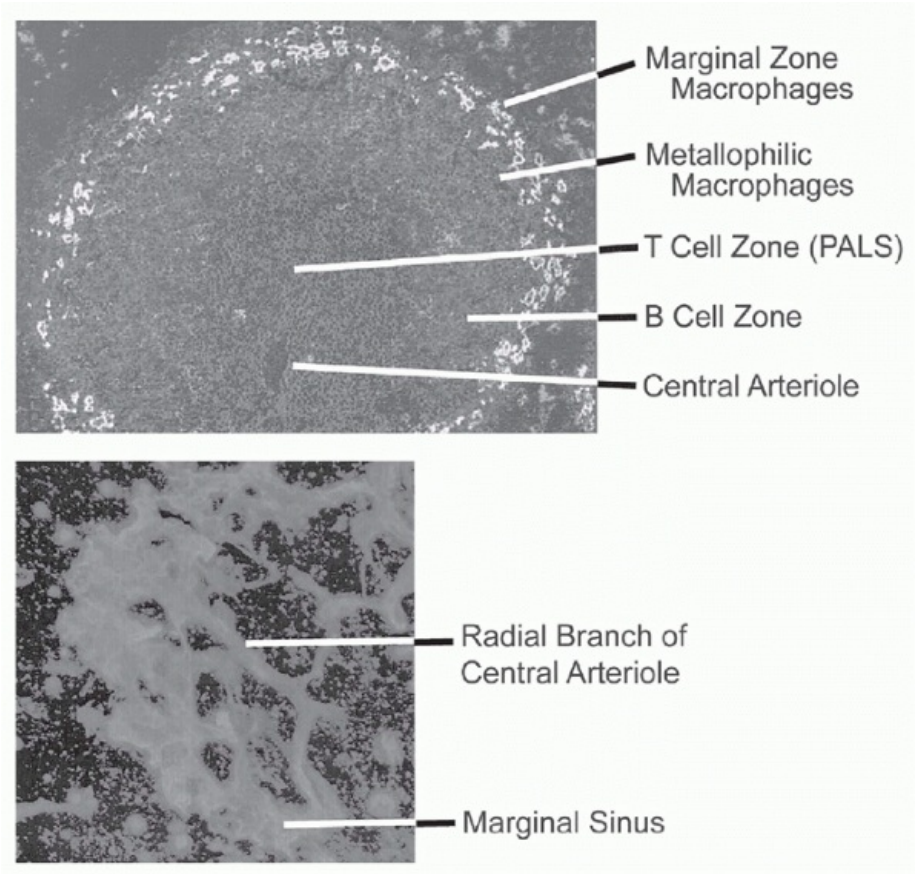

FIG. 3.4. Organization of the Spleen White Pulp. Immunofluorescence staining of a white pulp unit in the mouse spleen. T cells (anti- cluster of differentiation [CD]4+anti-CD8+, *red*) are localized around the central arteriole. B cells (anti-immunoglobulin M, *green*) are localized in follicles around the T-cell area, surrounded by a layer of metalophilic macrophages (labeled with monoclonal antibody-1) and a more peripheral layer of marginal zone macrophages (labeled with monoclonal antibody ERTR9, *orange*). The marginal zone is located between the metalophilic macrophage and the marginal zone macrophage layers (not shown).[357] From Chaplin[358] with permission.

The spleen does not have an afferent lymphatic system, and initial antigen transport must occur through the blood vasculature. A conduit system has been described that allows antigens and chemokines to be transported through the white pulp in a manner similar to that described for the lymph node.[234] This conduit differs from that in the lymph node with regard to the identity of the transported molecules by the fact that it contacts the blood rather than the lymphatic system.

Traffic In and Out: Chemokines and Adhesion Molecules

Cell trafficking in the spleen is similar to that which occurs in the lymph node in some respects, and differs in others. The MZ is the main transit area for blood cells that enter the

white pulp. This process seems to be controlled by marginal sinus lining cells[235] and chemokines, involving signaling through G-couple protein receptors.[236] Stromal cell-produced lymphoid chemokines CXCL13, CCL19, and CCL21 control the migration of lymphocytes and their organization in the various compartments in the white pulp. CXCL13 is essential to positioning of B cells in the follicles, whereas T cells respond to CCL19 and CCL21. After the immune response, germinal center B cells differentiate into plasma cells in the white pulp, then migrate to the red pulp or return the bloodstream to migrate to peripheral tissues. In the migration to the red pulp, plasma cells upregulate CXCR4, a receptor that binds the chemokine CXCL12, which is expressed in the red pulp.

The role of adhesion molecules with regard to lymphocyte traffic in the spleen is not fully well understood. Lymphocytes enter into the white pulp through the marginal sinus and cells lining that structure express MAdCAM-1 and ICAM-1.[226,237] MadCAM-1 expression in these cells seems to be involved in splenic structure development and therefore migration of B and T cells.[235] However, treatment with anti-MAdCAM-1 or anti-α1β7 antibodies does not totally inhibit homing to the spleen, suggesting that this ligand-receptor pair is not the only receptor required for lymphocyte entrance into the white pulp. Early studies indicating that treatment with an antibody that blocks the αL-integrin chain of LFA-1 inhibits homing by only 20%, and that lymphocytes deficient in LFA-1 enter the white pulp,[237] suggested that LFA-1 is not absolutely essential for entry of all cells into the white pulp. However, both $\alpha_4\beta_1$ and LFA-1 integrins are necessary for B-cell retention in the MZ,[238] indicating a role for VCAM-1 and ICAM-1 in cell trafficking in spleen. Once lymphocytes have encountered antigen, they most likely undergo changes in chemokine receptor and adhesion molecule expression similar to those noted in the lymph nodes, leave the white pulp and enter the red pulp (plasma cells) or the circulation. The mechanisms by which lymphocytes leave the white pulp are unclear. The observation of channels that bridge into the MZ[239] suggests one route of egress of lymphocytes. In the lymph nodes, the process of egress of activated lymphocytes through the efferent lymphatic vessels is mediated by upregulation the expression of $S1P_1$. In the spleen, $S1P_1$ is required for B-cell localization in the MZ, and the interplay with CXCR5 regulates the constant trafficking of these cells between the MZ and the white pulp,[232,240] as MZ B cells from $S1P_1$-deficient mice are not found in the MZ but are found in the follicles.

Although it is still unclear which molecules are involved in the egress of lymphocytes from the spleen, and splenic egress cannot be compared to egress in the lymph nodes,

recent studies attribute an important role to the transcription factor Nkx2.3 in the regulation of spleen vasculature and homing of lymphocytes.[241,242]

Development

Because the spleen has characteristics of both a hematopoietic organ and a secondary lymphoid organ, the genes that regulate its development include, in addition to LT, others that are concerned with patterning and hematopoiesis. Several genes that contribute to the development of the spleen are also crucial for normal development of other nonlymphoid organs. The first sign of splenic development in the mouse occurs at E10.5-11. Segregation of red and white pulp starts to be regulated during embryogenesis and continues after birth.

Some structures, such as the MZ, develop during the 3 first weeks after birth. At E10.5-11, progenitor cells begin to condense within the dorsal mesogastrium, adjacent to the stomach and dorsal pancreas. The spleen and pancreas are so intimately associated that it is difficult to distinguish between them at these early stages. In fact, many genes that affect splenic development also contribute to pancreatic development. Several of these are homeobox genes and transcription factors that are expressed in the splenopancreatic mesenchyme at E10.5.[215] The effects of just one of these genes, *Hox11* (now called *Tlx1*[215]), are on the spleen. The others affect multiple organs. *Tlx1* was originally described as an oncogene in T-cell childhood acute leukemias involving the (10;14) translocation breakpoint.[243] *Tlx1* -deficient mice are asplenic,[244] and the product of this gene is a cell survival factor.[245] Several additional genes that are important for development of lymph nodes, NALT, and Peyer's patches also contribute to splenic development. Mice deficient in members of the LT/TNF ligand receptor family and their downstream signaling molecules in the classical and alternative pathways exhibit defects in splenic development. However, none of these molecules is necessary for the early splenic anlagen, as mice deficient in any of the chemokines or cytokines retain a spleen. Recent studies address a role for Glce, an enzyme that modifies heparan sulfate, in early lymphoid tissue morphogenesis, as fetal spleen in Glce deficient mice exhibit a reduced size.[246] The changes in lymphoid tissue organization in mice deficient in LT/TNF ligand receptor family members are due in part to a reduction or near absence of lymphoid chemokines (CXCL13, CCL19, CCL21).[247] Lymphoid chemokine messenger ribonucleic acid (mRNA) expression is reduced in the spleens of mice deficient in TNFR1, TNF, LTα, or LTβ, though CXCL12 mRNA levels are normal. However, treatment with an agonistic LTβR antibody induces expression of the lymphoid chemokines and CXCL12, suggesting that signaling through both the classical and alternative NF-κB pathways are responsible for organization and maintenance of splenic white pulp architecture. Mice deficient in LTα exhibit a disorganized white pulp with loss of T- and B-cell compartmentalization, MZ macrophages, metallophilic macrophages, MZ B cells, MAdCAM-1 sinus lining cells, and germinal centers. *Lt*β-/- mice exhibit similar characteristics except that the disorganization is somewhat less pronounced. However, these lymphoid cytokines seem to be dispensable during fetal spleen development, when segregation between white and red pulp begins, but essential for maintenance of this structure during postnatal development of the white pulp.[248] *Tnf-/-* and *Tnfr1-/-* mice show defects similar to lymphotoxin deficient mice, with the exception of MZ B cells. T cells, B cells, and CD4+CD3- cells produce the cytokines necessary for maintenance of splenic architecture.[249,250]

Plasticity after Virus Infection

Though much is known regarding changes in the lymph node after immunization, the spleen has not been studied as extensively in this regard. However, after infection with cytomegalovirus, white pulp T:B compartmentalization is disrupted.[251] The spleens of *Ltα-/-* deficient mice exhibit a marked reduction in expression of CCL21-ser. This is even further reduced in cytomegalovirus infection, indicating that, in the adult, LT-independent pathways can contribute to maintenance of expression of lymphoid chemokines.

Mucosal-Associated Lymphoid Tissues

General Features

The MALT covers all mucosal surfaces not only in the gut, but also the oropharyngeal and lacrimal mucosae, the nasal and bronchial airways, and the genitourinary tracts. MALT protects a huge surface area and contains approximately half of the lymphocytes of the entire immune system.[252] MALT is considered to be the body's gatekeeper because it is in intimate contact with the commensal flora at the mucosal surfaces.

Although the location of some mucosal lymphoid tissues like the palatine tonsils and appendix are fixed, all MALT are somewhat plastic because of their constant exposure to environmental antigens that induces them to change and remodel. Tonsils, adenoids, and their equivalent in rodents, the NALT, have a fixed location, whereas the location, number, and size of Peyer's patches in the small intestine vary according to antigen exposure. The BALT in the lung and ILFs in the colon are the most plastic MALTs, and their number and location are subject to change by environmental influences.

The mucosal epithelium that surrounds MALT is populated by a dense network of DCs, plasma cells, and intraepithelial lymphocytes that helps to maintain the epithelial barrier. These intraepithelial leukocytes provide retinoic acid and cytokines like IL-10 and TGF-β that condition the gut to become tolerant of antigens produced by the harmless commensal bacteria.[253,254] They are also responsible for inducing and maintaining tolerance to food antigens and commensal bacteria.[255]

The large MALT structures like the tonsils, NALT, and Peyer's patches share many features with lymph nodes. Like lymph nodes, MALT contains HEVs for the entry of naïve lymphocytes, and stromal cells that secrete chemokines that direct lymphocyte traffic in the MALT (CCL19, CCL21 and its receptor CCR7[256]; CCL25 and CCL28 and their receptors CCR9 and CCR10[257]; and CXCL13 and its receptor CXCR5[258,259]). MALT also contains separate T- and B-cell compartments with B-cell follicles, FDCs, germinal centers, and interfollicular T cells and DCs.[260]

MALT differs importantly from other secondary lymphoid organs with regard to its capsules and afferent lymphatic vessels. Unlike the spleen and lymph nodes, which are surrounded by a dense fibrous capsule, MALT often has no capsule, with the exception of the tonsil that has a partial capsule that separates it from the pharyngeal constrictor muscles. Because MALT can sample antigens directly at the epithelial surface, it has no afferent lymphatics. MALT epithelium, especially that of the Peyer's patch, is replaced by specialized lymphoepithelial cells called microfold (M) cells, which because of their high transcytotic capacity, transport antigens to the underlying lymphoid tissue. Tonsils and adenoids are covered by a squamous epithelium and have few M cells. They can sample surface antigens using epithelial DCs that push dendrites through the epithelial surface.[261,262] M cells have not been characterized in human BALT.[263]

The proximity of MALT to the epithelium is an important point, because it helps differentiate MALT from tertiary lymphoid organs (see following discussion). MALT can be defined as organized lymphoid structures in the mucosa that are in direct contact with the epithelium. Using these criteria, a lymphoid aggregate in the submucosa that is not directly in contact with the epithelium (ie, below the lamina propria) is more correctly defined as a tertiary

lymphoid organ.[264]

The Mucosal-Associated Lymphoid Tissue Immune Response: Inductive and Effector Sites

MALT can simultaneously be a site for the induction of an immune response and an effector organ. The MALT surface containing M cells and DCs efficiently samples and transports antigens across the epithelium. Immediately below this single-cell epithelium is a dense network of DCs that can extend dendrites through the epithelium to grasp antigen to present to lymphocytes. Two distinct types of DC have been identified in MALT: CD103+ DC and CX3CR1+ DC.[265] Both types of DC produce tolerogenic responses to commensal bacteria by enhancing the differentiation of Foxp3+ T_{reg}s and inhibiting that of inflammatory Th17 cells. CD103+ DCs express αE integrin, make retinoic acid, induce T_{reg}s, and increase T-cell expression of the two gut homing receptors CCR9 and $\alpha_4\beta_7$. CD103+ DCs exit MALT via the lymphatics and present antigen in the draining lymph nodes. CX3CR1+ DCs that express the chemokine receptor for fractalkine do not migrate to the lymph node. CX3CR1+ DCs are longer-lived mucosal resident DCs that produce less retinoic acid than CD103+ DCs.[265]

MALT has three effector roles: local antibody secretion, systemic antibody secretion, and effector lymphocyte dispersal. MALT plays an important role in defense against pathogens by generating cells that migrate to other sites. MALT can dispatch lymphocytes to lymph nodes, the spleen, and plasma cells to the bone marrow. MALT also sends lymphocytes to other MALT effector sites including the salivary and lacrimal glands, the lactating breast,[266] and the vagina. There are some differences between the effector cells made at different MALT sites. NALT-derived B cells express CCR7 and do not home back to the gut. Instead, cells induced in the NALT home to the salivary glands and the vaginal mucosa lymph nodes,[267] whereas lymphocytes leaving the Peyer's patch express $\alpha_4\beta_7$ and migrate to the gut mucosa. These “preferred pathways” for effector cells coming out of the different MALT has led to the suggestions that MALT is compartmentalized and cells circling in the BALT are in a separate compartment from the GALT. It is more likely that the nature of antigen influences the homing of effector cells. There needs to be flexibility, and there is much overlap and redundancy in the system. For example, after the removal of the tonsils and adenoids in humans, or the NALT in the mouse, the cervical lymph node can act as an inductive site.[268] Likewise, the mouse BALT can mount an immune response in the absence of secondary lymphoid organs.[269,270]

Tonsils and Adenoids

Waldeyer's ring is a group of lymphoid tissues encircling the wall of the throat that are the first defense against pathogens entering through the mouth or nose.[271] Humans have several tonsils with indistinct borders: one pharyngeal tonsil (adenoid), two tubal, two palatine, and one lingual. In addition to T cells, the tonsils contain a large complement of B cells, many of which are positive for IgA.[271] The tonsil epithelium makes the polymeric IgA receptor, or secretory component,[272] crucial for transport of IgA dimers across the epithelium. Secreted IgA provides an early form of defense against pathogens and toxins. Overall, the adenoids produce more secreted IgA than the tonsils.

The common cold virus uses ICAM-1 as receptor to invade the nasal mucosa. ICAM-1 is also an expressed HEV in tonsils.[271] As noted previously, HEVs are specialized vessels that express adhesion molecules that allow naïve lymphocytes enter the tonsil. Naïve L-selectin^{hi} lymphocytes adhere to PNAd on HEVs.[258,259] L-selectin^{hi} cells also bind to MAdCAM-1 predominantly found in the gut HEVs. Considering the "mucosal name" MAdCAM-1, it may be surprising to discover that tonsil HEVs express MAdCAM-1 only weakly or not at all.[273] In mice, the HEVs also manufacture the chemokine CCL21 that can recruit naïve T cells and mature DCs that express CCR7. Human tonsil HEVs do not manufacture CCL21 but are able to display chemokines that have been made and secreted by fibroblasts.[274] During tonsillitis, inflammatory chemokines, cytokines, and adhesion molecules such as CCL19,[256] VCAM-1, and E- and P-selectin are upregulated.[165]

Nasal-Associated Lymphoid Tissue

The NALTs are a pair of lymphoid organs above the soft palate in mice and rats that are considered analogous to Waldeyer's ring.[275] Despite being anatomically separate from the genitourinary tract, NALT has an important "effector" role concerning the generation of immune responses in the genitourinary tract.[276] After nasal immunization with human papillomavirus 16 or ovalbumin, human papillomavirus 16-specific or ovalbumin-specific IgA is detected in vaginal washes,[163,277,278] and cytotoxic T cells are found in vaginal draining lymph nodes.[267] However, the NALT itself is clearly an inductive site for both humoral and cellular immune responses,[279] and supports class switching to IgA.[280]

The stromal cells in murine NALT produce both CCL19 and CXCL13, whereas, in contrast to lymph nodes, only HEVs transcribe CCL21 mRNA.[163] NALT HEVs express high levels of luminal and abluminal PNAd and HEC-6ST.[163] Similar to the tonsils, the major homing receptor-ligand pair in NALT is L-selectin and PNAd, rather than MAdCAM-1 as might have been expected of this mucosal-associated tissue.[281]

Development

Human NALT and tonsils appear early in fetal development, are cellular, and have primary follicles. After birth, secondary follicles and germinal centers appear in response to bacterial antigens.[266] By contrast, the NALT in the mouse and the rat is hypocellular at birth and undergoes dramatic changes after weaning, strongly suggesting that bacterial colonization is important for NALT development in these species. Id2 is required for initiation of the rodent NALT,[282] although RORγT, LTα, or LTβ are not required for this step.[162] The expansion of rodent NALT at weaning includes changes in the expression of LTα and LTβ and lymphoid chemokines, leading to T- and B-cell compartmentalization and HEV maturation.[162,163] The alternative NF-κB pathway is required for the expression of chemokines and the HEV genes *glycam-1* and *chst4* in NALT.[183] LTα, LTβ, IL7R, and the NIK signaling pathways are required for NALT organization and function, and mice that are deficient in these cytokines have a hypocellular NALT.[163,183,283,284]

Bronchus-Associated Lymphoid Tissue

BALT is less organized but more responsive to environmental antigens than the NALT. The number of lymphoid aggregates varies depending on the level of microbial exposure and germ-free pigs have no BALT.[252,285] BALT is found commonly in rabbits and rats, is less frequent in guinea pigs and pigs, and is absent in cats.[264] BALT is not a prominent structure in the laboratory mouse, and its presence varies by strain and age.[286]

An inducible form of the BALT (iBALT) has been described in *Lta-/-* mice after infection with influenza.[287] The term iBALT is misleading because these aggregates have no contact with the bronchial lumen and cannot sample inspired antigens. Therefore, iBALT should be considered as a tertiary lymphoid organ.[288] Splenectomized, lethally irradiated LTα-/- mice reconstituted with normal bone marrow have no lymphoid organs. However, these mice can generate immunological memory in the iBALT.[269,270]

BALT is rare in normal adult human lungs, but tertiary lymphoid organs are common in chronic pulmonary diseases.[283] BALT is frequent in children and is found in fetuses after infections in utero.[289,290] Like NALT, the HEVs in human BALT express PNAd and not MAdCAM-1.[291]

Gut-Associated Lymphoid Tissue

Gut-associated lymphoid tissue is the largest immune system in the body. The gut-associated lymphoid tissue in the small intestine includes the Peyer's patches, smaller isolated lymphoid follicles, and cryptopatches. In the large intestine, there is the appendix, caecal patches, and lymphoglandular complexes.[292]

Peyer's Patches

Peyer's patches are lymphoid aggregates aligned on the antimesenteric border of the small intestine (Fig. 3.5A). They are present in most species, though their number and location vary. They are dome shaped and are covered by a specialized epithelium that lacks surface microvilli and goblet cells; they have numerous M cells. Because Peyer's patches lack afferent lymphatic vessels, these M cells are critical transporters of antigen. Pathogens, including human immunodeficiency virus and salmonella take advantage of the M cells to facilitate their own invasion.[293,294] Below the epithelium is a diffuse area, the subepithelial dome, divided into three to six parts. Peyer's patch organization is similar to that of the lymph node (see Fig. 3.5). Peyer's patches contain 6 to 12 basally located germinal centers, but the B-cell areas are larger with a T:B cell ratio of 0.2; CD4+ cells predominate over CD8+ cells.[295] Although M cells transport antigen across the epithelial barrier, they are not believed to have a crucial role in processing or presenting antigen. Peyer's patches are populated by several subsets of DCs that can carry out these functions.[296,297]

Trafficking In and Out

Cells enter Peyer's patches through HEVs. In contrast to peripheral lymph nodes and the NALT, the HEVs of Peyer's patches express MAdCAM-1,[298] and homing depends on the

interaction of MAdCAM-1 with the integrin $\alpha_4\beta_7$ on lymphocytes. Luminal PNAd is rarely found in Peyer's patch HEVs; only occasional abluminal expression is detected. This pattern is identical to that seen in lymph node HEVs in *chst4-/-* mice.[128] However, lymphocytes from mice that lack both L-selectin ligand and $\alpha_4\beta_7$ home less efficiently to Peyer's patches than do lymphocytes from mice that lack only one or the other of the ligands,[299,300] suggesting that an L-selectin ligand does contribute to homing to Peyer's patches. Even though P-selectin is expressed only weakly on HEVs in Peyer's patches, cells from mice deficient in P-selectin show reduced rolling and adhesion in vivo. This suggests that P-selectin, as well as MAdCAM-1, is important for homing to Peyer's patches.[299]

Lymphoid chemokines CCL19, CCL21, and CXCL13 are found in the T- and B-cell areas[301] (see Fig. 3.5B). Stromal cells make CXCL12 mRNA, but the protein is also found on HEVs, presumably transported in a manner similar to CCL19.[117] The CXCL16/CXCR6 chemokine/receptor pair is important in Peyer's patches but not in lymph nodes. Even under germ-free conditions, CXCL16 is constitutively produced by the dome epithelium.[295] CD4+ and CD8+ cells that express CXCR6 are found in Peyer's patches and require CXCL16 to home to the subepithelial dome. CCL20 and its receptor CCR6 are also important in Peyer's patches. CCL20 is made by the intestinal epithelium and plays a crucial role in dendritic cell trafficking to Peyer's patches.[302] Peyer's patch HEVs express CCL25, the ligand for CCR9, which has been defined as a mucosal homing chemokine receptor for intraepithelial lymphocytes and plasma cells.[78]

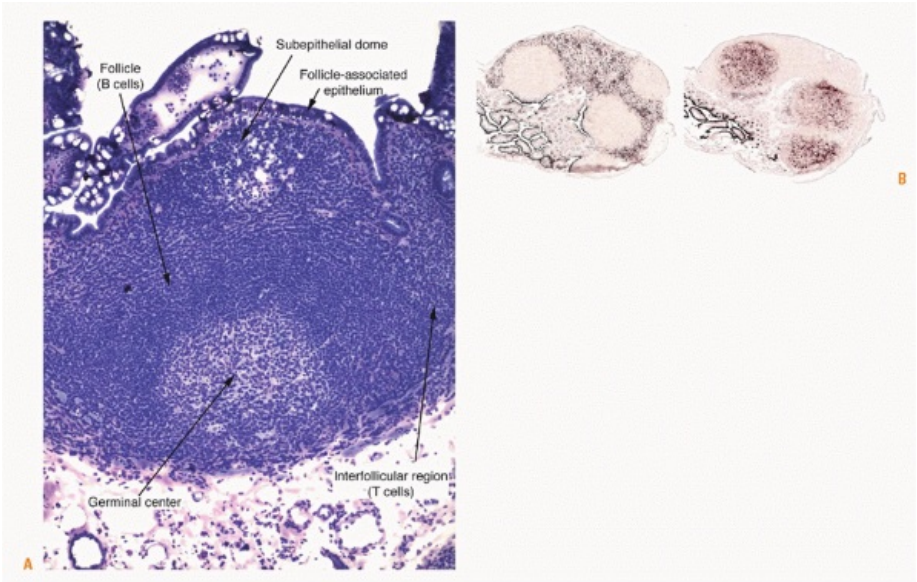

FIG. 3.5. Organization of Peyer's Patches. A: Photomicrograph of Peyer's patch. Peyer's patches are located in the intestine near intestinal villi. The follicle associated epithelium (FAE) is in contact with the gut lumen. M cells (not shown) in the FAE transport antigen into the subepithelial dome, populated by dendritic cells and T cells. The interfollicular T-cell-rich region surrounds the B-cell follicle and germinal center. Courtesy of A. Iwasaki (Yale University School of Medicine, New Haven, CT). **B:** In situ

hybridization of chemokine messenger ribonucleic acids (mRNAs). On the *left*, CCL21 mRNA defines the T-cell zone and high endothelial venules; on the *right*, CXCL13 defines the B-cell zone.

Development

Several cytokines and chemokines have been shown to be crucial for Peyer's patch development. *Lta-/-* and *Lt*β-/- mice completely lack Peyer's patches,[161,303] as do *Cxcr5-/-* mice.[174,175,301] Because mice deficient in the LTβR also lack Peyer's patches,[304] these effects are mediated in large part through $LT\alpha_1\beta_2$. However, some *Tnfr1-/-* mice lack organized Peyer's patches, suggesting that either LTα3 or TNFα also influences generation or later stages in maintenance of Peyer's patches.[305] Mice deficient in IL-7, RORγt, Id2, NIK, and factors in the classical and alternative NFκB pathways[170,177,304] lack Peyer's patches, although RANKL is not required.[172]

A model for the embryonic development of Peyer's patches[306,307,308] provided the framework for studies in that organ. The first sign of Peyer's patch development at E15.5 in the mouse is the appearance of regions on the small intestine that stain positively with antibodies to ICAM-1, VCAM-1, and LTβR. The cells in these aggregates are called the lymphoid tissue organizer cells and express CXCL13, CCL19, CCL21, and IL-7. At E17.5, clusters of IL-7R+CD4+CD3+ inducer cells are found. These express LTα and LTβ, CXCR5 and CCR7, Id2, and RORγ. They also express $\alpha_4\beta1$ integrin activated by CXCR5[309] that allows interaction with the VCAM-1+ organizer cells. At E 18.5, mature T and B cells enter through HEVs, CCL20 is produced by the FAE, and DCs expressing CCR7 and CCR6 are found. By day 4, the typical microarchitecture is apparent, with M cells and T- and B-cell compartmentalization.[310]

Lymphocytes influence the maintenance of Peyer's patches. Mice that lack mature T and B cells have either undetectable or small Peyer's patches that lack follicles and germinal centers.[311,312] B cell-deficient mice retain some M cells, suggesting that T cells may regulate M-cell maintenance. When B cell-deficient mice are reconstituted by a membrane IgM transgene, M cells are found at levels comparable to those of normal mice,[311] indicating that cells in addition to CD4+CD3+ lymphoid tissue-inducer cells are crucial for the maintenance of mature, functioning Peyer's patches.

Cryptopatches and Isolated Lymphoid Follicles

The small intestine of a mouse contains 100 to 200 isolated lymphoid follicles and more numerous cryptopatches. The cryptopatches in the lamina propria containing lymphoid tissue-inducer cells and DCs can be precursors of ILFs. The cryptopatches are composed of lin-c-kit+ cells, DCs, and VCAM-1+ stromal cells with few or no mature T and B cells. The cryptopatch cells express RORγt, IL-7R, and CCR6,[313] and their development is dependent on IL-7, CCR6, and its receptor CCL20. Cryptopatches are quite plastic, and although the LT family is necessary for their development, they can be restored by administration of wild-type bone marrow to adult *Lta-/-* mice.

After mice are exposed to microbes or during some forms of autoimmunity, cryptopatches give rise to ILFs,[314,315] which resemble small Peyer's patches and usually only have a single

dome. ILFs require B cells that express LT, but not T cells, for their formation.[316]. In contrast to lymph nodes, they also require the TNFR1.[317] The location of ILFs is antigen driven, and they resolve completely after mice are treated with antibiotics or cytokine inhibitors.[121,185,314,316,317]

Appendix

Both rabbits and humans have an appendix,[318] a vestigial organ distal to the ileocecal junction that divides the small intestine from the colon. The appendix has epithelial M cells and dense lymphoid accumulations and germinal centers that are similar to Peyer's patches. Similar to the tonsils and adenoids, the appendix involutes and regresses after puberty.

Colon Lymphoglandular Complexes

The colon has the highest bacterial load of any of the MALTs, and the distribution of the MALT is more random than in the small intestine. Lymphoglandular complexes are smaller than Peyer's patches. As their name suggests, the lymphoid cells of the lymphoglandular complexes surround the mucus glands.[292]

TERTIARY LYMPHOID TISSUES

Similarities to Secondary Lymphoid Organs

Tertiary lymphoid tissues, also termed tertiary lymphoid organs, are ectopic accumulations of lymphoid cells that arise in nonlymphoid organs during chronic inflammation through a process termed “lymphoid neogenesis” (also “lymphoid neo-organogenesis”).[2] The iBALT could be considered as either a secondary or tertiary lymphoid tissue. This semantic issue epitomizes the plasticity of all lymphoid organs and the fact that lymphoid organ regulation represents a continuum from ontogeny through chronic inflammation. A notable difference between secondary lymphoid organs and tertiary lymphoid tissues is the fact that the latter can arise in almost any organ in the adult. Nonetheless, tertiary lymphoid tissues exhibit remarkable morphologic, cellular, chemokine, and vasculature similarities to secondary lymphoid organs. They exhibit T- and B-cell compartmentalization; naïve T and B cells; DCs; FDCs; germinal centers; plasma cells; lymphoid chemokines CCL19, CCL21, and CXCL13[1]; HEVs[135,196,319]; and conduits.[320] Lymphatic vessels have also been noted in tertiary lymphoid tissues in chronic graft rejection[321,322] and mouse models of Sjögren syndrome[134] (Fig. 3.6) and Type 1 diabetes.[323] Although it is not completely clear whether they function as afferent and/or efferent vessels, the fact that the tertiary lymphoid tissues respond to S1P inhibitors suggest that their lymphatic vessels function similarly to those in lymph nodes.[323]

Lymphoid neogenesis has been noted in humans in autoimmunity, microbial infection, and chronic allograft rejection. A few examples are shown in Table 3.2 and are described in more detail in Drayton et al.[1] These accumulations also occur in atherosclerotic plaques with

FDCs, organized B-cell follicles, HEVs (HECA-452), and CCL19 and CCL21 in addition to those chemokines more often associated with acute inflammation.[324] Tertiary lymphoid tissues have also been noted in non-small-cell lung cancer[325] and many other solid tumors.[326] The tendency for tertiary lymphoid tissues to develop into lymphomas has also been noted in many studies.[327]

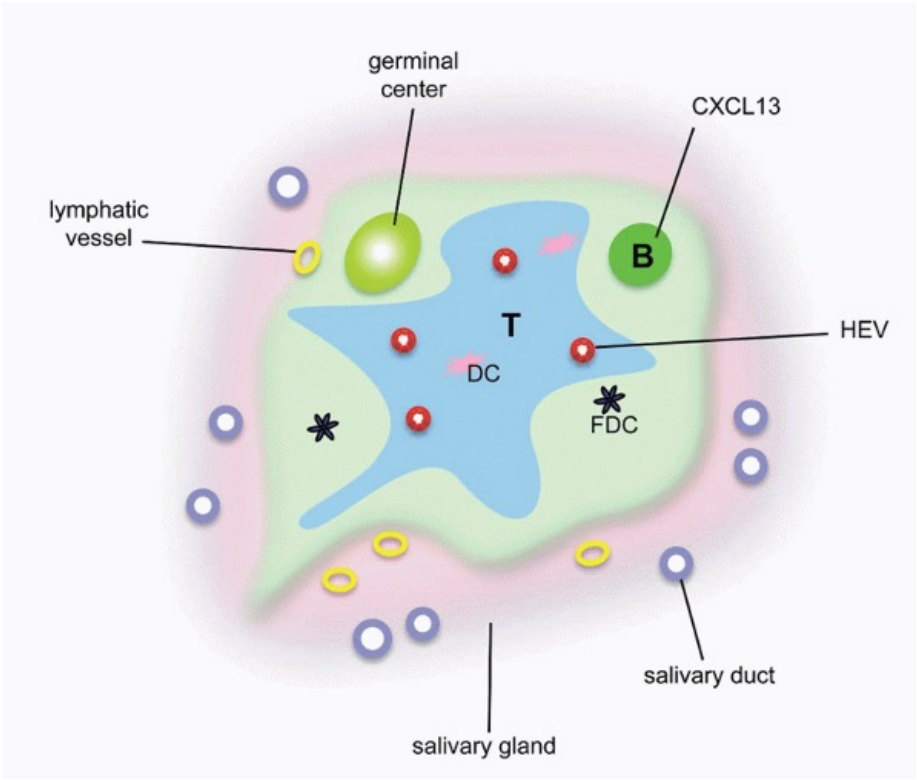

FIG. 3.6. Tertiary Lymphoid Tissue. Schematic diagram of Sjögren syndrome salivary gland. Note similarities with the organization of a lymph node.

Ectopic lymphoid tissues are also apparent in several animal models. The pancreatic infiltrates in early stages of diabetes in the nonobese diabetic mouse express lymphoid chemokines[328] and HEVs expressing MAdCAM-1,[329,330] PNAd, and HEC-6ST.[135] The brain in experimental autoimmune encephalomyelitis, a model of multiple sclerosis, has HEVs, CCL19, CCL21, CXCL13, and FDCs.[331,332,333] The thyroid in the BioBreeding (BB) rat has T- and B-cell compartmentalization and DCs,[334] and the gut in autoimmune gastritis in the mouse has HEVs and CXCL13.[335] Atherosclerotic plaques of apoprotein-E-deficient mice exhibit a marked increase in T and B cells, expression of CCL19 and CCL21, and PNAd+ HEVs.[336,337,338] Lymphoid neogenesis also occurs in chronic mouse heart allograft rejection.[339,340] Tertiary lymphoid tissues have been induced in several transgenic mouse models with the use of tissue-specific promoters driving the expression of inflammatory cytokines or lymphoid chemokines.[1] These mouse models, in addition to serving as examples of human disease, have provided valuable insight into the regulation of secondary lymphoid

organ development.

From Chronic Inflammation to Organized Lymphoid Microenvironments

Data generated from analyzing the cellular and molecular requirements for secondary lymphoid organ development have provided a paradigm for understanding the development of tertiary lymphoid tissues in chronic inflammation. This paradigm proposes that the processes and molecules governing secondary lymphoid organs are also the basis of tertiary lymphoid tissue development,[2] and informs understanding of both secondary and tertiary lymphoid tissues. The physiologic event(s) that precipitate lymphoid neogenesis remain unclear. Data obtained from experiments in knockout and transgenic

mice and clinical observations indicate that cooperative activities of TNF/LT family members and the lymphoid chemokines play central roles in this process.

TABLE 3.2 Lymphoid Neogenesis in Human Autoimmunity, Infectious Diseases, and Graft Rejection

Disease	Affected Tissue	Characteristics
Autoimmunity		
Rheumatoid arthritis	Synovial membrane	T cells and B cells, plasma cells, GCs, FDCs, CXCL13, CCL21, HEVs (PNAd, HEC-6ST)
Sjögren syndrome	Salivary glands	T cells and B cells, plasma cells, GCs, FDCs, CCL21, CXCL12, CXCL13 HEVs (PNAd)
Myasthenia gravis	Thymus	T cells and B cells, GCs, FDCs
Hashimoto thyroiditis	Thyroid	T cells and B cells, GCs, FDCs CCL21, CXCL13, CXCL12, plasma cells, HEVs (PNAd)
Grave disease	Thymus	T cells and B cells, GCs, FDCs, CCL21 CXCL13, CXCL12, HEVs (PNAd)
Multiple sclerosis	Brain	Lymphatic capillaries, B-cell

		follicles and centroblasts, GCs, CCL19, CCL21, CXCL12, CXCL13
Ulcerative colitis	Colon	CXCL13
Inflammatory bowel disease (Crohn disease)	Bowel	T cell-B compartments, LVs, HECA-452+ HEV
Psoriatic arthritis	Joint	T cells and B cells, CXCL13, CCL19, CCL21, HEVs (PNAd)
Infectious Diseases		
Borrelia burgdorferi/Lyme disease	Joints	T and B cells, FDCs, HEVs
Borrelia burgdorferi/neuroborreliosis	Central nervous system/cerebrospinal fluid	CXCL13
Hepatitis C virus	Liver	T-cell and B-cell compartments, MAdCAM-1
Bartonella henselae/cat scratch disease	Granuloma	CXCL13
Graft Rejection		
Organ		
Heart		GCs
Kidney		GCs, LVs

FDC, follicular dendritic cell; GC, germinal center; HEV, high endothelial venule; LV, lymphatic vessel; MAdCAM-1, mucosal addressin cell adhesion molecule; PNAd, peripheral node addressin. Original references are in Drayton et al.1

Inflammation is a localized response to tissue injury, irritation, or infection often marked by tissue damage. Acute inflammation is an early innate immune response that is generally short-lived and self-limiting. However, in some situations, acute inflammation transitions to a

chronic inflammatory response that is long-lived and self-perpetuating. Tertiary lymphoid tissues arise under conditions of constitutive cytokine and/or chemokine expression, but the precise signal(s) that initiates their development is unknown. By integrating studies of lymphoid neogenesis in human pathologies and in animal models, it is becoming clear that at least three critical events promote tertiary lymphoid tissue formation: inflammatory (eg, TNF/LT) cytokine expression, lymphoid chemokine production by stromal cells, and HEV development. It is not known if lymphoid tissue-inducer cells are necessary for lymphoid neogenesis, though such cells have been noted in the mouse models of lymphoid neogenesis,[341] and lymphoid tissue-inducer-like cells have been described in several instances.

Functions of Tertiary Lymphoid Tissues

Ectopic accumulation of lymphoid cells has been considered the hallmark of destructive inflammation. Indeed, some tertiary lymphoid tissues are accompanied by tissue damage. However, it is likely that tertiary lymphoid tissues in chronic inflammation have roles in addition to tissue destruction. In the case of microbial infection, it is likely that lymphoid neogenesis occurs as a way to sequester pathogens and to prevent their access to the other parts of the body. This may represent a primitive form of immunity. Local antigen presentation within the tertiary lymphoid tissue itself likely prevents bacteremia or viremia. Enhanced long-term survival has been noted for those individuals whose lung or breast tumors included tertiary lymphoid tissues.[325,326] The propensity for tertiary lymphoid tissues to develop into lymphomas, as noted previously, the ability of lymphatic vessels to serve as conduits for tumor metastasis, and the ability of tertiary lymphoid tissues to serve as sites of prion accumulation are obvious manifestations of detrimental functions.[342] Furthermore, the development of tertiary lymphoid tissues in autoimmunity may perpetuate clinical disease through epitope spreading.

Data from human and mouse studies provide compelling evidence that tertiary lymphoid tissues are permissive microenvironments for the induction of antigen-specific immune responses. Extensive immunohistochemical analyses of tertiary lymphoid tissues in autoimmunity and other chronic inflammatory states have established the presence

of germinal centers and FDC networks in these tissues; several groups have demonstrated that tertiary lymphoid tissue germinal centers can support B-cell differentiation. Microdissection of discrete lymphocytic foci and subsequent deoxyribonucleic acid sequence analysis of germinal center B cells from the inflamed synovial tissue of patients with rheumatoid arthritis revealed a restricted number of Vκ gene rearrangements, a result consistent with oligoclonal B-cell expansion in the synovial tissue.[343] Somatic hypermutation is apparent in synovial germinal center B cells.[344] Furthermore, synovial B cells exhibit a limited number of heavy and light chain gene rearrangements consistent with local clonal expansion of these cells. The molecular analysis of tertiary lymphoid tissue germinal centers from the salivary glands of patients with primary Sjögren syndrome or the thymus of patients with myasthenia gravis demonstrates oligoclonal B-cell proliferation in these tissues in addition to somatic hypermutation of Ig variable genes.[345,346,347] Together, these studies indicate that tertiary lymphoid tissue germinal centers in several autoimmune pathologies can support antigen-driven clonal expansion and extensive diversification.

Another important hallmark of antigen-driven B-cell responses is the terminal differentiation of activated B cells into Ig-secreting plasma cells. Plasma cells have been detected in tertiary lymphoid tissues associated with germinal centers in rheumatoid arthritis[348] and in Sjögren syndrome. Mice expressing LTα under the control of the rat insulin promoter (RIPLTα) exhibit tertiary lymphoid tissue at the sites of transgene expression (pancreas, kidney, and skin). After immunization with sheep red blood cells, evidence of isotype switching is apparent in these cellular infiltrates.[2] Although the presence of plasma cells in tertiary lymphoid tissues is consistent with local antigen presentation, it is occasionally unclear whether these cells develop in the tertiary lymphoid tissues themselves or migrate from canonical secondary lymphoid tissues. Nonetheless, taken together, these studies indicate that tertiary lymphoid tissues in several human pathologies and animal models support antigen-driven B-cell differentiation marked by somatic hypermutation of Ig variable genes, affinity maturation, isotype switching, and terminal differentiation into antibody-secreting plasma cells.

T-cell priming occurs in tertiary lymphoid tissues as suggested by the presence of isotype switched plasma cells in the RIPLTα tertiary lymphoid tissues,[2] accelerated graft rejection,[349] and T-cell epitope spreading in the central nervous system during experimental allergic encephalomyelitis.[350] The restricted TCR repertoire in a melanoma-associated tertiary lymphoid tissue[351] further supports the concept that tertiary lymphoid tissues can act as priming sites. The demonstration of naïve T-cell proliferation in the islets of nonobese diabetic mice after surgical removal of pancreatic lymph nodes[352] suggests, together with evidence noted previously, that tertiary lymphoid tissues present antigen to naïve cells at the local site and generate an immune response. Determinant or epitope spreading, a phenomenon that arises in several autoimmune diseases, occurs when epitopes other than the inducing antigen become major targets of an ongoing immune response. It is considered to occur subsequent to the tissue damage induced by the initiating autoreactive T cells and therefore is the result of the presentation of new antigens.[353] Data generated in murine models of central nervous system inflammation support the possibility that intermolecular and intramolecular epitope spreading occur in tertiary lymphoid tissues in the central nervous system.[350] More recently, it has become apparent that T_{reg}s can populate tertiary lymphoid tissues,[338] again suggesting that manipulating the immune response at the local site is an avenue of control.

Plasticity and Adaptability of Tertiary Lymphoid Tissues

Tertiary lymphoid tissues are the most plastic and adaptable of the lymphoid tissues. First, lymphoid neogenesis can be induced by a variety of stimuli. Their nimbleness in this regard suggests that they might represent the most primitive tissues in the immune system. Tertiary lymphoid tissues can be “turned off” (ie, resolve) upon removal of the initial stimulus or after therapeutic intervention. The destruction of the islets of Langerhans β cells in type I diabetes mellitus is an example of a situation in which removal of the antigen stimulus is accompanied by tertiary lymphoid tissue resolution. Antibiotic treatment results in the resolution of tertiary lymphoid tissues and even MALT lymphomas.[354] Treatment has been shown to resolve some established tertiary lymphoid tissues, reversing insulitis and protecting against diabetes

in nonobese diabetic mice.[355] Such treatment can also "turn off" established tertiary lymphoid tissues in a mouse model of collagen-induced arthritis.[356] These studies are similar to those described previously regarding the plasticity of lymph nodes after mice are immunized or treated with LTβR-Ig,[198,199] again emphasizing the commonality of these tissues.

CONCLUSION

The immune system depends on a remarkable organization of tissues and cells. The organs have defined functions that include generation of an immune repertoire (primary lymphoid organs) and responding to antigen (secondary lymphoid organs and tertiary lymphoid tissues). Development of primary and secondary lymphoid organs depends on precisely regulated expression of cytokines, chemokines, and adhesion molecules. Similar signals regulate the transition from inflammation to tertiary lymphoid tissues. Chemokines and adhesion molecules regulate trafficking in and out of lymphoid organs. Secondary lymphoid organs are remarkably plastic in their response to antigenic assault and adapt with changes in expression of chemokines and adhesion molecules to maximize encounter of antigen with antigen-specific cells. Tertiary lymphoid tissues, characteristic of many pathologic states, may actually represent the most primitive form of lymphoid tissues in their even greater plasticity and ability to develop directly at the site of antigen exposure.

Chapter 4

Evolution of the Immune System

Martin F. Flajnik

Louis Du Pasquier

INTRODUCTION

Defense mechanisms are found in all living things, even bacteria, where they are surprisingly elaborate. Although new adaptive or adaptive-like (somatically generated) immune systems have been discovered in invertebrates and the jaw-less fish, adaptive immunity based upon immunoglobulin (Ig), T-cell receptors (TCRs), and the major histocompatibility complex (MHC) is only present in jawed vertebrates (gnathostomes); because of clonal selection of lymphocytes, positive and negative selection in the thymus, MHC-regulated initiation of all adaptive responses, etc., the major elements of the adaptive immune system in gnathostomes are locked in a coevolving unit that arose in concert over a short period of evolutionary time.[1,2,3] In addition, a large cast of supporting players, including a large array of cytokines and chemokines, adhesion molecules, costimulatory molecules, and well-defined primary and secondary lymphoid tissues, evolved in the jawed vertebrates as well. This scheme was superimposed onto an innate system inherited from invertebrates, from which many innate molecules and mechanisms were coopted for the initial phase of the adaptive response and others for effector mechanisms at the completion of adaptive responses. Over the last 10 years, we have learned that various components of the innate immune system are also incredibly complex and locked as well in a coevolving unit.[4,5]

In each group of organisms, one can detect a basic set of immune functions, and these are employed in different ways in representative species. For example, we detect that in the jawed vertebrates fine tuning, or adaptations, or even degeneration of molecules/mechanisms in each group (Taxon) are observed, and not a steady progression from fish to mammals as is documented for most other physiologic systems.[6] Given that all the canonical adaptive immune system features are present in cartilaginous fish and apparently none were lost (except in particular groups of organisms that will be discussed), differential utilization of defense molecules rather than sequential installation of new elements is observed. In this chapter, there are only isolated cases of increasing complexity in immune systems, but many examples of contractions/expansions of existing gene families; thus, “more or less of the same” rather than “more and more new features” is the rule. We observe a bush growing from a short stem rather than a tall tree with well-defined branches, and thus deducing the primitive, ancestral traits is not clear cut.

GENERAL PRINCIPLES OF IMMUNE SYSTEM EVOLUTION

The Common Ancestor Hypothesis

Figure 4.1 displays the extant animal phyla ranging from the single-celled protozoa to the metazoan protostome and deuterostome lineages. It is often suggested or assumed by those unfamiliar with thinking in evolutionary terms that molecules or mechanisms found in living protostomes, like the well-studied arthropod *Drosophila*, are ancestral to similar molecules/mechanisms in mouse and human. While this is true in some cases, one must realize that *Drosophila* and humans have taken just as long (over 900 million years) to evolve from a common ancestral triploblastic coelomate (an animal with three germ layers and a mesoderm-lined body cavity, features shared by protostomes and deuterostomes) that looked nothing like a fly or a human, and thus *Drosophila* is not our ancestor (ie, the manner by which flies and humans utilize certain families of defense molecules may be quite different and both may be disparate from the common ancestor). Thus, understanding of how model invertebrates and vertebrates perform certain immune tasks is an important first step in our understanding of a particular mechanism, but we only deduce what is primordial or derived when we have examined similar immune mechanisms/molecules in species from a wide range of phyla. We will touch upon each of the defense molecule families and will emphasize those which have been conserved evolutionarily and those that have evolved rapidly.

Rapid Evolution of Defense Mechanisms

Immune systems are often compared to the Red Queen in *Alice in Wonderland*, (Red Queen's Hypothesis[7,8]) who must continually keep moving just to avoid falling behind. Because of the perpetual conflict with pathogens, the immune system is in constant flux. This is exemplified by great differences in the immune systems of animals that are even within the same phylogenetic group (eg, mosquito [*Anopheles*] and fruitfly [*Drosophila*], both arthropods, or human and mouse, both mammals). In fact, in contrast to what was believed previously, defense mechanisms are extremely diverse throughout the invertebrate phyla, and Kepler et al. have aptly and succinctly described the situation in the title of a recent review: “not homogeneous, not simple, not well understood.”[9] In the jawed vertebrate (or *gnathostomes*), the most rapidly evolving system is an innate system, natural killer (NK) cell recognition, governed by different classes (superfamilies) of receptors in mice and humans, and also extremely plastic even

within the same species, exemplified by the large number of killer immunoglobulin superfamily (KIR) haplotypes found in humans.[10] Studies of Ig superfamily (SF) genes expressed in the nervous system and immune system showed definitively that the immune system molecules evolve at a faster rate.[11] Finally, rapid evolution of immune system molecules and mechanisms is the general rule, but molecules functioning at different levels of immune defense (recognition, signaling, or effector) can evolve at widely varying rates.

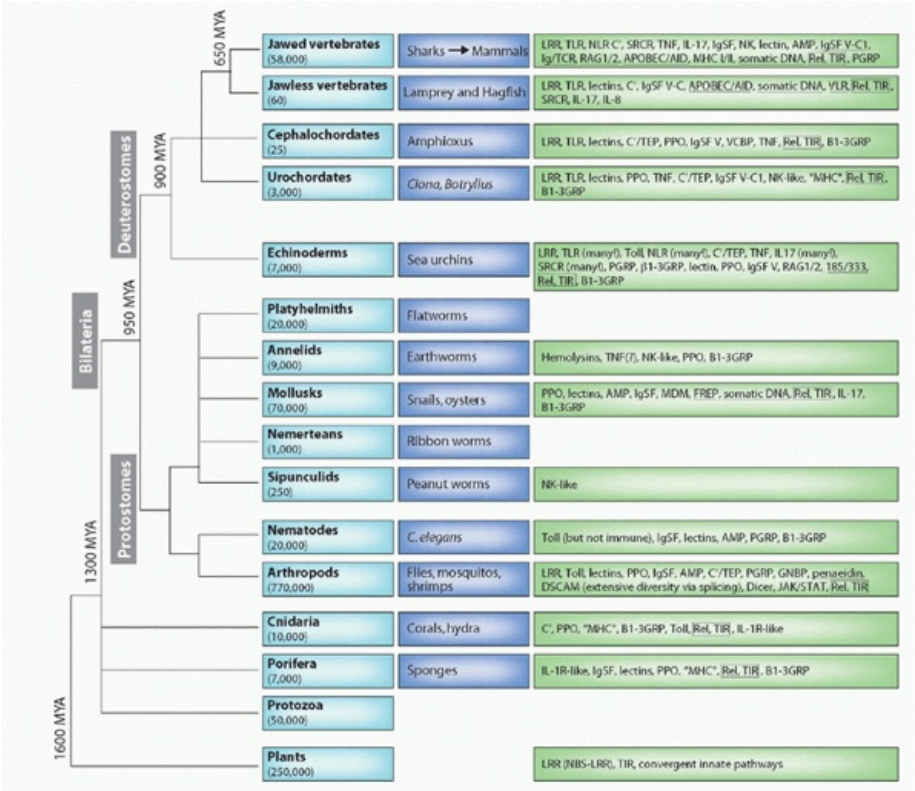

FIG. 4.1. Major Animal Groups and Immune Mechanisms/Molecules Described to Date in Each Group. The first box on the left in each row describes the animal taxon and the approximate number of species in that group. The next box shows specific examples of species or subgroups. The third box lists molecules/mechanisms found in each group: *underlined terms* indicate somatic changes to antigen receptors or secreted molecules. Figure modified from Hibino et al.[48] and Flajnik and Du Pasquier.[61] See Table 4.1 for definition of the acronyms.

Conservation of Defense Mechanisms

While the immune system is the most rapidly evolving physiologic system, nevertheless there is also deep conservation of defense families and mechanisms. Klein[11a] has compared this dichotomy to the two-headed god Janus, the major idea being that certain basic mechanisms/functions are obligatory for immune systems to function, but they still must evolve rapidly to avoid pathogen subterfuge. For example, MHC class I molecules have similar structure/function/features in all gnathostomes, but even within groups of primates class I genes are not orthologous (ie, they can be derived from totally different ancestral class I genes[10]). So, the idea is to preserve vital immune functions but rapidly modify the gene or pathway to outwit the pathogen. Additionally, certain features are conserved (eg, development and function of conventional αβ T cells), but a second, similar system, can be exploited in very different ways in closely related

species (eg, the function[s] of γδ T cells). The “Janus paradigm,” therefore, can be quite useful when examining any pathway in the immune system.

Convergent Evolution

Early on in the comparative study of immunity, it was assumed that the same features appearing in different taxa proved that they were present in the common ancestor as well (ie, they were submitted to divergent evolution). While this dictum still holds true and establishes one of the dogmas of comparative immunology, later we discovered, because of the aforementioned rapid evolution of immune systems, *convergence* of similar functions has occurred in evolution (ie, the same function or even molecular conformation has arisen independently in different organisms, sometimes in species that are relatively closely related). While we will discuss several cases of convergent evolution throughout the chapter, for frame of reference, the NK cells, which use different receptor families in primates and rodents to achieve precisely the same ends of recognizing polymorphic MHC class I molecules, is a striking example of convergence.[12] Additionally, the emergence of a lymphocyte-based somatic generation of two entirely different receptor families for the same function in jawless and jawed vertebrates is another remarkable illustration of convergent evolution.[13] Finally, in innate immunity, the cytosolic nucleotide-binding domain leucine-rich repeat (NLR) proteins, despite their striking similarity in deuterostomes and plants, arose (at least) twice in evolution.[14]

Multigene Families

Genes involved in immunity are often found in clusters, with extensive contraction and expansion via so-called birth and death processes.[15] It is well known that such gene clusters can change rapidly over evolutionary time due to unequal recombination crossovers and gene conversion (and not only in the immune system, but in any *cis* -duplicating gene family). Often, families of related immune genes— especially those involved in recognition events —are found near the telomeres of chromosomes, presumably because this further promotes gene-shuffling events. Nonclassical MHC class I loci, NK receptors, and NLRs are conspicuous examples of this phenomenon, again believed to be a consequence of the race against pathogens. We will discuss many examples of how such multigene families have been exploited in different species throughout the chapter.

Gene duplication, either in the clusters mentioned above or as a consequence of en bloc duplications, certainly has been a major feature of immune system diversity and plasticity. The two types of duplications are not equivalent, the former being more taxon-specific and the latter (en bloc) having a lasting impact on the entire system. It is now universally accepted that two = =genome-wide duplications (the so-called 2R hypothesis[2,16]; see Fig. 4.13) occurred early in vertebrate history, tracking very well with the emergence of the Ig/TCR/MHC-based adaptive immune system.[2,17] This theory forms the basis for much that will be discussed concerning the evolution of the vertebrate adaptive immune response as one can track the emergence of new immune mechanisms, as well as fine tuning of old ones, by examining the paralogous syntenic groups of genes. Our view is that these genomewide duplications were as crucial as the “RAG transposon”[18,19,20] in the development of the Ig/TCR/MHC-based adaptive immunity. In addition, the common ancestor of bony fish (teleosts) underwent a third round of genomewide duplication, which many believe to have played the major role in these fishes' unique outlier status regarding immune system genetics and physiology.[2,21]

Polymorphism

In addition to gene duplications, polymorphism also augments the diversity of immune recognition within a population. It can be generated any time during the history of a gene family of either receptor or effector molecules: MHC, toll-like receptors (TLRs), Ig, TCRs, NK receptors (NKRs) and related molecules, and antimicrobial peptides (AMPs) are just a few examples. Polymorphism, either within the gene itself or in its regulatory elements, provides populations with flexibility in function of the changing pathogenic environment. This subject, central to the studies on MHC, leukocyte receptor complex (LRC), and NK cell complex (NKC), is becoming well documented for immunity-related genes in insects as well. In *Drosophila*, polymorphism in regulatory networks is indeed expected as parasites often target their elements.[22] In humans, there are two major NK cell haplotypes found in all subpopulations, which are under "balancing selection." In such a case, the polymorphisms presumably adopt a division of labor required for the maintenance of the species: one haplotype is believed to be involved in protection from virus and the other perhaps for promoting reproduction.[23]

Somatic Generation of Diversity

Somatic modifications can take place at multiple levels to generate immune system diversity. Long believed to be the sole domain of jawed vertebrates, modifications at the deoxyribonucleic acid (DNA) level via somatic hypermutation, gene conversion, and rearrangement (primary and secondary [eg, receptor editing]) irreversibly modify genes within an individual. The well known V(D)J joining, class switch recombination (CSR), and somatic hypermutation (SHM) are examples of this processes in the IgSF receptors of jawed vertebrates, but modifications to genomic DNA can also occur in the jawless fish and some invertebrates.[7,13] The list of organisms undergoing such diversity of germline immune genes will only grow as more organisms are examined and more genome and expressed sequence tags (EST) sequencing projects are undertaken (see Fig. 4.1).

Alternative splicing can be a source of tremendous diversity in some gene families encoding receptors involved in immunity in insects and crustaceans. The Down syndrome cell adhesion molecule (DSCAM) gene in several arthropods (described in detail in the following) was shown to generate enormous diversity via ribonucleic acid (RNA) processing.[7,24] In the vertebrates, this mechanism is important in

determining the function of different molecules, best known for the Igs (transmembrane [TM] versus secreted forms, as well as inflammatory versus neutralizing forms in non-mammalian vertebrates). Further diversity can be obtained by the assembly of multichain receptors in which different components are combined. The classical example in the jawed vertebrate adaptive immune system is that of Ig light (L) and heavy (H) chains of antibodies but similar combination can occur with insect peptidoglycan-recognizing proteins (PGRP), vertebrate TLRs, and many others.

The study of the evolution of immunity has resulted in a fundamental appreciation of the heart of immunity, both innate and adaptive. Especially now, with studies in many plants and in both invertebrate and vertebrate animals, we can see what features have been conserved and when they arose. "Simple" genetic models such as *Drosophila* and *Candida elegans*

provide a glimpse into these elemental mechanisms and also allow us to remove the clouds that surround studies of mouse and human, with so many interconnected pathways. As mentioned, examination of the well-studied mammalian models in combination with studies of invertebrates allows us to deduce the condition of the common ancestor. Interestingly, major pathways of defense known to all immunologists, such as the ones involving TLR, JAK-signal transducer and activator of transcription (STAT), NOTCH, and tumor necrosis factor (TNF) pathways, clearly arose in an early animal ancestor and have been perpetuated in derived fashions in all major taxa. We shall see how these pathways are manipulated in different animals, always drawing upon the best-known mammalian model as a foundation (whenever possible).

MAJOR GENE FAMILIES INVOLVED IN IMMUNITY

Defense molecules can be composed of a very large number of protein folds, some of which are clearly some used to a large extent.[25,26,27] Some of the most common families (Fig. 4.2) are IgSF, leucine-rich repeats (LRRs), C-type lectins, and the TNF family, and certain other domains in immune recognition (eg, scavenger receptor cysteine-rich [SRCR]). All of the domains discussed in this chapter are found in Table 4.1 and a few are displayed in Figure 4.2. As a means of introduction, two of these families, which constitute the "top two" quantitatively, will be described in the following.

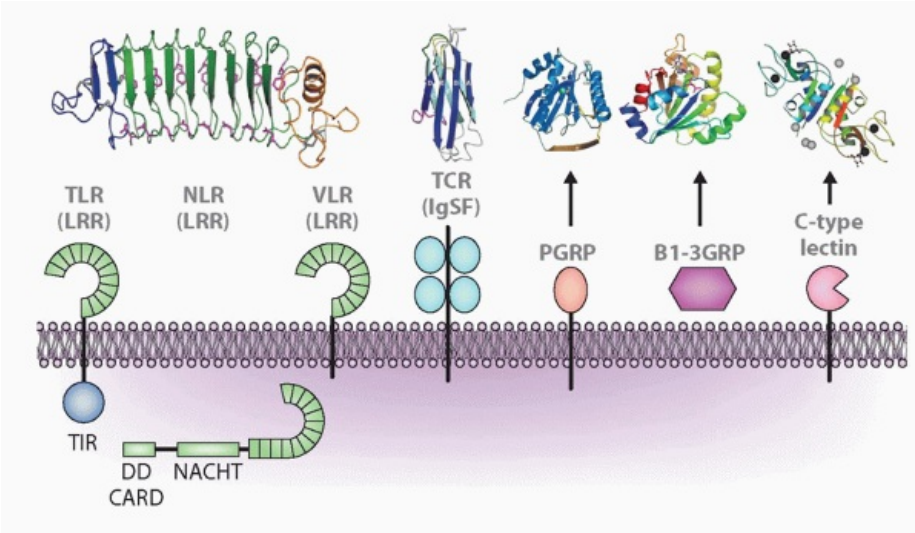

FIG. 4.2. Major Molecular Families Described in the Text and Representatives of Each Family: Leucine-Rich Repeats (LRRs), Immunoglobulin Superfamily (IgSF), Peptidoglycan-Recognition Protein (PGRP), β1-3 Glucan Recognition Protein (β1-3GRP), and C-Type Lectins. Representative structures are shown above for LRR (toll-like receptor, nucleotide-binding domain leucine-rich repeat [NLR], variable lymphocyte receptor), IgSF, PGRP, β1-3GRP, and C-type lectin. Other acronyms are defined in Table 4.1. For the NLR model, the echinoderms have N-terminal death domains, whereas all other animals have caspase-recruitment domains. Figure modified from Hibino et al.[48]

Leucine-Rich Repeats

LRRs consist of 2 to 45 motifs of 20 to 30 amino acids in length (XLXXLXLXXNXHXXHXXXXFXXLX) that fold into an arc shape (see Fig. 4.2).[28] Both the concave and convex parts of the domain have been shown to interact with ligands. Molecular modeling suggests that the conserved pattern LxxLxL is sufficient to impart the characteristic horseshoe curvature to proteins with 20- to 30-residue repeats. LRRs are often flanked by cysteine-rich domains. LRRs occur in proteins ranging from viruses to eukaryotes and are found most famously in the toll/TLRs, as well as tyrosine kinase receptors, cell-adhesion molecules, resistance (R) factors in plants found at the cell surface, and in the cytosol, extracellular matrix (ECM)-binding glycoproteins (eg, peroxidasin), and are involved in a variety of protein-protein interactions: signal transduction, cell adhesion, DNA repair, recombination, transcription, RNA processing, disease resistance, apoptosis, and the immune response. LRR-containing proteins can be associated with a variety of other domains, whether they are extracellular (LRR associated with IgSF or fibronectin [FN] type III) or intracellular (caterpillar family LRR associated with a variety of effector domains; see subsequent discussion). In these chimeric molecules, the LRR moiety is involved in recognition, most likely due to its extraordinarily malleable structure. There are at least six families of LRR proteins, characterized by different lengths and consensus sequences of the repeats.[29] Repeats from different LRR subfamilies never occur simultaneously and have most probably evolved independently in different organisms.

TABLE 4.1 Molecules and Abbreviations Found Throughout the Text

Acronym/Defense Molecule	Full Name	Function
AID	Activation-induced cytidine deaminase	SHM/gene conversion/CSR
APOBEC	Apolipoprotein B mRNA editing enzyme catalytic polypeptide	Innate immunity (antiviral)
AGM	Aorta/gonad/mesonephros	Intraembryonic origin of hematopoietic cells
AMP	Antimicrobial peptide	Innate immunity (eg, defensins)
APAR	Agnathan paired antigen receptor	Similarities to Ig/TCR and NKRs
AVR	Avirulence protein	Pathogen effector recognized by plant NLR

Bf	Factor B	Enzyme of C′ cascade
B1-3GNP	Beta 1-3 glucan-recognizing protein	Binds to gram-negative bacteria
C′	Complement	Innate/adaptive immunity
CARD	Caspase-recruitment domain	Domain in intracellular defense molecules
CATERPILLER or CLR	CARD, transcription enhancer, R(purine)-binding, pyrin, lots of leucine repeats	Apoptosis/immunity/inflammation
CDR	Complementarity-determining region	Portion of Ig/TCR that binds to antigen
CSR	Class switch recombination	Adaptive humoral immunity modification
DD	Death domain	Cytosolic interacting domain
DSCAM	Down syndrome cell adhesion molecule	Insect immune (adaptive?) defense and neuron specification
ECM	Extracellular matrix	
ETI	Effector-triggered immunity	Immunity in plants triggered by NLR
FBA	F box-associated domain	Intracellular domain
FcRN	Fc receptor neonatal	MHC-like FcR
FN3	Fibronectin type III repeat	Domain found in many innate molecules
FREP	Fibrinogen-related protein	Mollusk (adaptive?) defense
FuHC	Fusion histocompatibility	Histocompatibility locus in tunicates

GALT	Gut-associated lymphoid tissue	
GPI Hemolysin	Glycophosphatidylinositol	Lipid linkage to cell membrane (eg, VLR) Cell lysis
ICE	Interleukin-converting enzyme	IL-1β processing
Ig	Immunoglobulin	Adaptive immunity
IgSF	Immunoglobulin superfamily	Innate/adaptive immunity
IFN	Interferon	Innate (type I)/adaptive (type II) immunity
IMD	Immune deficiency	Insect innate defense
IRF	Interferon regulatory factor	Innate (transcription factor)
IRG	Immunity-related GTPases	Innate immunity
ITAM	Immunoreceptor tyrosine-based activation motif	Signaling motif for NK and antigen receptors
ITIM	Immunoreceptor tyrosine-based inhibitory motif	Signaling motif for NK and antigen receptors
JAK	Janus kinase	Signaling molecule associated with cytokine receptors
KIR	Killer IgSF receptor	NK cell receptor
lectins	For example, galectin, C-type, S-type	Many (eg, NKRs, selectins)
LITR	Leukocyte immune-type receptors	Fish NK-like receptors of the IgSF

LMP	Low-molecular-weight protein	Proteasome subunit
LRC	Leukocyte receptor complex	Gene complex containing KIR and many IgSF molecules
LRR	Leucine-rich repeat	Innate/adaptive immunity module
MAC	Membrane-attack complex	C′, pore-forming
MACPF	MAC-perforin domain	Potential pore former
MASP	MBP-associated serine protease	Lectin C′ pathway
MBP (or MBL)	Mannose-binding protein (lectin)	Lectin C′ pathway
MDM	Mollusk defense molecule	IgSF defense molecule
MHC	Major histocompatibility complex	T-cell recognition; innate immunity
MIF	Macrophage inhibitory factor	Innate immunity; inflammation
MyD88 (also dMyD88)	(Drosophila) Myeloid differentiation primary response gene 88	TLR adaptor
NITR	Novel immune-type receptors	Teleost fish NK-like receptors of the IgSF
NK cell	Natural killer cell	Vertebrate innate cellular immunity
NKC	Natural killer cell complex	Gene complex with many C-type lectin genes (especially NK cells)
NKR	Natural killer cell receptor	Receptor on NK cells
NALP	NACHT leucine-rich	Intracellular PRR

	repeat and PYD-containing protein	
NBD-LRR	Nucleotide-binding domain LRR	Motif of intracellular defense molecules
NFκB	Nuclear factor-κB (Rel homology domain)	Evolutionarily conserved transcription factor
NLR	NACHT leucine-rich repeat protein	Intracellular PRR
NOD	Nucleotide oligomerization domain protein	Intracellular PRR
NOS	Nitric oxide synthase	Intracellular killing innate defense molecule
PAMP	Pathogen-associated molecular pattern	Conserved target epitopes on pathogens
PCD	Programmed cell death	Many pathways
Penaedins		Defense molecule in shrimp
PGRP	Peptidoglycan-recognition protein	Gram-positive bacteria defense family; receptor and effector
PPO	Propolyphenol oxidase	Plant/invertebrate defense (melanization)
PRR	Pattern-recognition receptor	Recognize PAMP, innate/adaptive immunity
PMSB	Proteasome subunit beta subunit	Proteolytic member of 20S proteasome
Polμ	DNA polymerase μ	Error-prone polymerase (related to TdT)
PPO	Prophenoloxidase	Invertebrate defense molecule
PYD	Pyrin domain	Domain in intracellular defense molecules

RAG	Recombination-activating gene	Ig/TCR rearrangement
RFP-Y	Restriction fragment polymorphism-Y	Chicken nonclassical MHC gene cluster
RFX	Regulatory factor X	Transcription factor, class I regulation
RIG	Retinoic acid-inducible gene	Intracellular double-stranded RNA recognition
RSS	Recombination signal sequence	DNA element next to Ig/TCR gene segments necessary for RAG-mediated rearrangement
RXR	Retinoid X receptor	Transcription factor encoded in MHC
SHM	Somatic hypermutation	Adaptive humoral immunity
SPE	Spaezle-processing enzyme	Insect defense molecule in toll cascade
SRCR	Scavenger receptor cysteine-rich	Innate immunity recognition molecule
TAK	TGF-β activated kinase	ubiquitin-dependent kinase of innate pathways
TAP (and TAP-L)	Transporter associated with antigen processing	Rransports peptides from cytosol to ER lumen
TAPBP	TAP-binding protein	Tethers TAP to class I
TCR	T-cell receptor	Adaptive defense
TdT	Terminal deoxynucleotidyl transferase	Involved in Ig/TCR rearrangement
TEP	Thioester-containing protein	Opsonization (like C3)

TGF	Transforming growth factor	Immunosuppressive cytokine
TNF	Tumor necrosis factor	
UPD	Unpaired	Protostome cytokine induced by viral infection
TLR	Toll-like receptor	Innate receptor on the cell surface or in endosomes
TM	Transmembrane	
TNF	Tumor necrosis factor	Proinflammatory cytokine (and family)
TRIM	Tripartite motif-containing proteins	Large family of cytosolic innate defense molecules
V-, C1-, C2-, I-	Variable, constant 1 and 2, intermediate IgSF domain	IgSF domain types
VAV	Guanine exchange factor, the “onc F” proto-oncogene	Encoded in MHC, involved in adaptive signaling pathways
VCBP	Variable domain chitin binding	Amphioxus defense molecule
VLR	Variable lymphocyte receptor	Agnathan adaptive defense molecule
WKRY		Plant transcription factor used to upregulate defense genes (analog of NF-κB)
XMIV	*Xenopus* MHC-linked IgSF V region	*Xenopus* MHC-linked NKR-like genes
XNC	*Xenopus* nonclassical	*Xenopus* class Ib cluster
185/333	Sea urchin defense molecule	(Adaptive?) Defense

DNA, deoxyribonucleic acid; ER, endoplasmic reticulim; IL, interleukin; mRNA, messenger ribonucleic acid; RNA, ribonucleic acid.

LRR-containing proteins are involved in immunity from plants to animals. The functions in the immune systems range from control of motility of hemocytes and lymphocytes[30] to specific recognition of antigens via a novel system of gene rearrangement (the variable lymphocyte receptors [VLR] described in the following; see Fig. 4.9). LRRs can occur in soluble forms, the ECM, in the cytosol, or as TM forms, either integral membrane proteins or glycophosphatidylinositol (GPI)-anchored. The bottom line is that because of its basic structure and malleability, the LRR module was locked in early in evolution as an ideal motif for recognition of essentially any ligand.

Immunoglobulin Superfamily

IgSF domains are encountered in a very large number of molecules in the animal kingdom (see Fig. 4.2).[31] They are found intracellularly (eg, connectin) or as cell adhesion molecules, many of which are in the nervous system (eg, the neural cell adhesion molecule, NCAM), coreceptors and costimulatory molecules of the immune system (eg, cluster of differentiation [CD]79, CD80), molecules involved in antigen presentation to lymphocytes (eg, class I molecules), certain classes cytokine receptors (eg, interleukin [IL]-1R), and of course Ig (and TCR), where they were first characterized and were bestowed with their name (Ig). They can be associated with other domains such as FN (eg, titin and FREP) and LRRs,[32] or they can be the sole constitutive elements of the polypeptide chain often associated to a transmembrane segment and a cytoplasmic tail (or GPI-linked). The β barrel IgSF structure was adopted independently in other families such as cadherins, calycins, lipocalin, etc., and the super (or über) family has hundreds of members and has been selected for several different functions. These functions are somehow related, almost all involved in protein-ligand interactions. The vertebrate lymphocyte surface can express 30 different IgSF members simultaneously.

IgSF domains are commonly classified according to different domain constitution in their β strands and loops.[31,33] All conform to the stable shape of a β barrel consisting of two interfacing β sheets, usually linked by a disulfide bridge. There are three types of domains: variable (V), and two types of constant (C1 and C2); the so-called I set domain is intermediate between the C1 and C2. The V domain is most complex with more strands (C′ and C″), which make up complementarity determining region (CDR)[2] in conventional Igs and TCRs. C1 domains lack these strands entirely, and C2/I domains have varying sizes in the C′/C″ region. V domains, either alone (eg, the new antigen receptor [NAR]) or in association with another V domain (eg, Ig H/L), recognize the antigenic epitope and are therefore the most important elements for recognition. Domains with the typical V fold, whether belonging to the true V-set or the I-set, have been found from sponges to insects (eg, amalgam, lachesinm and fascicilin) and even in bacteria. The mollusk fibrinogen-related proteins (FREPs, described in the following) have one or two V-like domains at their distal end, associated with a fibrinogen-like domain. For V domains, the interface between dimers is the

beta strand bearing the C, C′, C″, F, and G strands, so that in Igs the CDR3 are in the center of the binding site; for C domains, the other beta strand bearing the A, B, D, and E strands forms the interface.

The binding capacities of V domains in molecules besides Ig/TCR can reside in different areas of the molecule (interstrand loops, A-A′ strand, F strand), while in Ig/TCR, CD8, and certain NKR, these regions are the targets for variation in shape and charge. The binding capacities can be modulated whether one domain acts as a single receptor unit (eg, IgNAR) or whether it is associated with a contiguous domain (eg, KIR, variable domain chitin-binding protein [VCBP]) or with another polypeptide chain (eg, TCR, Ig). In the case of a dimer, the binding capacity can again be modulated by the presence or the absence in the G strand of a diglycine bulge, which can modify the space between the faces of the Ig domain. In several cases, the sites responsible for binding are known (KIR, Ig, TCR); in many other cases, they are not known but inferred from crystal structures and/or variability plots (leukocyte immune-type receptor [LITR], chicken Ig-like receptor [CHIR], triggering receptor expressed on myeloid cells [TREMs], DSCAM, hemolin).

HEMATOPOIEIS AND CELL TYPES IN THE INVERTEBRATES

Invertebrate Cell Types

Examples of conservation of fundamental mechanisms of genetic control of developmental pathway between protostomes and deuterostomes, even in the absence of homology of the cells or organ considered, are accumulating: the organization and expression of the homeotic gene clusters and eye formation through the function of a complex of proteins including Pax-6.[34] The cell types involved, besides direct interaction with the external layer of cells on the skin, or external teguments, have been specialized cells of mesodermal origin devoted to defense. This is true for all coelomates where effector cells have been identified, but recent data have shown that cnidarian diploblastic organisms that lack mesoderm also have many of the same genetic systems as the coelomates[35] (see Fig. 4.1). The cells can be circulating or sessile, and often are found associated with the gut. Several morphologically distinct hemocyte types in insects cooperate in immune responses: they attach to invading organisms and isolate them, trapping larger organisms in nodules or forming large multi-cellular capsules around them. Indirect evidence for the role of hemocytes in immune responses can be derived by contrasting properties of such cells in healthy and parasitized animals (ie, modifications in adherence and opsonic activity).

All animals show heterogeneity of the free circulating cells, generically called hemocytes (arthropods), coelomocytes, amebocytes (annelids, mollusks, and echinoderms), or leukocytes (sipunculids). However, the repertoire of insect “blood cells” is clearly less heterogeneous than that of vertebrates. Basically, three or four types of cell lineages can be identified in *Drosophila* (Fig. 4.3[36]): plasmatacyte, crystal cells, and lamellocytes, and an equivalent number in *Lepidoptera* (butterflies). The functional roles they play consist of immune defense, disposing of apoptotic and other debris, contributing to the ECM, and modeling of the

nervous system. The immunity role encompasses phagocytosis, encapsulation, and sometimes production of effector molecules (see Fig. 4.3[36]). These roles all require

recognition of pathogen-associated molecular patterns (PAMPs) or self-derived defense molecules (ie, opsonization) at the cell surface.[37,38,39,40]

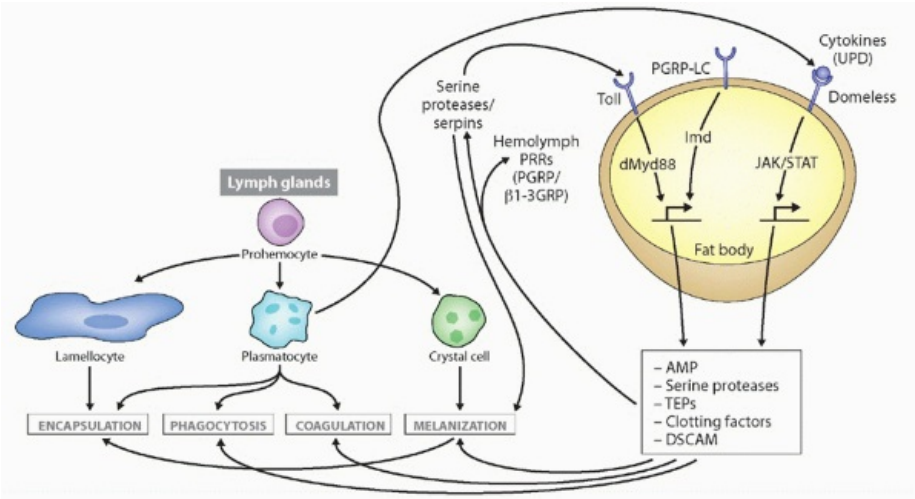

FIG. 4.3. Types of Immune Responses and Cells in Insects, with *Drosophila* as the Prototype. Secreted defense molecules are made by fat body cells in response to pathogens, which either act as direct effector molecules or feed back on hemocytes to stimulate their defense functions. Unpaired (UPD) is produced after virus infection, stimulating defense molecule upregulation via the JAK/signal transducer and activator of transcription pathway. Not shown is the RNAi pathway, also induced upon virus infection. Details on stimulation of the toll and immune deficiency pathways are found in Figure 4.4. This figure was modified from Lemaitre and Hoffmann.[36]

Only in a few organisms has the characterization of hemocyte lineages gone beyond morphologic or basic physiologic functions. Among these free circulating cells are always one or more types that can undergo phagocytosis. Different cells participate in encapsulation, pinocytosis, and nodule formation, and can upon stimulation produce a great variety (within an individual and among species) of soluble effector molecules that may eliminate the pathogen. In an attempt to integrate all of the data available in invertebrates, Hartenstein has proposed a unified nomenclature of four basic types: prohemocytes, hyaline hemocytes (plasmatocytes or monocytes), granular hemocytes (granulocytes), and eleocytes (chloragocytes).[37] These designations will be found in the following description of the blood cell types.

Earthworm (annelid) coelom-tropic coelomocytes are called eleocytes. They contain glycogen and lipid and are considered of the same lineage as the chloragocytes involved in the production of immune effector molecules such as fetidin or lysenin. The phagocytic cells of annelids are apparently granular “leukocytes” derived from the somatopleura and involved in wound healing, whereas the ones derived from the splanchnopleura participate in immunity. Heterogeneity of annelid coelomocytes is not encountered in primitive oligochaetes or in hirudinae (leeches). Phagocytic coelomocytes show an acid phosphatase activity and a beta glucoronidase activity.[41] The large coelomocytes and free chloragocytes (eleocytes) in the typhlosole of *Eisenia foetida* appear to produce the bacteriolytic and cytolytic factor

lysenin.[42] From electron microscopy studies, macrophage-like cells seem to be involved in graft rejection. In the closely related sipunculid phylum, two main cell types can be identified in the blood: erythrocytes (a rare occurrence in invertebrates) and granular leukocytes. The latter are capable of cytotoxicity and even have dense granules reminiscent of vertebrate "NK cells."[43]

Two developmental series have been described in mollusks, the hyaline and granular cells, but cephalopods seem to have only one lineage. They participate in encapsulation, with hemocytes adhering around the foreign body like *Drosophila* lamellocytes. Phagocytosis is carried out by the wandering granular cells, which resemble vertebrate monocytes/macrophages. In oysters, electron microscopy revealed different types of circulating hemocytes, including granular hemocytes resembling the granulocytes of sipunculus mentioned previously.[44,45] In crustaceans, the situation is similar to that in mollusks, with three main populations identified based again on the presence of granules in the cytoplasm.

The hyaline cells are involved in the clotting process and the granular cells in phagocytosis, encapsulation, and the prophenoloxidase (PPO) pathway. The hematopoietic organ is located on the dorsal and dorsolateral regions of the stomach.[39] Crustacean hemocytes can now be cultured and their response to virus can be examined,[46] and markers of the three hematopoietic lineages are available.[47]

In insects, the so-called prohemocytes are believed to be stem cells. They are only found in the embryonic head mesoderm and the larval lymph glands but not in the hemolymph. However, prohemocytes are frequent in both the hemolymph and hematopoietic organs of the lepidopteran *Bombyx* (silkmoth). Plasmatocytes of *Drosophila* have a phagocytic function. This type of hemocyte is equivalent to the granulocytes of *Bombyx*, which play a key role in phagocytosis in larvae. Lamellocytes seem to be unique to *Drosophila*, but they are probably the equivalent of the lepidopteran plasmacytoid cells. Their precursors reside in the larval lymph gland, where they differentiate in response to macroscopic pathogens, following a brief phase of mitosis linked to the presence of the pathogens and under hormonal control via ecdysone. The transcription factors (GATA, Friend-of-GATA, and Runx family proteins) and signal transduction pathways (toll/NF-κB, Serrate/Notch, and JAK/STAT) that are required for specification and proliferation of blood cells during normal hematopoiesis, as well as during hematopoietic proliferation that accompanies immune challenge, have been conserved throughout evolution. The specific differentiation of lamellocytes requires the transcription factor Collier. The mammalian early B-cell factor, an ortholog of Collier, is involved in B-cell differentiation in mice. The *Drosophila* crystal cells are responsible for melanization through the PPO system (see subsequent discussion). In silkworm oenocytoids, crystallike inclusions are also found, but they disappear later after bleeding.[36,37,40]

Echinoderm coelomocytes express a diversity of effector functions, but no studies of lineages have been performed. In echinoderms, the number of different coelomocytes may vary according to the particular family. The sea urchin is endowed with at least four cell types, only one of which only is phagocytic and corresponds to the bladder or filiform forms. Another type is described as the round vibrating cell involved in clotting. Pigment cells (red spherule cells) have been detected ingesting bacteria; the morphology of phagocytic cells can vary

enormously, precluding any easy classification.[48]

In tunicates, amoeboid cells circulate in the blood and are involved in a large number of processes, such as clotting, excretion, nutrition budding, and immunity. Large numbers of blood cells are present (average of 10^7 per mL) in the blood of ascidians such as *Ciona*. Hemoblasts are considered to be undifferentiated cells, perhaps the equivalent of the prohemocytes of arthropods or the neoblasts of annelids. Blood cells in ascidians proliferate in the connective tissue next to the atrium. The pharyngeal hematopoietic nodule of this animal contains a large number of hyaline and granular cells called “leukocytes” with supposed intermediary forms of differentiation between blast and granular mature types. The granular form is likely to be involved in postphagocytic activity, like in earthworms.[49] Adoptive transfer of alloimmunity in the solitary tunicate *Styela* can be achieved via lymphocyte-like cells.

In *Amphioxus*, cells with phagocytic capacity have been identified in the coelom with a morphology resembling more the phagocytic echinoderm cells than urochordate blood cells, a fact that is consistent with the new systematic positions of amphioxus and echinoderms.[50] Both free cells and the lining of the perivisceral coelom are able to phagocytose bacteria. Cells with the morphologic appearance of lymphocytes and expression of lymphocyte-specific genes were detected in this species, the earliest identification of such cells in phylogeny.[51]

Hematopoiesis in the Invertebrates

The history of the hemocytes is associated with that of the mesoderm among triploblastic organisms. The bilaterian ancestor was most likely a small acoelomate or pseudocoelomate worm similar to extant platyhelminths (flatworms) (see Fig. 4.1). A specialized vascular system or respiratory system was probably lacking, although cells specialized for transport and excretions were likely present because they exist in most extant bilaterian phyla. One can further assume that groups of mesoderm cells in the bilaterian ancestor could have formed epithelial structures lining internal tubules or cavities (splanchnopleura). In coelomates, the mesoderm transforms into an epithelial sac, the walls of which attach to the ectoderm (somatopleura) and the inner organs (splanchnopleura). Blood vessels are formed by tubular clefts bounded by the splanchnopleura. Excretory nephrocytes are integrated into those vascular walls, which also gives rise to blood cells circulating within the blood vessels (the pronephros of anurans and head kidney of teleost fish are important hematopoietic organs in vertebrates). Thus, further evolutionary changes separated the three systems, but there was a close original connection between them.

The origin of hemocytes has been investigated mainly in arthropods. When examining principles that govern hematopoietic pathways, similarities have been observed with vertebrates, raising interesting evolutionary issues.[37,40] In jawed vertebrates, the yolk sac or its equivalent gives rise to blood precursors that are primarily erythroid in nature (but see the following: recent data suggest that B1 cells and macrophages are also derived from this embryonic tissue). In succession, definitive hematopoiesis occurs in the aorta/gonad/mesonephros (AGM) region of the embryo, encompassing all of the different cell types and multipotent progenitors (although this is controversial). Like in the vertebrates, hematopoiesis in insects is biphasic. One phase occurs in the embryo and the other during larval development. Additionally, these waves occur in distinct locations of the embryonic

head mesoderm and the larval lymph gland. In the early embryo expression of the GATA factor, serpent (*Srp*) can be detected in the head mesoderm. This GATA family of zinc-finger transcription factors is conserved from yeast to vertebrates where they are involved in various aspects of hematopoiesis. Blood cell formation in the head

follows *Srp* expression, whereas in the lymph gland there is a long delay between *Srp* expression and the appearance of the lymph gland-derived hemocytes.[38] Hematopoiesis in the head mesoderm and yolk sac may be related evolutionarily. A further similarity occurs at the AGM/lymph gland level in *Drosophila*. The lymph gland develops from a part of lateral mesoderm that also gives rise to vascular and excretory cells, much like the vertebrate AGM. The conserved relationship between blood precursors and vascular and excretory systems is intriguing.

Hematopoiesis and Transcription Factors in the Vertebrates

As mentioned previously, transcription factors of the family PAX 2/5/8; GATA 1, 2, 3; ets/erg; and runt domain-containing factors have been cloned in several invertebrates. One plausible model to explain the genesis of true lymphocytes in vertebrates is that closely related members of transcription factor families are the result of a relatively late divergence in lineage pathways followed by specialization of duplicated genes.[52] These duplications could be those that apparently occurred during the history of chordates (see MHC and “Origins” section[2]). Within deuterostomes, the generation of true GATA 2 and 3 probably occurred after echinoderms diverged from the chordate branch and the GATA, ets, early B-cell factor, and Pax5-dependent pathways of T-/B-cell differentiation are thus specific to vertebrates. It is already known that lampreys express a member of the purine box 1/spleen focus-forming virus integration-B gene family that is critically and specifically involved in jawed vertebrate lymphocyte differentiation. Expression has been detected in the gut, which may be related to the fundamental nature of “gut-associated lymphoid tissue (GALT)” as a lymphoid cell-producing organ.

In vertebrates, the generation of T-, B-, and NK lymphocyte lineages from pluripotent hematopoietic stem cells depends on the early and tissue-specific expression of *Ikaros* (and related loci), which by means of alternative splicing produces a variety of zinc-finger DNA-binding transcription factors. The orthologs of *Ikaros*, *Aiolos*, *Helios* , and *Eos* have been identified in the skate *Raja eglanteria*, where two of the four *Ikaros* family members are expressed in their specialized hematopoietic tissues (epigonal and Leydig's organs; see subsequent discussion) like in mammals.[52] In lower deuterostomes, single genes that seem to be related to the ancestor of the Ikaros and Ets family of transcription factors exist, further suggesting that the division of labor between the family members in the jawed vertebrates was a result of en bloc duplications.[52,53] The conservation of *Ikaro*s structure and expression reinforces its role as a master switch of hematopoiesis. We discuss this topic further in the lymphoid tissues section.

Responses of Hemocytes

In this section, we simply touch on classical and specific responses in the invertebrates, responses that are more universal are found in the innate immunity section. Proliferation of hemocytes upon stimulation is an unresolved issue in the invertebrates; clearly, clonal

selection resulting in extensive proliferation is not the rule. The turnover of cell populations has been the object of numerous, often unconvincing experiments. Still, new data have emerged, and it is clear that in several invertebrates, proliferation occurs in certain cell types following encounters with pathogens. Very little cell proliferation occurs in the circulation of crayfish, but cells in the hematopoietic tissue divide after an injection of the PAMP β1-3-glucan. New cells in the circulation developed into functional synthetic germinal centers (GCs) and GCs expressing the proPO transcript. RUNT protein expression was upregulated prior to release of hemocytes. In contrast, proPO was expressed in these cells only after their release into the circulation.[54]

By contrast to the study of transcription factors that regulate hematopoiesis, relatively little is known about cytokines that drive hematopoiesis among invertebrates. It was reported that differentiation and growth of hematopoietic stem cells in vitro from crayfish required the factor astakine, which contains a prokineticin domain[55]; prokineticins are involved in vertebrate hematopoiesis, another case of conservation during the evolution of growth factors and blood cell development.

Parasitization of *Drosophila* by the wasp *Leptopilina boulardi* leads to an increase in the number of both lamellocytes and crystal cells in the *Drosophila* larval lymph gland. This is partially due to a limited burst of mitosis, suggesting that both cell division and differentiation of lymph gland hemocytes are required for encapsulation. In genetic backgrounds where ecdysone levels are low (*ecdysoneless*), the encapsulation response is compromised and mitotic amplification is absent. This ecdysone-dependent regulation of hematopoiesis is similar to the role of mammalian steroid hormones such as glucocorticoids that regulate transcription and influence proliferation and differentiation of hematopoietic cells.[56]

Phagocytosis

To obtain phagocytosis at the site of microorganism invasion implies recruitment of cells via chemoattraction. In vertebrates, this can be done by several categories of molecules such as proinflammatory chemokines/cytokines or the complement fragments C3a and C5a (as mentioned in the following section, C3a fragments as we know from mammals may be found in tunicates but not other nonvertebrates; yet, C3 may be cleaved in different ways in the invertebrates). C3b, mannose-binding lectin (MBL), and many other lectins can function as opsonins, and recent studies of the PGRPs, thioester-containing proteins (TEPs), DSCAMs, and eater have added to this repertoire.[36] Ingestion follows phagocytosis, and then killing occurs by an oxidative mechanism with the production of reactive oxygen radicals and nitric oxide. These mechanisms are conserved in phylogeny, and other basic mechanisms are being examined in more detail now in protozoan models.[57] Signaling pathways in common between vertebrates and the protozoon *Dictyostelium* include involvement of cyclic AMPs, integrins, and perhaps mitogen-activated protein (MAP) kinase cascades. Unique to all jawed vertebrates studied to date, the activation of

phagocytes also leads to upregulation of the antigen processing machinery, costimulatory molecules, and proinflammatory cytokines that can enhance adaptive immunity.

INNATE IMMUNE RESPONSES

Immune responses are often subdivided into recognition, signaling, and effector phases, which are subjected to different pressures, defined by whether orthology is maintained and the relative divergence rates of the genes responsible for the various phases. Recognition molecules are from evolutionarily conserved families, but as described previously, their genes are subjected to rapid duplication/deletion so that orthology is rarely preserved. By contrast, signaling pathways can be conserved (see Fig. 4.5), despite the fact that the genes are often divergent in sequence. Effector molecules can either be extremely conserved (eg, reactive oxygen intermediates) or extremely divergent to the point of being species-specific (eg, AMP). Here, we break the immune response down into these three phases, beginning with the recognition phase.

Initiation of an immune reaction can theoretically involve either the recognition of nonself, altered self, or the absence of self. Nonself-recognition can take place with receptors (pattern recognition receptors [PRRs]) that detect PAMPs, which were originally defined by Janeway and colleagues as evolutionarily conserved epitopes displayed by pathogens but not host cells.[58,59] The second mode, altered self, is typified by molecules that are induced in self-cells during infections and recognized by conserved defense molecules, similar to the SOS systems mentioned in the MHC section, or by peptide presentation on MHC molecules. A third mechanism, “am I still myself,” depends upon recognition of self-tags and their changes in expression[60] (eg, NK recognition of self-MHC molecules through KIR and C-type lectins). These latter two mechanisms have not been described in the invertebrates for immune defense against pathogens, but it would not be surprising if they were revealed in the future, considering the new features of invertebrate immune systems that have been discovered recently and the usage of this mode of recognition in many invertebrate histocompatibility systems.

Whether the invader is related to its host (cells from individuals of the same species or cells from a parasitoid) or are very distant from the host (fungi and bacteria in metazoa), there are different principles of recognition. Yet PAMP determinants have been identified on very different organisms—sugars such as β1-3 glucan of fungi, lipopolysaccharide (LPS) and peptidoglycans of bacteria, phosphoglycan of some parasites, and especially nucleic acids of bacteria and viruses—and they can trigger similar cascades of events. The foreign ligand can be bound by a molecule in solution that initiates an effector proteolytic cascade (eg, clotting or the complement cascade). On the other hand, a proteolytic cascade can be initiated and result in the production of a self-ligand that interacts with a cell surface or endosomic or cytosolic receptor. In this way, there need not be a great diversity of cell surface receptors, especially in the absence of clonal selection.

Of the over 1 million described species of animals (see Fig. 4.1), approximately 95% are invertebrates representing 33 phyla, some with one species (*Placozoa*, *Cycliophora*) and others with over 1 million (*Arthropoda*). Because they have major differences in body plans, development, size, habitat, etc., wildly different types of immune systems in diverse species should be expected. Early studies of invertebrate immunology reached no consensus of how immunity should be examined, but because vertebrate cellular adaptive immunity was often defined (indeed, was discovered for T cells) through transplantation reactions, attempts to reveal specific memory by allograft rejection were often used. After many unsuccessful attempts to demonstrate memory of such responses (see the following) and after extensive molecular studies, a consensus was reached that an invertebrate adaptive immune system

involving somatic generation of antigen receptors and their clonal expression was highly unlikely. However, the term “innate” is rigid and masks the possibility of other somatic alterations of invertebrate immune system molecules, as will be discussed.[61,62] We will categorize the molecules based on their location within the cell.

Intracellular Recognition

Nucleotide-Binding Domain Leucine-Rich Repeat (NLR)

One major group of intracellular sensors in animals and plants is the NLR family (see Figs. 4.2 and 4.4).[14,63] Each of the family members has a central NB/NACHT (nucleotide-binding domain) and C-terminal LRR used for recognition, and a unique N-terminal domain. The subfamilies are defined by their N-terminal domains, coiled-coil and toll-IL-1 receptor (TIR) in plants, and baculoviral inhibitory repeat, caspase-recruitment domain (CARD), pyrin domain (PYD), and activation domain in animals (see Fig. 4.4). Thus far, the NLRs have been found in deuterostomes but not protostomes (see Fig. 4.1), which is surprising considering that plants have intracellular defense proteins with a similar structure, and seem to have been derived via convergent evolution.[14]

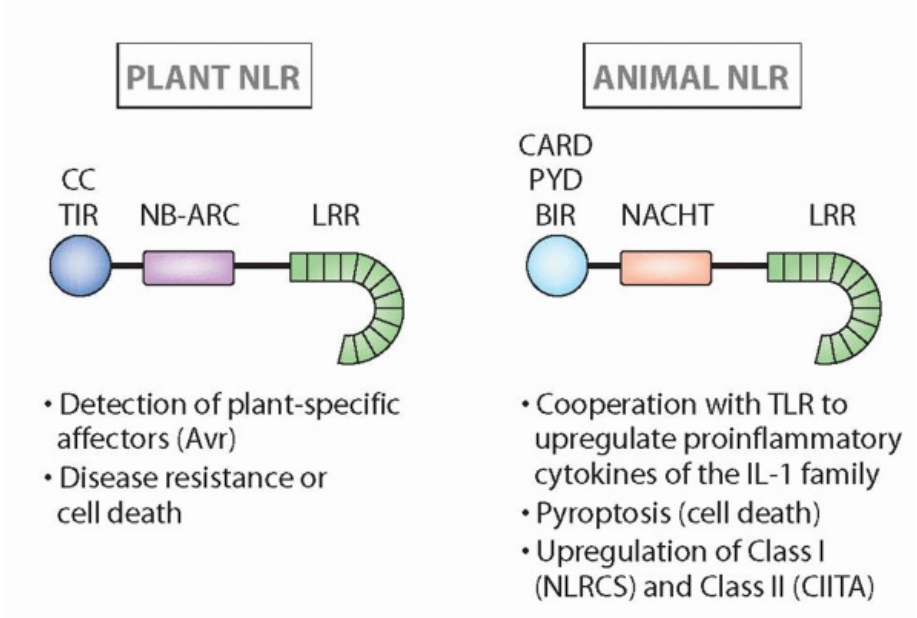

FIG. 4.4. Structure and Major Functions of Nucleotide-Binding Domain Leucine-Rich Repeats in Plants and Animals.[14] Although the structures are quite similar, and recognition can be analogous, these families seem to have arisen via convergent evolution (see text for more details).

The specificity of plant NLR depends principally on the LRRs, and these are targets for diversifying selection, as described previously for multigene families. Plant NLR can recognize pathogen effectors (pathogen-derived avirulence factors), or viral and fungal PAMPs directly via the LRR domains, or via modifications of a host target that interacts with

the N-terminal domains, altered self if you will (see Fig. 4.4). This type of activation in plants is termed effector-triggered immunity, which is specific of the NLRs (see Fig. 4.4). A host of downstream effectors are generated, some involved in defense but others activating cell death pathways.[14,64]

Best described in mammals, the nucleotide oligomerization domain (NOD)/NLR recognizes PAMPs such as peptidoglycan and induces an autophagy-mediated destruction of intracellular pathogens as well as production of proinflammatory cytokines; however, it remains controversial whether there is direct or indirect recognition of the PAMPs (similar to some responses in plants). Polymorphisms in the NOD proteins are associated with inflammatory bowel diseases. The NLRP and NAIP NLRs are activated by in ways that are not well understood by various PAMPs or dangerassociated molecular patterns and form inflammasomes, best known for the activation of caspase 1 and the processing of pro-IL-1beta (or mature IL-18) for release from cells.[14,65] The founding member of the family, CIITA, has long been known to upregulate class II genes (and associated genes, such as cathepsins and invariant chain), and its function is somewhat outside the norm. Another member, NLRC5, has been shown to upregulate MHC class I expression, but the mechanism is unknown.[66] While the shuttling of the vertebrate NLRs CIITA and NLRC5 to the nucleus seems to be a derived characteristic, movement of plant NLRs into the nucleus to activate transcription occurs, either directly or after recruitment of transcription factors like WRKY described in the following.

NLRs are expressed by echinoderm coelomocytes, again representing a highly diversified family[48] (> 200 members, similar to the TLRs and SRCRs). As mentioned, it is surprising that these genes do not seem to be represented in protostomes, and thus the emergence of the family in plants and deuterostomes occurred through convergent evolution.[67] On the contrary, in the vertebrates a search of the *Danio rerio* (and other teleosts) database have yielded a large number of NLR sequences, more similar to the situation in plants.[63] In humans, most NLR genes are encoded in clusters on chromosomes 11p15, 16p12, and 19q13, where six sequences are found in a single telomeric region.

Rig-I-Like Receptors (RLR)

The retinoic acid-inducible gene (RIG)-I is an intracellular defense molecule that is unrelated to the NOD proteins, with N-terminal CARD and C-terminal helicase domains.[68] With the helicase domain, RIG-1 binds to an uncapped 5′ phosphate group, which is diagnostic of viral RNAs. RIG-I also recognizes short double-stranded RNAs, while a second member of this family MDA5 recognizes long double-stranded RNAs. These molecules contain two CARD domains at the N-terminus, a DEXDc domain, a helicase domain, and a regulatory domain. Ligands bind to the regulatory domain, inducing a conformational change leading to interaction with the adaptor protein MAVS (or IPS-1) and ultimately to the induction of type I interferons (IFNs). A third member of the RLR family is LPG2, which lacks the CARD domain; this molecule was originally believed to be a negative regulator of RIG-I/MDA5-induced signaling, but that has been called into question.

This family is found in all of the vertebrates and in lower deuterostomes, such as amphioxus and echinoderms.[63] Somewhat surprisingly, the RLR family is only mildly expanded in sea

urchins (12 members). While there is no report of bonafide RLR family members in protostomes but RLR activity is present,[69] the cnidarian sea anemone has been reported to have a RLR homologue,[70] again showing the importance of studying this taxon for the emergence of immune-related molecules.

Cytosolic Deoxyribonucelic Acid (DNA) Sensors

There are four mechanisms of cytosolic DNA sensing, three of them, the DNA-dependent activator of IFN-regulatory factor, IFI16, and RNA polymerase III (which converts viral DNA into RNA recognized by RIG-I), induce type I IFN production through the intermediate STING, a protein associated with the endoplasmic reticulum (ER).[71] In addition to being an intermediate in IFN upregulation (through IFN regulatory factor-3), STING is also a PRR in its own right, responding to the PAMP cyclic dinucleotides produced by intracellular bacteria like *Listeria*; this suggests that STING was originally a PRR, and then was co-opted by several other PRR sensors to induce effector functions.[72] IFI16 is part of the AIM2-like receptor family; the founding member, AIM2, like the inflammasome, activates caspase-1 to process pro-IL-1beta.

These new molecules/mechanisms have so far only been studied in mammals, but it would be surprising if they were not operative (at least) in other vertebrates as a way to combat DNA viruses. To date, they have not been found in the sea urchin or jawless fish databases.

Tripartite Motifs

Tripartite motif (TRIM) proteins belong to a family induced by type I and II IFNs, with 68 members in the human genome. TRIMs are involved in resistance against pathogens in mammals, especially lentivirus (eg, human Trim 5α is a retroviral restriction factor with activity against human immunodeficiency virus).[73,74] The activity of proteasomes, responsible for cytosolic protein degradation, has been implicated in the TRIM5α-dependent attenuation of retroviral reverse transcription. TRIMs contain an N-terminal moiety composed of three modules: RING (with an E3 ubiquitinase activity)-Bbox-coiled xoil motif followed by different C-terminal domains. TRIMs fit into two major categories by the function of their C-terminal domain: Category 1 with a PHD, MATH, ARF, FNIII, exoII, or NHL domains, and Category 2 with a B 30-2 domain shared with butyrophilins and other proteins and essential for ligand binding.[75] The tertiary structure of TRIM21 revealed two binding pockets in the B30.2 domain formed by six variable loops.[76]

Despite reports to the contrary, the TRIM family is ancient.[77] The family has been greatly diversified in vertebrates and in a taxon-specific manner, as observed for many multigenic immune families.[77] The zebrafish genome harbors a striking diversity of a subset of Category 2 TRIMs not encountered in mammals, called finTRIM, with 84 genes distributed in clusters on different chromosomes. This subset, specific of teleosts, is overexpressed after virus infection in the trout. In the B30.2 domain, residues under positive selection are concentrated within a viral recognition motif first recognized in mammalian Trim 5α.[78]

Finally, *trim* genes encoding Category 2 proteins are preferentially located in the vicinity of MHC or MHC gene paralogs both in fish and human, suggesting that they may have been

part of the ancestral MHC.[79] The B30.2 domains most closely related to finTRIM are found among NLRs, indicating that the evolution of TRIMs and NLRs was intertwined by exon shuffling.[80] Exon shuffling was likely responsible for the presence of the B30.2 domain in butyrophilin and TRIM genes where it was perhaps favored by the proximity of gene in the MHC. It has been argued that during evolution the combination of SPRY and PRY motifs that build up the B30.2 domain were selected and maintained for immune defense.[81]

P47 GTPases

Among IFN-inducible immunity-related genes with an interesting evolutionary history, immunity-related GTPases (IRG/p47 in mouse) function as cell-autonomous resistance factors by disrupting the vacuolar membrane surrounding parasites (eg, toxoplasma).[82] The IRG system studied primarily in mice (absent in humans[83]) is present throughout mammals but the number, type, and diversity of genes differ greatly even between closely related species, one of the common themes in immunity described previously.

Concerning the evolutionary origin of the IRGs, the homologs of zebrafish and pufferfish seem to form two teleost-specific groups, another common theme in this chapter. Their putative promoter regions suggest an expression regulated by an IFN. Homology searches failed to find any convincing ancestral form to the vertebrate IRG proteins in the genomes of invertebrates, but in phylogenetic trees vertebrate IRGs clusters with some families of bacterial GTPases. Thus, IRGs may be derived from a prokaryotic GTPase acquired by a horizontal transfer subsequent to the appearance of eukaryotes.[82]

Integral Membrane (and Sometimes Secreted) Proteins

C-Type Lectins

Lectins were originally defined by their ability to bind carbohydrates in a calcium-dependent manner (how C-type lectins got their name[84]) and some have been described previously (and throughout the chapter). They are found in many phyla in both the deuterostome and protostome lineages in both membrane and/or secreted forms (eg, MBL described in the following). A large number of C-type lectins have been uncovered in the mosquito genome, and some are involved in bacterial defense through direct binding and others through the melanization reaction.[85] Some C-type lectins are encoded in the NKC, including the Ly49 and NKG2 families, as well as CD94 and several other members of the family are central to NK-cell function in mammals. A molecule resembling CD94 but unlikely to be an ortholog (see the following) has been detected on a subset of hemocytes in *Botryllus* and *Ciona*, the functions of which are unknown.[86] Another large gene family that is implicated in the response of the sea urchin to immune challenge includes 100 small C-type lectins,[48] consistent with the enormous expansion of several immune defense families in this animal. We describe other functions of C-type lectins in the NK cell sections.

Scavenger Receptors

The SRCR superfamily is an ancient (from sponges to chordates) and highly conserved group of cell surface and/or secreted proteins, some of which are involved in the development of the immune system as well as the regulation of both innate and adaptive

immune responses; they are especially well known for their function in macrophages.[87] Group B SRCR domains usually contain eight regularly spaced cysteines that allow the formation of a well-defined intradomain disulfide-bond pattern. Scavenger receptors are best known for their housekeeping function of taking up lipids modified by oxidation or acetylation, but they have many other functions as well, such as uptake of apoptotic bodies (eg, croquemort in *Drosophila* of the CD36 subfamily[88]).

SRCRs have been studied mainly in the coelomocytes of echinoderms. Within a few hours after bacterial injection, sea urchin coelomocytes upregulate a variety of genes including an extremely diverse family of SRCRs.[48,89] A very large number of SRCR domains are present (approximately 1,200), but each individual may express different groups of SRCR genes at different levels (and even with differential splicing). To assume that they are all involved in defense is premature, as SRCR genes can be both up- and downregulated after infection with bacteria. As mentioned, this high level of gene duplication is a general rule in the echinoderms.

In mammals, the SRCR family as a whole is also poorly defined but is involved in endocytosis, phagocytosis, and adhesion, and some members acts as PRRs that bind to LPS or other bacterial components. SRCRs are widespread in the human genome and participate as domains in the structure of numerous receptors (eg, S4D-SRCRB, CD6, CD5-L, CD163), but without showing the high level of duplication seen in the echinoderm families.[87]

Down Syndrome Cell Adhesion Molecule

DSCAM in *Drosophila* and other arthropods was described originally by neurobiologists as an axon-guidance protein, dependent upon a large number of isoforms (> 30,000) generated by alternative splicing for the IgSF domains and the transmembrane segment. DSCAM is also involved in insect immunity, expressed in cells of the hematopoietic lineage, and clearly capable of binding to bacteria; like in the nervous system, a large number of splice variants are generated,

clearly different from the ones expressed in neurons.[24] In *Drosophila*, the DSCAM gene is composed of 115 exons, 95 of which encode alternative possibilities for splicing of exons 4, 6, and 9. The molecule consists of 10 IgSF domains and 6 FN domains, and present as either a membrane or soluble form, presumably generated by proteolysis of the membrane form. Each cell expresses only a fraction of the isoform repertoire.

Knock out (RNAi) and anti-DSCAM treatment significantly suppresses phagocytosis, at least in *Drosophila*. Soluble DSCAM constructs with different exon combinations were found to have differential pathogen-binding properties.[90] In addition, suppression of DSCAM in mosquitoes results in an impaired immunity to *Plasmodium*; exposure of hemocytes to different pathogens in culture gives rise to specific modifications and selection of alternative splicing patterns. A similar finding was made in crustaceans, in which particular DSCAM isoforms were induced in response to different pathogens in one species[91] and epitope II was under selection in a study in *Daphnia*.[92] The diversification of DSCAM seems to be specific of arthropods as neither flatworm nor sea urchin nor vertebrate DSCAM are diversified. The vertebrate DSCAM has only two forms, using two alternate TM exons. The

cytoplasmic tail can also be modified by alternative splicing that could change its signaling properties by modulation of tyrosine-based motifs.[93] Human DSCAM is duplicated on chromosomes 21 and 11, but does not appear to be involved in immunity.

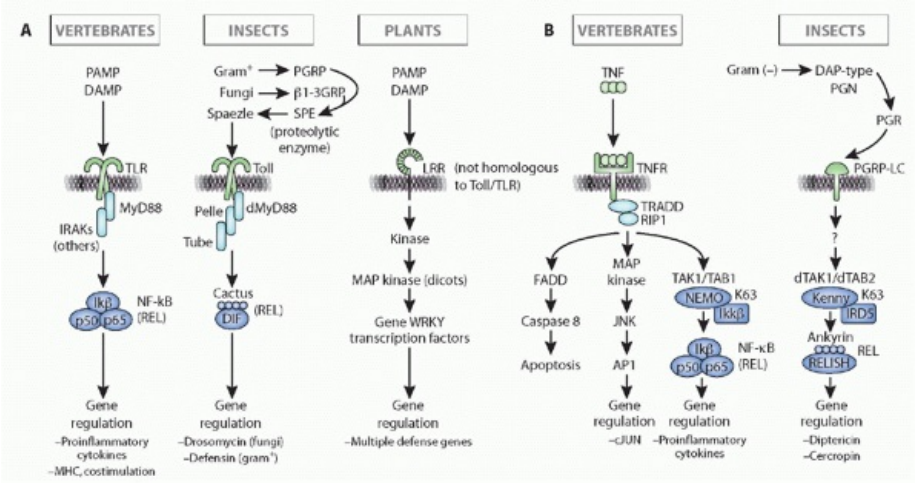

FIG. 4.5. Comparison of Immune Response Induction, Intracellular Pathways, and Immune Outcome in Insect (eg, *Drosophila*), Vertebrates (eg, human), and Plants (a Composite of Pathways in Monocots and Dicots). Note that the initiation of the response and the outcome(s) in insects and vertebrates are quite different for both the toll/toll-like receptor pathway (*left*, **A**) and the immune deficiency/tumor necrosis factor pathways (*right*, **B**), but the intracellular signaling pathways are well conserved evolutionarily in insect and vertebrate (details in the text). Note as well that plants use similar molecules for recognition (leucine-rich repeat-containing molecules) and have similar intracellular pathways with kinase cascades, but *all* of the molecules of recognition, signaling, and effector are derived by convergent evolution as compared to animals. This figure was modified from Beutler et al.[152]

Peptodoglycan-Recognizing Protein and β1-3 Glucan Receptors

PGRPs are found in a wide range of organisms but have been best studied in insects, where they are classified into short (S) and long (L) forms. S forms are soluble and found in the hemolymph, cuticle, and fat-body cells.[94] L forms are mainly expressed in hemocytes as integral membrane proteins where their final structure depends on combinatorial association of different isoforms, modulated by alternative splicing. We provide a short description here, but delve more deeply in the discussion of the insect toll and immune deficiency (IMD) pathways subsequently (Fig. 4.5).[36] The expression of insect PGRPs is often upregulated by exposure to bacteria. PGRPs can activate the toll or IMD signal transduction pathways (see the following) or induce proteolytic cascades that generate AMPs, melanization, or induce phagocytosis. PGRPs directly kill bacteria by inducing a suicide mechanism, first demonstrated to be activated by a type of unfolded protein (stress) response in prokaryotes.[95] Besides their defense functions, insect PGRPs expressed in the gut are believed to promote homeostasis with commensal bacteria (also discussed briefly in the

following). Both soluble and transmembrane forms are present in sea urchins, some with potential catalytic function.[48]

In vertebrates, PGRPs are all secreted and have direct microbicidal activity. Best studied in zebrafish, PGRPs are

expressed in many tissues such as gills, skin, and intestine, providing immune defense. They are expressed before the development of adaptive immunity and likely provide an important protective role.[96] The human PGRP genes are found on the MHC chromosomal paralogs 1q21 and 19q13/p13. All detected splice-variant isoforms bind to bacteria and peptidoglycan. Like the fish molecules, mammalian PGRPs are also positioned at epithelial surfaces and promote intestinal homeostasis by discriminating somewhat between commensal (eg, lactobacilli) and pathogenic bacteria. Knockout mice have increased pathogenic bacteria on mucosal surfaces that induce colitis after injury in the dextran sulphate sodium autoimmune assay.[97]

β1-3 glucan receptor proteins (β1-3GRPs, formerly known as gram-negative binding proteins (GNBPs) are related to bacterial β1-3 glucanases.[98] They are found in insects and other arthropods where they bind bacteria, fungal β-1, 3-glucans, LPS, and/or bacterial lipoteichoic acid (without necessarily showing glucanase activity). An ortholog is present in the sea urchins, but not in vertebrates to date. *Drosophila* GNBP1 together with PGRP-SA are required to activate the toll pathway in response to infection.[36]

Toll and Toll-like Receptors

The toll receptors were originally described in *Drosophila* as genes involved in early development, specifically in dorsoventral patterning. Later, they were also shown to be essential sensors of infection, initiating antimicrobial responses.[36,99] This family was then revealed to be a major force in innate immunity in the vertebrates as well.[100,101] As mentioned previously, across the metazoa structurally closely related members of the toll family range from not being involved in immunity (in *C. elegans* and apparently in the horseshoe crab), to being the equivalent of a cytokine receptor (in *Drosophila*), to being PRR in the vertebrates and invertebrates.[102] Six spaetzle-like and eight toll-like molecules have been identified in *Drosophila*, but only one or two of them are clearly immunity-related.[36,102] In jawed vertebrates, they belong to a multigene family of PRR specific for diverse PAMPs and exhibiting different tissue distributions and subcellular locations.[27] In humans, many are on chromosome 4p and q (TLR 2, 1, 6, 10) but the others are distributed on chromosomes 9, 1, 3, and X.

Ectodomains of TLRs comprise 19 to 25 tandem repeats of LRR motifs made of 20 to 29 aa capped by characteristic N- and C-terminal sequences. All of the toll receptors are homologous and appear similar in domain constitution among all animals. They also share the TIR domain, which is the intracellular segment shared with the IL-1/-18/-33 receptors of vertebrates, as well as other molecules in plants. TIR domains associate with Myd88 to initiate signaling cascades culminating in the activation of NFκB/Rel (see the following) (see Fig. 4.5).

In *Drosophila*, the toll dimer is triggered by an interaction with the unique ligand spaetzle, which is the product of a series of proteolytic cascades, with the most critical enzyme identified (spaetzle-processing enzyme). Activation of the cascades triggers the production of antimicrobial peptides (see Fig. 4.5). The specificity of recognition is not achieved at this receptor level but rather in solution via other intermediates (see the following). *C. elegans* has only one toll receptor, and rather than being antimicrobial responses, it promotes avoidance of a flatworm pathogen upon engagement; the signaling mechanism for the *C. elegans* TOL (toll) is not evolutionarily conserved (it clearly does not induce the NF-κB pathway) and is under investigation.[67] A toll/TLR gene is present in the sea anemone, a cnidarian, but not in other cnidarians such as hydra or coral, which nevertheless have TIR domains associated with other molecules.[35] A TIR domain of the toll-receptor types was detected in sponges, but, like IL-1R in vertebrates, it is associated with a receptor with three IgSF domains.[103] Plants do not have toll/TLR per se, but do have LRR-containing transmembrane sensors that function in a similar fashion[102] (see Fig. 4.5). In summary, toll/TIR arose before the split of protostomes and deuterostomes, but has been lost in some invertebrate groups and has been recruited to perform multiple functions.

The arsenal of TLRs in vertebrates is endowed with specific and diverse capacities. Each vertebrate TLR has its range of specificities and, in addition, combinations of different TLR can create different binding specificities (eg, the association of TLR2 with TLR6 or TLR1 and 2[104] or even TLR2 homodimers in regulatory T cells[105]). This divergence in recognition function is well illustrated by the phylogenetic analysis of the toll and toll-related receptors in different phyla such as arthropods and vertebrates. Toll and related proteins from insects and mammals cluster separately in the analysis, indicating independent generation of the major families in protostomes and vertebrates.[102] Consistent with the expansion of SRCR and NLR genes in sea urchins, hundreds of TLRs also were found in this species.[48] TLRs of the protostome type are in small numbers (3 members) while the vertebrate type has been enormously amplified, all within a single family (222 members) and most without introns. Vertebrate TLRs do not diverge rapidly and evolve at about the same rate, and while there have been some duplications in amphibians and fish, they are not greatly expanded like in the echinoderms (no more than approximately[20] genes in any species).

Signaling Through Innate Surface Recognition Molecules

Four pathways of innate immunity triggering have conserved elements in eukaryotes: the toll/TLRs, the TNF-α/IMD receptors, the intracellular NOD, and the JAK/STAT. Although toll receptors have been found in almost all triploblastic coelomates, most of the work and the elucidation of pathways have been accomplished in *Drosophila* and *Anopheles*.[36] The diversity of AMPs that can be produced via the toll/IMD pathways is substantial, and as described previously is classified in several categories depending upon the type of pathogen recognized (eg, gram (+), drosocin, gram (-), diptericin; fungal, drosomycin) with different effector functions (see Fig. 4.5). Insect antimicrobial molecules were originally discovered by the late Hans G. Boman and colleagues in 1981, a seminal finding that

heralded the molecular analyses of innate immunity in the invertebrates.[106]

Toll and Immune Deficiency Pathways

As described, invertebrate toll receptors are homologous to the vertebrate TLR, in the sense that they are integral membrane LRR-containing proteins (see Fig. 4.5). *Drosophila* toll is activated after it binds spaetzle, the product of a proteolytic cascade activated in solution after the interaction of molecules produced by fungi or gram-positive bacteria with GNBP and PGRP.[107] The TIR cytoplasmic domain of the toll receptor then interacts with MyD88 (itself having a TIR domain) followed by Tube and Pelle, leading to activation of the homologous NF-κB system (Cactus or Diff) that then induces transcription of various defense peptides.[36,99,108] This is remarkably similar to the cascade of events following activation of mammalian TLRs where after their interaction with PAMPs at the cell surface, a cascade is induced through TLR including MyD88, IRAK, TRAF, TAK1, to NF-κB via the IKK signalosome. Thus, infection-induced toll activation in *Drosophila* and TLR-dependent activation in mammals reveal a common ancestry in primitive coelomates (or previous), in which defense genes under the control of a common signaling pathway lead to activation of Rel family transactivators.

The *Drosophila* IMD pathway is employed in responses to gram-negative bacteria[109] (see Fig. 4.5). After interaction with the cell surface receptor PGRP-LC mentioned previously, in a cascade similar to the mammalian TNF-αR signaling pathway, *Drosophila* tak1, an IKK signalosome, and a Relish-mediated (instead of Diff) NF-κB step, results in transcription of antibacterial peptides like diptericin. The *Drosophila* intracellular pathway is similar to the mammalian TNF-α receptor cascade, which also progresses via a death domain Mekk3, the signalosome, and NF-κB resulting in cytokine production. In both cases, a link to pathways leading to programmed cell death is possible; overexpression of *Drosophila* IMD leads to apoptosis. When the activation of either the fly toll or IMD pathway is considered, they are analogous to a mammalian cytokine/cytokine receptor system (eg, TNF-α) in which a soluble self-molecule activates cells via a surface receptor. Fitting with the paradigm put forward on recognition, signaling, and effector phases of the immune response, the diversity of external recognition systems is not matched by an equivalent diversity of intracellular signaling pathways.[22] There are conserved signaling cascades coupled to the receptors, giving the impression of conservation of the innate immunity pathways; yet, these pathways are also used in development, so which is primordial remains an open question.

Plants do not have toll/TLR, but do have transmembrane LRR-containing microbial sensors, of which FLS2 that binds to flagellin, is best characterized[27] (see Fig. 4.5). These molecules do not have an intracellular TIR domain (note that TIR domains exist in plants, but not associated with the TM sensors), but do recruit a kinase of a similar nature to the toll/TLR kinases (the so-called non-RD kinases) to activate downstream mitogen-activated protein kinase cascades. However, as mentioned previously, the NFκB transcriptional system arose early in the animal kingdom[110]; plants employ a different system of transcriptional activators, the WRKY molecules, which are activated directly by the mitogen-activated protein kinase cascades, similar to transcription factor found in animals, AP1.

Extracellular Soluble Receptor with Effector Cascade

Proteolytic cascades are initiated immediately following interaction of foreign material bound by preformed proteins in solution, and this principle is conserved throughout evolution.

Indeed, the proteolytic cascade upstream of production of the toll ligand spaetzle resembles the complement or clotting cascades. The PPO cascade of arthropods leading to melanization and the genesis of antibacterial products described in the following is another example in which peptidoglycans on microbial surfaces initiate the cascade resulting in the degranulation of hemocytes.

The Complement System

The best-studied immune proteolytic cascade that is surprisingly well conserved in the animal kingdom is complement[111,112] (Fig. 4.6). In contrast to the other defense molecules that we have discussed, orthologous complement genes can be detected in all of the deuterostomes without a great deal of expansion/contractions of the gene family. The three major functions of complement in jawed vertebrates are 1) coating of pathogens to promote uptake by phagocytes (opsonization); 2) initiation of inflammatory responses by stimulating smooth muscle contraction, vasodilatation, and chemoattraction of leukocytes; and 3) lysis of pathogens via membrane disruption. Additionally, in the vertebrates, C′ is vital for the removal of immune complexes as well as elicitation of adaptive humoral immunity. The focal point of complement is C3, which lies at the intersection of the alternative, classical, and lectin pathways of complement activation. It is the only known immune recognition molecule (besides its homologue C4) that makes a covalent bond with biologic surfaces via a thioester linkage. C3 has a nonspecific recognition function, and it interacts with many other proteins, including proteases, opsonic receptors, complement activators, and inhibitors. In the alternative pathway, C3 exposes its thioester bond in solution, and in the presence of cell surfaces lacking regulatory proteins that block C3 activation (by cleaving it into iC3b), it associates with the protease factor B (B or Bf). After binding to C3, B becomes susceptible to cleavage by the spontaneously active factor D, resulting in formation of the active protease Bb that in combination with the covalently attached C3 cleaves many molecules of C3 in an amplification step. Another nonadaptive recognition system, the lectin pathway, starts with the MBL (or the lectin ficolin), which is a PRR of the collectin family that binds mannose residues on the surface of pathogens and can act as an opsonin. MBL is analogous to C1q with its high-avidity binding to surfaces by multiple interaction sites through globular C-terminal domains, but apparently it is not homologous to C1q. Like C1q, which associates with the serine proteases C1r and C1s, the MBL-associated serine proteases (MASPs) physically interact with MBL and not only activate

the classical pathway of complement by splitting of C4 and C2 (the same function as C1s; MASP2 appears to be the active protease), but also can activate the alternative pathway in ways that are not understood and thus completely bypass the classical pathway. Indeed, MASP-1 and -2 are homologs of C1r and C1s (see Fig. 4.6). Both C1q and MBL can promote the uptake of apoptotic bodies by phagocytes, via collectin receptors. Another lectin, ficolin, can also initiate the MASP pathway,[113] and it would not be surprising if other activators were discovered in the future (eg, the ancient molecule C-reactive protein is also capable of activating C′). Finally, the classical pathway, which is dependent upon antibody molecules bound to a surface, results in the same potential effector outcomes described previously for the alternative pathway. Novel molecules initiating this pathway are C1q, C1r, C1s, C4, and C2, as well as specific negative regulatory proteins such as C4-binding protein.

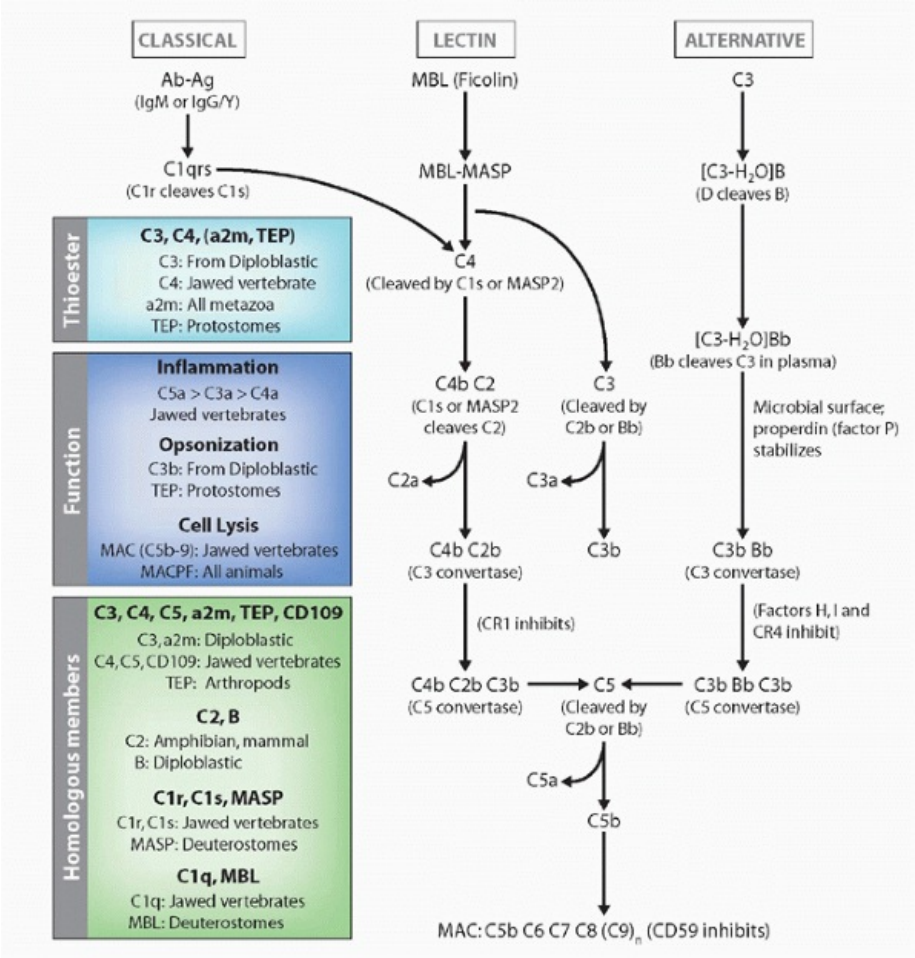

FIG. 4.6. Evolution of the Complement System. The general pathways and appearance of the various components in the phylogenetic tree are emphasized.

C3 and MBL (and ficolin) are vital players in the immediate innate immune response in vertebrates, and both have been described in nonvertebrate deuterostomes.[48,112] Thus far, the best-studied invertebrate systems for investigation of C3 evolution are the sea urchin and the ascidians *Halocynthia* and *Ciona*, in which C3 and B molecules and genes have been analyzed in some detail. In contrast to the very high levels of C3 found in the plasma of jawed vertebrates, sea urchin C3 is not expressed at high levels but is induced in response to infection in coelomocytes.[114] The C3 opsonic function clearly has been identified, but so far initiation of inflammatory or lytic responses (if they exist) has not been obvious. Receptors involved in the opsonization in echinoderms have not been identified, but in the ascidian gene fragments related to the C3 integrin receptor CR3 were identified, and antisera raised to one of the receptors inhibited C3-dependent opsonization.[115]

Hagfish and lamprey C3-like genes were thought to be ancestral C3/C4 genes because the sequence predicts two processing sites (leading to a three-chain molecule), like C4, but a C3-like properdin-binding site is clearly present.[116] However, like C3 in other animals the hagfish protein is composed of only two chains of 115 and 72 kDa, and sea urchin and ascidian C3 sequences predict only two chains (one proteolytic processing site). The

lamprey, but not sea urchin C3, has a recognizable C3a fragment known from gnathostomes to be involved in inflammation, so the role of complement in inflammation may be a vertebrate invention (but see the following).

TEPs have been isolated from *Drosophila* and the mosquito *Anopheles*, as well as several other arthropods.[117,118] While the insect molecules function in a C3-like fashion (opsonization), phylogenetic analysis shows them to be more related to α2-macroglobulin (note that a few insects actually have molecules more related to C3). TEPs in insects function as opsonins, binding to parasites and promoting their phagocytosis or encapsulation. The evolution multimember TEP families in *Drosophila* and mosquito followed independent evolutionary paths, perhaps as a result of specific adaptation to distinct ecological environments as described in the introduction. The *Drosophila* genome encodes six TEPs (whereas there are 15 genes in *Anopheles*, again consistent with the major expansion of many immune gene families in the mosquito), three of which are upregulated after an immune challenge. Mosquito TEPs are involved in killing of parasites, and the reaction is regulated by LRR-containing molecules to avoid destruction of self-tissues; thus, full-blown complement-like systems complete with inhibitors have arisen independently in protostomes and deuterostomes.[119,120]

C3-like genes are present in cnidarians[121,122] and in the horseshoe crab *Limulus*.[123] Good phylogenetic support was obtained for their relationship to C3, as compared to other members of the thioester-containing family like the TEPs. Thus the emergence of C3 as a defense molecule predates the split between protostomes and deuterostomes. A gene resembling the proteolytic enzyme Bf was discovered in these protostomes as well (and in sea anemones), suggesting that the fundamental system was in place a billion years ago (see Fig. 4.1). The lack of C3 in many other protostomes suggests that the ancestral gene was lost and replaced by the TEPs.[117,118]

In jawed vertebrates and some lower deuterostomes, certain species express more than one C3 gene, suggesting that the innate system might compensate in animals that do not optimally make use of their adaptive immune system.[124] Changes in the amino acid composition of the C3-binding site are found that may somehow regulate the types of surfaces bound by the different isotypes.[125] Likewise, in lower chordates such as *Ciona*, C3 and other complement components can be duplicated.[115] Diversification of the carbohydrate recognition domains has been observed also in the *Ciona* MBP family (nine members).

Like Ig/TCR/MHC, the classical pathway and the terminal pathway membrane-attack complex (MAC) appears first in cartilaginous fish.[112] However, as MBL can activate the classical pathway in mammals, it is possible that some portion of this pathway exists in prejawed vertebrates. Nevertheless, C4 and C2 genes have not been detected to date in jawless fish or invertebrates. A bonafide C2 homologue has only been identified to the level of amphibians, although duplicate B genes were isolated from cartilaginous fish and teleost fish that may function both in the classical and alternative pathways. The lytic or MAC pathway, which is initiated by the cleavage of C5 into C5a and C5b, also has not been described in taxa older than cartilaginous fish. Thus, opsonization and perhaps the induction of inflammatory responses were the primordial functions of the lectin/complement pathways. However, a complementary DNA clone for CD59, a molecule that inhibits MAC formation in

self-cells, was identified from a hagfish library, and some of the terminal components of the pathway have been detected in lower deuterostomes with no described functions.[116] Interestingly, proteins with the MAC/perforin domain have been detected throughout the animal kingdom,[48] and some are even involved in cytotoxic reactions; however, it seems that only vertebrates have bonafide terminal C′ components that are highly evolved for targeted destruction of cell membranes. The perforin gene itself also seems to have arisen in gnathostomes, from an ancient MAC/perforin domain-containing gene, macrophage-expressed gene 1 protein, which dates back to sponges; thus, cellular cytotoxic reactions in the invertebrates described in the following must use novel cytotoxic effector molecules.[126]

C3, C4, C5, and α2m (and TEP) are members of the same small family. A cell-surface-expressed (GPI-linked) member of this family, CD109, has been shown to associate with the transforming growth factor (TGF)-β receptor and modulate its expression.[127] The protease inhibitor, α2m, clearly present in invertebrates (protostomes and deuterostomes) and vertebrates, is thought to be the oldest, but obviously this must be viewed with caution considering the data in cnidarians. Along with its ability to bind to and inactivate proteases of all known specificities through a “bait region,” it also has been shown to be opsonic in some situations. α2m, C3, C4, and CD109 (as well as the TEPs) have internal thioester sites, so this feature is primordial; C5 subsequently lost the site. The first divergence probably occurred between α2m and C3, with C5 and then C4 emerging later in the jawed vertebrates.[128] Consistent with Ohno's vertebrate polyploidization scheme is the fact that C3, C4, and C5 genes are located on three of the four previously described paralogous clusters in mammals, and this is also fits with the absence of classical (no antibody) and lytic (no MAC) pathways in phyla older than cartilaginous fish.[2] α2m is encoded at the border of the NKC in mice and human, and there are similarities between these regions and the other MHC paralogs (see Fig. 4.13). The C3a and C5a receptors that promote the inflammatory responses upon complement activation have been identified in several vertebrates and (perhaps) some lower deuterostomes; like the chemokine receptors they are G-protein coupled receptors whose genes may also be found on the ohnologs (C3aR, chr 12p13; C5aR, chr 19q13). If indeed such receptors are found in the prejawed vertebrates

as suggested by recent pioneering experiments in *Ciona* and *Styela*, it will be interesting to determine whether they are involved in some type of inflammation, thought to be the domain of the vertebrates.[129]

Melanization (Prophenoloxidase Cascade)

A major defense system in invertebrates is the melanization of pathogens and damaged tissues,[130] popularized by poor Gregor in Kafka's *Metamorphosis*, when the cockroach Gregor undergoes a melanization reaction from an apple thrown into his thorax by his father. The process is controlled by the circulating enzymes PPO and phenol oxidase. The system is activated by β1-3GRP, PGRP, LPS-binding proteins, and other proteins that can bind to various PAMPs (see Fig. 4.3). The complexes launch a cascade of serine protease activities resulting in cleavage of the pro-form of a prophenoloxidase-activating enzyme into the active form that in turn activates the PPO into phenol oxidase. This leads to the production of quinones and finally melanin. Melanization can completely inhibit parasite growth, whereas

concomitant with PPO activation, many other immune reactions are initiated, such as the generation of factors with antimicrobial-, cytotoxic-, opsonic-, or encapsulation-promoting activities. The presence of specific proteinase inhibitors (of the serpin family) prevents unnecessary activation of the cascade and overproduction of toxic products. Phenoloxidase is the key enzyme responsible for the catalysis of melanization. It is a marker of the PPO activating system, and it can be an immune effector by itself as demonstrated in ascidians. It is therefore interesting to assess its conservation within all metazoa. A survey of the different organisms revealed the presence of phenoloxidase in many deuterostome and protostome phyla, and related molecules are also present in sponges. In arthropods, several PPO genes are present in the genome (nine in *Drosophila* and *Aedes*). Some may have different "immune" functions such as injury repair. Several components that would maintain the role of melanization in immunity may be lacking in different phyla even if many elements are conserved, and so far the best examples of melanization associated with immunity are still found almost exclusively among arthropods and to a lesser extent in annelids. Despite the presence of molecules involved the pathway, the PPO cascade per se does not exist in vertebrates.

Effector Molecules

Peroxidasin

Among molecules containing LRR motifs, peroxidasin occupies a special place because of its involvement in hemocyte biology in insects and because of its homology to the LRR motifs in the agnathan VLR and Ig domains similar to Ig itself. *Drosophila* peroxidasin is an assembly of a cysteinerich motif, six LRR, and four IgSF domains.[131] The molecule is conserved in vertebrates, although a role in immunity has not been reported. Another molecule called peroxinectin, with similarity at the level of the peroxidase region, has been described in crustaceans and shown to be associated with immunity via the PPO cascade.[132] Its involvement in immunity is unlike any other effector so far described but illustrates the utility of LRR in many different types of molecules and processes. Pathogens bound by AMPs can be phagocytosed or walled off by a barrier of flattened hemocytes and ECM. The ECM forms a basement membrane that becomes stabilized partly through peroxidases that generate tyrosine-tyrosine bonds. The combination of LRR and Ig structures suggests that peroxidasin may precisely mediate adhesion of cells to the ECM.

As mentioned, a large number of LRR-Ig-containing proteins has been discovered, most of them playing roles in embryologic development.[32] Many LRR-Ig proteins are encoded in paralogous regions in the vicinity of immune genes, showing an ancient direct connection between the families (see the following).

Fibrinogen-Related Proteins

FREPs are proteins that were first discovered in the hemolymph of snails with an IgSF moiety (one or two V-like domains) and a fibrinogen domain. The fibrinogen domain is found in a large number of defense molecules throughout the animal kingdom (eg, the ficolins). FREP gene expression is upregulated following exposure to the mulluscan parasites such as schistosomes[133]; a snail strain resistant to schistosomes shows an upregulation of the FREP 2 and 4 genes of up to 50-fold. The original discovery of FREPs followed the recovery

of snail proteins that bound to worm antigens, and thus this is one case in which the correlation between an invertebrate receptor and its ligand is clear. However, it is not known whether the IgSF or fibrinogen domain (or both) bind to the antigen or which effector functions are induced after FREP binding.

FREP diversity is remarkable in that there are many polymorphic genes as well as alternate messenger RNA splicing to generate the diversity. In addition, based on the number of genes and alleles in individual snails, there appears to be a somatic diversification mechanism that modifies FREP genes, either via mutation or gene conversion in the region that encodes the IgSF domains.[134] Over 300 unique sequences were found in 22 snails, consistent with a somatic diversification mechanism. Currently, there is no mechanism to account for the mutations, but data accumulate for somatic modifications and the use of FREPs in critical defense against pathogens.[135]

FREPs are also present in arthropods where they lack the Ig domains,[136] once again with an expansion of genes in the mosquito *Anopheles gambiae* as compared to *Drosophila*. RNAi studies have shown that subsets of FREP genes are vital for defense against malarial parasites, and different FREPs bind to bacteria with different affinities.[137] Homo-and heterodimers can form between different FREPs, and multimers can be fashioned that likely increase the avidity of binding. In summary, this ancient family of defense molecules has all of the attributes described in the introduction: rapidly evolving multigene family, conservation in divergent protostomic invertebrate phyla, somatic diversification via alternative splicing, and perhaps an unknown mutational/gene conversion mechanism, as well as heterodimeric (and multimeric) association.

185/333

There are a number of additional expanded gene families in the sea urchin genome that encode proteins with immune-related functions. The *185/333* genes were first noted because they are highly upregulated in coelomocytes after exposure to LPS, constituting up to 7% of the messenger RNAs in such cells.[138] Subsequently, transcripts were shown to be upregulated by many different types of PAMPs. The encoded proteins have no detectable similarity to any other gene family, but they are highly diversified and are produced (at least) by a subset of coelomocytes.

There are estimated to be at least 50 185/333 genes in the sea urchin genome.[139] The gene is composed of two exons, one encoding the leader and the other encoding the mature protein. The second exon is made up of so-called elements and repetitive sequences that are quite different from gene to gene, which can to a large extent explain the diversity of expressed loci. However, there are hints of RNA editing, a unique form of alternative splicing, somatic mutation (perhaps targeting cytosine residues), and other (perhaps) novel mechanisms of diversity to explain the incredible number of different isoforms; additionally, like many other defense molecules, there is evidence of protein multimerization. Whatever the mechanism of diversity generation, it would be surprising if this family were not vital for defense in echinoids. Furthermore, the presence of this unique multigene family in sea urchins is consistent with the great expansion of other immune gene families in this group, including TLRs, SRCRs, and NLRs.[7]

Variable Domain Chitin-Binding Proteins

VCBP, first discovered in *Amphioxus* but present in *Ciona* as well, consist of two Ig domains of the V type but with a different folding motif when compared to Ig or TCR V domains[140] followed by a chitin-binding domain. The chitin-binding domain resembles chitinases found throughout the animal kingdom, and like dedicated chitinases VCBP is usually expressed in the gut. Apparently, there are no cell-surface-expressed forms and thus all VCBPs are likely to be secreted, effector molecules. In *Amphioxus*, their diversity is enormous, apparently entirely because of polymorphism and polygeny, and not somatic alterations. Each individual can carry up to five genes per haplotype, and in limited studies (11 individuals), no identical haplotype has been encountered.[141,142] The general structure of the V domain is like that of the vertebrate rearranging antigen receptors, but with some unusual properties, including packing in a "head-to-tail" dimeric fashion, totally unlike Ig and TCR. VCBP diversity does not reside in the Ig/TCR CDR resides, but rather in the A, A′, and B strands, like in DSCAM.

By contrast to the *Amphioxus* VCBP, there are only a few nonpolymorphic *Ciona* VCBP genes, which are expressed by gut epithelium and amebocytes. Soluble VCBPs bind to bacteria and induce opsonization in amebocytes. It is hypothesized that these molecules may perform a function similar to mucosal IgA in vertebrates, which provides a "firewall" protecting from invasion of intestinal bacteria and promoting homeostasis.[143] If true, this would provide a link to the regulation of commensals in early deuterostomes. It should be noted here, however, that recent data suggest that "tolerance" of commensals occurs in the protostomic invertebrates as well.

Antimicrobial Peptides (Defensins)

Each metazoan taxon produces a variety of molecules with intrinsic antimicrobial activity,[144,145] the majority of which fall into three major categories: defensins, catelicidins, and histatins. Even in species with very small genomes (such as the tunicate *Oikopleura* [60 Mb genome]), selection pressures have been strong enough to lead to expansion of the Phospholipase a2 family, with 128 members.[146] Some families are evolutionarily conserved but generally they diverge rapidly and orthologous relationships are not apparent. The best studied group of AMPs is the *defensins*, which are amphipathic cationic proteins; their positively charged surface allows them to associate with negatively charged membranes (more common in pathogens), and a hydrophobic surface that allows them to disrupt the membranes, either by disordering lipids or actually forming pores. Most of the molecules are proteins, but an antimicrobial lipid called squalamine, which also is modeled to have hydrophobic and positively charged surfaces, is found at very high levels in dogfish and lamprey body fluids.[147] Defensins can either be constitutively expressed (eg, in respiratory epithelia in mammals) or inducible (eg, see the following for *Drosophila* and see Fig. 4.5). Certain responses that seem systemic, like the production of *Drosophila* defensins, can also take place locally in the damaged tissues themselves; otherwise, a systemic response is initiated in organs distant from the site of infection such as the fat body in *Drosophila* where induction of bactericidal peptide expression occurs.[36] Defensins are the focus of great attention in commercially bred species such as oysters, mussels, and crustaceans. Besides their direct defense functions, in mammals defensins play other roles, such as chemotaxis

and immune regulation.

Penaedins. One set of diverse AMPs is the penaedins, present in crustaceans (shrimp). Penaedins are small antimicrobial peptides (5 to 7 kda) that bind to bacteria and fungi, and consist of a conserved leader peptide followed by an N-terminal proline-rich domain and a C-terminal cysteine-rich domain.[7,148] Most of the diversity is found in the proline-rich domain,[149] suggesting that it is most important for recognition, but both domains are required for recognition of bacteria and fungi. Four classes of penaedins, PEN2 to 5, are expressed by shrimp hemocytes. A great diversity of isoforms is generated, with substitutions and deletions within the proline-rich domain, suggesting that this domain recognizes ligand; nevertheless, both domains seem to be required for function. Like the VCBPs, each penaeidin class seems to be encoded by a unique gene and isoform diversity is generated by polymorphism. Multiple copies of penaedin genes are present in different species, and there is rapid expansion and contraction even within closely related organisms.

Responses to Viruses in the Invertebrates

Compared to immunity to extracellular pathogens in the invertebrates, the study of responses to intracellular pathogens like viruses is in its infancy.[150] First discovered in plants and in *C. elegans*, the RNAi pathway of defense against viruses is also operative in *Drosophila* and *Anopheles*.[151] Doublestranded RNAs (viral or otherwise) are recognized by the enzyme Dicer 2, generating small interfering RNAs that can associate with complementary RNAs and induce their degradation.

Viruses also induce an “IFN-like response” through a cytokine receptor (domeless) that is homologous to the IL-6 receptor and signals through the JAK/STAT pathway.[152] After viral infection, unknown signals (RNA, perhaps) induce the production of cytokines of the unpaired family that bind to domeless on neighboring cells and upregulate a large number of genes involved in defense (see Fig. 4.3). Nothing is known about the effector pathways of these responses, but mutants of one of the induced genes results in increased viral load. It should be noted that this pathway is not cell autonomous, inconsistent with the IFN pathway in vertebrates.

In a paradigm-changing paper, foreign antigen was shown to directly interact with *Drosophila* toll7, resulting in the induction of antiviral autophagy and inhibition of viral replication.[153] Toll-7 interacted with the glycoprotein from vesicular stomatitis virus at the cell surface to initiate the response. Thus, the dual paradigm of indirect and direct recognition by toll and TLR, respectively, must now be modified. There are several other tolls without functions in insects that might be involved in immunity, perhaps via such mechanisms.

In summary, arthropods (and presumably other invertebrates) use an RNAi pathway as well as a signaling pathway to combat viruses.[150,152] As opposed to the systemic plant RNAi response, the same pathway in protostomes is rather cell autonomous. This response was lost in the vertebrates, presumably because 1) viruses have been able to effectively counter this response and render it ineffective; 2) there have been remarkable evolutionary innovations in the vertebrate innate and adaptive immune systems to combat viruses; and 3) vertebrates use a Dicer pathway extensively to regulate expression of their own genes. The

discovery of a viral immune response quite like a type I IFN response in vertebrates demonstrates that the three major signaling pathways of defense in *Drosophila*, toll, IMD, and JAK/STAT, are similar to the vertebrate TLR/IL-1R, TNF, and IL-6/IFN pathways, respectively (the first two homologous). Finally, other insect tolls may interact directly with PAMPs to promote antiviral defense such as autophagy or apoptosis. This is a field in which rapid progress will be made in the near future.

Natural Killing Activity Across Metazoa

The word "cytotoxicity" encompasses vastly different protocols of cell killing by of different cell types. It can be an effector function of cells of the adaptive (cytotoxic T-lymphocyte [CTL] or NKT cells) or of the innate arm (bonafide NK, see the following) of the jawed vertebrate immune system. Similarly the term "NK cells" covers different cell types and different functions. NK cells of vertebrates can "recognize" missing self-MHC class I, but also ligands induced on stressed cells following virus infection, transformation or stress. They can also have an immunoregulatory role by interactions with antigen-presenting cells (APCs). Many of these features obviously profit from a comparative approach.

In natural killing, the common denominator is a spontaneous reaction (ie, it does not require any [known] antigenic priming but only cell contact). Some form of natural killing can be observed from the earliest metazoans onwards. Some marine sponge and corals avoid fusion with one another by mechanism of cytotoxic cells or induce apoptosis at the level of the teguments.[154] Phenomena more similar to vertebrate NK killing are observed in sipunculid worms where allorecognition among populations was shown to result in killing of allogeneic erythrocytes by lymphocyte-like cells.[155] Similar cases can be also encountered in annelids and mollusks,[156] The role of IgSF and lectin receptors known to be involved as NK cell receptors in vertebrates has not been examined in these invertebrates, even though some candidate homologs have been identified. Note that the mechanism(s) cannot be perforin-mediated, based on the recent bioinformatics analysis on MAC/perforin domains described previously in the complement section.[126]

When comparative morphology or function is not informative, searching for conservation of transcription factors or cell surface markers may be useful. Survey of IgSF genes across databases have not yielded any promising candidates to date. Despite the presence of polymorphic IgSF members of the receptor tyrosine kinase family in sponges, their role in allorecognition or killing has not been demonstrated.[157] As mentioned, similarities were found among the lectin families, especially in prochordates where cytotoxicity has been reported and associated with a discrete population of hemocytes the granular amoebocytes. The urochordate genome (*Botryllus*, *Halocynthia*, *Ciona*) encodes many lectins with or without typical carbohydrate recognition signatures, among them a putative CD94 homolog has been cloned and its expression followed in *Botryllus*[158]; its predicted sequence does not match well to vertebrate CD94. This gene is differentially regulated during allorecognition in *Botryllus*, and a subpopulation of blood cells has the receptor on their surface in both *Botryllus* and *Ciona*. Phagocytosis is inhibited by an antiserum recognizing the *Ciona* homologue.[159]

Other C-type lection homologs of CD209 and CD69 are linked to the CD94/L gene on *Ciona*

chromosome[1] (L.D.P., personal observation). Could they be part of a “pre-NK complex”? Interestingly, all the human homologs of those lectin genes are present either in the NK complex on 12 p13 (CD94, CD69) or on an MHC paralog 19p13 (CD209). Taken together with studies of the chicken MHC which encodes some C-type lectins (see the following), the data suggest that a conserved MHC-linked region containing several lectin genes was present before the emergence of MHC class I and II genes.[2]

In addition, a number of genes encoding membrane proteins with extracellular C-type lectin or immunoreceptor tyrosine-based inhibitory motifs (ITIMs) and immunoreceptor tyrosine-based activation motif s (ITAMs) (plus their associated signal transduction molecules) were identified in *Ciona*, which suggests that activating and inhibitory receptors have an MHC class I- and II-independent function and an early evolutionary origin.[160] The ligands of these *Ciona* molecules are of great interest to uncover.

Natural Killer and Natural Killer-Like Cells

NK cells express both activating and inhibitory cell surface receptors; in fact, the paradigm for positive and negative signaling via such receptors began with these cells[60,161]; however, activating and inhibitory receptors (often paired) are conserved throughout vertebrates and invertebrate deuterostomes, and are expressed in hematopoietic cells of all types. In NK cells, stimulation of the activating receptors, which associate with proteins having an intracellular ITAM (CD3ζ, DAP12, or DAP10 conserved at least to the level of bony fish[162]), results in killing of target cells. Inhibitory signaling receptors all possess cytoplasmic ITIMs, which recruit phosphatases and generally are dominant over the activating receptors. These receptors fall in two categories IgSF and C-type lectin group V(II). In general, NKRs recognize MHC class I molecules of either the classical or nonclassical type, the latter sometimes encoded by viruses.[163]

General Evolution of Natural Killer Receptor Families . As mentioned, NK cells in mammals can use different types of receptors, even encoded by different gene families, IgSF (KIR) in primates and C-type lectins (Ly49) in rodents. A few receptors are conserved but most others are highly variable. Very few families show conservation of domains throughout the jawed vertebrates.[163] When dealing with the origin of these genes in invertebrates, one has to imagine under what pressures they evolved. The question remains as to whether NK cells, or NK-like cells, preceded the emergence of T- and B-lymphocytes.

As described in the introduction, NKRs are the most rapidly evolving molecular component of the gnathostome immune system. Most ligands for these diverse NKRs are MHC class I molecules, or molecules of host or pathogen origin related to MHC class I. The KIR families are divergent, as very few genes are conserved even between chimpanzees and humans, and there are different numbers of genes in KIR haplotypes within a species. Humans have two KIR haplotypes A and B, one encoding a large number of activating receptors and the other very few.[23] It is speculated that the haplotypes are under balancing selection within the population both for defense against virus and for maternal/fetal interactions. By contrast, CD94 and NKG2 receptors are conserved throughout mammals. So whereas receptors for polymorphic class I molecules are divergent, those for nonpolymorphic or stress-induced

class I molecules are relatively conserved (despite the fact that their ligands Qa1 and HLA-E are not orthologous). NK cells play other important roles in other innate immune responses, for example in antiviral immunity. NK cell recognition of virus-infected cells engages the activating KIR and Ly49 receptors and NKG2D in this process. Thus, viruses are hypothesized to supply the evolutionary pressure on diversification of NKRs. In fact, it has been shown in mice that inhibitory receptors can rapidly mutate into activating receptors when viral "decoy" class I molecules evolve to engage inhibitory receptors.[164] Generally speaking, inhibitory receptors are older and more conserved, whereas activating receptors evolve more rapidly and can be derived from inhibitory receptors via mutations that result in loss of the ITIM.[165]

Comparative Studies of Natural Killer Function . NK cells were detected in *Xenopus* by in vitro ^{51}Cr-release assays. Splenocyte effectors from early thymectomized frogs spontaneously lyse allogeneic thymus tumor cell lines that lack MHC antigen expression.[166] This activity is increased after the injection of tumor cells or after treating the splenocytes in vitro with mitogens, suggesting lymphokine activation of the killers. Splenocytes isolated with an anti-NK monoclonal antibody (mAb) revealed large lymphoid cells with distinct pseudopodia. Immunohistology indicated that each anti-NK mAb routinely labeled cells within the gut epithelium but NK cells were difficult to visualize in spleen sections.[167]

In amphibians, NK cell studies are especially interesting because of natural experiments done by nature (ie, the absence or low levels of MHC classical class I during larval life of some species like *Xenopus*).[168] They are bonafide NK cells, distinct from T cells, as they fail to express TCR Vβ transcripts. NK emerge in late larval life, 7 weeks postfertilization, which is about 2 weeks after the time when cell surface class I can be detected. The proportion of splenic NK cells remains very low until 3 to 4 months of age, but by 1 year there is a sizeable population. Therefore, NK cells fail to develop prior to MHC class I protein normal expression (at least NK cells of the type that can be measured with these assays and with NK cell-specific mAbs) and do not contribute to the larval immune system, whereas they do provide an important backup for T cells in the adult frog by contributing to antitumor immunity.

NK cells have also been described in a number of teleost fish with the most in-depth studies in catfish, in which there are clonal likes of cytotoxic cells,[167] some that clearly lack TCR expression.[169] A subset of the fish NK cell bears a highaffinity FcR that can be utilized for antibody-dependent cellular cytotoxicity.[170] Other subsets of NK cells spontaneously kill allogeneic targets. Further study of these cloned lines may provide much needed information on NK function in phylogeny.

Phylogeny of Natural Killer Lectins

Besides the well-described Ly49 family of receptors in rodents (and horse) and the CD94 and NKG2 families in all mammals, other mammalian NKRs are of interest. Studies in mammals have shown that some NKC-encoded lectin-like receptors in the Nkrp-I family can recognize other lectin-like molecules, termed Clr, also encoded in the NKC.[171] Having linked loci encoding receptor-ligand pairs suggests a genetic

strategy to preserve this interaction; perhaps the CD94 homologs of invertebrates are

genetically linked to genes encoding their ligands. In addition, as described in the following, the close genetic linkage of receptor and ligand genes is a common theme in "histocompatibility reactions" throughout the animal and plant kingdoms described below.

In chickens, a single gene similar to CD94/NKG2 is encoded in a region syntenic with the mammalian NKC.[172] It is linked to CD69, another C-type lectin also encoded in the NKC of mouse/human. Chickens and quail MHC encode two C-type lectin NKR B-lec and B-NK, the latter being most similar to NKPR1.[173] Other C-type lectins are found in the RFP-y locus, one that is also most similar to NKRP1.[174] These linkages give credence to the idea that the NKC and MHC were syntenic in early jawed vertebrates (see the following). While C-type lectin genes with some similarity to mammalian NKR have been detected in ectothermic vertebrates, no convincing orthology or synteny to the NKC has been found to date. In mammals including marsupials, NKG2D is conserved, and CD94/NKG2 is found in mammals and birds (as well as NKPR1).[163] If such C-type lectin NKR are found in the future in cold-blooded vertebrates, they will have to be studied in functional assays.

Given the apparent lack of MHC class I and class II in agnathans and their convergently acquired adaptive immune system (see the following), it is difficult to envisage how NK cells with receptors of any type might function in these animals. It should be mentioned, however, that sequence similarity might be difficult to detect for an MHC peptide-binding region (PBR), given the rapid rate of evolution of this gene family. Furthermore, it would not be shocking if there were NK cells with ligands encoded by other gene families—in mammals, ligands for some activating NKRs have not been identified. It would be of interest to study the non-VLR-expressing lymphocytes in agnathans (if such cells exist) for their killing potential or gene expression.

Phylogeny of Immunoglobulin Superfamily Natural Killer Receptors

IgSF-activating receptors have been recognized from cartilaginous fish onwards with a convincing activating NKp44 homolog first found in carp (called NILT), but with no functional data.[175] Subsequently, this family was found in other bony and cartilaginous fish and definitive orthology to mammalian NKp44 was shown. The activating receptor NKp30 is also conserved, with orthologs found to the level of cartilaginous fish[176]; in addition, as described in the MHC section, there are V(J) genes within the frog MHC called XMIV that are ancient homologues of NKp30 and may be NKRs of both activating and inhibitory types.[177] The ligand for NKp30 has recently been uncovered, the stress-induced molecule B7H6.[178] Interestingly, there is a perfect correlation between the presence or absence of NKp30 and B7H6 in the vertebrate line, with both genes lacking in birds and bony fish but present in all other gnathostome classes.[176] Furthermore, phylogenetic trees suggest a close relationship between NKp30 and NKp44, consistent with their ancient origins within the vertebrate line.

There are other bony fish-specific IgSF NKR families. One family, the novel immune-type receptors (NITRs),[179] have one or two Ig domains with a charged residue in the TM and could therefore be associated (by analogy) to an ITAM DAP12 equivalent, and indeed was shown to interact with mammalian DAP12.[162] Like NKp30, the NITR N-terminal V domain is also of the VJ type. NITRs were originally believed to be part of the LRC, but this was shown to be unlikely upon further analyses. NITRs can be expressed by cells of the hematopoietic

lineage, presumably lymphocytes. NITRs have been found in all bony fish, with rapid contraction and expansion of the gene family, with the majority of proteins predicted to have inhibitory ITIMs in their cytoplasmic tails. In zebrafish, there are many NITR genes that group into 12 distinct families.[180] An extreme level of allelic polymorphism is apparent, along with haplotype variation and family-specific isoform complexity. By contrast, only 11 related genes encoding distinct structural forms have been identified in the channel catfish, and the relatively small number of genes allowed functional studies to be performed. Additionally, taking advantage of the ability to grow clonal lines of catfish hematopoietic cells, one granular cell line lacking all markers of B/T cells was shown to express several NITRs. Expressed NITRs were fused to an ITAM-containing motif and transfected into a T-cell hybridomas line with a nuclear factor of activated T cells (NFAT) promoter, and the specificity for particular catfish MHC alleles was maintained.[181] Subsequent crystal structure analysis showed the NITR V domains to form dimers, much the same as Ig/TCR heterodimeric V regions. Thus, the sequence analysis (ITAM/ITIM), signaling properties, involvement in cytotoxicity, and recognition of MHC molecules identify the NITRs as excellent candidates for NKRs in bony fish. Furthermore, the work serves as a paradigm for study of potential NKRs when homology and/or conserved synteny are lacking or ambiguous.

IgSF inhibitory receptors usually form larger families of molecules in comparison to activating receptors. This function can be devoted to two distinct families of receptors, giving another example of the extremely rapid evolution of these molecules. There are many ITIM-carrying IgSF integral membrane receptors across the classes of vertebrates, and they seem to have had independent histories as it is difficult to convincingly detect orthologous genes between species. This is especially true of multigene families in fish, with members equipped with possible ITIMs, including the teleost NITR and LITR, and bird CHIR and CD300L.[163] Several members of these families can be expressed on NK cells, but expression studies are in their infancy in fish. It is sometimes difficult to distinguish FcR families from NK KIR-like domains, and both FcR and KIR seem to stem from a same lineage. Given the role of the FcR binding to bonafide antibodies and conferring specificities to cells of the innate arms of the immune system, it is likely that these molecules will be restricted to jawed vertebrates. The KIR activity that can incorporate pathogen and virus recognition may be more primitive, but the ancestry of KIR is not well understood, and the bonafide KIR family seems to be restricted to primates.[163]

Genes encoding the classical FcRs on the long arm of human chromosome 1 (1q21-23) are linked to other FcR-like genes. A large multigene family, which includes genes encoding the FcγR and the NK cell Ig-like receptors, is located in the LRC (human chromosome 19q13). This region could in fact be paralogous to 1q23 and may even have been originally associated with the MHC (see the following). These families belong to a larger class of activating or inhibitory receptors. Their phylogenetic conservation in birds, amphibians, and bony fish suggests a biologic importance even though the size of the families, their expression pattern, and the specific nature of the receptors vary greatly among species.[182] In several cases, a commitment to a task in the immune system may not be conserved among homologous members, and the evolutionary fate of the family will be probably affected. Comparison of key residues in the domains may suggest a possible common involvement in

MHC recognition for the two families recently discovered in birds (CHIR)[183] and the teleosts (LITR).[184] Other families were generated within a single class or even within a single order of vertebrates (eg, the KIR described previously). The relationships of KIR with many other multigene families such as IpLITR or NITR remain to be explored. What was the scenario that led to the present mammalian situation? If the fish observation on potential MHC binding holds true, the IgSF type of receptor seems to be the most primitive NKR.[163]

Other Immunoglobulin Superfamily Families to Explore Further

In more primitive vertebrates, the physical or genetic linkage of relatively large IgSF families is well documented in the teleost NITR but not yet elucidated in the case of other interesting families in prochordates like the VCBP. In the sea urchin genome, many IgSF await a complete analysis and will certainly contribute to a better understanding of the evolution and origin of Ig/TCR.[48] Large families of LRR-IgSF in amphioxus[185] could perhaps represent interesting intermediaries in the genesis of either VLR in agnathans or Ig/TCR in gnathostomes (see Fig. 4.10). In hagfish, the discovery of leukocyte expressed receptors agnathan-paired receptors (APARs) revealed what might have been a precursor of Ig or TCR.[186] APARs resemble Ag receptors and are expressed in leukocytes and predicted to encode a group of membrane glycoproteins with organizations characteristic of paired Ig-like receptors. Based on their transmembrane regions, APAR-A molecules are likely to associate with an adaptor molecule with an ITAM and function as activating receptors. In contrast, APAR-B molecules with an ITIM are likely to function as inhibitory receptors Thus, the *APAR* gene family has features characteristic of paired Ig-like receptors. APAR V domains have a J region and are more closely related to those of TCR/B-cell receptor (BCR) than any other V-type domain identified to date outside of jawed vertebrates. Thus, the extracellular domain of APAR may be descended from a VJ-type domain postulated to have acquired recombination signal sequences (RSS) in a jawed vertebrate lineage (see Fig. 4.10).

In jawed vertebrates, three such receptor families with VJ-type domains have been identified: a small family of mammalian proteins known as signal-regulatory proteins, a large family of the previously described teleost NITR, and the MHC-linked XMIV in *Xenopus*. These molecules are examined in more detail in the conclusion. Many IgSF proteins expressed in the immune systems are also expressed in nervous systems where the signaling cacscades may be conserved. This selection of IgSF domains, in two different systems in which homologies are found in molecules with quite different functions, may reveal adaptation capacities and constraints exerted on surface receptors.[187]

VERTEBRATE ADAPTIVE IMMUNITY

Not long ago, it was believed that only jawed vertebrates had a true adaptive immune system. From the previous discussion of invertebrate immune responses, clearly mechanisms exist to generate high levels of immune diversity—even at the somatic level—one of the hallmarks of an adaptive response.[7] As described in the introduction, many in the field agree that the boundary between innate and adaptive immunity is artificial, and it may not be a useful dichotomy when studying immune responses in diverse organisms.[61,62] Despite this reluctance to exclusively classify systems as innate or adaptive, some features clearly fall into the latter category, such as clonal expansion of uncommitted lymphocytes and specific

memory. These conditions are not fulfilled for the DSCAM, FREP, 185/333, or any other invertebrate systems described previously, but of course we must be open to new mechanisms besides the conventional outlook of adaptive immunity. Additionally, such adaptive immunity arose in concert with the emergence of lymphocytes in the lower chordates, as these cells clearly are the major players; we will discuss this in the conclusion.

Immunoglobulins

A typical Ig molecule is composed of four polypeptide chains (two heavy [H] and two light [L]) joined into a macromolecular complex via several disulfide bonds (Fig. 4.7). Each chain is composed of a linear combination of IgSF domains, and almost all molecules studied to date can be expressed in secreted or transmembrane forms.

Immunoglobulin Heavy Chain Isotypes

Like all other building blocks of the adaptive immune system, Ig is present in all jawed vertebrates (see Fig. 4.7). Consistent with studies of most molecules of the immune system, the sequences of IgH chain C region genes are not well conserved in evolution and insertions and deletions in loop segments occur more often in C than in V domains. As a consequence, relationships among non-μ isotypes (and even μ isotypes among divergent taxa) are difficult to establish.[188] Despite these obstacles, the field has developed a working evolutionary tree among all of the isotypes.

Immunoglobulin M

IgM is present in all jawed vertebrates and has been assumed to be the primordial Ig isotype. It is also the isotype expressed earliest in development in all tetrapods; until recently, it was believed to be the case in fish as well, but

this view has changed (see the following). The secretory μ H chain is found in all vertebrates, usually consists of one V and four C1 domains, and is heavily glycosylated. H chains associate with each other and with L chains through disulfide bridges in most species, and IgM subunits form pentamers or hexamers in all vertebrate classes except teleost fish, which form tetramers.[189] The μ C_H4 domain is most evolutionarily conserved, especially in its C-terminal region, whereas the CH2 domain evolves at the fastest rate.[188] There are several μ -specific residues in each of the four C_H domains among vertebrates suggesting a continuous line of evolution, which is supported by phylogenetic analyses. Like TCR TM regions, μ TM regions are also well conserved among sharks, mammals, and amphibians, but the process by which the Ig TM messenger RNA is assembled varies in different species. In all vertebrate classes except teleosts, the μ TM region is encoded by separate exons that are spliced to a site on μ messenger RNA located approximately 30 basepairs from the end of the C_H4-encoding exon. By contrast, splicing of teleost fish μ messenger RNA takes place at the end of C_H3 exon.[190] In holostean fish (gar and sturgeon), cryptic splice donor sites are found in the C_H4 sequence that could lead to conventional splicing, but in the bowfin there is another cryptic splice donor site in C_H3.[191] The TM region itself is interesting as it is the only one that does not contain a residue capable of making an ionic bond with the ITAM-

containing molecule (in this case, Ig-α and Ig-β.) As mentioned, some modifications apparently related to the particular environment were noticed in the Antarctic fish *Trematomus bernacchii*. There are two remarkable insertions, one at the V_H-C_H1 boundary and another at the C_H2-C_H3 boundary; the latter insertion results in a very long CH2-CH3 hinge region. Rates of nonsynonymous substitutions were high in the modified regions, suggesting strong selection for these modifications. These unusual features (also unique glycosylation sites) may permit flexibility of this IgM at very low temperatures.[192]

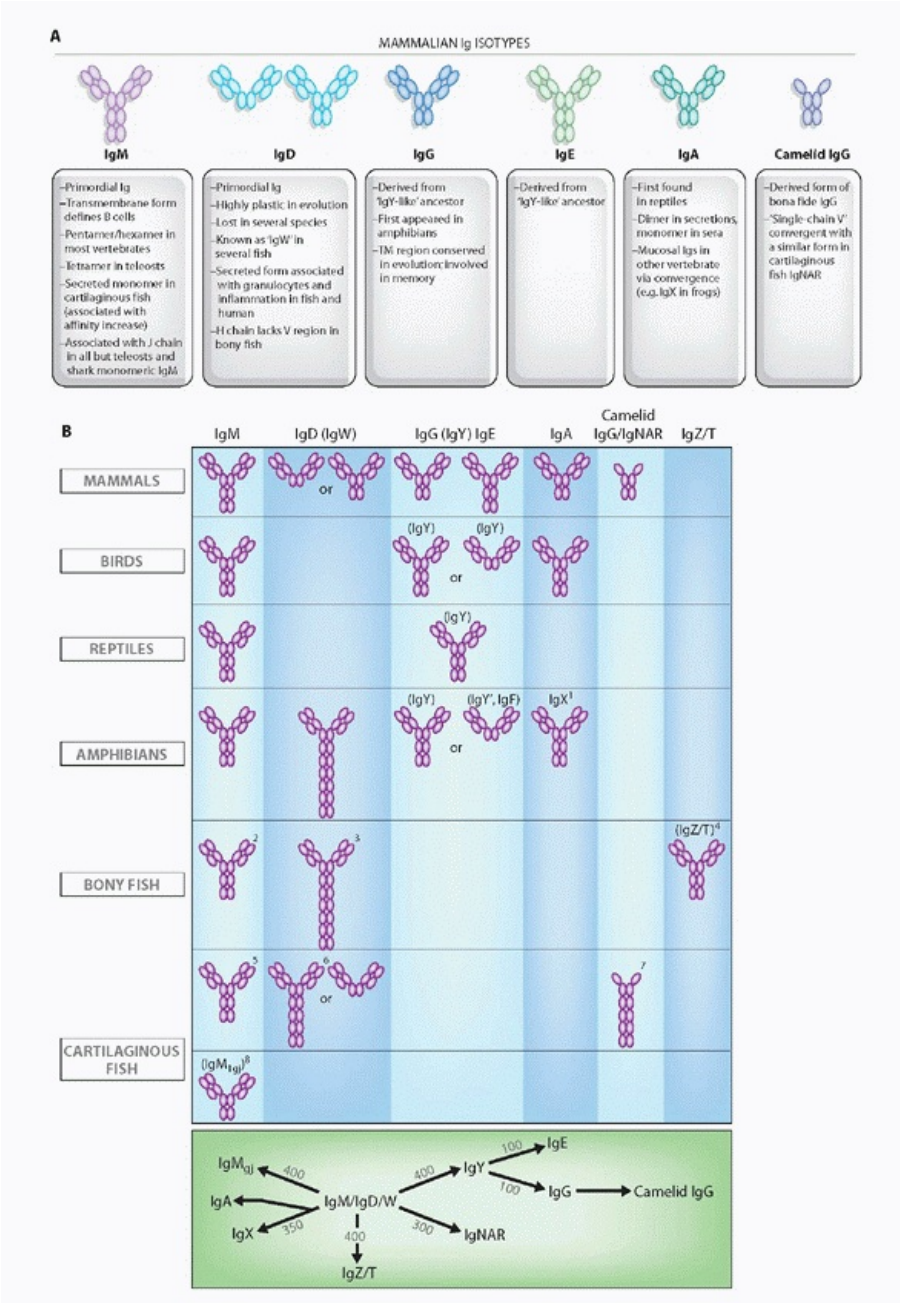

FIG. 4.7. Immunoglobulin (Ig) Isotypes in the Jawed Certebrates. A: Mammalian isotypes and their relationships to Igs in vertebrates from other classes. Each oval represents an Ig superfamily C1 domain. IgD is shown in two forms, mouse (*left*) and human (*right*).[2] **B:** Major Ig isotypes in all vertebrates. The *bottom panel* displays the approximate divergence times of all isotypes. IgM/D/W was found at the inception of

adaptive immunity. 1, IgX is in the IgA column because it is preferentially expressed in the intestine, and IgA seems to have been derived from an IgX ancestor; IgX seems to have been derived from both IgM and IgY ancestors; 2, secreted IgM in teleost fish is a tetramer, and the transmembrane (TM) form only has three C domains; 3, the teleost fish IgD H chains incorporate the μC1 domain via alternative splicing in the TM form, and the secretory form does not have a V region and does not associate with L chains; 4, the new bony fish isotype, IgZ/T, may not be found in all fish species; 5, the secreted form of shark/skate IgM is present as a pentamer and monomer at approximately equal levels; 6, the TM form of IgW has four C domains; 7, a major TM form of IgNAR has three C domains, and IgNAR is related to camelid IgG by convergent evolution; 8, no TM form has been found (to date) for IgM_{1gj}. The *bottom panel* displays the approximate divergence times of all isotypes. IgM/D/W was found at the inception of adaptive immunity.

It has been known for a long time that in all elasmobranchs, IgM is present at very high amounts in the plasma of cartilaginous fish and that it is found in two forms: multimeric (19S) and monomeric (7S).[193] It is unlikely that the two forms are encoded by different gene clusters because 1) peptide maps are identical; 2) early work by Clem found the sequences of the cysteine-containing tail of 19S and 7S H chains to be identical; and 3) all identified germline VH families are represented for the 19S form.[194] Although most studies (but not all) reported that 19S and 7S are not differentially regulated during an immune response, in a recent study, the 19S response wanes over time and a stable 7S titer is maintained for periods of up to 2 years after immunization.[195] In addition, antigen-specific 7S antibodies observed late in the response have a higher binding strength than those found early, suggesting a maturation of the response, also generally at odds with the previous literature. Finally, when specific antibody titers were allowed to drop, a memory response was observed that was exclusively of the 7S class. This work has shown that a “switch” indeed occurs in the course of an immune response; whether the “switch” is due to an induction of the 19S-producing cells to become 7S producers or whether there are lineages of 19S-and 7S-producing B cells is an open question. One working hypothesis is that J chain expression is important for regulating whether a B cell makes 19S or 7S Ig, but of course that could be at the lineage level or the switch level (see the following).

Immunoglobulin M_{1gj}

Nurse shark *Ginglymostoma cirratum* expresses an IgM subclass in neonates.[196] The V_H gene underwent V-D-J rearrangement in germ cells (“germline-joined” or “gj,” see the following). Expression of H_{1gj} is detected in primary and secondary lymphoid tissues early in life, but in adults only in the primary lymphoid tissue, the epigonal organ (see the following). H_{1gj} associates covalently with L chains and is most similar in sequence to IgM H chains, but like mammalian IgG it has three rather than the typical four IgM constant domains; deletion of the ancestral IgM second domain thus defines both IgG and IgM_{1gj}. Because sharks are in the oldest vertebrate class known to possess antibodies, unique or specialized antibodies expressed early in ontogeny in sharks and other vertebrates were likely present at the inception of the adaptive immune system. It is suggested that this isotype interacts either with

a common determinant on pathogens or a self-waste product.

Immunoglobulin New Antigen Receptor and New Antigen Receptor-T-Cell Receptor

A dimer found in the serum of nurse sharks and so far restricted to elasmobranchs, IgNAR is composed of two H chains each containing a V domain generated by rearrangement and five constant C1 domains.[197] IgNAR was originally found in sera, but TM forms exist as ccomplementary DNA and cell-surface staining is detected with specific mAbs. The single V resembles a fraction of camel/llama (camelid) IgG that binds to antigen in a monovalent fashion with a single V region, but it clearly was derived by convergent evolution. In phylogenetic trees, NAR V domains cluster with TCR and L chain V domains rather with that V_H. A molecule with similar characteristics has also been reported in ratfish, although it was independently derived from an ancestral Ig like the camelid molecule emerged from bonafide IgG.[198] IgNAR V region genes accumulate a high frequency of somatic mutations (see the following).

The crystal structure of a Type I IgNAR V regions showed that, in contrast to typical V regions, they lacked CDR2 and had a connection between the two IgSF sheets much like an IgSF C domain.[199] The domain wraps around its antigen (hen egg lysozyme [HEL]), with the CDR3 penetrating into the active site of the enzyme. The structure of a Type II V region has a disulfide bond between CDR1 and CDR3 that forces the most diverse regions of the molecule to form raised loop, similar to what has been described for camelid V domains. In total, the differential placement of disulfide bonds forces major changes in the orientations of CDR1 and CDR3, and provides two major conformations for antigen binding.[200] The structure of a Type II NAR bound to HEL showed that it also interacted with the active site of the enzyme.

While analyzing the TCRVδ repertoire in nurse sharks, an entirely new form of this chain, which encodes three domains, V-V-C, was detected.[201] The C is encoded by the single-copy Cδ gene, and the membrane-proximal V is encoded by a Vδ gene that rearranges to the DJδ elements. The membrane distal V domain is encoded by a gene in the NAR family, found in a rearranging VDJ cluster typical of all cartilaginous fish Ig clusters. The NAR-TCR V genes, unlike IgNAR V genes which have three D segments, only have a single D region in each cluster. The particular Vδ loci linked to each NAR-TCR gene—called NAR-TCR-supporting V δ—encode a cysteine in CDR1 that likely makes a disulfide bridge with the NAR-TCR V domain. The J segment of the rearranged NAR-TCR V gene splices at the RNA level directly to the supporting Vδ segment, which has lost its leader exon (Fig. 4.8). This organization likely arose from an IgNAR V cluster that translocated to the TCRδ locus upstream of a Vδ gene segment. After modifications of the supporting Vδ genes, this entire V-V gene set duplicated and diverged several times in different species of sharks. About 25% of the expressed nurse shark TCR δ repertoire is composed of this TCR (encoded by 15 to 20 V-V genes in this species), and have proposed that the typical γ/δ TCR acts as a scaffold upon which sits the single chain NAR V.

Our interpretation is that, true to the proposal that γ/δ TCRs interact with free antigen, the NAR V is providing a binding site that can interact with antigen in a different way than

conventional heterodimeric Vs. Thus, this is the first case in which a particular V region family has been shown to be associated with a BCR and TCR; in the case of the BCR, the function likely resides within the Fc portion of IgNAR and for the TCR the function (cytokine secretion, killing) lies within the T cell itself. Interestingly, a second TCRδ chain locus has also been described in marsupials and monotremes with properties similar to NAR-TCR.[202] In this case, there are also two V domains, but in marsupials one (proximal to the membrane) is germline-joined, and only the membrane-distal domain undergoes rearrangement. In monotremes, both of the V regions undergo rearrangement, like for the NAR-TCR. This new TCRδ locus is preferentially expressed early in development. This type of TCR is described in more detail in the TCR section.

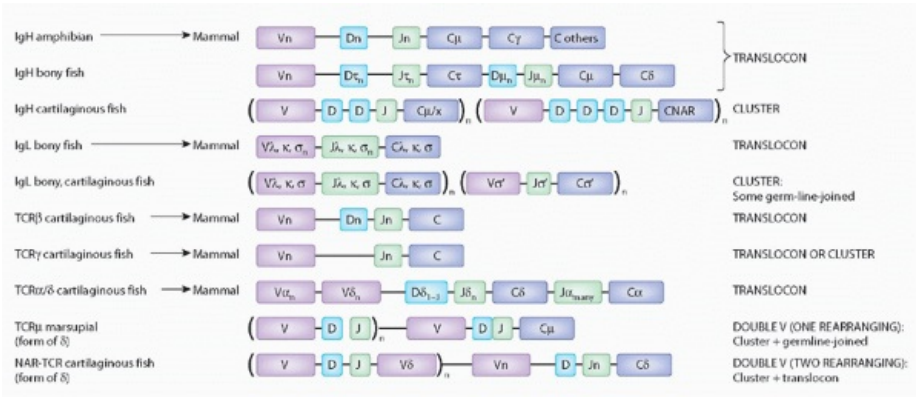

FIG. 4.8. Organization of Immunoglobulin (Ig) Heavy and Light (L) Chain and T-Cell Receptor (TCR) Genes in All Jawed Vertebrates. All coldblooded gnathostomes except bony fish have three L chain isotypes, κ, λ, and σ; mammals have κ and λ; and birds have only λ. RSS are found at the 3′ end of V segments, 5′ end of J segments, and on both sides of D segments. Marsupial μ TCR is related to Ig in its V regions and TCRδ in its C region (and is not related to the μ of IgM).

Immunoglobulin R/Immunoglobulin New Antigen Receptor/Immunoglobulin W/Immunoglobulin X/Immunoglobulin D

All elasmobranchs studied to date have another isotype called IgW. It was probably discovered long ago in skates as a non-IgM secreted isotype called IgR, but no protein sequence of this molecule has been obtained for confirmation.[203] Subsequently, an Ig gene was discovered in skates encoding a three-domain molecule with an unusual secretory tail that was named IgX (not to be confused with another isotype with that name in amphibians).[204,205] A high molecular weight (MW) species detected by northern blotting with an IgW probe suggested that there might be a longer form of this isotype, subsequently shown to be true in the sandbar shark (IgW), nurse shark (IgNARC—it was so-named because the C domains had highest similarity to IgNAR C domains), and skate.[206,207] It was originally believed that sharks only expressed the long (seven-domain) IgW form, but they were later shown to have both secretory forms; the reason for the discrepancy was shark-to-shark variation in expression of the short form, for unknown reasons. The major IgW TM form, like IgM, is composed of five domains, but variants with three domains—like the

secretory forms—were also detected.[208] Very little is known about the function of this isotype, as IgW-specific mAbs have not been generated as they have for IgM and IgNAR.

IgW was thought to be a dead-end isotype in the cartilaginous fish, but a homologue was found in the lungfish.[209] It also is present in two secreted forms, one with eight domains and the other, like in the elasmobranchs, with three domains (unfortunately the secretory tail was not sequenced, and the TM form was not studied.) An Ig isotype was found in *Xenopus tropicalis* most related to the lungfish IgW.[210,211] Computer searches of databases for the *X. tropicalis* genome project uncovered a new isotype flanked by the IgM and IgX genes at the IgH locus. The deduced amino acid sequence obtained from the exons on the genomic scaffold suggests a nine-domain molecule. The N-terminal C domains and the TM regions are most similar to mouse and human IgD regions, and its genomic location also suggest that it is an IgD equivalent. Thus, these new data reveal that like IgM, IgW/D is an isotype that was present at the emergence of all extant vertebrate taxa.

Catfish IgD was the first member of this Ig class found outside of mammals,[212] but this was not well accepted until the isotype was found in all vertebrate classes. It is found attached to FcR on a subset of myeloid cells, and the secreted form does not contain a V region as the leader is spliced to the CH2 domain in plasma cell RNA.[213] This strongly suggests that the IgD is acting as a PRR, perhaps interacting with a conserved region of a pathogen leading to innate immunity. The work on catfish prompted a reappraisal on the role of secreted IgD in humans.[214] Like the fish IgD, the human IgD is bound to a subset of myeloid cells, which are activated upon IgD cross-linking. The receptor on human cells has not been identified, but this new work argues for strong evolutionary conservation of the function of secreted IgD.

An interesting feature of the IgD/W locus is its high plasticity in evolution, both in terms of the number of domains in different fish species and the plethora of splice variants found, at least in cartilaginous fish.[194,215] In sharks, two of the C domains were derived approximately 250 million years ago by a tandem duplication event, and there was a *Xenopus*-specific, two-domain tandem duplication event as well. Within teleost fish, the number of C exons for this isotype is different in various species and the secreted and TM forms are encoded by different loci in the catfish. In addition to the splice variants previously described in the cartilaginous fish and lungfish, in teleosts the IgM C1 domain exon is spliced into the IgD transmembrane transcript.[212] Even in mammals, there are different numbers of C domains in different species, and even exons that have emerged quite recently in evolution (see Fig. 4.7). It is our impression that this is the Ig locus that evolution “plays with,” perhaps using it for different functions in vertebrate taxa. The beginning of understanding the function of the secreted form of IgD is a triumph for comparative immunology; likely the evolutionary approach will reveal the function of the TM form as well.

Immunoglobulin Z/T

A third, novel bony fish isotype was uncovered in screens of the EST and genomic databases called IgZ in zebrafish[216] and IgT in trout.[217] Its genomic organization parallels the TCR α/δ locus in that the IgZ/T D, J, and C elements are found between the VH and Cζ/Cμ exons (see Fig. 4.8). IgZ/T is a five-domain H chain that associates with L chains (see

Fig. 4.7). The authors of the zebrafish paper proposed that lymphocytes bearing IgZ may be B1-cell equivalents, but a preliminary VH repertoire analysis did not suggest that unique sets of V regions are expressed on IgZ compared to IgM. IgT is not preferentially expressed over IgM early in trout development.

Recent work has shown that IgT is the mucosal Ig of trout, with preferential expression in the intestine and skin.[218] Mucosal immunization with the parasite *Toxoplasma gondii* showed a preferential induction of specific IgT. While all teleosts have lost the J chain in evolution,[219] biochemical analysis of IgT showed that it contained a secretory piece derived from the poly-Ig receptor (pIgR). Furthermore, like mammalian dimeric IgA, IgT coats trout commensal bacteria, presumably acting as a "firewall" preventing commensals from breeching the blood-brain barrier. In sum, IgT, while displaying unique evolutionary features, has attained almost all of the characteristics of IgA via convergent evolution.

Other Isotypes Related to Immunoglobulin G, Immunoglobulin E, Immunoglobulin A, and the Class Switch

Other isotypes consist of four C domains in nonmammalian vertebrates including *Xenopus* IgY and IgX, non-μ isotypes of *Rana*, IgY of axolotl, and IgA and IgY of birds. [194,220] In *Xenopus*, IgY is thymus-dependent; IgM and IgX are not, although thymectomy impacts specific IgM antibody production (ie, antigen-specific IgM can be produced, but there is neither an increase in affinity after immunization nor elicitation of plaque-forming cells). IgM and IgX plasma cells are abundant in the gut,[221] whereas IgY is expressed primarily in spleen. Axolotl IgM is present in the serum early during development and represents the bulk of specific antibody synthesis after antigenic challenge.[222] In contrast to *Xenopus* IgY, the axolotl ortholog appears late in development and is relatively insensitive to immunization. From 1 to 7 months posthatching, axolotl IgY is present in the gut epithelium associated with a secretory component.[223] IgY progressively disappears from the gut and is undetectable in the serum of 9-month-old animals. Thus, axolotl IgY, like *Xenopus* IgX and trout IgT, may be analogous to mammalian IgA. *Xenopus* IgX seemed to be most similar to IgM, but as more sequences have become available it does seem to be orthologous to IgA, obviously consistent with its assumed function (Criscitiello, personal communication). In addition, IgX was formerly believed to be derived from IgM, but recent data suggest that the N-terminal C-domains were derived from an IgY ancestor and the C-terminal domains from IgM.[224]

The TM and cytoplasmic domains of *Xenopus* TM IgY share residues with avian IgY and mammalian IgG and IgE, suggesting that mammalian/avian isotypes share a common ancestry with amphibian IgY.[225] This homology is especially interesting because studies in mice suggested that the IgG cytoplasmic tail is the central molecular element promoting rapid memory responses of plasmablasts.[226,227] The motif in

the IgY/G tail is also found in other receptors and seems to recruit PI3kinase, which amplifies the signal derived from Ig-α and -β. Finally, another *Xenopus* isotype was discovered from the databases, called IgF or IgY′ (because it is closely related to IgY, probably duplicating within the *Xenopus* lineage). Like other isotypes described in this section, it only has two C domains, but rather than alternative splicing, the gene is organized in such a manner.[211]

There has been no biochemical identification of IgF.

CSR results from fusing switch regions upstream of the μ gene and another 3′ isotype gene, accompanied by the deletion of the intervening sequences. Among vertebrates, mammalian and bird class switch regions are GC-rich and contain tandem repeats in which certain motifs, such as TGGGG, GGGGT, AGCT, and GGCT, are abundant. Because of the GC richness of these regions, transcription generates stable R loops, which provide single-stranded substrates for activation-induced deaminase (AID) activity. The first comparative studies on switch were done in the amphibian *Xenopus* where the switch regions are not GC-rich but adenine-thymine (AT)-rich and cannot form R loops.[228] Replacement in mouse of the switch region with a *Xenopus* switch region showed that it mediated efficient CSR and that the junctions were associated with the short palindromic AGCT motifs, already recognized as the main component in *Xenopus* switch.[229] As predicted from the absence of R loops, the *Xenopus* switch region supported recombination in both orientations. The breakpoints were located in the AGCT palindrome-rich region of the switch box. Other motifs have been identified in the other switch regions, such as in IgX and chicken isotypes; all of these correspond to the DGYW hotspot consensus. AID-mediated deamination in the context of these motifs may be the conserved major event in the initiation of CSR. As described in the following, until recently it was believed that CSR first appeared in amphibians, but recent data have uncovered a precursor to switch in cartilaginous fish (but not teleosts). Thus, we should add another conserved feature of adaptive immunity that appears to have arisen in the early gnathostomes.[230]

As mentioned, a single gene can encode different Ig forms, like for duck IgY, cartilaginous fish IgW, and camelid IgG loci. It has been suggested that the two avian IgY short and long forms could be the functional equivalents of both IgE and IgG, respectively; the same may be true of the cartilaginous fish IgW short and long forms with two and six domains, respectively. Also as mentioned, IgF or IgY′ also falls into this category but not through alternative splicing.[194,211]

Immunoglobulin Light Chains

L chains can be classified phylogenetically not only by their sequence similarity, but also by the orientation of their V and J RSS, which differ for mammalian λ and κ. There has been much debate regarding the affiliations of L chains in various vertebrates, but as sequences have accumulated, we have a grasp on their phylogenetic emergence. Contrary to what was believed, κ and λ L chains emerged early in vertebrate evolution, in the cartilaginous fish or placoderms. In addition, a third L chain, σ, originally described in *Xenopus* as a dead-end isotype, is in the ancestral clade and is present in all cold-blooded vertebrates.[231]

Elasmobranchs have four L chain isotypes (Type I, II, III, and IV), and the combined data suggest that they are present in all chodricthyans.[231] Type IV is the ortholog of the unusual *Xenopus* σ L chain, and Type I is a dead-end variant of this isotype called σ′ or σ-cart (for cartilaginous fish). Type II L chains are of the λ isotype and have been cloned from all groups of cartilaginous fish; all genes of this isotype are “germline-joined.” The type III is clearly κ-like, at least in the V region and RSS orientation (κ is the only antigen receptor gene in which the V is associated with a 12mer RSS). These relationships are more noticeable in the V sequences, which have defining characteristics such as CDR length; although, the C

sequences also fall into the same clusters, they do so with much less phylogenetic support. Different elasmobranch species express the L chain isotypes preferentially (eg, κ in nurse sharks, σ in horned sharks, and λ in sandbar sharks); this pattern of expression may be due to expansions/contractions of the different isotype genes in various elasmobranch lineages.

Almost all of the L chains in bony fish can be categorized as either κ or σ, despite the large number of gene expansions and contractions in this group.[232] As expected, recent data have shown that λ exists in some species, consistent with the work in sharks.[233] Genes in different species can be found either in the cluster type organization, translocon, or some intermediate type, and this organization is especially well suited to allow for receptor editing, either to generate the repertoire or as a consequence of binding to self-ligand.[234,235]

mAb studies suggested the existence of three *Xenopus* L chain isotypes of 25, 27, and 29 kD with heterogeneous two-dimensional gel patterns and preferential association of some L chain isotypes with IgY H chains.[236] Indeed, three *Xenopus* L chains genes have been isolated: ρ (now κ), σ, and λ. Only one C gene is present in the ρ locus, and it encodes the most abundant L chain. The V and J RSS are of the κ-type and the five identified J segments are nearly identical. The locus is deleted, like mammalian κ, when the other isotype genes are rearranged. Southern hybridizations with genomic DNA from different animals showed V_L sequences to be both diverse and polymorphic. The λ *Xenopus laevis* L chain isotype predicted from the biochemical studies consists of six distinct V_L families. In the σ locus, the J segment has an unusual replacement of the diglycine bulge by two serines. The *Rana* major L chain type has an unusual intrachain disulfide bridge that is seemingly precludes covalent association of its H and L chains.[237]

Two L chain types were identified in reptiles. Chickens and turkeys only express one L chain (λ) with a single functional V and J gene, and the manner by which diversity is generated is likely responsible for this unusual evolutionarily derived arrangement (see the following). Nonproductive rearrangements are not detected on the unexpressed L chain allele, and thus there is a strong pressure to generate functional joints (see the following). Such a system probably rendered a second (or third) L chain locus

superfluous.[236] Within mammals (marsupial *Monodelphis domestica*), the Vλ repertoire is comprised of at least three diverse families related to distinct placental families, suggesting the divergence of these genes before the separation of metatherians and eutherians more than 100 million years ago. Opossum λJC sequences are phylogenetically clustered, as if these gene duplications were recent and the complexity of the λ locus seems greater than that found at the H chain locus.[238]

In summary, all vertebrate groups except the birds have two to four L chain isotypes, all of which can be categorized as κ, λ, or σ (and in cartilaginous fish σ-cart).[231] However, we are still at a loss to understand the significance of possessing multiple isotypes as there is scant evidence that L chains have any effector functions. It has been suggested that different isotypes may provide distinct CDR conformations in association with H chains, or there may be L chain/H chain preferences that provide some advantage that is not obvious.[239,240] At least the differential CDR sizes for σ as compared to κ/λ suggest that the former rationale is plausible. The preferential association of certain L chains with particular IgH isotypes is

suggestive of different functions as well, but there is no evidence for such functions to date.

V_H Evolution

Diversity of the immune repertoire depends on the variety of V segments inherited in the germline and upon the further diversification by rearrangement (CDR3 only) and SHM (all CDR). Early in life, the repertoire depends chiefly on the inheritable genes as one finds little N-region diversity and somatic mutation (with exceptions; see the following). A central question is how antibody germline V genes diversify CDR during evolution while they are subject to homogenizing forces operating in most multigene families. Perhaps environmental antigens have played a major role in shaping the germline repertoire and have selected some V_H/V_L germline sequences used by neonates. V_H families arose in a bony fish lineage and have been conserved for hundreds of millions of years.[241] Conserved regions defining families are found on solvent-exposed faces of the V_H, at some distance from the antibody-combining site. Phylogenetic analyses show clustering of V_H into groups A, B, C, D, and E. All cartilaginous fish V_H belong to the monophyletic group E; bony fish V_H genes to cluster into all Groups (one group [D] unique only to them). By contrast, group C includes bony fish sequences as well as V_H from all other classes except cartilaginous fish. Another phylogenetic analysis classifies mammalian V_H genes in three "clans" (I, II, and III), which have coexisted in the genome for > 400 million years. Only in cartilaginous fish does it appear that V_H gene families have been subjected to concerted evolution that homogenized member genes (except for the $IgM1_{gj}$ V region described previously). It has been debated whether Ig V genes could be under direct positive selection or not because these genes hypermutate somatically. However, several features (eg, codon bias) and discovery of high replacement/silent ratios in germline gene CDR codons indeed argue for positive selection during evolution.[242,243]

In summary, much of the V_H germline repertoire has been conserved over extremely long periods of vertebrate evolution. The birds and some mammalian species that rely on GALT to generate Ig diversity (see the following) are exceptions with a reduced germline repertoire (at least expressed repertoire), but as will be seen in the following, gene conversion and SHM compensate for this situation in formation of the primary repertoire. Even in the cartilaginous fish where there is a single V_H family, there is nevertheless great heterogeneity in CDR1 and CDR2 sequences (as well as hypermutation) that must boost diversity in the expressed repertoire.

The J Chain

The joining (J) chain is a small polypeptide, expressed by plasma cells, that regulates polymer formation of IgA and IgM.[244] J-chain incorporation into dimeric IgA and pentameric IgM endows these antibodies with the ability to be transported across epithelial cell barriers. J chain facilitates creation of the binding site for pIgR (secretory component in the Ig polymers), not only by regulating the polymeric structure but apparently also by interacting directly with the receptor. Therefore, both the J chain and the pIgR/secretory component are key proteins in secretory immunity. J chain complementary DNAs have been reported in all jawed vertebrates except the teleost fish, which have lost it.[245] The existence of *Xenopus* J chain

suggests that, unlike mouse IgM, *Xenopus* IgM forms hexamers with J chain; alternatively, the previous electron microscopy studies identified IgX as the hexameric isotype (the ξ chain has a stop codon before the Cys of C_{H4} domain and thus cannot make a covalent attachment to J chain). The highest level of J chain expression was detected in frog and bird intestine, correlating well with a role for J chain in mucosal immunity (although obviously not for IgX secretion). Elasmobranch J chain shows high similarity to the N-terminal half of J chains from other vertebrates, but is divergent or even absent in the other regions. This result suggests that the function of J chain may be solely for IgM polymerization in elasmobranchs, and the transporting function arose later in evolution; consistent with this idea, *Xenopus*, but not shark, J chain is capable if interacting with human IgA and pIgR.[245] As mentioned previously, the loss of J chain in bony fish does not preclude the interaction of IgT with pIgR and transport across epithelia, implying a strong pressure to maintain a mucosalspecific Ig.[218] There was a claim for the presence of J chain in many protostomes because a homologue was cloned in earthworms, but no J chain sequences have appeared in the numerous protostomes or deuterostome invertebrate databases.[246]

T-Cell Receptors

Ig, TCRs, and MHC class I and class II are all composed of IgSF domains. The membrane-proximal domains of each Ig/TCR/MHC chain are IgSF C1-set domains, while the N-terminal domains of Ig and TCR proteins are V-set domains encoded by genes generated via rearrangement of two or three gene segments during ontogeny (the membrane-distal domains of

MHC are a special case; see the following). In all vertebrates studied to date, TCRs are membrane-bound and never secreted, while almost all Ig proteins have transmembrane and secreted forms.[247]

α/β Constant Domains

Genes encoding the two types of TCR, α/β (which accounts for all known MHC-restricted regulatory and effector functions) and γ/δ (which to the best of our knowledge recognizes antigens in an Ig-like manner and may play immunoregulatory or homeostatic roles during certain infections), existed in the earliest jawed vertebrates. The α/β TCR is considered rather “boring” evolutionarily, as all gnathostomes from the basal cartilaginous fish appear to have this MHC restricted form.[248] As mentioned, although many IgSF members exist in the invertebrates, thus far no bonafide Ig/TCR sequences (ie, IgSF genes generated by somatic rearrangements) have been isolated from jawless vertebrates or invertebrates, although a renewed search in jawless vertebrates may be fruitful (see the following).

While TCR genes have been cloned from representatives of most vertebrate classes, few biochemical data are available, except in birds where α/β and γ/δ TCR have been identified with mAbs.[249] In amphibians, the *Xenopus* α/β TCR was coimmunoprecipitated with cross-reactive antibodies raised against human CD3ε chains[250] (note that this same antibody indentifies CD3 epsilon from many divergent species, which is quite unusual,[251] in turtles). α chains from diverse vertebrates are poorly conserved and the structure of the Cα IgSF domain itself is unusual: only strands A, B, C, E, and F can be identified, although strands E

and F are shorter than those of mammals and strand D is absent; this modification has an important role in TCR dimerization and subsequent signaling.[252] The lack of conservation in this extracellular domain as well as deletions found in bird and teleost fish TCR (especially in the connecting peptide) suggest that the coreceptor may be structurally distinct from mammalian CD3 complex components.

Pre-Tα, which associates with TCR β chains during thymocyte development, has been identified only in warmblooded vertebrates.[253] The pre-Tα protein has no V domain, and its interaction with the TCRβ chain is unique, based on recent structural studies.[254] Unlike all of the other TCR chains, pre-Tα has a long cytoplasmic tail, which seems to be important for T-cell differentiation. Interestingly, the pre-Tα gene is linked to the MHC in mammals, and more phylogenetic studies should be performed to determine whether this linkage group is ancient (see the following).

The TM region and cytoplasmic tail of Cα are the most conserved parts of the molecule. Cα and Cβ TM segments in all species have the so-called conserved antigen receptor transmembrane motif (CART) motif, in which conserved amino acids form an interacting surface with the CD3 complex.[255] Besides CART, the opposite TM face with conserved residues Ile-Lys-Leu interacts with other CD3 components. The cytoplasmic region is remarkably conserved among all vertebrates. TCR β genes have been sequenced from several species of cartilaginous and bony fish and two species of amphibians (axolotl and *Xenopus*). In addition to the typical IgSF domain features, there are several conserved regions among vertebrate TCRβ chains, especially at positions 81 to 86, probably involved in TCR dimerization. There are also remarkable differences: the solvent-exposed segment 98 to 120 in mammals is absent in all nonmammalian vertebrates. This loop has been shown in mouse TCR to be important for negative selection events in the thymus; perhaps the absence of this region in nonmammalian vertebrates results in subtle differences in tolerance induction as compared to mouse/human.[256] The number of Cβ genes varies in different species.

Like Cα, Cβ sequences are not well conserved in evolution (eg, the *X. laevis* Cβ gene does not cross-hybridize with *X. tropicalis* genomic DNA, and catfish Cβ has only 41% to 42% identity with other teleost Cβ and 26% identity with horned shark Cβ). Two different catfish Cβ complementary DNA sequences were identified, suggesting the existence of either two loci or allotypes, as is found in mammals.[257] Indeed, the damselfish Cβ was shown to be encoded by two polymorphic genes, and this feature seems to extend to other teleosts. As the polymorphic sites are believed to interact with the associated CD3-signaling molecules, the authors suggested that signals might be transduced to T cells in different ways depending on the particular expressed Cβ allele. The damselfish Cα gene seems to be encoded by polymorphic alleles as well.[258]

α/β T-Cell Receptor Variable Domains

Because T-cell recognition is MHC-restricted, TCR V regions have been evolutionarily selected for different properties as compared to Ig; indeed, TCR V regions are much less similar to each other than are Ig V regions from other antigen receptor loci.[257] Furthermore, TCR Vs, unlike IgV_H, have conserved CDR3 lengths, suggesting that there is a restricted size for recognition of MHC-peptide complexes.[259] α loci in all vertebrates examined have

many J segments, and consistent with the mammalian paradigm, the absence of D and the large numbers of J segments favors the potential for receptor editing during thymic positive selection.[260] A number of Vβ gene families are another evolutionarily conserved feature. There are 12 families in nurse sharks and 19 in *Xenopus*. In axolotls Vβs are classified into nine categories each with 75% or more nucleotide identity; as only 35 genes were cloned, there are probably more families, and several are related to mammalian Vβ genes (human Vβ13 and Vβ20[257]).

There is evidence that the TCR has coevolved with MHC, displayed by the canonical types of interactions seen in crystal structures.[261] Vβ sequences from many different vertebrates share residues in CDR2 that interact with class II and CD1 MHC molecules (Y-46 and Y-48, especially).[262] It will be of interest to search for other conserved interaction sites as crystal structures become available.

Studies of several teleost α/δ loci suggests an organization similar to mouse/human, but with more rearrangement by inversion and more gene segments than are found in mammals.[263] Pulsed field gel analysis suggested that the horned shark α and δ TCR loci are closely linked.[264] There

has been a recent, major modification in our thinking of the α/δ locus that will be described in the following.

The γ/δ TCR

Complementary DNA sequences from the skate have significant identity with prototypic mammalian γ and δ TCR genes with extensive V region diversity, putative D segments in δ, and varying degrees of junctional diversity.[248] In the nurse shark, there is a great diversity of the δ V regions, the highest among the TCR chains; consistent with this diversity is the presence of the NAR-TCRδ, which is found in approximately 25% of the δ Vs.[257] The NAR-TCR has been found in all cartilaginous fish to date, including holocephalins, whereas NAR and IgW have only been detected in elasmobranchs. Thus, it is possible that NAR (especially the V region) arose as a TCR and was transferred to an Ig cluster sometime in evolution.

In axolotls, Vδ diversity was diminished in thymectomized animals and TCR δ chains are expressed by cells in lymphoid organs, skin, and intestine.[265] Chicken γ/δ T cells were identified long ago. Expression is found in thymus, spleen, and a γ/δ T-cell line, but not in B cells or α/β T-cell lines. Three V subfamilies, three J gene segments, and one C gene were identified at the TCR γ locus. All Vγ subfamilies participate in rearrangement during the first wave of thymocyte development, and the γ repertoire diversifies from embryonic day 10 onwards with random V-J recombination, nuclease activity, and P- and N-nucleotide addition.[249]

In ruminants and chickens (so-called GALT species; see the following), the γ/δ repertoires are quite diverse, and there seems to be ligand-mediated selection of γ/δ cells during ontogeny. In sheep, where γ/δ TCR diversity is thymus-dependent and follows a developmentally regulated progression, no invariant γ/δ TCRs are found.[266] The degree of γ/δ expression is correlated with the evolution of the TCR V families in warm-blooded vertebrates. Indeed,

mammals can be classified into “γ/δ low” (humans and mice, in which γ/δ T cells constitute limited portion of the T-cell population) and “γ/δ high” (chicken, sheep, cattle, and rabbits, in which such γ/δ cells comprise up to 60% of T cells). TCR V genes form subgroups in phylogenetic analyses, and humans and mice have representative loci in most subgroups whereas the other species appear to have lost some.[267] Thus, γ/δ-low species have a high degree of TCR-V gene diversity, while γ/δ-high species have limited diversity. Interestingly, this pattern is similar to that found for IgV$_H$ genes.

Recent work in *Xenopus* has shown that the presence of prototypic V$_H$ at the TCRδ locus, in addition to typical α and δ V domains.[268] Furthermore, consistent with the presence of VH, the αδ locus is closely linked to IgH and IgL λ in the frog genome. These data suggest that these heterodimeric loci arose via a *cis* duplication early in vertebrate history.[263] The TCRμ locus in monotremes and marsupials[202,269] can now be extended to the chicken as well,[270] although like *Xenopus* there are chicken V$_H$ with a three-domain molecule as is found in monotremes, marsupials, and sharks. In total, all of the nonplacental mammals except bony fish show some sort of chimeric Ig/TCR locus, with TCR δ V domains that are more Iglike than TCR-like. Generally speaking, comparative studies have revealed that the γ/δ TCR can either be used for innate recognition (eg, the cells in the skin of mice or the blood of humans) or adaptively with an enormous repertoire in ways we do not understand—this will be discussed in more detail in the conclusion. Consistent with the potential of γδ TCR to interact with nominal antigen, SHM has been detected in the γ genes of the sandbar shark, although it is not known whether the mutations generate the repertoire or appear in mature T cells after immunization.[271,272]

Immunoglobulin Gene Organization

V$_H$ Regions

A rearranged V$_H$ gene consists of a leader segment, encoded by a canonical split exon, followed by four framework regions and three CDRs (see Fig. 4.8). Canonical V$_H$ CDR1 nucleotide sequences are conserved in all jawed vertebrates and serve as targets for SHM.[242,243] A major germline difference is the lack of conserved octamers and TATA box in the 5′ region of shark Vs. In all species, functional V genes are assembled by rearrangement and joining of germline V, D, and J elements. Cartilaginous fish H chains are encoded by large numbers of clusters (> 100 in horned shark and dogfish; approximately 15 in the nurse shark). For IgNAR, there are only four V genes/haploid genome and only a few IgW V genes are detected in nurse sharks, but a large number in skates and dogfish.[273] There are widely varying numbers of V genes in different species; importantly, the V$_H$ complexity does not seem to limit diversity of the antibody repertoire in any ectothermic vertebrate studied to date. There are actually fewer functional human V$_H$ (44 functional, 79 pseudogenes that fall into seven families) than in many ectotherms. Dynamic reorganization of the H chain V regions seems to have occurred at least eight times between 133 and 10 million years ago.[241] Perhaps species that utilize somatic mutation/selection “optimally” rely less on germline diversity and therefore fewer functional genes are required. Only approximately 10% of *Xenopus* V$_H$ are pseudogenes in the three families (V$_{H1-3}$) that have been exhaustively

studied; thus, *Xenopus* with fewer lymphocytes has a greater number of functional V_H genes than humans.

Chondrichthyan Germline-Joined Genes

In all vertebrate species, functional Ig genes are assembled by rearranging DNA segments scattered on the chromosome. However, in cartilaginous fish some V genes are the products of V(D)J rearrangement in eggs/sperm.[196,274,275] Type I L chain (σ) genes are all germline-joined in skates but split in horned sharks, and the piecemeal germline joins (eg, VD, VDD, VDDJ) found in many horned shark H chain gene clusters and in nurse shark L chain Type I (σ) clusters strongly suggest that the germline-joining is a derived feature. Definitive proof came from a study of a germline-joined nurse shark Type III (κ) L chain gene, shown by phylogenetic analysis to have been joined within the last 10 million years[236]; this was followed by the identification of the nurse shark germline-joined $IgM1_{gj}$ described previously.[196] When there is a *mixture* of joined and conventional genes, the split genes are expressed in adults, while the joined genes are

expressed at significant levels only early in ontogeny. When *all* of the genes in a particular family are joined (eg, skate Type I L chain genes and Type II [λ] L chains in all elasmobranchs), they continue to be expressed into adult life at high levels. In mammals, what may appear like germlinerearranged V genes are in most cases processed pseudogenes (eg, pseudo Vκ on chromosome[22] in human or in mouse). However, it is possible that the surrogate L chain gene VpreB is the product of a germline-joining event in the line leading to mammals.[276] Additionally, as described previously, there is a marsupial germline-joined V that serves as the membrane-proximal domain of TCRμ.[202]

Organization of Rearranging Genes

As mentioned, shark IgH-chain genes are structured into tens to hundreds of clusters, each consisting of V, D, J, and C elements[277]; all evidence from studies in horned shark, nurse shark, skate, and sandbar shark (and holocephalin rat-fish) suggest that V, D, and J genes rearrange only within one cluster (but, as detailed in the following, switch may occur between clusters, most likely as a consequence of antigen stimulation). While there is extensive N-region diversity and sometimes usage of two D segments (three Ds in IgNAR), and there are V_H subfamilies having substantial CDR1/2 heterogeneity, diversity of the primary repertoire is lower than in other vertebrates as there is no (or infrequent) rearrangement between clusters. The special constitution of the shark H and L chain loci suggests an exclusion mechanism similar to that of mouse TCR γ loci, also found in clusters. It appears that only one V_H transcript is expressed in each lymphocyte, consistent with isotypic exclusion, despite the many clusters (see the following).[278,279] Bony fish (teleosts and chondrosteans like the sturgeon), frogs, reptiles, and mammals have very similar architectures of their H chain locus —the so-called translocon configuration. As described previously, multiple families of V_H genes, each consisting of many apparently functional elements (1 to 30 per family), are separated from a smaller number of genomic D and J elements. The possibility of combinatorial rearrangement enables more diversification than is possible with the cartilaginous fish clusters for a given number of segments. In birds, the organization is similar

but all V genes except those most 3′ to the D elements are pseudogenes (see the following). One exception is the coelacanth (*Latimeria*), in which V genes are immediately followed by D segments, and then multiple J segments as are found in all tetrapods.[280]

L chain gene organization is variable. In elasmobranchs, the organization is the same (ie, in clusters) as the H-chain locus without the D segments. The prototypic horned shark Type I (σ) L chain has a cluster organization in which V, J, and C segments are closely linked. As mentioned previously, bony fish L-chain genes have the shark cluster-type organization, but some species have multiple V genes in some clusters, demonstrating that there is rapid evolution of not only sequence but gene organization as well in this taxon.[232] In *Xenopus*, there are multiple Vκ(ρ) presumably derived from one family: five J and a single C gene segment. In cartilaginous fish and birds there has been coevolution of Ig gene architecture for H and L loci, but the teleosts have shown that this is not a rule. As mentioned previously, two groups have suggested that the teleost gene organization seems to promote receptor editing.[234,281]

D Segments

D segments are always present in one of the two loci encoding an Ig/TCR heterodimer (IgH and TCR β,δ), and the pressure maintaining this asymmetry is unknown. Cartilaginous fish usually have two D genes/H chain cluster, and there are only minor variations among the clusters; one RSS follows the 12-12 paradigm seen in tetrapods and the other is like the TCR 12-23. In teleosts, amphibians, and reptiles where the organization of the H chain locus is similar to humans, the number of Ds deduced from complementary DNAs ranges from 10 to 16. Two germline D segments have been identified in *Xenopus*, and their RSS follow the rules defined in mammals. In birds, there are 15 very similar D_H.

There are several reasons why D segments may have been preserved throughout evolution. Incorporation of D segments augments CDR3 diversity and size, obviously directly influencing the combining site.[259] Three different Ds contribute to IgNAR CDR3, and besides generating great diversity, CDR3 length and amino acid composition fulfills special tertiary structure requirements: D-encoded cysteine residues bond with cysteine(s) in the body of the V domain, thereby stabilizing a loop involved in the antigen-binding of this unusual monomeric receptor.[197,200] A similar situation has been reached by convergence in the monomeric variant of camel IgG.[198] Finally, rearrangement of one locus “locks it in” and allows the second locus to undergo receptor editing, as is the case for negative selection of the B-cell repertoire and positive selection of the T-cell repertoire. Finally, in mice, one of the TCRδ D segments encodes a section that interacts with the ligand, the nonclassical class I molecule T lymphocyte antigen (TLA).[282]

Agnathan Variable Lymphocyte Receptor Structure and Function

In the 1960s, jawless vertebrates (hagfish and lampreys; see Fig. 4.1) were reported to mount humoral responses to foreign antigens. However, for anti-group A streptococcal antigens, the hagfish “antibodies” (at least a proportion of them) were actually the complement component C3[283]! Lamprey and hagfish were long known, however, to possess cells resembling lymphocytes and plasma cells,[284] with expression of lymphocyte- or at least

leukocyte-specific genes,[285] but the quest for RAG or bonafide Ig/TCR/MHC genes was a complete failure. Reports of specific memory in allograft rejection and other specific humoral responses were difficult to reconcile with absence of the RAG-based rearranging machinery and the possibility of generating specific lymphocyte clones.

Our view of the jawless fish immune system was radically transformed when Pancer et al. prepared complementary DNA libraries of naïve lymphocyte RNA subtracted from lymphocyte RNA derived from lamprey larvae (ammocoetes) that had been immunized to a bacterial/PAMP mixture, and found a highly diverse set of LRR sequences enriched in the

immunized animals.[286] The clones were not only diverse in sequence, but also in the number of LRR "cassettes" found between invariant 5′ (LRR NT) and 3′ (LRR CT) cassettes. Unlike what has been discussed previously for immune genes many species (especially sea urchins), there were not a great number of the germline NT and CT cassettes, suggesting that a somatic recombination process, convergent with Ig/TCR rearrangement, occurred in the developing lamprey lymphocytes (Figs. 4.9 and 4.10). The genomic organization of germline VLR (the original gene discovered was VLRB) have 5′ and 3′ LRR cassettes separated by an intron. Upstream and downstream of the invariant exons are a large number of LRRs, which become inserted between the 5′ and 3′ cassettes during lymphocyte differentiation. Individual lymphocytes apparently express a uniquely rearranged VLR gene in monoallelic fashion. The potential VLR repertoire can be as great as 10^{14}, vastly outnumbering the lymphocytes within an individual.[287,288]

Fragments of homology between the LRR cassettes allow for joining and then priming of synthesis of a copy of the particular transferred cassette.[289] Because these small regions of homology are found throughout the cassettes, "hybrid" LRR can also be formed, further enhancing the diversity over a simple insertion of cassettes. The insertion of LRRs can occur at either end of the somatic recombinant, but it is always 5′-to-3′ on the growing strand. This type of genomic modification resembles the initial stage of gene conversion, but because there is not a complete transfer of genetic material between two homologous gene segments, but actually an addition of sequence, the assembly of the mature VLR is more similar to a recombinatiorial mechanism described in yeast called "copy choice." The enzymology of "copy choice" has not been examined; because a gene conversion-like process occurs, it is likely that an APOBEC family member is involved. Indeed, APOBEC family members were detected in the lamprey genome project and are expressed in a lymphocyte-specific fashion[288]; in fact, the two members that have been discovered, CDA1 and CDA2, are differentially expressed in agnathan lymphocyte subsets (see the following). Because APOBEC family members are involved in repertoire building in jawless and jawed vertebrates, mutation/gene conversion may have predated RAG-mediated repertoire building of the repertoire (see the following).

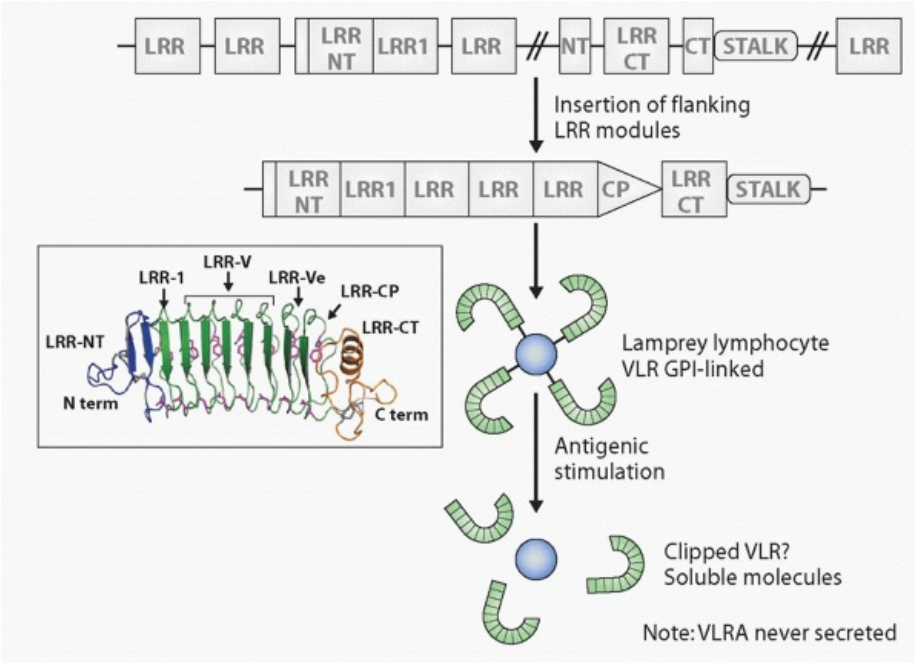

FIG. 4.9. Genetics, Generation of Diversity, and Speculative Cell Biology of the Hagfish Variable Lymphocyte Receptor (VLR) System.[13] The *top line* shows an incomplete VLR gene (NT and CT, N-terminal and C-terminal cassettes, respectively). During lymphocyte ontogeny, upstream and downstream LRR cassettes are inserted between the NT and CT gene segments, resulting in an intronless, mature VLR gene (*second line*). VLR proteins are attached to the lymphocyte surface via a glycophosphatidylinositol linkage, and may be released into the blood upon antigenic stimulation (also see Fig. 4.10). *Boxed* is a hagfish VLR protein, the first structure to be elucidated by Kasahara and colleagues.[499] Note the loop at the C-terminal leucinerich repeat, which is mentioned in the text as a prominent region inserting into antigens, like single-domain antibodies.[293,294]

VLR homologs were found in two additional lamprey species and in hagfish, the only other order of living jawless vertebrates reviewed in Boehm et al.[13] As in the sea lamprey, the incomplete hagfish germline VLR generate somatically highly diverse repertoires. Interestingly, the *Amphioxus* genome harbors a large number of intronless VLR-like sequences that could represent an alternative germline VLR diversity akin to the echinoderm gene families (TLR, SRCR) described previously; one could even speculate that they are related to the ancestral VLR before invasion of its analogous “RAG transposon” (see the following).

There are three VLR types: A, B, and C. VLR-B cell-surface receptors and secreted molecules are analogous to the jawed vertebrate membrane and secreted BCR, and it was proposed that cell activation was similar to T-independent pathways in jawed vertebrates (ie, either direct stimulation through the surface VLR or surface VLR stimulation in combination with a PRR/PAMP interaction). It was suggested that the jawless vertebrate adaptive system might be dedicated exclusively to humoral immunity, with the PAMPs providing the second signal to activate lymphocytes.[290] Thus, it was proposed that the lamprey system was “B

cell-centric" and therefore focused on humoral immunity.

This model has been disproved as subsequent work demonstrated that the VLRA and VLRB were differentially expressed (see Fig. 4.10). The former receptor could not be found in plasma and was expressed exclusively as

a cell-surface receptor, while, as described, the latter was present as both a lymphocyte receptor and a secreted molecule.[291] When microarray expression analysis was performed on VLRA- and VLRB-positive cells, the patterns were consistent with expression profiles in gnathostome T cells and B cells, respectively. The lamprey adaptive scheme, therefore, parallels the situation in jawed vertebrates where Ig is found both as a cell-surface receptor on B cells and as a secreted effector molecule in the serum, whereas the TCR is present only as a cell-surface receptor on T cells; effector functions in T cells, such as cytokine secretion or production of cytotoxic mediators, are properties of the T cells themselves. It is not clear how VLRC fits into this scheme at the moment.

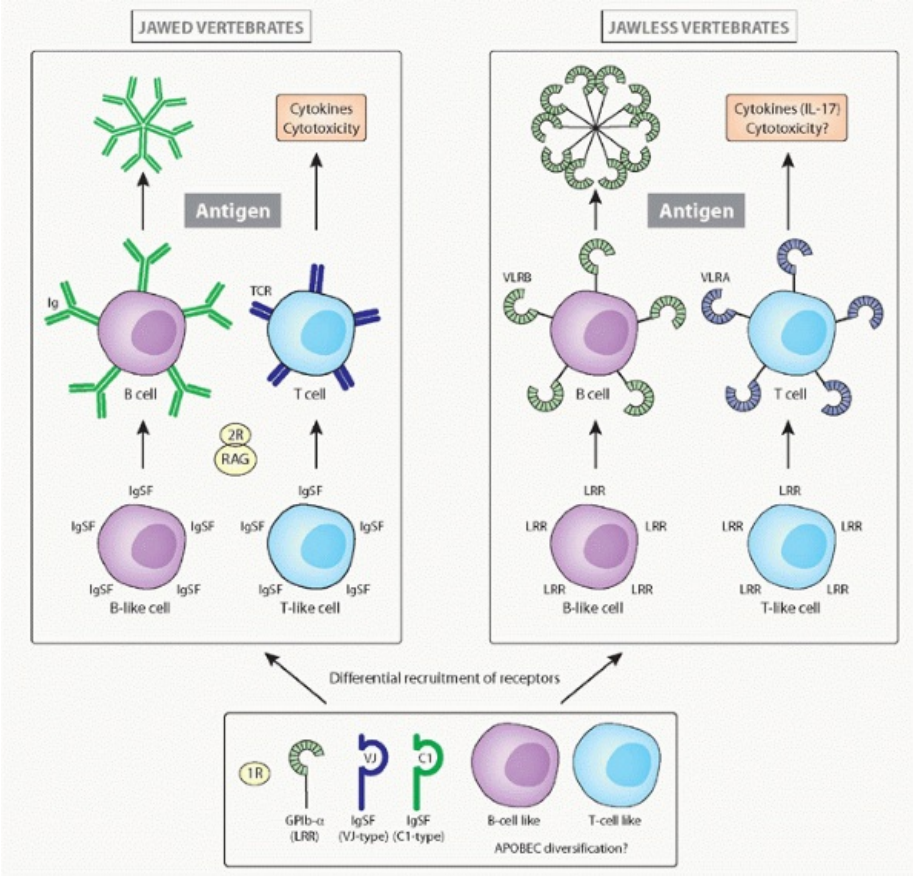

FIG. 4.10. Emergence of Variable Lymphocyte Receptor (VLR) and Immunoglobulin (Ig) Early in Vertebrate Evolution. T and B cells likely preceded the divergence of the leucine-rich repeat and Ig superfamily antigen receptors. The VLR is most similar to a molecule called GPIb-α[288] present in *Amphioxus*, and Ig superfamily antigen receptors are derived from molecules with so-called VJ and C1 domains, probably in the proto-major histocompatibility complex (see text for candidates). Both precursor genes were present in basal chordates. The RAG transposon and 2R likely ignited the appearance of the Ig superfamily receptors (Ig/T-cell receptor) (see text for

full explanation). This figure also shows B and T cells today in jawless and jawed vertebrates, with secretion of IgM from gnathostome B cells and a VLR tetramer of dimers from VLRB-secreting lamprey B cells. Figure modified from Flajnik and Kasahara.[2]

As expected for members of this family, the framework, or backbone, of the LRR is very similar between the cassettes. Diversity between cassettes is concentrated in the concave surface, presumably the region coming in contact with antigen. The crystal structures of two VLR-B molecules have been determined, one specific for HEL[292] and the other for H-trisaccharide.[293] In both cases, the concave surface makes contacts as well as a loop in the LRR-CT, which in the case of HEL inserts into the active site, similar to

what has been found for single-domain camelid and shark Vs.[198] One VLR-A crystal structure was determined, also specific for HEL.[294] This VLRA was derived from a HEL-hyperimmunized adult lamprey, which apparently underwent affinity maturation with induced molecules having affinities in the picomolar range. The antigen is bound in the region of the molecule that is most diverse among all VLRAs; surprisingly, the LLRNT among all VLRA are not diverse, suggesting that this region might bind to a self-"restricting element" and the rest of the binding site to the true antigen.

These are early days, but the comparisons to date suggest that VLRA and VLRB recognize antigen in different ways. Like gnathostome BCR, VLRB is expressed at the cell surface and is secreted as a pentamer of dimers, much like IgM (see Fig. 4.10). The affinities detected to date from immunized animals are in the micromolar range, again similar to low-affinity pentameric IgM in gnathostomes. By contrast, VLRA has never been detected in the sera or secreted in culture, fitting with its similarity to TCR. The affinity of VLRA for soluble antigen was high (in the nanomolar range) for the HEL-immunized animal, which appeared to undergo affinity maturation.[294] Combining the information with the conserved and diverse regions of the VLRA biding site, perhaps VLRA recognizes antigen (budding virus?) associated with a self-protein (MHC analogue?) at the cell surface. It remains to be seen whether VLRA clones will be found from other immunized animals, and the HEL experiment was an artifact of the immunization schedule and not physiologic.

The independent development of two different strategies for receptor somatic diversification at the dawn of vertebrate evolution approximately[500] million years ago reveals the magnitude of the selective pressure applied on to the immune system and the emergence of individualized adaptive responses (see Fig. 4.10). Are VLR responsible for the graft rejection results seen in the old experiments? If so, this is most likely a "convergent MHC" coopted for the VLR system. Skin grafting experiments (or other tests of alloreactivity) should be repeated to study potential VLR involvement. The VLR system is discussed below as well in the lymphoid tissues section and the conclusion.

Adaptive Immune Responses in Gnathostomes

The quality of T-cell and B-cell responses depends on the heterogeneity and the diversity of the antigen receptor repertoires, and the ability to select cells in secondary lymphoid tissues.

Because of the indefinite number of potential Ig/TCR V region sequences in most taxa, potential diversity exceeds the number of available lymphocytes; furthermore, all jawed vertebrates are capable of AID-dependent SHM or gene conversion after antigen stimulation. Yet, while potential repertoires are diverse in all vertebrate classes, and polymorphic MHC class I and II and TCR genes have been isolated from all classes, antibody diversity in nonmammalian vertebrates is relatively low.[295,296,297] The expressed repertoire has been studied via structural studies, affinity measurements during the maturation of the immune response, enumeration of antigen-binding Igs by isoelectrofocusing (IEF), and idiotypic analysis. Sequences of Ig and TCR genes expressed over the course of a response help to estimate diversity at another level, allowing studies of V genes diversified by gene conversion and/or somatic mutation during a response in a precise way. In the following survey, we describe studies of specific antibody synthesis, T-cell responsiveness (T-B collaboration, MHC restriction).

Cartilaginous Fish

Natural antibodies binding many antigens have been detected at surprisingly high levels in chondrichthyans and in some teleosts. In older experiments, after immunization the horned shark mounted a low-affinity 19S (pentameric) IgM antibody response, which varied little among individuals and did not increase in affinity after prolonged immunization.[298]

The relative homogeneity and large number of V genes hindered SHM studies until a single unique reference horned shark IgM V_H gene was found. Mutations in this gene were slightly more frequent than those in *Xenopus* (see the following). This first study proved that SHM preceded diversity obtained by combinatorial association of gene segments in evolution.[299] In contrast to mutations in the horned shark IgM V_H genes, unusual patterns of somatic mutation were detected in nurse shark IgNAR (see the following) and Type II (lambda) germline-joined L chains. Half of the mutations (338/631) occur in tandem without the GC bias seen in *Xenopus* or horned shark H chain V genes. Tandem mutations and point mutations that take place simultaneously were not generated by gene conversion as there are no repeated patterns or potential donor genes.[300,301] The germline-joined L chain genes can only diversify through SHM, perhaps like the hypothetical prototypic V region gene prior to RAG-mediated rearrangement (ie, SHM may have preceded gene rearrangement as the primordial somatic diversification mechanism)[300] (see the following). Lastly, a reappraisal of mutation at H chain and other L chain loci in the nurse shark showed that the mutations were not so different from the L chains; the differences from the previous work were the different shark species and the analysis of all H chain loci in the species rather than only one unusual locus.[302]

As mentioned, the small number of IgNAR genes also made it possible to analyze SHM, and in the first experiments, random complementary DNAs were examined.[197,296] The mutation frequency was about 10 times that of *Xenopus* and horned shark IgM, and even higher than in most studies in mammals. It was difficult to establish a pattern for the mutations due to their high frequency and because they are often contiguous, like in the L chain gene study described previously. Mutations even in randomly isolated clones appeared to be under positive selection in IgNAR secretory but not TM clones, strongly suggesting that mutations do not generate the primary repertoire like in sheep but arise only after antigenic

stimulation.[303,304] In total, the shark mutations seem quite mammalian-like but with unusual features. Analysis of the mutations in noncoding DNA suggests

an AID-dependent process coupled with an error-prone polymerase.[305]

Affinity maturation and memory generation can be detected in sharks.[195] Soon after immunization with HEL, an IgM response can be detected, primarily of the pentameric class. Over time, 7S IgM and IgNAR responses develop, and the 7S antibodies have a higher binding strength than those of the 19S class. When titers were permitted to drop to baseline (or close to baseline), a memory response was induced by immunization of antigen without adjuvant. However, unlike responses in higher vertebrates, the titers do not increase over those in the primary response, suggesting a unique type of regulation of antigen-specific IgM and IgNAR. Nevertheless, these data strongly suggest that the hallmarks of an adaptive response occur in sharks. This type of response is reminiscent of IgA responses of intestinal lymphocytes in mice.[306] In another study, a family of HEL-specific IgNAR clones was followed over time after immunization, and a 10-fold increase in the affinity of an already high-affinity germline clone (10^{-9} M) was observed.[307] These results suggest that affinity maturation, memory, and “switch” to the monomeric IgM isotype occurs, but it takes much longer to attain these adaptive hallmarks compared to mammals, perhaps a paradigm for ectotherms (see the following).

Recent work showed that isotype switch can occur in sharks, despite many reports to the contrary.[230] Previously, studies of nurse and horned sharks complementary DNAs showed that the V and C regions were derived from the same gene clusters. By contrast, in the new work, immunized animals showed switching between IgM clusters and even between IgM and IgW clusters. It is not known whether there is any functional significance to the switch, but one might predict the switch could dictate a change from 19S to 7S antibodies (see the following), or a modification of effector class in IgM and IgW. None of the classic hotspots (RGYW) upstream of constant region genes in tetrapods vital to switch appear to be targeted to initiate the switch in sharks, but other repetitive elements were detected that might play a role.

The role of T cells in shark immune responses has not been studied in detail. No thymectomy experiments have been performed, and T cells have not been monitored during an immune response. Shark mixed lymphocyte responses (MLR) and graft rejection have been attempted, MLR with little success (probably for technical reasons) and grafts with the demonstration of a chronic type of rejection for which the genetics has not been analyzed. However, from the MHC and TCR studies, it is clear that all of the molecular components are available for proper antigen presentation in sharks and skates, and studies of splenic architecture suggestive class II+ dendritic cells in the white pulps argue for a prominent T-cell regulatory role in adaptive immunity.[308] Furthermore, an increase in binding strength and memory response, as well as mutation and now switch, also strongly suggests a T-cell involvement in humoral immunity. Finally, recent studies of the thymus have shown that the architecture and expression of well-known markers are wholly consistent with a typical T-cell regulation of adaptive immunity.[257] In summary, it appears that all of the components of adaptive immunity in mammals occur in the cartilaginous fish.

Bony Fish

There are high levels of low-affinity natural antibody (up to 11% of total Ig) to nitrophenylacetate in some bony fish. Natural antibodies in catfish have been correlated with resistance to virus infection or furonculosis. As a rule, and similar to cartilaginous fish, little affinity maturation has been detected in fish, although some changes in fine specificities were noticed in the trout with a sensitive enzyme-linked immunosorbant assay-based test.[309] The mild increase in trout antibody affinity (similar to that found in *Xenopus* and shark IgNAR) is attributed to selection of either minor preexisting B-cell populations or somatic mutants. In partially-inbred self-fertilized or gynogenetic trout, variability of specific responses is even more restricted. Affinity measured by equilibrium dialysis was of the order of 2.0×10^{-6} M for trinitrophenol (TNP)-specific antibodies. A large literature deals with vaccination attempts in teleost fish, due to their economic importance. The availability of catfish B-cell, macrophage, and T-cell lines have been instrumental in analyses of antibody production.[310] There are puzzling differences in responses from different teleost groups, much like differences between urodeles and anurans (amphibians). Cod, for example, do not respond well to specific antigen and have very high levels of “natural antibodies”; recent studies showing that cod have lost class II genes provides an explanation for the poor humoral responses (see the following).

Like the sharks, isolation of TCR genes and the existence of a polymorphic class I and class II molecules suggest that antigen presentation is operative teleosts, but unlike sharks, functional experiments examining mammalian-like T-APC interactions have been performed. TCR messenger RNAs are selectively expressed, and specific TCR rearrangements have been detected in catfish clonal cell lines, which produce factor(s) with leukocyte growth-promoting activity reviewed in Miller et al.[310] Modifications of the trout T-cell repertoire during an acute viral infection (rhabdovirus) have also been followed.[311,312] In nonintentionally immunized trout, adaptation of the spectratyping technique for TCRβ CDR3 length revealed a polyclonal naïve T-cell repertoire. After an acute infection with viral hemorrhagic septicemia virus, CDR3 size profiles were skewed for several Vβ/Jβ combinations, corresponding to T-cell clonal expansions. Both “public” and “private” T-cell expansions were detected in the infected genetically identical individuals. The “public” response resulted in expansion of Vβ4/Jβ1-positive T cells that appeared first in the primary response and were boosted during the secondary response. Further work examined fine specificity of the viral T-cell response, which is a model for studies in cold-blooded animals.

Recent results suggest that, despite the fact that IgM is the major Ig expressed in an immune response, high- and lowaffinity IgM appears to be a function of the degree of polymerization of the tetramer.[309] It is suggested that high-affinity interactions of TM IgM on B cells modifies the enzymes

involved in disulfide-bond formation, resulting in modifications of secreted IgM.[313] In addition, expression of transcription factors in different subpopulations of trout B cells suggests that the typical populations of naïve, memory, and long- and short-lived plasma cells exist in bony fish; these populations have been followed in blood, spleen, and head kidney by measuring proliferation and B cell-specific transcription factors.[314,315,316] Such studies

should prove very useful for vaccination of large populations of teleosts.

Studies of SHM in teleost fish have been hampered by the lack of good reference genes, but it has been clear that AID-targeting motifs are found in Ig V genes.[317,318] Furthermore, AID is expressed in the spleen during immune responses, again consistent with its role in SHM.[319] A recent study examined mutations in a reference zebrafish L chain gene and detected the typical mutational pattern described previously (without the tandems seen in sharks).[320] AID from several bony fish species is capable of inducing CSR in mammalian B cells, despite the fact that teleosts do not undergo CSR[318]; perhaps the new results that demonstrate switching in sharks may shed light on this conundrum.[230]

As mentioned, species living in extreme cold develop adaptive structural differences in their Igs.[192] At the level of global immune response, temperature exerts a great influence in ectothermic vertebrates in general, low temperature generally being immunosuppressive. Lowering the water temperature from 23° to 11°C over a 24-hour period suppresses both B- and T-cell functions of catfish for 3 to 5 weeks as assessed by in vitro responses.[321] Virgin T cells are most sensitive to this cold-induced suppression, a property shared with mammals when tested appropriately. Fish have developed ways to adapt to the lack of fluidity of their B-cell membranes by altering the composition of fatty acid by using more oleic acid at low temperatures. After appropriate in vivo acclimation, catfish T cells are better able to cap cell surface molecules at low assay temperatures than are B cells, suggesting that capping is not the low temperature-sensitive step involved in T-cell immunosuppression in catfish.

In the NK section, we briefly discussed fish cytotoxic cells.[169] In vitro studies have now shown that leukocytes from immunized fish specifically kill a variety of target cells (allogeneic erythrocytes and lymphocytes, hapten-coupled autologous cells); fish CTL of the αβ (and perhaps γδ) lineages as well as NK cells were found (see previous discussion). Naïve catfish leukocytes spontaneously kill allogeneic cells and virally infected autologous cells without sensitization, and allogeneic cytotoxic responses were greatly enhanced *by in vitro* alloantigen stimulation.[322] Cloned cytotoxic cells contain granules and likely induce apoptosis in sensitive targets via a putative perforin/granzyme or Fas/FasL-like interactions. All catfish cytotoxic cell lines express a signaltransduction molecule with homology to the Fcγ chain of mammals; this chain with an ITAM is an accessory molecule for several activating receptors on mammalian NK cells.[161] Importantly, these cytotoxic cells do not express a marker for catfish nonspecific cytotoxic cells. As described previously, nonspecific cytotoxic cells have been found in other fish species, including trout, carp, damselfish, and tilapia, and they spontaneously kill a variety of xenogeneic targets, including certain fish parasites and traditional mammalian NK cell targets.

Amphibians

Differences in immune system features between urodele (axolotl) and anuran (*Xenopus*) amphibians, already discussed for MHC and Ig complexity, are also seen in immune responses. Rarely is such divergence seen within one vertebrate class (although the two groups diverged over 250 million years ago!). Urodeles express a very restricted antibody repertoire in response to specific antigen that peaks at 40 days postimmunization, and is entirely of the IgM class, even though the serum also contains IgY.[323] They do not respond

well to thymus-dependent antigens, which may be due to lack of T-cell help, yet their expressed TCR diversity looks normal. A population of axolotl B cells proliferates specifically in response to LPS and also secretes both IgM and IgY. Moreover, a distinct lymphocyte subpopulation proliferates significantly in response to the T cell mitogens Con A. T cells from young axolotls (before 10 months) do not have this functional ability. Axolotl T cells also can be stimulated with to SEA/SEB, known from mammalian studies to be superantigens.[324]

Anuran larvae can respond specifically (with only 10^6 lymphocytes) to many antigens, with a modest affinity maturation of the IgM anti-dinitrophenol (DNP) response.[325] In adults, the number of different anti-DNP antibodies does not exceed 40, versus 500 in mammals. In secondary responses, the peak of the response is about 10-fold higher and is reached in 2 weeks; there are no major changes in affinity over this initial rise. Isogeneic *Xenopus* produce homogenous antibodies to DNP, xenogeneic red blood cells, or phosphorylcholine with identical or similar IEF spectrotypes and idiotypes, while outbred individuals differ.[326] Both IEF spectrotypes and idiotypes are inheritable, suggesting that diversity is a reflection of the germline repertoire without a major contribution from somatic mutations. Thus, somatic mutations were followed during the course of an antigenspecific immune response at the peak of the modest affinity maturation.[327] The V_H genes, like their mammalian homologues, contain the sequence motifs that target hypermutation, as described previously. Of the[32] members of the V_H1 family involved in the anti-DNP response, expression of only[5] was detected, indicating that immunization was being monitored. Few mutations were detected (average: 1.6 mutations per gene; range: 1 to 5), and there was not a strong preference for mutations in CDR1 and 2 and virtually none in CDR3. Like in the horn shark IgM study noted previously (but not IgNAR or Type II L chains), the mutations were targeted to GC bases, and such a pattern has been suggested to be the first phase of the SHM phase in mouse/human; perhaps *Xenopus* has lost the second phase of the process that results in an evening of mutation frequency for all bases. While the mutation frequency was lower than in mammalian B cells, the rates were only four- to sevenfold less in *Xenopus*. Thus, there is no shortage of variants, and the reasons for the low heterogeneity and poor affinity maturation

may be due to less than optimal selection of the mutants. Indeed, because of a relatively low ratio of replacement to silent mutations in the CDRs, it was argued that there is no effective mechanism for selecting mutants, which in turn might be related to the absence of GC in *Xenopus*. In summary, the data from hypermutation, complementary DNA heterogeneity, and spectratype dominance suggests that in the absence of refined modes of selection in late-developing clones, B cells producing somatic mutants may be outcompeted by antibodies generated earlier in the response.

Essential T-cell functions in anurans have been demonstrated with in vitro assays for T-B collaboration and MHC restriction, demonstrating the similarity of the role of MHC in *Xenopus* and mammals.[328] Regulatory T cells have been shown indirectly in hematopoeitic/thymic chimaeras for control of CTL generation and in antibody responses. Ig synthesis can be enhanced following late thymectomy in axolotl or *Xenopus*, again implying a role for thymic-dependent regulatory cells. Thymectomy early in life totally prevents CSR from IgM to IgY, but not IgX synthesis; thus, T cells are absolutely required for the switch to the “IgG-like isotype”

and for high-affinity IgM responses, but switch to the mucosal Ig can be T-independent. Switching can also be induced in tadpoles, although one must hyperimmunize animals for this response, due to a paucity of T cells in larvae. The switch is also temperature-dependent, and as described previously for channel catfish, ectotherm T cells are quite temperature-sensitive. AID is expressed in lymphocytes in the spleen as well as in secretory cells.[329] However, consistent with many previous studies, there is no evidence for a typical GC response to date in amphibians or any other ectothermic species. The continued expression of AID in plasma cells (and, presumably, early in embryogenesis) is of interest and deserves further study.

Similar to studies in mammals, the chaperone gp96 has been shown to shuttle peptides into cells making them targets for MHC-restricted CTL lysis.[330] Immunization of frogs with gp96 from a thymic tumor results in the elicitation of CTL that display antitumor activity. Elegant experiments with gp96 vaccination have also shown that CTL activity against minor histocompatibility antigens is MHC-restricted. As mentioned previously, NK cells have been characterized in *Xenopus* with mAbs that recognize non-B/T cells. Those cells kill MHC class I-negative target tumor cells but not class I-positive lymphocytes, and after thymectomy these cells are enriched in the spleen.[331] CD8+ cells expressing TCR were isolated with the same mAb, suggesting the existence of amphibian NKT cells; expression of the mAb epitope on cells is induced by phorbol 12-myristate 13-acetate (PMA)/ionomycin, and is also detected in CTL when MHC-dependent cytotoxicity is reduced.[332] Robert and colleagues have developed one of the best-defined model of innate and adaptive immunity to viral infection in cold-blooded vertebrates, the ranavirus FV3 in *Xenopus*.[70,333] Involvement of CD8 cytotoxic cells and humoral responses have been studied over the course of primary and secondary infections with this virus.[334,335] The system is now primed for the study of other cell type involvement, ontogeny, repertoire, etc.

Reptiles

Lack of an increase in affinity and homogeneity of IEF spectrotypes suggest low-antibody heterogeneity in reptiles. In the turtle *Pseudemys scripta*, a number of genomic VH sequences, representing possibly four families, were isolated, as was a genomic Cμ, all shown to be encoded at a single locus. In northern hybridizations, the Cμ4 probe detected two transcripts; of the four VH groups, only one was expressed, and multiple bands indicated the presence of at least two non-μ transcripts. Among 32 unique VDJ rearrangements from one animal, there were 22 sequence variants in FR4, suggesting either a large number of J segments or somatic modification.[336] The latter interpretation is supported by point mutations found in FR3 and CDR3. For T cells, there are no data on T effector function, but there are studies on the behavior of T-cell population changes due to seasonal and hormonal variations. Thymocytes from the turtle *Mauremys caspica* proliferate in response to phytohemagglutinin (PHA) and ConA, and can kill tumor target cells by both antibody-dependent cellular cytotoxicity-mediated and NK-mediated cytotoxicity. Proliferative responses to PHA and Con A were higher for both sexes in spring and for females in winter than in the other seasons.[337]

Birds and Mammals

The poor increase in affinity of chicken anti-DNP and anti-fluorescein antibodies again indicates lower heterogeneity in chickens. Few changes occur after immunization, even if one waits 1 year after several injections. Perhaps similar to the trout study described previously, a restricted population of high-affinity antibodies was found only after immunization in complete Freund's adjuvant (CFA).[338] Hyperconversion and somatic mutation in Ig genes have been found in splenic GC B cells after immunization.[339] The relatively poor affinity maturation of the chicken response may be due to a balance between gene conversion and somatic mutation. Indeed, modification of V genes with segments of DNA is not an optimal strategy for fine-tuning antibody responses.[340] In the rabbit, there is also conversion/mutation by B cells in GCs after immunization. Within mammals, large variations are found from marsupials with no obvious secondary response, to mouse with 1,000-fold increases in affinity, but the basis for the relatively poor responses has not been established.

In conclusion, although all vertebrates have a very large potential for generating diverse antibodies after immunization, only some mammals studied to date make the most of this potential. Perhaps pressures on the immune system of cold-blooded vertebrates have been less intense due to a stronger innate immunity, and architecture of their lymphoid system is not optimal for selecting somatic mutants, or the great rises in affinity detected in antihapten responses are not physiologically relevant.[297] An immune system using somatic diversification at its “best” is well adapted to species where the value of single individuals is important (ie, species with small progenies); has that been the condition for the creation and selection of somatic rearrangement and of the optimal usage of somatic mutations? If this explanation provides a rationale for the utilization of somatic mechanisms

in generating a repertoire and improving it, it does not tell us why it works so well in certain species and not in others. Perhaps one key is the organization of secondary lymphoid organs. Likely a combination of factors (eg, quantitative and qualitative effects such as endothermy, secondary lymphoid tissues, mutation versus conversion, the hypermutation mechanism itself, rates of proliferation thogen and lymphocyte], etc.) are at work in the regulation of antibody responses.[296,297] Finally, significant differences have been detected in the mutational mechanism and targeting in ectotherms (eg, GC-richness in amphibians, tandem mutations in sharks, TCR loci mutation in sharks, etc.) that may enrich our understanding of the general mutational mechanism, including the enzymes involved and the targeting to V genes.[318]

Lymphoid Tissues

In addition to the molecules and functions characteristic of adaptive immunity, primary (lymphocyte-generating) and secondary (immune response-generating) lymphoid tissues also define the specific immune system[341] (Fig. 4.11). The thymus is present in all jawed vertebrates, and recent evidence suggests its origin at the dawn of vertebrate emergence.[342] *All* animals have hematopoietic cell-generating tissues, and outside of the so-called GALT species, B cells develop in such bone marrow equivalents in all jawed vertebrates. With the advent of clonal selection, the accumulation and segregation of T and B cells in specialized organs for antigen presentation became necessary and indeed the spleen as such an organ is found in all jawed vertebrates, but not in agnathans or

invertebrates.

All jawed vertebrate species rearrange their antigen receptor genes somatically (except the case mentioned previously for some shark germline-joined genes[276]). Besides rearrangement, with combinatorial joining of gene segments and imprecision of the joins, there are two other sources of diversity to generate the repertoires: the terminal deoxynucleotidyl transferase (TdT) enzyme that modifies boundaries of rearranging gene segments, and somatic mutations, found exclusively in B cells usually introduced during immune responses. However, progression of rearrangement during B- and T-cell development and diversification follow different rules in different vertebrates.[220] It is conceivable that species hatching early with just a few lymphocytes are under pressures to develop a rapid response and may not use the same mechanisms as species protected by the mother's uterine environment. It is also possible that immune systems of species with few offspring are under stronger pressures than species that have many offspring, and this could be reflected in the manner diversity is generated. Studies of B- and T-cell differentiation have been performed in many vertebrates. RAG and TdT genes have been cloned in representatives of all vertebrate classes, probes that allow the monitoring of lymphocyte development (see the following). Reagents have become available permitting a monitoring of T-cell appearance in the lymphoid organs of ectotherms (crossreactive anti-CD3 sera mentioned previously or TCR probes), as well as mAbs and gene probes specific for Ig H/L chains that allow examination of B cells. As a rule, the thymus is the first organ to become lymphoid during development. Another emerging rule is that development of the thymus-dependent MHC-restricted T-cell repertoire is similar in all species, and this is reflected in the evolution of TCR gene organization described previously as well as a core set of molecules that are required for thymocyte migration and differentiation[343]; in contrast, B-cell repertoire generation differs dramatically among different species, at times even within the same class of vertebrates.[220]

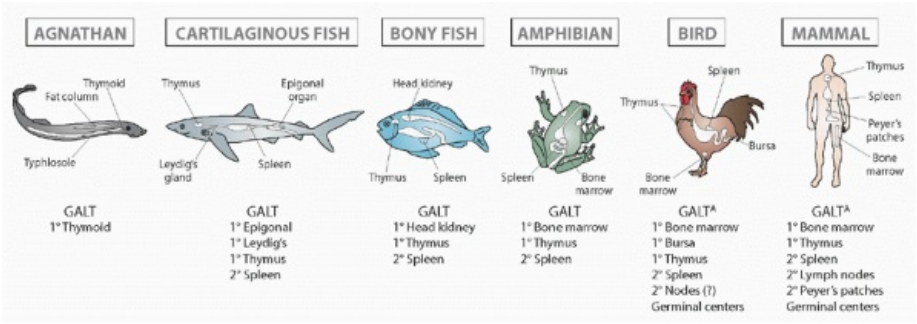

FIG. 4.11. Evolution of Lymphoid Tissues in the Vertebrates. All jawed vertebrates have a thymus and a spleen with demarcated T- and B-cell zones. Fish have different bone marrow equivalents (epigonal, Leydig's gland, head kidney), and amphibians are the oldest group with lymphopoietic bone marrow (also the first to have a typical immunoglobulin [Ig]H chain class switch, although sharks seem to have switch as well, despite the IgH cluster organization). Germinal centers are found only in warm-blooded vertebrates. A thymus equivalent (thymoid) has recently been discovered in

agnathans.[375]

Cartilaginous Fish

Like all other major adaptive immune system components, cartilaginous fish are the first in evolution to possess a prototypic thymus originating from pharyngeal pouches. As

in mammals, it has a distinct cortex/medulla structure, and TdT expression was detected in thymocytes with crossreactive antisera and more recently by northern blotting and in situ hybridization, where it is found throughout the cortex.[257] Interestingly, unlike most other vertebrates, age is not an indicator as to the size of the cartilaginous fish thymus; it can be small or large at any stage of development. GALT is also found in elasmobranchs, but lymphoid tissue in the spiral valve (intestine) clearly does not have typical secondary lymphoid tissue structure; the spleen is the only tissue with compartmentalization of cells into discrete T-cell and B-cell zones.[308] The Leydig's and epigonal organs (associated with the gonads) are lymphopoietic and erythropoietic, producing mainly granulocytes and lymphocytes, and there is high RAG expression in these tissues (see the following). Lymphocytes form nodules in the epigonal organ, probably indicative of differentiative events. In addition, many plasma cells are found peppered throughout the epigonal, fitting with the bone marrow connection.

At hatching, when dogfish embryos are exposed to waterborne antigens, structural development of the lymphomyeloid tissues is well advanced.[344] In the nurse shark, neonatal spleen white pulp consists entirely of class II-negative B cells; by 5 months after birth, T-cell zones appear adjacent to the B-cell zones. Both the B-cell and T-cell zones are vascularized, and no detectable marginal zone separates red pulp from white pulp. Class II-positive dendritic-like cells are found throughout the white pulp.[345]

In the skate *Raja eglanteria*, Ig and TCR expression is sharply upregulated relatively late in development (8 weeks) by quantitative polymerase chain reaction. IgM expression is first detected in the spleen of young skates but IgW is expressed first in gonad, liver, Leydig's organ, and thymus.[346] In adults, Leydig's organ and spleen are sites of the highest IgM and IgW expression. In nurse sharks, IgM1gj and 19S IgM appears in the serum before 7S IgM and IgNAR, and this profile is reflected in the lack of IgNAR+ cells in the spleen until 2 months after birth. RAG and TdT expression in the thymus and epigonal organ of the nurse shark suggests that lymphopoiesis is ongoing in adult life. In contrast to most other vertebrates, N-region diversity is detected (albeit reduced by approximately 50%) in skate and nurse shark IgM and IgNAR CDR3 from the earliest stages analyzed, suggesting that a diverse repertoire is important for young elasmobranchs.[308] As mentioned previously, a subset of Ig genes is prerearranged in the germline of chondrichthyans, and many of those germline-joined genes are transcribed in the embryo and hatchling, but not in the adult. This pattern fits with the expression of the nurse shark IgM_{1gj} with its germline-joined V region, and suggests that some germline-joined genes “take advantage” of their early transcriptional edge and thus some clusters can be selected for specialized tasks in early development. With many gene clusters, it is not known how “clusteric exclusion” is achieved at the molecular

level (and why the germline-joined gene expression is extinguished in adult life), but as mentioned previously, studies in two cartilaginous fish species suggest that only one H chain cluster is expressed in each lymphocyte.[278,347] It was suggested, based on the paucity of rearranged gene segments at the nonexpressed IgH loci, that there are limiting factors regulating accessibility to RAG proteins and a short time window for rearrangement of accessible loci in B cells.[347]

The architecture of cartilaginous fish Ig loci allows greatest diversity only in CDR3 because the CDR2 and CDR1 are always encoded in the germline and V segments do not combine with (D)J segments from other clusters. Yet the number of possible CDR3 is essentially limitless, and the number of germline clusters is also high (at least 15 genes in each species and as many as 100 genes; and usually three rearrangement events take place because two D segments are in each cluster). Thus, the potential diversity is greater than the number of lymphocytes, the general rule for generation of diversity in the vertebrates.

Bony Fish

In all teleosts examined, the thymus is the primary organ for T-lymphocyte generation and head kidney the primary organ for B-cell development. The teleost thymus gland originates from the pharyngeal pouches and can be uni-, bi-, or trilobed, depending on the species,[348] and it is the first organ to become lymphoid. The cortex/medulla architecture is not as precise in other vertebrate species, but the duality of the compartment is apparent and varies from species to species.[349] The spleen contains the basic elements seen in other vertebrates —blood vessels, red pulp, and white pulp—but the distinction between red and white pulp is less obvious (the white pulp being poorly developed). In spleen, the ellipsoids, which are actually terminal capillaries, have a thin endothelial layer surrounded by fibrous reticulum and an accumulation of cells, mainly macrophages. Lymphocyte accumulations are often seen in their vicinity, especially during immune responses, which have been suggested to be primitive GCs, but they are not homologous; as mentioned, AID expression is found in cells[319] during immune responses. Red pulp is rich in melanomacrophage centers, groups of pigment-containing cells at bifurcations of large blood vessels, which may regulate immune responses. The other main lymphoid organ is head kidney, believed to function as mammalian bone marrow. The transparent zebrafish is being developed as a new model to study T-cell differentiation.[343]

In the sea bass *Dicentrarchus labrax*, a mAb detects differentiating T cells (perhaps pre-T cells) as well as mature T cells as evidenced by the presence of TCR messenger RNA in the sorted populations. Cells seem to migrate from surrounding mesenchyme and subsequently mature in the thymus like in all vertebrates studied so far. T cells appear earlier in ontogeny (between 5 to 12 days after hatching) than cytoplasmic Ig+ pre-B cells, which are detected only at 52 days posthatching. Adult levels of T and B cells are reached between 137 to 145 days after hatching, which is quite a long time compared to young amphibians.[350,351]

Teleost RAG1 differs from mammalian RAG1 genes by the presence of an intron of 666 base pairs (an intron is also found in the sea urchin RAG1 gene in a similar position[352]).

Compared with other RAG1 sequences, trout RAG1 has a minimum of 78% similarity for the

complete sequence and 89% similarity in the conserved region (amino acid 417-1042). RAG1 transcripts are detected starting at day 20 after fertilization. Trout TdT is highly expressed within the thymus and to a lesser extent in the pronephros beginning at 20 days postfertilization, which correlates with the appearance of lymphocytes in these two tissues.[353] Because the H chain cluster is in the translocon configuration and there are many V_H families, it is assumed that diversity is generated in the mouse/human mode.

As described previously, studies of mature B-cell activation and homing have been done in trout. Immunization of animals results in the production of short-term Ig-secreting cells in the blood and spleen and long-lived plasma cells in the head kidney. Further analysis with B cell-specific transcription factors like PAX5 and BLIMP1 reinforced the functional studies and showed that the blood contains primarily “resting” B cells and the head kidney both plasma cells and B-cell precursors.[314,354] These last findings appear to be true of the cartilaginous fish as well, with the epigonal organ as the head kidney primary lymphoid tissue equivalent. Interestingly, recent studies have shown trout B cells to be quite efficient at phagocytosis, raising questions about myeloid/lymphoid lineage commitment in the vertebrates.[355] It is predicted that B cells from all ectothermic vertebrates are capable of phagocytosis (shown for *Xenopus*), and the work was recently extended to B1 cells in mice.[356] It certainly will be of interest to study these innate characteristics of B-cell subsets in the future, considering the early appearance of B1 cells and macrophages differentiating from the yolk sac of mouse embryos.[328,357]

Amphibians

In anurans, the thymus develops from the dorsal epithelium of the visceral pouches (the number of pouches varies with species) and is the first tissue to become lymphopoietic. It is colonized from days 6/7 onward by precursors derived from lateral plate and ventral mesoderm through the head mesenchyme. Precursors proliferate in situ as the epithelium begins to express MHC class II molecules but not classical class I molecules. By day 8, thymic cortex/medulla architecture resembles that of other vertebrates.[328] Amphibians possess a spleen with red and white pulp, GALT with no organized secondary lymphoid tissue, and many nodules (but no lymph nodes), with lymphopoietic activity in the kidney, liver, mesentery, and gills. The general morphology of lymphoid organs varies greatly according to species and changes with the season. In *Xenopus*, splenic white pulp is delineated by a boundary layer, and the central arteriole of the white pulp follicle terminates in the red pulp perifollicular area, a T-dependent zone. Anurans, like all ectothermic vertebrates, lack GCs. In *Bufo calamita*, colloidal carbon particles injected via the lymph sac are trapped by red-pulp macrophages, which then move through the marginal zone to the white pulp.[358] Giant, ramified, nonphagocytic cells found in both white and red pulp have been proposed to be dendritic cells. *Xenopus* bone marrow does not appear to be a major lymphoid organ from histologic observation, but high RAG expression in this tissue suggests lymphopoietic activity.[359] The maintenance of RAG expression throughout adult life suggests that lymphocytes are continually produced.

Thymectomy decreases or abolishes allograft rejection capacity, MLR and PHA responsiveness, IgY antibody synthesis, and all antibody responses that increase in affinity to

classic thymus-dependent antigens.[331,360] MLR reactivity matures before the ability to mount IgY responses in primary responses. Thymectomy at 7 days of age delays allograft rejection and abrogates specific IgY responses, whereas later in life it only abrogates antibody responses. Thymectomy performed later greatly affects the pool of peripheral T cells, as monitored with mAbs specific for molecules such as CD8. Early thymectomy results in the complete absence of T cells, but lymphocytes with T-cell markers, perhaps corresponding to NKT cells, can still be detected. In *Xenopus*, thymocytes induce weak graft-versus-host reactions, whereas splenic T cells are good helpers and strong graft-versus-host inducers. The thymus contains some IgM-producing B cells and memory cells poised to switch to IgY synthesis, and in vitro responses are downregulated by naïve thymus cells. *Xenopus* B cells respond in vitro to low doses of LPS not by proliferation, but rather by Ig synthesis, and also respond to PMA. Old reports of B-cell proliferation can be attributed to contaminants in LPS preparations.[328]

Urodele embryos initially produce five pairs of thymic buds, the first two of which disappear.[284] This results in a three-lobe thymus in *Ambystoma*, but in *Pleurodeles* and *Triturus* it forms one lobe. No cortex-medulla boundary is present, and the thymus generally resembles a canonical cortex. There are at least three types of stromal epithelial cells. There is no lymphopoietic activity in axolotl bone marrow, and hematopoiesis takes place in the spleen and in the peripheral layer of the liver. The spleen is not clearly divided into white and red pulp.

About 40% of TCR-β VDJ junctions in 2.5-month-old *Ambystoma* larvae have N-additions, compared to about 73% in 10- to 25-month-old animals.[247] These VDJ junctions had approximately 30% defective rearrangements at all stages of development, which could be due to the slow rate of cell division in the axolotl lymphoid organs and the large genome in this urodele. As mentioned previously, many axolotl CDRβ3 sequences, deduced from in-frame VDJ rearrangements, are the same in animals of different origins. In contrast, in *Xenopus*, rearrangement starts on day 5 after fertilization for the V_H locus, and within 9 days all V_H families are used. V_H1 rearranges first followed by V_H3, and by day 9/10 V_H 2, 6, 9, and 10 begin being rearranged and then V_H 5, 7, 8, 11 on day 13. For VL, the κ locus is the first to rearrange on day[7] (2 days after V_H), a situation similar to that found in mammals. During this early phase, B cells are present in the liver, where their number increases to approximately 500 cells.[325] Later in larval life, rearrangement resumes at metamorphosis, as suggested by the low incidence of pre-B cells and by the reexpression of RAG during the second histogenesis of the lymphoid system. T cells show a similar type of RAG expression/cell renewal during

ontogeny as the B cells, and the larval and adult Vβ T-cell repertoires differ significantly. Even early in development, tadpoles express a highly variable TCR-β repertoire despite the small number of lymphocytes (8,000 to 10,000 splenic T cells); little redundancy in TCR complementary DNA recovered from young larvae implies that clone sizes must be extremely small, unlike in axolotls.

In *Xenopus*, no lymphoid organ apart from the thymus is detectable until day 12 when the spleen appears and with it the ability to respond to antigen. For B cells, until this time no

selection occurs as suggested by the random ratio of productive/non-productive VDJ rearrangements (2:1). After day 12, this ratio becomes 1:1 (ie, the rearrangements have been selected). Complementary DNA sequences on days 10 to 12 (when the number of B cells increases from 80 to 500) are not redundant as if each sequence was represented by one cell.[325] RAG expression together with the detection of DNA rearrangement circles in the bone marrow suggests that rearrangement is ongoing throughout life and is not restricted to an early period, like in birds and rabbits. Tadpole rearrangements are characterized by a lack of N-region diversity, like in mammals but not axolotls or shark/skate (see previous discussion), and thus very short CDR3.[361] During ontogeny, TdT appears in significant amounts in thymus of tadpoles at metamorphic climax, but little expression is detected at earlier stages, which correlates well with the paucity of N-region addition in larval IgH chain sequences.[362] Studies of the ontogeny of the *Xenopus* immune system have revealed a less efficient tadpole immune response (skin graft rejection and Ig heterogeneity and affinity); the absence of TdT expression during tadpole life fits well with the findings of lower larval Ig (and perhaps TCR) diversity.

Reptiles

In all reptiles studied, the thymic cortex and medulla are clearly separated. The spleen has well-defined white and red pulp regions, but T- and B-cell zones have not been delineated with precision.[348] In *Chrysemys scripta*, white pulp is composed of two lymphoid compartments: lymphoid tissue surrounds both central arterioles and thick layers of reticular tissue called ellipsoids. Even after paratyphoid vaccine injection, splenic GCs are not formed, as in fish and amphibians. Splenic red pulp is composed of a system of venous sinuses and cords. In *Python reticulatus*, dendritic cells involved in immune complex trapping have been identified and may be related to mammalian follicular dendritic cells. GALT develops later than spleen during development, and it appears to be a secondary lymphoid organ (but does not seem to contain the equivalent of the bursa of Fabricius). Lymph node-like structures, especially in snakes (*Elaphe*) and lizards (*Gehyra*), have been reported.

Reptiles, the evolutionary precursors of both birds and mammals, are a pivotal group, but unfortunately the functional heterogeneity of reptile lymphocytes is poorly documented. There seems to be T-/B-cell heterogeneity because an antithymocyte antiserum altered some T cell-dependent functions in the viviparous lizard *Chalcides ocellatus*. Embryonic thymocytes responded in MLR at all stages, but ConA responsiveness increased gradually during successive stages and declined at birth. In the alligator (*Alligator mississippiensis*), like in mammals after glass-wool filtration, nonadherent peripheral blood leukocytes (PBL) responded to PHA and not to LPS, whereas adherent cells were stimulated by LPS.

Birds

The thymus, which develops in chickens from the third and fourth pharyngeal pouches, consists of two sets of seven lobes each with definitive cortex/medulla. The thymus becomes lymphoid around day 11 of incubation. Splenic architecture is less differentiated than in mammals. It is not lymphopoietic during embryogenesis as RAG-positive cells are found mainly in yolk sac and blood. Birds are the first vertebrate group where follicular GCs and T-dependent areas comprising the periarteriolar lymphatic sheath are encountered. Plasma cells are located in the red pulp. γ/δ TCR+ T-lymphocytes are chiefly concentrated in

sinusoids, whereas α/β T cells fill the periarteriolar lymphatic sheath.[249] Lymph nodes seem to be present in water and shore birds but not in chickens and related fowl.

The bursa of Fabricius is a primary lymphoid organ unique to birds in which B cells are produced.[363] It arises at day 5 of development and involutes 4 weeks later. T-B heterogeneity is obviously well defined in birds (indeed, the "B" in B cell stands for bursa.) The effects of thymectomy—T- and B-cell collaboration and generation of MHC-restricted helper and killer cells—are very similar to mammals, the other class of warm-blooded vertebrates.

During the embryonic period, chicken stem cells found in yolk sac and blood rearrange their IgH and L V genes simultaneously over a very restricted period of time, and very few cells colonize each bursal follicle (about 10^4 follicles).[364] Three weeks after hatching, these cells have differentiated in the bursa and then seed the secondary lymphoid tissues, after which time B cells are no longer be generated from multipotent stem cells; thus, only approximately 2×10^4 productive Ig rearrangements occur in the life of the chicken. When an antiserum to chicken IgM was administered in ovo to block this early bursal immigration, there were no stem cells arising later in development that can colonize the bursa, and these chickens lacked B cells for their entire lives.[365] Although the general Ig locus architecture is similar to that of frogs and mammals, only one rearrangement is possible as there is only one functional V_L or V_H on each allele.[366,367] Diversity is created during bursal ontogeny by a hyperconversion mechanism in which a pool of pseudogenes (25 ψL and approximately 80 ψH) act as donors and the unique rearranged gene acts as an acceptor during a proliferative phase in bursal follicles. For H chains, the situation is more complex as there are multiple D elements. During ontogeny, selection of productive rearrangements parallels the selection of a single D reading frame, suggesting that the many D segments favor D-D joins to provide junctions that are diversified by gene conversion; the hyperconversion mechanism can also modify Ds because most donor pseudogenes are fused VD segments. The gene conversion process requires AID, which is also required for SHM and CSR.[368]

Because diversification by gene conversion occurs after Ig rearrangement and cellular entry into bursal follicles, and there is only a single germline V_H and V_L expressed on all developing B cells, it was tempting to implicate a bursal ligand binding to cell surface IgM to initiate and sustain cellular proliferation and gene conversion. However, surface expression of IgM devoid of V regions permitted the typical B-cell developmental progression, demonstrating that such receptor/ligand interactions are not required.[369] Thus, currently we know little of how cells enter the bursa, which signals induce them to proliferate/convert, and how cells arrest their development and seed the periphery.[364]

Generation of Diversity in Mammals

Mechanisms leading to the generation of repertoire diversity vary among mammalian species.[220] Categories can be made depending upon the mode of B-cell development: rabbits, cattle, swine, and chickens, unlike fish, amphibians, reptiles, and primates/rodents, use a single V_H family, of which only a few members (sometimes only one) are functional. To

diversify their antibody repertoire, this group uses gene conversion or hypermutation in hindgut follicles of GALT early in life (rather than bone marrow throughout life) and is therefore known as the “GALT group.” At the rabbit H locus, as in the chicken, a single V_H is expressed in most peripheral B cells. During development, B cells that have rearranged this particular V in the bone marrow (and other sites) migrate to the appendix where this rearranged gene is diversified by gene conversion using upstream donor V segments.[370,371] This development of B cells in rabbits is dependent on the intestinal microflora, and efforts are being made to define the potential bacterial superantigens involved, as well as binding sites on IgM necessary for the differentiation.[372] In ruminants, the ileal Peyer patches are the bursa-like primary B cell-generating tissues.[373] Although bursa, appendix, and sheep ileal Peyer patches show morphologic similarities, the mechanisms generating diversity are different: conversion in the chicken and hypermutation in sheep, and both in the rabbit. As described previously, most of the “GALT group” also appears to lack IgD; thus, IgD might serve some purpose in repertoire development in some groups of mammals and not others.

In summary, the organization of the lymphoid tissues is perhaps the only element of the immune system that shows increasing complexity that can be superimposed on the vertebrate phylogenetic tree. The absence of primary and secondary lymphoid tissues (thymus and spleen) is correlated with the absence of a rearranging and/or hypermutating receptor family in other animals, with the exception of the agnathan VLR in which the relevant lymphoid tissues are being defined (see the following). While all jawed vertebrates have a true secondary lymphoid tissue (spleen), ectotherms lack lymph nodes and organized GALT. In addition, while ectotherms clearly have B-cell zones resembling follicles, and despite the clear ability for ectothermic B cells to undergo SMH and at least some degree of affinity maturation, GCs with follicular dendritic cells are not formed after immunization; clearly, this was a major advance in the evolution of the vertebrate immune system.

The potential repertoire of Ig and TCR as well as VLR-combining sites is enormous in all vertebrates. The potential antigen receptor repertoire in all species for both T and B cells is far greater than could ever be expressed in an animal because of cell number limitations. Not all species or all gene families use combinatorial joining for repertoire building, but all species assemble V, (D), and J gene segments to generate their functional Ig genes during B-cell ontogeny, and the imprecision of this assembly creates great somatic diversity. Thus, from this survey in various species, one could not predict that there would be major differences in immune responses in representatives of different vertebrate classes, and yet as mentioned previously the mouse/human antibody responses are superior to those in many taxa.

More on Evolution of the Thymus

The discovery of a second (cervical) functional thymus in mice has raised ontogenetic and immunologic questions.[342,374] Is this second thymus the result of an atavism, or does it correspond to what is seen in human when a cervical thymus can form under certain pathogenic conditions during the migration of the thymus to its final mediastinal location? There are examples of cervical thymi in primitive mammals such as marsupials but also in some prosimians. An “extra” thymus also is reminiscent of the multiple thymi encountered quite frequently in cold-blooded vertebrates.

As described, the thymus is promiscuous with regard to its precise developmental origin.[284] The thymus arises from pouches two to six in cartilaginous fish, from the second pouch in frogs, the second and third in reptiles, and from the third and/or fourth in bony fish, birds, and mammals. The final number of thymi can also be variable. It ranges from five pairs of organs in sharks, to four in caecilian amphibians, to three in urodeles, and finally to one in many teleost fish species, anurans, and many mammals. The thymus of reptiles varies in term of location and number of lobes, reflecting variation in embryonic origin. The adult thymus may be found anywhere from the base of the heart to the neck. For example, in lizards and snakes, there are two lobes on each side of the neck with no subdivision in lobules. The crocodilian thymus is an elongated chain-like structure, not unlike that of birds. In turtles, the thymus is a pair of lobes divided in lobules at the bifurcation of the common carotid associated with the parathyroids. The multilobed thymus in birds is not the equivalent of the multiple thymi found in sharks because the subdivision is secondary to primary organogenesis. Regardless of the underlying ontogenetic mechanism leading to the development the cervical thymus in mice, the result is suggestive of the secondary “thymus spreading” in birds, but it differs with regard to an uneven final size distribution. All marsupials, except koalas and some species of wombats that only have a cervical thymus, have a thoracic thymus similar to that of placentals. Some marsupials (kangaroos and possums) also have a cervical thymus; their thoracic thymus derives from the third and fourth pharyngeal pouches, whereas the cervical thymus arises mainly from the ectoderm of the cervical sinus with some participation from the second and third pouch (like in reptiles).

The second mouse thymus seems to show primitive characteristics such as the existence of a single lobe as is found in amphibians, a superficial location, and a position compatible with an origin involving another pharyngeal pouch (presumably the second) that would be a marsupial and therefore perhaps a reptilian character. Embryology helps in determining the possible scenarios: During mouse ontogeny, the canonical thymus anlage can be recognized, beginning on day 11.5 in development, as a group of Foxn1-expressing cells located ventrally in the third pharyngeal pouch. If the cervical thymus were derived from an independent anlage, one would rather expect to detect Foxn1+ cells in the endoderm outside the third pouch. This argues for a common origin of thoracic and cervical thymi and against a second thymus anlage outside the third pouch, and, hence, against the above hypothesis that the cervical thymus represents an atavistic organ.

A Thymus in Jawless Fish?. Until recently, it was believed that the thymus appeared in evolution with the emergence of adaptive immunity in the extinct placoderm lineage approximately 500 million years ago. There has never been any controversy concerning the presence of a thymus in all living jawed vertebrates, and as described, its requirement for T-cell differentiation is universal. The lack of a thymus in the jawless fish was consistent with the non-Ig/TCR adaptive immunity in these animals, but this has changed in a new study.[375]

The finding that lampreys have two types of lymphocytes heralded a renewed search for a thymus equivalent in these animals.[291] Indeed, there was an extensive literature on this topic over the past century identifying accumulations of cells in various cranial regions, suggesting that lymphocytes could be differentiating in these areas. However, it has always been clear that there is no specialized tissue with a defined cortex and medulla in lampreys or hagfish, as is seen in all gnathostomes. This conclusion was not well supported because there were

no molecular markers for either lymphocytes or thymic epithelium in jawless fish. Indeed, consistent with almost all other accumulated data, a recent study concluded that there was "no evidence for a thymus in lampreys."[343(p189)] In that study, the major transcription factor involved in the development of T cells described previously, *foxn1*, was expressed by the pharyngeal epithelium, but the lack of expression of any known lymphocyte markers made it unlikely that this region was truly the thymus equivalent; a similar transcription profile was seen in the gill epithelium of the model basal chordate *Amphioxus*, which truly seems to lack an adaptive immune system.

The discovery of "T cells" in lampreys opened a new panorama with the expression of T cell-specific genes besides the antigen receptors. As mentioned, Pancer and colleagues discovered that lamprey lymphocytes express two APOBEC family member genes, CDA1 and CDA2, and suggested that they were involved in the rearrangement (and perhaps mutational) events in the VLR genes.[288] In the T/B split paper described previously, these APOBEC family members seemed to be expressed specifically in either VLRA (CDA1) or VLRB (CDA2) cells. In the new study, CDA1 was shown to be expressed by lymphocytes in close proximity to the *foxn1* -positive pharyngeal epithelial cells.[375] Furthermore, only in these "developing" lymphocytes, but not in mature VLRA-positive cells, could a high percentage (approximately 25%) of out-of-frame VLRA genes be detected, implying that cells were differentiating in this region. In summary, this tissue in lampreys, which was christened the "thymoid," 1) is derived from the pharyngeal epithelium, 2) expresses classical thymic epithelial markers such as *foxn1* and notch ligands, and 3) is associated with developing VLRA cells, based on expression of the APOBEC family member CDA1, out-of-frame VLRA gene sequences, and failure to respond to activation signals (such as the T cell mitogen PHA) that stimulate mature lymphocytes. In addition, consistent with the high percentage of cells with a nonfunctional receptor, many lymphocytes undergo apoptosis in the thymoid, which is also comparable to the situation in jawed vertebrates. Much more work is necessary to understand this system, but the basic finding is extraordinary.

Because the thymoid is expressed at the tips of all of the gill filaments,[375] thymectomy will not be possible in jawless fish. Perhaps procedures will be developed to block the interactions between the VLRA cells and the pharyngeal epithelium, or the development of the thymoid itself can be disrupted. Assuming that this tissue indeed is the thymic equivalent in lampreys, what is the significance of having the VLRA cells develop in a unique organ? In gnathostomes, T cells recognize antigen in the form of peptides in association with MHC class I or class II molecules. Because of the high levels of MHC polymorphism, as mentioned previously, T cells are positively selected in the thymus for cells that recognize antigen in association with the thymic MHC. Despite major effort, neither MHC molecules nor the specialized proteins associated with antigen processing have been detected in the jawless fish, and thus if there is positive selection it must be orchestrated by a convergent system of antigen processing/presentation. In the same vein, perhaps there is an AIRE equivalent expressed by the thymoid that ensures deletion of self-reactive clones[376]; if so, it would also imply that a convergent antigen presentation system will be discovered in lampreys. It will be of interest to reexamine differentiation of lymphocytes in the pharyngeal epithelium of basal chordates; perhaps this will lead us to an understanding of the origins of adaptive immunity in the vertebrates. Finally, what is the significance of T cells developing in association with the pharyngeal epithelium? Is it because this area in the gill region is evolutionarily plastic or is

there some relevance to exposure of the thymoid to the external environment?

Discovery of a New Proteasome Element Expressed in Thymus . Recently, a new form of the proteasome only expressed in the thymus was discovered in mammals, called β5t. The β5t gene was generated via a cis duplication from LMPX (β5), and in its absence cytotoxic T cells are impaired.[377] Like many other components of adaptive immunity we have discussed, β5t is found in all gnathostomes, beginning with the cartilaginous fish. As we will see in the following, the LMPX equivalent of the immunoproteasome, β5i or LMP7, is polymorphic in amphibians and bony fish,

suggesting that it is a lynchpin in formation of the immunoproteasome.[378] It is interesting as well that both β5t and β5i (and all of the immunoproteasome elements) have been lost in birds (see the following).

The Major Histocompatibility Complex

T cells distinguish self from nonself through the presentation of small peptides bound to MHC class I and class II molecules (ie, MHC restriction). The genetic restriction of T cell-APC collaboration, processing of antigen by professional APCs, and T-cell education in the thymus described in mice hold true (or is assumed) for most jawed vertebrate classes. For technical reasons, no MHC-regulated T-cell responses have been documented in cartilaginous fish, but the identification of polymorphic class I and II and rearranging TCRα/β genes and segregated T- and B-cell zones in spleens (see previous discussion) strongly suggest that functional analyses will reveal MHC restriction of adaptive responses.[257] By contrast, urodele amphibians and teleost cod are notorious for their poor immune responses (see the following), but biochemical and molecular evidence suggests that class II polymorphism is low in the axolotl and cod have lost the entire class II-based immune system. Recent results in agnathans and other vertebrates have opened our eyes to new functions in MHC.

Class I/II Structure Through Evolution

The three-dimensional organizations of class I and class II are remarkably similar: the two membrane-distal domains of both molecules form a PBR composed of two antiparallel α helices resting on a floor of eight β strands, and the two membrane-proximal domains are IgSF C1. Although sequence identity among class I and class II genes in vertebrates is low (like most other immune genes), the four extracellular domain organization and other conserved features are likely to be found in the ancestral class I/II gene.[379] An intrachain disulfide bridge exists within the class I PBR α2 and class IIβ1 domains, but not the class I/II PBR α1 domains, and phylogenetic trees show that these respective domains are most similar. Bony fish class II α1 domains, like class II DMα molecules, do have a disulfide bridge. The exon/intron structure of class I and class II extracellular domains is also well conserved, but some teleosts have acquired an intron in the exon encoding the IgSF β2 domain. Other conserved features of class I genes include a glycosylation site on the loop between the α1 and α2 domains important in biosynthesis (shared with class II β chains), a Tyr and one to three Ser in the cytoplasmic regions that can be phosphorylated in mammals, as well as several stabilizing ionic bonds. Class II with its two TM regions differs from class I with only one; conserved residues in the class II α and β TM/cytoplasmic regions facilitate dimerization. In summary, because sequence similarity is very low among MHC genes in different taxa,

these conserved features are important for function, biosynthesis, and maintenance of structure.

β2m was the second IgSF molecule (C1 type) ever to be identified, originally found at high levels in the urine of patients with kidney disease. It associates with most class I molecules (see the following). Besides mammals, β2m genes have been cloned from representatives of all jawed vertebrate classes. The β2m gene is outside the MHC in all tetrapods and bony fish tested, and is a single copy gene in all species except cod and trout, in which it has undergone multiple duplications. Based on the levels of similarity between the various domains of class I and class II, it was predicted that β2m was originally encoded in the MHC; indeed, recent work has shown that it is linked to the MHC in the nurse shark, adjacent to the ring3 gene.[380] Like TCR/Ig/class I/II, β2m has not been found in jawless vertebrates, so its origin remains mysterious.

Classical and Neoclassical Class I and Class II

Class Ia (classical) and class Ib (nonclassical) genes are found in all of the major groups of jawed vertebrates. Class Ia genes are defined by their ubiquitous expression, their presence in the MHC proper, and by high polymorphism (in most species). In addition, class Ia proteins almost always have eight conserved residues at both ends of the PBR that interact with "mainchain" atoms of bound peptides and constrain their size to eight or nine residues; this feature often distinguishes class Ia from class Ib (see the following). Thus, tight binding of peptides, a likely source of conformational changes in class I allowing transport through the endoplasmic reticulum and cell surface expression, is an evolutionarily conserved trait.[381] In nonmammalian vertebrates, one of these residues at the C-terminus is lysine rather than tyrosine, the functional significance of which is unclear.[379]

The class Ia/Ib distinction holds in most taxa: one to three polymorphic class Ia genes are expressed ubiquitously in most species, whereas other minimally polymorphic or monomorphic class Ib genes are expressed in a tissue-specific fashion. The class Ib genes can be split into two major groups: one set that is most related to the class Ia genes within a taxon and thus recently derived, and one group that is ancient and emerged early in evolution.[381] In mouse and human, the set most closely related to class Ia genes are closely linked within the MHC. In nonmammalian vertebrates, however, this first set is found in gene clusters on the same chromosome as the MHC proper but far enough away to segregate independently from MHC (eg, chicken [*Rfpy*] and *Xenopus* [*XNC*]). One *Xenopus* class Ib gene is expressed specifically in the lung and thus likely has a specialized function, and another gene (XNC10) is expressed by T cells and may serve as a ligand for unconventional subsets of T cells.[382,383] Chicken Rfpy is associated with resistance to pathogens, and the recent structure of one of these class Ib genes has shown an unusual hydrophobic structure in the groove.[384] Class Ib genes related to but unlinked to the classical class I have also been found in bony and cartilaginous fish, and a lineage of class II-linked class I genes was discovered in bony fish.[385] Thus, class Ib genes that arise in each taxon seem to have true class I-like functions, but perhaps have become specialized (sometimes the distinction between class Ia and class Ib is blurry; see the following). The second set of older class Ib genes that predates divergence of taxa can have very different functions.[381] For example, the neonatal Fc receptor is involved in binding

and transport of IgG molecules across epithelia as well as protecting them from degradation (the Brambell receptor). Furthermore, molecules only described so far in mammals are composed only of a PBR without IgSF domains; these unusual class I molecules do not bind peptides but rather are important for the regulation of NK- and T-cell function during infection. The paradigm for these SOS responses is the MHC class I-related protein (MIC) and UL16-binding protein (ULBP) class Ib molecules, which clearly do not bind peptides. Some teleost class Ib genes that fall outside the major cluster of fish class I genes may fit into this category.[385,386] Finally, molecules like CD1 bind nonpeptidic antigens for presentation to innate-like NKT cells. The phylogenetic analysis predicts that CD1 and FcRN are old class I genes (see the following on CD1); the age revealed by the phylogenetic tree also correlates well with the hypothesis that ancient duplication events predating the emergence of jawed vertebrates resulted in the appearance of CD1, FcRN, and MHC-linked class I genes (see the following). Was the original function of class I linked to antigen presentation (peptidic or otherwise), induction of an SOS response, or to housekeeping functions? We do not have the answer because class Ia and class Ib molecules are present in the oldest living gnathostomes. The discovery of class I-like genes in animals derived from ancestors predating adaptive immunity or in the jawless fish would help resolve this question, but to date no recognizable MHC molecules or their kin have been detected in prejawed vertebrates; this topic is especially of interest since the dichotomy of lymphocytes as well as a thymus candidate in jawless fish were discovered.[291,375]

Class II molecules also have nearly invariant and evolutionarily conserved residues that bind to main-chain atoms of peptides, but these are in the center of the groove.[379] Thus, tight binding to main-chain peptide atoms occurs in the center of the class II PBR, and peptides are free to protrude from both ends. The only nonclassical class II molecules so far identified are the previously mentioned DM molecules that lack these residues and DO proteins. DM molecules so far have been cloned only from tetrapods[177] and have not been detected in any fish species despite the large genomic and EST databases for the bony fish. Thus, they either had not emerged at the time fish arose or were lost in the bony fish lineage; phylogenetic trees suggest the latter, and would be consistent with the rapid rate of genome evolution in the teleosts. DO class II molecules, believed to modulate DM function, have only been detected in placental mammals.[387] The invariant chain is another protein found only in gnathostomes[388]; its recent role in class I cross-presentation suggests that it may have been important for biosynthesis of both class I and class II.[389]

Class I/II Expression

In *Xenopus* species, immunocompetent larvae express high levels of class II on APCs such as B cells, but express only very low levels of class Ia molecules on all hematopoietic cells until metamorphosis.[328] Expression of the immunoproteasome element *Imp7* and all identified class Ib isotypes is also very low.[390] Larval skin and gut, organs with epithelia in contact with the environment, appear to coexpress class I (transcripts) and class II. Such expression may provide immune protection during larval life; perhaps expression of class Ia is limited to organs that undergo massive destruction and remodeling at metamorphosis. Class II molecules also change their distribution after metamorphosis and are highly expressed by

unstimulated T cells.[391] Axolotl class II molecules are also regulated differentially during ontogeny, expressed in young animals on B cells, and then expanded to all hematopoietic cells, including erythrocytes, later in life.[392] Changes in MHC expression are not correlated with cryptic metamorphosis in axolotls, but class II expression by erythrocytes is correlated to the switch from larval to adult globins. Unlike *Xenopus*, class I transcripts isolated so far are expressed early in ontogeny, from hatching onwards.

Carp class I and class II transcripts are detected in embryos 1 day after fertilization and reach a plateau at day 14. However, the suspected class Ia protein does not appear until week 13, whereas β2m can be detected several weeks earlier.[393] It was suggested that another class I molecule is expressed during early development of the carp hematopoietic system, perhaps one of the unusual nonclassical molecules that groups outside the teleost cluster. Interestingly, class I is expressed in the brain of young, but not adult fish, suggesting that class I molecules may play a role in neurogenesis.[394]

As mentioned previously, the cod was recently shown to have lost class II genes, as well as the invariant chain and CD4 genes.[395] The apparent lack of the entire class II system of antigen recognition correlates well with the inability of cod to make antigen-specific antibody responses.[396] The authors speculate that the large numbers of class I molecules in cod may somehow compensate for the loss of a class II system. Axolotls, which have very low class II polymorphism,[397] also have a highly expanded class I system.[398] It is possible that in both cases there has been a “use it or lose it” scenario, in which a major arm of the immune system was lost due to a low pathogen load.

Major Histocompatibility Complex Gene Organization

As class I and class II proteins are structurally similar, it is no surprise that their genes are linked, a primordial trait subsequently lost only in bony fish (Fig. 4.12).[2] But why are structurally unrelated class I processing genes, including the immune proteasome components *Imp2* and *Imp7* and the *TAP* and *TAPASIN* genes, also found in the MHC? There are two possible scenarios: primordial linkage of ancestral processing and presenting genes in the MHC, or later recruitment of either the processing/presenting genes into a primordial MHC. Based on the presence of similar clusters of MHC genes on paralogous chromosomal regions in humans and mice, Kasahara et al.[17,399] proposed that ancestors of class I, class II, proteasome, transporter, and class III genes were already linked before the emergence of the adaptive immune system. Genomewide duplications around the time of the origin of vertebrates (the so-called 2-Round or 2R hypothesis), as proposed by Ohno et al.,[16] may have provided the raw material from which the immune system genes was assembled (see the following; Fig. 4.13). As for all other adaptive immune genes described so far, neither class I/II nor immunoproteasome/transporter associated with antigen processing (TAP) have been isolated from hagfish nor

lampreys, and all of these genes as well as other genes involved in immunity could have emerged as a consequence of the duplications. Because class I genes are found on two or three of the clusters, class I-like molecules may have predated class II in evolution. Indeed,

NK-like recognition of a class I or class I-like molecule encoded in an ancestral linkage group may have been at the origin of the adaptive immune system (see the following).

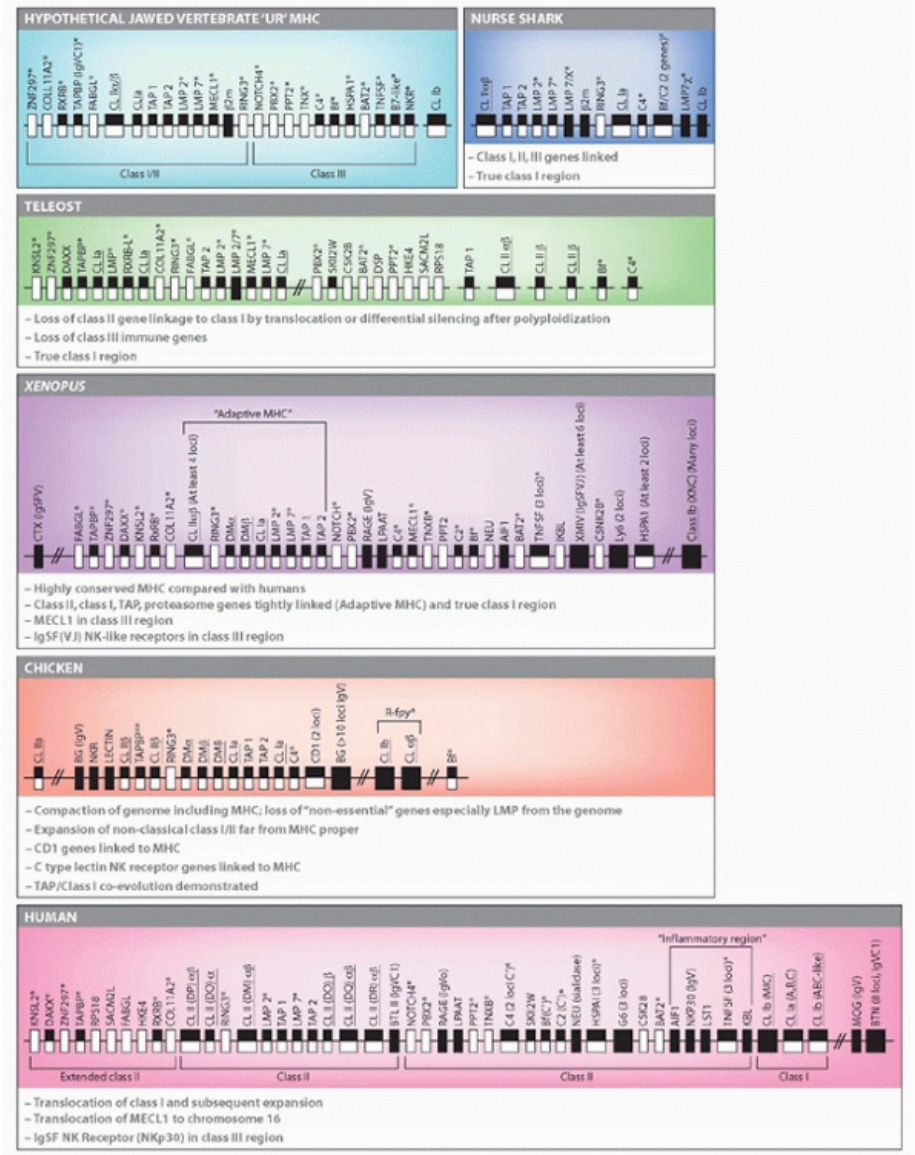

FIG. 4.12. Major Histocompatibility Complex (MHC) Evolution. *White* indicates that the gene is found in at least one other species besides human; *black* designates a gene with known or inferred immune function; *asterisk* indicates an ancestral gene found on at least two paralogous MHC regions in mammals; *large box* indicates at least two genes in the particular region; *double slash* indicates linkage far away on the same chromosome; *space between lines* indicates that the genes are on different linkage groups. The teleost MHC is a composite of the zebrafish, trout, *Fugu*, and medakafish maps. Extensively modified from Flajnik and Kasahara.[498]

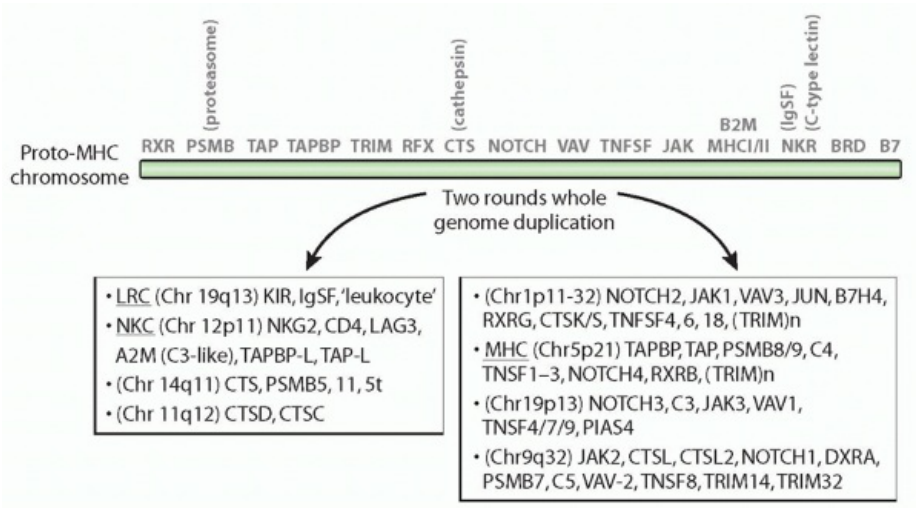

FIG. 4.13. Genomewide Duplication (2R) Model of Major Histocompatibility Complex (MHC) Evolution. Displayed are the MHC paralogous regions and their human chromosomal designations, first identified by Kasahara and modified over the years.[2,17] Note that such paralogous regions have also been studied for chemokine receptors,[477] tumor necrosis factor and tumor necrosis factor receptors,[459] immunoglobulin superfamily molecules involved in cell-cell interactions,[442] and others. Note that the natural killer cell complex and leukocyte receptor complex, respectively, are likely to have been in the Ur MHC based upon linkages seen today in various taxa. The *box on the right* indicates the original MHC paralogous regions identified by Kasahara on chromosomes 1, 6, 9, and 19.[17] The *box on the left* shows paralogous regions uncovered in further analyses.[500] Modified from Flajnik and Kasahara.[2]

TAP is an interesting case in that the MHC-linked TAP 1/2 genes were clearly not part of the Ur MHC, but rather they were "recruited" to the MHC early in evolution. TAPs are members of the very large ABC transporter family, and are most closely related to bacterial ABC transporters; this suggests that TAP1/2 were derived from a bacterial, or more likely a mitochondrial gene, via horizontal transfer.[400] Furthermore, a close homologue of TAP1/2, TAP-L (TAP-like), unlike all of the other Ig/TCR/MHC genes we have discussed, is present in jawless fish.[401] The function of TAP-L is not known, but it may be involved in cross-presentation[402] or "typical" presentation in jawless fish. In summary, the TAP genes are not following any of the "rules" that seem to hold true for the other genes involved in adaptive immunity, and this story will be exciting to monitor, especially in the context of the agnathan VLR system.

In all nonmammalian vertebrates, and even in marsupials, the immunoproteasome and TAP genes are closely linked to class I genes, not to class II, in a true "class I region."[2] This result is most striking in bony fish (*Fugu*, zebrafish, medaka, trout) because class I/Imp/TAP/TAPBP and class II are found on different chromosomes.[403,404] The class III region, historically defined by the innate immune genes such as Bf/C2, and C4 are also present in the *Xenopus* and elasmobranch MHC, showing that the class III association of class I/II with such genes is

ancient.[177] If Kasahara's interpretation is correct (ie, MHC syntenic groups found on different mammalian chromosomes resulted from ancient block duplications), it is expected that the physical association of ancestral class I, II, and III genes predated the emergence of jawed vertebrates, and such syntenies in ectothermic vertebrates are not surprising. Indeed, linkage studies in nonvertebrates *Amphioxus* and *Ciona* do support an ancient linkage of class I, II, and III genes.[405] Taken together, the data reveal that lack of synteny of class I, class II, and class III genes in teleosts is a derived character. Independent assortment of class I and class II may allow these genes to evolve at different rates: in some teleosts, class Ia alleles form ancient, slowly evolving lineages, whereas class II genes evolve at similar rates as mammalian MHC alleles.[406,407]

The chicken MHC, the B complex, is on a microchromosome, and intron sizes and intergenic distances are both quite small so that the entire complex is only a few hundred kb as compared to over 4,000 kb in humans and *Xenopus*.[408] Class Ia (BF), class IIβ (BL and DM), and TAP genes are in the MHC, but there is no evidence for immunoproteasome genes, and almost all class III genes have been deleted except for C4. The quail MHC is similar, although is somewhat expanded, especially in genes related to the C-type lectin NK receptors.[409] Although most class III genes are found on other chromosomes, *Imp2/7* and *MECL1* genes are actually absent from the genome; indeed, peptides bound to chicken class I molecules sometimes have C-terminal glutamic acid or aspartic acid, which are rare after proteolysis by mammalian proteasomes containing Imp2 and Imp7. Indeed, the recent crystal structure of a chicken class I molecule shows that the alleles can interact with a broader array of peptides as compared to mammalian class I alleles; the PBR is “broader” and one of the conserved peptide-binding residues is noncanonical.[410] To explain the correlation of

diseases with particular haplotypes, Kaufman proposed that the chicken has a minimal essential MHC composed of only those genes absolutely required to remain in the complex. This concept has been reinforced recently by an analysis of resistance to viral infection (Rous sarcoma virus) governed by classical class I molecules.[411,412] Additionally, the presence of polymorphic TAP alleles closely linked to particular class I alleles has demonstrated coevolution of the transporters and peptide-binding molecules.[413]

Surprisingly, CD1 genes are closely linked to the chicken MHC.[414,415] As mentioned previously, CD1 genes in mammals seem to be on one of the MHC paralogous regions and it was suggested that it arose as a consequence of the en bloc duplication. While this is still possible (ie, there was differential silencing of CD1 and other class I genes on the two paralogous chromosomes), the more likely scenario is that CD1 arose by gene duplication within the MHC itself in an ancestor of warm-blooded vertebrates; no bonafide CD1 genes have been detected to date in any fish or amphibians, so the entire NKT system may be specific of warm-blooded vertebrates.

In summary, in all animals except placental mammals, classical class I genes map closely to the *TAP*, *Imp*, and tapasin genes, suggesting that the processing, transport, and presenting genes were in an original “class I region.”[416] The tight linkage of the functionally, but not structurally, related genes strongly suggests that such genes coevolve within particular MHC haplotypes. Indeed, in *Xenopus* there are biallelic lineages of class Ia, LMP7, and TAP, which

are always found as a set in wild-caught animals.[417] Although teleosts underwent an explosive adaptive radiation 100 million years ago and primordial syntenies have been lost in many cases, there are deep lineages of class Ia genes in many species, also found for *Xenopus* and cartilaginous fish class Ia genes. A study in medaka suggests that divergent noncoding regions between the class I-processing and -presenting genes do not permit recombination between lineages, hence preserving the linkage disequilibrium.[418] Nonaka et al. proposed that these deep proteasome/class I lineages emerged at the dawn of vertebrate immunity and may even have been maintained perhaps by convergent evolution in certain groups.[419] In (most) eutherian mammals, the class I region is not closely linked to Imp/TAP and is very unstable, with rapid duplications/deletions expected in a multigene complex (see Fig. 4.12); the same class I instability extends to the non-MHC-linked class Ib genes in *Xenopus* species.[420]

EVOLUTION OF ALLORECOGNITION

Histocompatibility Reactions in Invertebrates

Scrutinizing graft rejection within a species (allograft) across the animal kingdom demonstrated that allorecognition was almost universal among metazoa. Scrutinizing specific memory in the same systems was *the* major tool to establish the universality or not of adaptive immunity. Moreover, it fueled speculations the origins of vertebrate MHC. Most of these studies led to inconclusive results because of the poor immunogenetic aspects of the reactions. However, the genetic regions and mechanisms responsible and molecular underpinnings of such alloreactions are now becoming known, and no (or little) resemblance to the vertebrate MHC has been found even though regions homologous of the extended vertebrate MHC have been identified in some organisms but without functional correlation.[405,421]

Colonies of *Porifera*, *Cnidaria*, *Bryozoa*, and *Tunicata* (see Fig. 4.1) often compete for space and may develop histocompatibility reactions in the zone of contact. In addition, cell-lineage parasitism, in which the somatic and/or germ cell lineage of one partner replaces that of the other, may ensue if colonies fuse into a chimera. Thus, effector functions following allorecognition also protect the genetic integrity of the individual. In some species, fusion is apparently restricted to tissues of the same individual (complete matching), in other species such as bryozoans, fusion also occurs between genetically distinct individuals if they share kinship (partial matching). Two divergent invertebrate phyla have been studied in detail: *Cnidaria* and *Tunicata*.

Porifera

Sponges (*Porifera*) and placoza are the phylogenetically oldest extant metazoan phyla. Sponges, whether marine or freshwater species, possess a sophisticated histocompatibility system.[422] Elements of the sponge immune system involved in these reactions have been analyzed at the molecular level. Sponge cells associate in a species-specific process through multivalent calcium-dependent interactions of carbohydrate structures on a 200 kd extracellular membrane-bound proteoglycan called “aggregation factor,” well studied in *Microciona* and *Geodia*.[422] The glycan moiety is involved in cell adhesion and exhibits differences in size and epitope content among individuals, suggesting the existence of allelic

variants. Therefore, strong carbohydrate-based cell adhesion evolved at the very start of Metazoan history. Other genes involved in these reactions include one that is similar to the vertebrate MHC-linked allograft inflammatory factor and another to the T-cell transcription factor. AIF-1 and T-cell transcription factor genes are upregulated in vivo after tissue transplantation, and in vitro in mixed sponge cell reaction.[423] Polymorphic IgSF molecules are found on the surface of sponge cells, but their relationship to allorecognition events (if one exists) is not clear.[424]

Allogeneic recognition in vitro led to apoptotic cell death in one partner and survival in the other.[425] The process is controlled by a differential expression of the proapoptotic and prosurvival proteins that are characteristic for the initiation of apoptosis (caspase, MA3, ALG-2 protein) and the prevention of programmed cell death (2 Bcl-2 homology proteins, FAIM-related polypeptide, and DAD-1-related protein). In an apoptotic mixed cell combination, characteristic apoptotic genes were expressed, while in the nonapoptotic aggregates the cell-survival genes are upregulated.[423] In another species, *Microciona*, allogeneic interactions also

induce cellular reactions involving gray cells (sponge immunocytes) and finally apoptosis. Analogous (but most likely not homologous) to T-cell responses, the response is inhibited by cyclosporin A.[426]

From observation of 50 pairs of larval grafts within one F1 progeny of the marine sponge *Crambe*, 75% could fuse, a proportion suggesting that the genetic control depends on one locus and sharing of one haplotype results in fusion; a 100% fusion between mother and offspring is consistent with this interpretation. Unfortunately, the issue is complicated as individuals from a given mother may not have the same father. Still, the few data available are consistent with a single or at least major histocompatibility locus (or region), the “rule” in other invertebrate phyla described in the following.

Cnidaria

The existence of highly polymorphic histocompatibility loci was demonstrated long ago in various corals where apoptosis induction was responsible for the death of partners in incompatible combinations,[154] whereas in sea anemone nematocyte discharge was induced between incompatible individuals.[427] The colonial cnidarian *Hydractinia* was the only species to provide a model to analyze genetic control of such reactions. In 1950, Hauenschild noticed that allorecognition seemed to be under the control of a single genetic region with multiple alleles.[428] Colonies of *Hydractinia* encrust the shells of hermit crabs, where they grow by elongation and branching of stolons. Embryos and larvae fuse indiscriminately. However, when two or more larvae are recruited to the same substratum, colonial forms may come into contact through their stolons. If the two colonies are histocompatible, stolon tips adhere and fuse, establishing gastrovascular connections and a permanent genetic chimera. If tips of incompatible colonies fail to adhere, they swell (hyperplastic stolons) with the migration of nematocysts, which discharge and damage the tissues. In addition, transitory fusions can also occur in a few cases. Similar to the genetics of the sponge alloreactions previously mentioned (and in other invertebrates and plants), colonies fuse if they share one

or two haplotypes, reject if they share no haplotypes, and display transitory fusion if they share only one allele at one haplotype and no alleles at the other. Examination of the polymorphic locus governing this reaction (*alr*) revealed the involvement of two closely-linked polymorphic loci 1.7 cm apart (likely encoding receptor and ligand), *alr1* and *alr2*.[429] *Alr1* encodes a three IgSF domain surface molecule, not unlike other metazoan nectin-like molecules, with a cytoplasmic tail equipped with multiple signaling motifs (including a ITAM-like motif). In the first domain, the molecule shows a high level of variability at particular residues, suggesting positive selection. Alr1 is embedded in a genetic region consisting of multiple IgSF members. Alr2 encodes another highly polymorphic gene with three IgSF domain IgSF with the distal V-like domain being the most variable, and an ITIM-like motif in the cytoplasmic tail adjacent to various phosphorylation motifs. Like the corals studied by Theodor,[430] a high level of allele diversity was found at the alr2 level as nearly all sampled alleles encoded unique gene products.[431]

Urochordates

Compared to *Cnidaria*, tunicates shared a recent common ancestor with the vertebrates (see Fig. 4.1), and thus might be expected to have a histocompatibility system more related to MHC. Allorecognition has been studied in both colonial and solitary ascidians. In *Botryllus*, a colonial ascidian, extra attention was afforded this system because the locus controlling histocompatibility was linked to (or was the same locus as) the locus controlling fertilization by preventing self-fertilization. For fusion, at least one histocompatibility locus must be shared between the colonies and for fertilization the sperm must be mismatched from the egg.[432]

Metamorphosis in *Botryllus* is followed by budding that eventually gives rise to a large colony of asexually derived genetically identical individuals (zooids), united through a vascular network. At the periphery of the colony, the vasculature ends in ampullae, which are the sites of interaction when two colonies meet during their expansion. The interaction results in either fusion of the two ampullae to form a single chimeric colony sharing a common blood supply or a rejection reaction during which the interacting ampullae are destroyed, thus preventing vascular fusion. Hemocytes (morula cells) are involved in the reaction.[433] Fusion or rejection is governed by a single highly polymorphic (tens to hundreds of alleles) locus called the FuHC (for fusion/histocompatibility; 10 wild-type individuals collected from around the Monterey Bay area yielded 18 cFuHC alleles). As mentioned, when two colonies share one or both FuHC alleles, they will fuse; rejection occurs if no alleles are in common. However, like in *Hydractinia*, intermediary pathways have been reported in the past and have not been entirely elucidated.

The C-terminal region of the FuHC molecule consists of a nectin-like segment with three Ig domains, showing most similarity to chicken Igsf4 and related members conserved in all vertebrates as well as to one of the *Ciona* nectins.[434] Those members are found in a tetrad of paralogs in vertebrates but not linked to the tetrad of MHC paralogs (see the following). The N-terminal region contains an epidermal growth factor (EGF) domain and some other unrecognizable regions not conserved among ascidians. Any two FuHC alleles differ by an average of 4% at the nucleotide level. Unlike MHC class I and class II, polymorphic residues in FuHC alleles are not concentrated in particular regions, and alternative splicing can generate a fragment devoid of the IgSF moiety.

Some[200] kb away from FuHC is a second polymorphic (and polygenic) locus, *fester*, which is inherited in distinct haplotypes.[435] Diversified through extensive alternative splicing, with each individual expressing a unique repertoire of splice forms (each individual expressing up to three splice variants in addition to the regular full-length product), it potentially exists as both membrane-bound and secreted forms, all expressed in tissues intimately associated with histocompatibility. After *fester* knockdown, the histocompatibility reaction is blocked at the stage of initiation as

if the colonies ignored each other. By contrast, when Fester was blocked with specific mAbs, fusion reactions were unaffected, but rejection reactions were turned into fusions in an allele-dependent manner. These data combined with its genetic location suggest that Fester encodes the FuHC ligand. Fester contains a short consensus repeat (or sushi domain) often found in vertebrate complement receptors. Beside these two polymorphic products, another *Botryllus* cell surface-expressed nonpolymorphic molecule related to fester, uncle fester, is required for incompatibility reactions, while fester seems to be required for allele discrimination and inhibition of killing.[436] So, several independent pathways seem to control the final outcome of the interaction between individuals.[437] It should be mentioned that a recent study, based essentially on the incongruence between histocompatibiity profiles and FuHC polymorphism, questions the validity of these reports.[438]

Solitary Ascidians

In *Halocynthia roretzi*, a "polymorphism of color" has been observed and histocompatibility reset by a mixed hemocyte technique in vitro resulting in a melanization reaction likely to involve the PPO cascade.[439] Depending on the strains, the percentage of positive reaction varied from approximately 55% to 70%, indicative of polymorphism. Grafting experiments had already shown the existence of allorecognition in solitary ascidians, and investigation at the cellular level had demonstrated the occurrence of cytotoxic cells in such organisms.[440] In order to shed light on allorecognition in urochordates and on the molecules involved in preventing self-fertilization, gonadal complementary DNAs of three genetically unrelated *Ciona intestinalis* individuals were compared by suppression subtractive hybridization. This led to the discovery of the highly polymorphic variable complement receptor-like 1 gene coding for a transmembrane protein with several short consensus repeat domains (short consensus repeat/complement control protein [CCP]), a motif shared with the variable fester receptor of *Botryllus* described previously.[441] Genes encoding variable complement receptor-like are in the same linkage group as a set of IgSF domains with homology to nectin (CD155/poliovirus receptor [PVR], cortical thymocyte protein [CTX]/junctional-adhesion molecule [JAM] family members, etc.) and other adhesion molecules of which related members can be found also on one genetic region in vertebrate, the 19q 34 human chromosome segment with the extended LRC (see the following).[442]

The Meaning of Histocompatibility Reactions in the Invertebrates

The association between allorecognition in *Botryllus* and fertilization led to the proposal that histocompatibility systems were selected during evolution to avoid inbreeding. The hypothesis made sense in the case of sessile colonial invertebrates that might have difficulty

dispersing their gametes and therefore are susceptible to inbreeding depression. Indeed, the partial matching mentioned previously is a general characteristic of fusion compatibility in colonial invertebrates, perhaps driven by “selection operating on an error-prone genetic system for self-recognition that is perhaps constrained by derivation from a gametic function selected to reduce inbreeding.[443] Furthermore, even in mammals there is a large literature suggesting a selection both at the mate-choice and pregnancy levels for preserving heterozygocity at the MHC.[443a] However, the possibility of a common genetic system, or linked systems, governing fusion and gametic compatibility awaits confirmation. Because animals that are neither sessile nor unable to disperse their gametes can possess alloimmune responses is inconsistent with the general hypothesis. Moreover, inbreeding avoidance can only explain the selection of histocompatibility alleles if the histocompatibility loci are genetically linked to a large fraction of its genome. This is inconsistent with the tight linkage of histocompatibility genes to a single major locus, especially in invertebrates. So inbreeding avoidance is unlikely to contribute significantly to the selection of histocompatibility alleles, although in jawed vertebrates, selection for heterozygocity at the MHC itself has obvious advantages.

Another hypothesis is that alloimmunity was selected because it avoided intraspecific parasitism and/or competition for attachment sites.[444] Indeed, after fusion of compatible colonies, bloodborne germline or totipotent stem cells are transferred between colonies, and can expand and differentiate in the newly arising, asexually derived individuals of the vascular partner.[445] This can result in a situation where only one genotype is represented in the gametic output of the fused individuals. The FuHC polymorphism in *Botryllus* could function to restrict to compatible individuals the vascular fusion and the germline parasitism. The high allelic polymorphism characteristic of all invertebrate recognition systems may have evolved in response to selection for fusion with self rather than kin. Fusion with self will allow the development of a colony that benefits from fusion while eliminating the possible cost of somatic cell parasitism, and thus would be the raison d'etre of the allorecognition mechanisms.[446]

However, most animals are not sessile and thus are neither prone to intraspecific competition nor to compete for limited substrate attachment sites. Tunicates besides *Botryllus* have evolved differently (eg, in *Diplosoma*, large numbers of chimaeras are encountered in nature). In addition, the intraspecific competition hypothesis demands that individuals maintain expression of histocompatibility alleles, even when the expression of these alleles enables their own destruction during intraspecific competition. These considerations suggest that intraspecific competition might affect histocompatibility allele frequencies in some organisms under certain conditions.

Both previous hypotheses are essentially based on observation made in colonial tunicates, but colonial living has evolved several times independently. Urochordates are most related to the vertebrates, but the data argue against any of the genes involved in their histocompatibility reactions being ancestral to MHC class I and class II. It is clear in all of these studies that a strong pressure for polymorphism is the rule, but the evidence from all of these fascinating

reactions suggests that such “pressures” select for similar systems via convergence, at least

at the level of the receptor. The selecting molecular environment can perhaps show more conservation (see the folllowing). On the other hand, as described previously, genetic regions with homology to the vertebrate MHC have been detected in the invertebrates, yet are (most likely) unrelated to the reactions detailed here (see conclusion).

As described, in all of these allorecognition systems, convergent mechanisms have been encountered to reach an analogous end, and thus it is unlikely that a unique "cause" arose for selecting them in diverse organisms. However, in an attempt to find an ultimate and general explanation to the selection during evolution of highly polymorphic allorecognition systems, it has been suggested that pathogen and retroviruses are the force behind the selection of allopolymorphism.[447] This does not imply intimate phylogenetic relationships between the systems observed but rather emphasizes analogous solutions when facing similar pressures. We discuss "connections" between vertebrate immunity and these histocompatibility reactions in the conclusion.

CYTOKINES AND CHEMOKINES

Many cytokines/chemokines and their receptors, like most molecules of the immune system, evolve rapidly. However, consistent with the "Big Bang" theory, it is an emerging picture that the majority of cytokines and chemokines found in mouse and human are also found in the genome and EST projects of nonmammalian jawed vertebrates, best studied in chickens and certain bony fish, but now extending to the cartilaginous fish as well. This suggests that whatever the initiating pressures in the evolution of the Ig/TCR adaptive immune system, the network of cytokines and chemokines emerged (practically) full blown early in evolution. A picture starts to emerge, but the gestalt is far from clear; this is, in part, because the situation in mouse human is clouded by the plasticity of T helper cell lineages, as well as an entirely new subset of immune cells, the innate lymphoid cells (ILCs), that produce cytokines previously thought to be within the domain of adaptive lymphocytes.

The Proinflammatory Cytokines, Interleukin-1 Family Members, Interleukin-6, Interleukin-8, and Tumor Necrosis Factor α

IL-1 and related family members IL-18 and IL-33, IL-6, TNF-α, and IL-8 (CXCL8) are the prototypic cytokines associated with inflammatory responses, which are defined by induction of vasodilatation and vascular permeability, and upregulation of innate immune system-specific molecules that have direct functions or that costimulate/attract T and B cells. Classically, many of these activities can be assayed in supernatants from PAMP (eg, LPS)-stimulated phagocytes by determining whether thymocytes are induced to proliferate when one also adds suboptimal concentrations of T-cell mitogens. It was reasonable to hypothesize that such cytokines, which act both at a distance as well as in a cognate fashion, might be found in the invertebrates. Indeed, IL*-1-like *activities* have been described for echinoderm coelomocytes (either IL-1-like production by such cells, or the ability of the cells to respond to mammalian IL-1), but unfortunately no molecular data revealing the structures of the active invertebrate cytokine/cytokine receptor have been reported. In fact, no ortholog has been detected in the genome projects from protostomic invertebrates (see Fig. 4.1), and only IL-17 and TNF homologues have been detected in nonvertebrate deuterostomes and protostomes,[48,448,449] and IL-8 in agnathans; thus, we may consider these as primordial cytokines related to the vertebrate versions. A molecule from earthworms capable of activating the prophenoloxidase defense pathway cross-reacted with a mAb directed to

mammalian TNF-α.[450] However, this molecule had no homology to TNF-α upon sequencing.

IL-1 activity as measured by costimulation assays or as a consequence of PAMP stimulation has been detected in all nonmammalian vertebrates. IL-1β upregulation has been detected after treatment of macrophages with LPS, consistent with its inflammatory function in mammals. In addition, injection of gram-negative bacteria into trout induced IL-1β expression in many tissues.[451] Identity with the mammalian IL-1β gene in all other species ranges from 28% to 40% (identity between mammalian IL-1α and IL-1β is about 25%). In nonmammalian species, IL-1β lacks the so-called ICE cleavage site, important for function in mouse/human.[452] IL-18 is an IL-1-related cytokine, and in contrast to IL-1 seems more focused in its function of potentiating TH1 responses. IL-18 has been detected in birds and fish, but the tissue distribution in fish seems to be expanded as compared to mammals. Additionally, IL-18 in nonmammalian vertebrates contains the ICE cleavage site, unlike its cousin IL-1β. Other IL-1-related cytokines, including IL-33 and the IL-1F series, have also been found in several jawed vertebrates, but with little study of functional activity. This will be of great interest to uncover, considering the IL-1 family members' roles in regulating Th1, Th2, and Th17 (and others?) differentiation.[453]

Both chicken IL-1β and the IL-1R were identified and have been expressed as recombinant proteins.[454] The IL-1R homology to mammalian orthologs is quite high (61% identity), but the highest similarity is found in the cytoplasmic domains. In addition, there are four blocks of high similarity to the cytoplasmic tail of toll/TLR proteins, and IL-1R and TLR use similar signal transduction cascades (see previous discussion).

As mentioned, IL-8 (actually, the CXC chemokine CXCL8) has been identified in the jawless lamprey and seems to be expressed specifically in B cells, whereas the IL-8 receptor is found in T cells; this has been one of the mechanisms proposed to permit the cells to interact in a cognate fashion.[13,291] IL-8 has also been found in various gnathostomes such as trout, flounder, and perhaps chicken; a chicken CXC chemokine called K60 clusters with IL-8 in phylogenetic trees and is upregulated in macrophages stimulated with LPS, IL-1β, and IFN. Interestingly, Marek disease virus expresses an IL-8 homologue (v-IL-8), which may be

involved in inducing immune deviation.[455] A molecule related to the IL-R was detected in the sea urchin genome, but the ligand has not been found[48]; becuase there are so many members of the IL-1 family, the search should continue.

The TNF family in mammals includes the canonical TNF-α, lymphotoxin (LT)α, and LTβ, all encoded at the distal end of the MHC class III region,[403] as well as a large number of other members with diverse immune functions. TNF-α is the best studied of these cytokines, and it is one of the key regulators of innate and adaptive immunity. The other two cytokines have a more limited tissue distribution and function, and are noted in their roles in lymphoid tissue development, especially in the formation of splenic white pulp and segregation of T and B cells in lymph nodes. In contrast to IL-1, TNF homologues have been detected in cnidarians, protostomes (see previous discussion), sea urchin,[48] *Ciona*,[448] and *Amphioxus*,[456] consistent with the idea that such a multifunctional cytokine would predate the jawed vertebrate adaptive immune system. Homologues have also been cloned from several teleost

species, and TNF-α expression in leukocytes is upregulated within 4 hours after treatment with LPS, IL-1β, and PMA. While there is good phylogenetic support for orthology of fish TNF-α to that of mammals, the other TNF genes seem to be teleost-specific duplicates rather than the LT genes.[457] Conversely, in *Xenopus*, the three TNF family members described previously in mammals are closely linked in the class III region of the MHC.[177] This is a bit of a surprising result as all of these family members seem to be lacking in chickens, consistent (according to the authors) with a lack of lymph nodes in these animals; however, the unusual nature of the MHC in birds (eg, the immunoproteasome genes are missing) rather is consistent with a loss of TNF genes in these animals, which is indeed surprising, especially for TNF-α.[458]

An excellent review detailing the evolution of all TNF and TNF receptor family members demonstrated that all of the genes are found in paralogs on four chromosomes, consistent with the 2R hypothesis. This work demonstrated that the earliest member was linked to the proto MHC, and thus it is not surprising that TNF is an ancient gene family.[459]

IL-6 and its related members IL-11 and IL-31 are also found in most gnathostomes examined, with few functional data.

Interleukin-2 and the γC Family of Cytokines

The family of cytokines that signals through the γC receptor includes IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. Similar to what was described for most molecules involved in adaptive immunity, all of these cytokines (except perhaps IL-9) are present in all gnathostomes studied.[460] Costimulation assays of thymocytes, as described previously for IL-1, and perpetuation of T-cell lines with stimulated T-cell supernatants are performed to detect IL-2 or "T-cell growth factor" activities. Unlike IL-1, IL-2-like factors generally stimulate cells only from the same species, and it is a "cognate" cytokine, meant for release only between closely opposed cells, or as an autocrine factor. From teleost fish to mammals, stimulated T-cell supernatants costimulate thymocyte proliferation or can maintain the growth of T-cell blasts, and the ortholog has been detected in bony fish and birds. The chicken IL-2 protein is only 24% identical to human IL-2 and only 70% identical to a near cousin, the turkey.[454] IL-15, a relative of IL-2, has also been cloned in the chicken. A candidate IL-2R in chicken was identified by a mAb recognizing a 50-kDa molecule only on stimulated T-cells (thus an IL-2Rα homologue). This mAb blocks costimulation by IL-2-like molecules in chicken T-cell supernatants and also reduces the capacity of T-cell blasts to absorb IL-2-like activity from supernatants. IL-2 has been studied in the bony fish *Fugu*. In both chicken and the deduced *Fugu* IL-2 protein, there is a second set of cysteine residues, which are found in IL-15 and thus is a primordial feature.[461]

As mentioned, γC is the signaling subunit of the IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 receptors; absence of this chain in mammals leads to major defects in lymphocyte development ("boy in the bubble"). In fish, a γC homologue was cloned in rainbow trout with unusually high identity (44% to 46%) to mouse/human genes.[462] IL-1β, but not LPS, upregulated the trout gene in macrophage cultures and a fibroblast cell line. Since then, many other orthologs have been uncovered in fish, often duplicated in various species.[460]

IL-21, which is encoded adjacent to IL-2 in mammals, has been found in ectothermic

vertebrates.[460] Because one of its major functions is the differentiation of T-follicular cells and the GC response, it will be of interest to study it role in those animals.

IL-7 is involved in lymphocyte differentiation as well as homeostasis of mature lymphocytes. Recently, mutations in Il-7R and downstream signaling molecules in the zebrafish have shown a block in T-cell development.[463] These mutants will permit future study of lymphocyte production in this crucial developmental model.

TH2 Cytokines: Interleukin-4, Interleukin-5, Interleukin-9, and Interleukin-13

Reponses to extracellular pathogens, especially filarial worms, are largely regulated by TH2 cytokines in mammals. IL-4 is the most pleiotropic cytokine in this regard, stimulating the production of neutralizing antibodies, stimulation of eosinophils and mast cells, and an antagonism of TH1 responses. IL-4, IL-5, and IL-13 (and granulocyte macrophage colony-stimulating factor) are encoded in the so-called TH2 cytokine complex in mammals, and all of the genes are coordinately upregulated after stimulation of a nearby locus-control region. This same "TH2 complex" is found in chickens but with a psuedogene for IL-5, but in *Xenopus* only the IL-4 gene has been identified to date. Fish have genes in which the ancestor of IL-4 and IL-13 seems to be in a preduplicated state, syntenic with genes in the TH2 complex.[464] Again, duplicates of IL-4/-13 and their receptor have been found in various fish.[460,465]

At this stage of study, it may be that lower vertebrates do not have "full-blown" TH2 responses, consistent with the lack of canonical allergic responses in ectothermic vertebrates. On the other hand, we must be careful because cytokine genes evolve rapidly and relying on synteny is not always

dependable, especially in the teleost fish. It will be of interest to see whether IL-4 in nonmammalian vertebrates will promote switching to isotypes that are incapable of promoting inflammatory responses. In addition, further studies of this family and its receptors in teleost and cartilaginous fish will reveal whether this facet of the adaptive immune response is indeed a relative newcomer.

Interferons

IFNs, classically known for their antiviral properties, are divided into three groups: type I, type II, and type III. Perhaps surprisingly, this entire group has only been uncovered in jawed vertebrates to date. However, as described previously, viral immunity in insects is partially regulated via a JAK/STAT response.[152] Types I (α and β) and III (λ) IFN are widely expressed in cells of many types and induces inhibition of viral replication in neighboring cells, as well as molecules of the innate immune system such as inducible nitric oxide synthase (iNOS) and IFN regulatory factor-1.[466] In contrast, type II IFN (IFNγ or immune IFN) is synthesized by activated T cells, activates macrophages, and upregulates class I, class II, immune proteasome subunits, and TAP, and a large number of other genes.

Antiviral activity is detected in supernatants from virally infected fish fibroblasts, epithelial cell lines, and leukocytes. All of the biochemical properties of mammalian type I IFN (eg, acid-stable, temperature-resistant) are present in these fish supernatants, and the putative IFN

reduces viral cytopathic effects in homologous cell lines infected with virus.[466] In vivo, passive transfer of serum from virally infected fish protects naïve fish from acute viral pathogenesis. There appears to be two lineages of type I IFNs in fish that are specific to this group. In chickens there are up to 10 closely related, intronless type I IFN genes.[455] Sequence identity to human type I IFN ranges from 25% to 80%, with the apparent functional gene having highest similarity. Interestingly, bats have greatly expanded their type I and III IFN genes and receptors (as well as many other genes associated with viral immunity).[467] These animals are highly infected with (and susceptible to) virus, and some IFN forms are constitutively expressed at low levels.

While type I/III IFNs can be highly duplicated in some vertebrates, this is not true of IFN receptors, and in some cases many cytokines will used two to four receptors within a species. How can such a system work and result in different readouts? It appears that even single amino acid changes in the cytokine can induce differential conformational changes in the receptor that can modify downstream signaling.[468] This paradigm will be exciting to follow in a phylogenetic context.

Type II or IFNγ has been cloned in most jawed vertebrates. The chicken gene is 35% identical to human type II IFN and only 15% identical to chicken type I IFN.[454,469] Recombinant chicken IFN stimulates nitric oxide production and class II expression by macrophages. The gene has been cloned in many fish, and has been studied mostly in the trout where it has been shown to upregulate CXCL10 and activate protein kinase C. Thus, at least in chickens and teleost fish, type II IFN seems to have the same function as in mammals, suggesting that the TH1-type responses emerged early in vertebrate evolution.[466]

Heterodimeric Cytokines

The IL-12 family are composed of heterodimers that share chains (p19, p40, p35, and EB13) and include IL-12, IL-23, IL-27, and IL-35. IL-12 is generally considered to be a proinflammatory cytokine produced by APCs that promotes a TH1 response after exposure to intracellular pathogens. Consistent with the ancient derivation of TH1 responses, the two subunits of IL-12 p70 (p35 and p40) have been found in chickens and several teleost species.[454,470] The p40 subunit of IL-12 can also associate with p19 to form the cytokine IL23, which is involved in the perpetuation of TH17 cells. IL-27 generally inhibits all TH subsets but expands regulatory T cells and is composed of p28 and EB13; IL-35 is a relatively new regulatory T-produced cytokine composed of p35 and EB13. All of these chains have been detected in gnathostomes and several studies have been done to examine their expression at the RNA level; however, to date no reagents have been prepared to the heterodimers for functional analysis.

Transforming Growth Factor-β and Interleukin-10

TGF forms a large family with pleiotropic effects in many developmental systems. For the immune system, TGF-β isoforms are best known for their capacity to suppress adaptive immune responses (even across species barriers), although they can also stimulate lymphocytes under certain conditions, especially in mucosal surfaces. TGF-β inhibits macrophage activation in trout and growth of T-cell lines in *Xenopus* species. Recombinant *Xenopus* TGF-β, like the mammalian form, also can inhibit IL-2-like dependent growth of

splenic lymphoblasts.[471] Four TGF-β isoforms were isolated from chickens, as opposed to three major forms in mammals.[455] The three major forms of the cytokine have been isolated in several teleost species.[470]

IL-10 is often considered along with TGF-β because it is mostly an immunosuppressive cytokine with multiple effects; both cytokines are expressed in subsets of "regulatory T" cells in mammals. This cytokine was originally discovered by its ability to suppress TH1 responses, but now is known to have a much expanded role in immunity. IL-10 has been found in chickens and a large number of teleosts.[455,470] As usual, functional experiments have lagged behind the molecular work, but recombinant chicken IL-10 can block IFNγ production by splenocytes. IL-10 is a class II cytokine, related to IFNγ, IL-19, IL-20, IL-24, and IL-26. IL-22, a cytokine released by TH17 cells and ILCs in mammals, is upregulated in fish vaccinated with pathogens and is correlated with immune protection.[472]

Note that there have been very few "regulatory T" experiments reported in the comparative literature, but many older experiments that suggest that such cells exist. Over 25 years ago, experiments in *Xenopus* showed that graft rejection could be delayed when lymphocytes from metamorphosing animals were adoptively transferred into adult frogs.[473] This

result suggested that a "wave" of suppressor cells emerged near the time of metamorphosis that evolved to protect animals from autoimmunity when adult-specific molecules were expressed. It is time to reexamine such experiments with modern tools. In a recent experiment in zebrafish, immunization of animals with central nervous system (CNS) antigens induced an autoimmune reaction. Overproduction of foxp3 inhibited the production of IL-17 and IFNγ in these animals, ameliorating the disease.[474]

Interleukin-17

TH17 cells in mammals are important for inflammatory responses to extracellular bacteria via indirect stimulation of neutrophils. Despite its late appearance in the immunologic literature, IL-17 appears to be one of the most ancient cytokines, with homologues in protostomes and lower deuterostomes, and extensively amplified in sea urchins. Even the different isoforms seem to be conserved among the jawed vertebrates, which should initiate many new avenues of study.[470] The family is composed of IL-17A/F, with the A and F forms being the best studied to date. IL-17A/F genes have been found in all mammals studied, as well as IL-17C/E. The most ancient IL-17 form is IL-17D, present in both oysters and agnathans.[291,449] This form is expressed in lamprey T cells but not B cells, and has been proposed as a helper factor for cognate interactions.[13] Finally, like many other immune genes, as many as 20 IL-17 genes have been found in sea urchins, again suggesting expanded innate immunity in this species.[475]

Cytokine Summary

The isolation of nonmammalian cytokines and cytokine receptor genes has lagged behind molecular characterization of antigen receptors and MHC. However, with the advent of the genome and EST projects, we are rapidly acquiring a comparative view of this field, at least at the genetic and molecular level. Teleost fish and chickens have paved the way in this field,

but cartilaginous fish and agnathan databases will soon be complete and provide the big picture. Already, it seems that cytokines like TNF and IL-17 seem to be most primordial, with homologues in *Ciona*, *Amphioxus*, and sea urchins, as well as deeper homologues in certain protostomes. Conversely, *none* of the other so-called adaptive cytokines (or even type I/III IFNs) seem to be present in the lower deuterostomes, consistent with the Big Bang theory of adaptive immunity.[1,2] If it is true that the jawless fish lack these genes as well, despite their convergent adaptive immune system, one can point to the evolution of lymphoid organs and the segregation of lymphocyte subsets into discrete areas to help to explain the explosion and recruitment of these genes. We discuss this concept in more detail in the conclusion section, especially regarding the relationship of adaptive lymphocytes with ILCs.

Despite our "big picture" knowledge of the emergence of cytokines, obviously functional experiments have lagged behind. Furthermore, is it true that TH2 responses are evolutionary latecomers, or are our early attempts at finding the genes in ectotherms because of some "missing pieces" in the databases (or our ability to find some of the genes)? Some genes may have been lost, as described previously for the chicken—again, further studies of amphibians and cartilaginous fish should help in our understanding. In mammals, the LT TNF family members are important in the development of lymph nodes and splenic white pulp, and yet the three genes are present in lymph node-less *Xenopus* —what are their functions in ectotherms? If we can uncover these other roles in nonmammalian vertebrates, it could be quite informative to reinvestigate such functions in mammals. Finally, chickens and fish have evolved their own paralogs of some of the well-known cytokine genes; their study should reveal selection pressures on particular species that could also be quite informative in our understanding of the gestalt of the cytokine network.

General Evolution of Chemokines and Their Receptors

Chemokines and chemokine receptors are essential for many aspects of the immune system, including inflammation, the differentiation of lymphoid tissues, trafficking of hematopoietic cells during ontogeny and immune responses, and even stimulation of cells under various conditions.[476] With the advent of the genome and EST projects, a seminal paper showed that, consistent with the Big Bang theory of adaptive immune system evolution, all of the major classes of chemokines and their receptors were present in the bony fish lineage, and probably will be found in cartilaginous fish as well when the genomes are completed.[477] Recently, the analysis was updated to include all of the vertebrates in the databases.[476] Similar to most of the immune-related genes discussed throughout the chapter, bony fish have more chemokines/receptors than any other vertebrate, including amphibians and mammals.

Interestingly, no CC (so-called homeostatic) or CXC (so-called inflammatory) chemokines/receptors were detected in lower deuterostomes like *Ciona* and sea urchin. The chemokine receptors are member so the G protein-coupled receptor family, and of course such molecules are found in all animals. However, no members of the specialized family (G protein-coupled receptor γ) to which chemokine receptors belong were found in lower deuterostomes. The chemokine receptor genes are found on four chromosomes in mammals, four of which contain the HOX genes, one of the gene families that provided evidence for the 2R hypothesis early in the reawakening of this theory. The distribution of chemokine receptor genes on these chromosomes correlates very well with 2R, and helps to account for the

large-scale gene expansion of this family in the jawed vertebrates. Thus far, very few chemokines/receptors (eg, IL-8 [CXCL8] and CXCR4) have been detected in agnathans, but as mentioned previously, agnathan T cells express IL-8R and B cells IL-8, believed to be a factor in promoting the cognate interactions between the cells.[291] CXCL12, a chemokine vital for thymic differentiation, is also present in lamprey, consistent with new work on the agnathan thymus discussed previously.[375] In summary, it appears that a few chemokines/receptors arose at the dawn of vertebrate adaptive immunity, and they

were greatly expanded by both en bloc and *cis* duplications and became "full-blown" shortly after the 2R Big Bang.[476] Currently, this is our most complete story of the evolution of a family of immune genes in deuterostomes.

ORIGINS OF ADAPTIVE IMMUNITY

The immune system of vertebrates is unique because the antigen-specific receptor expressed by lymphocytes, which initiates cascades leading to activation of the adaptive immune system, is not the product of a complete germline-inherited gene. Rather, receptors are generated somatically during lymphocyte ontogeny from gene segments scattered at a particular locus. As described previously, the receptors in gnathostomes are IgSF members composed of V and C domains, with the C domains being of the rare "C1" type, which is shared by MHC class II and class I molecules. There are many specific questions: 1) Did MHC class I or class II come first?; 2) What is the origin of the MHC PBR?; 3) Was the MHC involved with innate immunity before the emergence of adaptive immunity?; 4) Did somatic rearrangement or somatic mutation come first to diversify antigen receptors?; 5) Which of the extant antigen receptors in gnathostomes, α/β TCR, γ/δ TCR, or IgH/L (if any) resembles the primordial receptor?; and 6) How did two different antigen receptor gene families emerge in evolution, *after* the appearance of separate lymphocyte populations? The answers to these questions are speculative, but deductions can be made based upon the wealth of molecular and emerging functional data. We base many of our arguments on the large-scale duplications that were revealed for MHC by Kasahara[17] in 1996. The remarkable syntenies of paucicopy genes on the paralogous regions, and the recent finding that an animal that predated the duplications (*Amphioxus* and *Ciona*) has only single copy genes in the same syntenic group orthologous to the four mammalian copies, make it clear the en bloc duplications were involved.[405,421] Further analysis of this region in model lower deuterostomes, as described in the histocompatibility section, will continue to be vital in our understanding of early immunity. Genetic analyses in protostome lineages have not been very informative, but we must reevaluate once we piece together data from more deuterostome species.

Major Histocompatibility Complex Origins

Class I and class II molecules have been found only on the jawed vertebrates—so far, painstaking screenings of the lower deuterostome or lamprey/hagfish databases have yielded no indication of these proteins. Based upon phylogenetic analyses and thermodynamic arguments, most investigators believe that class II preceded class I in evolution.[478] However, as stated previously, class I is much more plastic than class II as there are many different types of class I molecules, some that do not even bind to peptides. Because class I genes

may be on two or three MHC paralogs, and they can have functions outside the immune system; this is evidence that the primordial "PBR" may not have even bound to anything. If this is true, and because class I and class II do bind peptides, it would suggest class I arose first. Again, genome scans of jawless fish and lower deuterostomes should be informative on this point, but to date no luck! As described previously, we should be diligent because with the discovery of T cells and a thymus-like structure in lamprey, one expects some sort of "MHC" in the agnathans[291,375]; to date, the only homologue we have uncovered to date is TAP-L, which may hold the key to antigen presentation in this group.[401]

From the paralog data, genes encoding the complement components C3 and Bf, TNF superfamily members, the signaling molecule Vav, B7 family members, and proteasome subunits among other genes (such as tripartite motifcontaining) should have been present in the proto-MHC, before emergence of the adaptive immune system (see Fig. 4.13). Some of these genes were found in the *Amphioxus* and *Ciona* "MHC" linkage groups, and C3 and Bf genes are linked in the sea urchin. A fifth paralogous region on human chr 12p13 contains the α2-macroglobulin gene (recall the C3/4/5 homologue), a tapasin homologue, the C3areceptor, and this "complex" is linked to the NKC. Taken together, the data suggest that the proto-MHC included vital nonhomologous genes of the innate immune system, which perhaps were linked to allow coordinate regulation of expression. After the en bloc duplications, Pontarotti et al. has suggested that "functional restraints upon the complex were relaxed" and hence the duplicated members could evolve new functions, including features indispensable to the adaptive system.[405] If indeed innate immunity genes were already linked to allow upregulation at times of infection, it is no surprise that the adaptive immune system piggybacked on such a gene complex. A final point: why did the duplicate genes survive rather well over hundreds of millions of years; *cis* duplicates have been shown to degenerate rapidly over evolutionary time. Evidence suggests that duplicates arising from polyploidy (and by inference large en bloc duplications) survive better than *cis* duplicates, most likely because they cannot be inactivated by unequal crossovers; the ability of the genes to survive over very long periods, perhaps combined with strong selection pressures, would allow for subspecialization.[479]

Origins of Rearranging Receptors

The Rearranging Machinery

Most models propose that the generation of somatically rearranging receptors occurred abruptly in evolution via the generation of the RAG machinery made of two lymphocytespecific proteins, RAG1 and RAG2. *RAG* genes have so far been isolated in all classes of jawed vertebrates and have been quite conserved. In every case examined, *RAG1* and *RAG2* genes are closely linked and in opposite transcriptional orientation. Some regions of RAG1 and RAG2 are similar to bacterial recombinases or to molecules involved in DNA repair (eg, RAD16) or the regulation of gene expression (such as rpt-1r). Similarities to prokaryotic proteins and the gene structure suggest that vertebrates acquired the RAG machinery by horizontal transfer and transposition from bacteria.[19,480] Indeed, *RAG* genetic organization has

some transposon characteristics: the RSS are reminiscent of sequences involved in targeting

excision of transposons. A class of transposons detected in several protostome and deuterostome invertebrate species that shows similarity to the catalytic domain of RAG1.[481] It is believed that RSS were derived from the terminal inverted repeats of this transposon, called *transib*. In invertebrate genomes there are many of such "RAG1 core regions," but only one has an open reading frame throughout the core and shows similarity to vertebrate RAG1 in other regions as well. Furthermore, a *RAG2* homologue is adjacent to the urchin *RAG1* gene, in a similar orientation as is found in gnathostomes.[352] This finding was a big surprise and suggests that both *RAG* genes were in place approximaltey 100 million years before the origin of the Ig/TCR system. Their tissue distribution and expression during ontogeny are not known; nor have any candidate genes been recognized to date with RSS that might be recognized by the echinoderm homologues. It must be admitted that it is unclear how this new result fits into the puzzle of the origins of adaptive immunity. Because transib is so often found in the animal kingdom, it is certainly part of the transposon. By contrast, RAG2 is now believed to have been present in the genome, and recent data have shown it to interact with active chromatin.[482,483] Thus, the new idea is that RAG2 recruits RAG1 to open chromatin, and rag1 is the active enzyme in the major rearrangement events, which is wholly consistent with the transposon hypothesis with RAG1 (ie, transib) being the genome "invader."

Another source of somatic antigen receptor diversity shared by all gnathostomes characterized to date is a unique DNA polymerase, TdT, which diversifies CDR3 during Ig and TCR gene rearrangement through the addition of nucleotides in a template-independent fashion.[484] Furthermore, as detailed previously, its expression serves as an unambiguous developmental marker for the sites of lymphopoiesis. TdT has been highly conserved in both sequence (> 70% amino acid similarity, > 50 amino acid identity) and overall structure during vertebrate evolution. An amino acid alignment of all known TdT sequences reveals that some, but not all, structural motifs believed to be critical for TdT activity are particularly well conserved in all vertebrates studied. TdT protein alignments, and the crystal structure for rat β-polymerase, support the hypothesis that both evolved from a common ancestral DNA repair gene. In addition, four protein kinase C phosphorylation sites are conserved, and hence may be involved in TdT regulation. Homologues related to the ancestor of polymerase β and TdT have been found in sea urchin and other lower deuterostomes. Thus, unlike RAG, TdT has evolved by gradual evolution from a polymerase family and was recruited for immune system function.

Rearrangement or Somatic Hypermutation First?

Because all antigen receptor genes use somatic rearrangement of V genes to generate diversity in CDR3 regions as well as to promote combinatorial diversity, there is no doubt that this mechanism is at the heart of adaptive immunity. Indeed, as described, most investigators believe that the introduction of the tranposable element into a V gene was *the* driving force in the abrupt appearance of vertebrate adaptive immunity; the finding of the RAG genes in sea urchins challenges this notion at some level. However, it cannot be overemphasized that SHM is also at the origins of the immune system; furthermore, all evidence to date suggests a gradual evolution of the SHM machinery (the AID/APOBEC family and associated polymerases/mismatch repair proteins) rather than the "hopeful monster" generated by the famous RAG transposon. Thus, diversity generated via SHM or gene conversion may have existed in an adaptive immune system prior to rearrangement, and V gene rearrangement

was superimposed onto this already existing system.[296,300] Indeed, the presence of APOBEC family members in the jawless fish (CDA1 and CDA2, as described previously) suggest that diversity generated via mutation/conversion preceded rearrangement. The RAG-induced rearrangement break and subsequent repair provided something new and novel in gnathostomes, not only diversity in sequence but heterogeneity in size[300]; this was a remarkable innovation and likely indeed heralded the sophistication of jawed vertebrate adaptive immunity.

Which Antigen Receptor First? Phylogenetic analyses have suggested that among IgSF receptors γ/δ TCR-like ancestor may have predated α/β TCR and Ig H/L.[485] This would suggest that direct antigen recognition, perhaps by a cell surface receptor, arose first in evolution followed by a secreted molecule and an MHC-restricted one. Hood and colleagues argue that phylogenetic analyses over such large evolutionary distances obscure true relationships among the antigen receptor genes (eg, the relationships of the molecules in the phylogenetic trees has to impose multiple loss/gain of D segments in the different antigen receptor families) and suggest a model based upon genomic organization, not so different from the Kasahara model.[263] They propose an alternative phylogeny in which an ancestral chromosomal region with linked genes encoding both chains of an ancestral antigen receptor heterodimer, one having D segments the other not (eg, IgH/IgL). The α and δ TCR loci are still closely linked in all vertebrates analyzed (human chromosome 14), and a pericentric inversion is suggested to have separated the TCR β and γ loci (linked on human chromosome 7). This model predicts that D segments only emerged once, and also explains the existence of inverted V elements in both the TCR β and δ loci. This model does not predict which antigen receptor is oldest, but does provide a "simple view" of receptor evolution, consistent with the Kasahara/Ohno model. Recent data have added to this scenario. First, as mentioned previously, VH elements have been found at the TCR-δ locus in many vertebrates, including sharks, amphibians, birds, and marsupial mammals.[269] In part, this is due to the close proximity of the IgH/L (lambda) and TCR alpha/delta loci in many living vertebrates (especially *Xenopus*[268]), consistent with the Hood hypothesis of ancient en bloc duplications of antigen receptor loci.[268] Additionally, the idea that most TCR-δ receptors do not recognize MHC-restricted antigen suggests that they can continue to "borrow" elements from Ig loci over evolutionary time.

Thus, an alternative scenario is that MHC-restricted antigen recognition arose first, perhaps derived from a NKR with a "VJ" IgSF domain that recognized SOS proteins, like the ULBPs or MIC today. The rearrangement break induced by

RAG occurs in CDR3, which is in the center of the antigen receptor-combining site, in perfect position to interact with peptide bound to MHC, which could have been another innovation to detect foreign antigens within cells.[486] Thus, such cells would be most like extant αβ T cells with an MHC-restricted antigen receptor encoded by linked genes. Once rearrangement was introduced, the combining site may have been "relaxed" so that it was no longer forced to be MHC-restricted (see the section on TCR above). The genomewide duplication then would provide two types of TCR, one MHC-restricted and the other not, like γδ TCR today. One locus, according to the Hood model, then underwent an en bloc cis duplication to give rise to the IgH/L loci. Ig, then, developed a new differentiation pathway with an alternative splicing

mechanism for the transmembrane and secreted forms of BCRs.

For the origin of the rearranging receptors, IgSF lineages have to be traced back through phylogeny as such receptors generated by somatic rearrangement do not exist outside the jawed vertebrates. In a quest for molecules related to elusive ancestors, without focusing on genes expressed in the immune systems of various phyla (ie, structure is more important than function in this case), the most homologous sequences and gene architectures in the various metazoan phyla must be scrutinized.

V(J) and C1 Domains

C1 domains are found in the antigen receptors, MHC class I and class II, and very few other molecules (see Fig. 4.10). This IgSF domain is so far most prevalent in gnathostomes, as if C1 domains arose concurrently with the adaptive immune system and coevolved with it. What was the value of the C1 domain, and why is it found almost exclusively in adaptive immune system-related molecules? All of these molecules interact with coreceptors such as CD3 (TCR), Igα and β chains (Ig on B cells), CD4, and CD8 (with MHC on opposing cells), and it is conceivable that in sections of IgSF domain in which C1 differs from the C2 there is a specific region favoring interaction with other molecules.

The G strand of Ig/TCR V domains is encoded by the J gene segment, separated from the V region-encoded A-F strands, and rearrangement is necessary in order to assemble a complete V gene. The primary structure of each Ig/TCR chain bears hallmarks of the dimeric nature of the receptor in which they participate. A diglycine bulge (Gly-X-Gly), present in all V domains, is thought either to be a beneficial adaptation, or to promote dimer formation by inducing a twist in the G strand that results in V domain pairing that appropriately orients the CDR. Monitoring this feature, therefore, might reveal genes that had the ability to form dimers similar to that of modern antigen-specific receptors. In V genes that do not somatically rearrange, the G stand is an integral part of the V exon. In other remotely related IgSF genes, introns have invaded the V domain exon creating a variety of V gene families. Many examples of such events can be found in the history of the Ig superfamily, for example in the genes encoding CD8 and CTX.[33,487]

As described, no Ig/TCR genes have been isolated from hagfish or lampreys, although there are some tantalizing molecules potentially related to their ancestors (eg, APAR, see previous discussion). Were Ig and TCR “invented” in a class of vertebrates now extinct (eg, the placoderms, which are more primitive than cartilaginous fish but more advanced than agnathans)? The discovery of the three tapasin paralogs all with C1 domains suggests an origin prior to the full establishment of the vertebrate genome.[33]

V domains, either alone (eg, IgNAR) or in association with another V domain (eg, Ig H/L), recognize the antigenic epitope and are therefore the most important elements for recognition. For this reason, they will be the first to be traced back in metazoan evolution by asking whether V domains exist in invertebrates. Domains with the typical V fold, whether belonging to the true V-set or the I-set, have been found from sponges to insects (although not necessarily involved in immune reactions; the first ones were discovered by nonimmunologists among molecules involved in nervous system differentiation in invertebrates [eg, amalgam, lachesin, and fascicilin]). Invertebrates also use IgSF members in immunity, but so far they are not V domains, but more I- or C2-set (eg, mollusk defense molecule, hemolin, DSCAM). However, the mollusk FREPs have a V domain at their distal

end, associated with a fibrinogen-like domain. As described, they are involved in antiparasitic reactions and form a multigenic family with polymorphism.[135] Similarly, as mentioned previously, prochordate VCBP has a VJ domain, but it mediates innate immunity.[143]

Besides searching for VC1-encoding genes in nonverte-brates, surveying the human genome for such genes has been fruitful. Indeed, nonrearranging V-containing molecules, either VJ alone, VC1, or C1 alone, have been found in the human genome. Interestingly, many of them are present in the MHC class III region (human chromosome 6p21) or its paralogs (see Fig. 4.12 and 4.13). Two MHC-linked gene segments stand out: a single VJ, NKP30, and a gene containing a VJC1 core, tapasin (TAP-binding protein), involved in antigen processing. NKP30, made of a single Ig domain of the VJ type, is an NK cell-activating receptor, and it may offer a link to cell types in invertebrates. It could be a relative of an ancient receptor whose history is linked to the emergence of MHC class II and class I; unlike most NKRs, NKp30 is evolutionarily conserved, present from sharks to mammals.[176] In order to resemble an ancestor, the NKP30 V domain need only be associated with a C1 domain. In fact, a C1 single-domain gene, pre-TCR-α, is also encoded in the MHC.[253] Besides Ig and TCR, tapasin is one of the rare cases, if not the only other case, of a gene segment with a VJC1 structure existing on several paralogous linkage groups (6, 9q33, 19q13). In other words, while this gene is related to the rearranging receptor structure, it is undoubtedly very old, and probably predated the ancient block (genomewide) duplications. It could have acted as a donor of C1 to a V domain-containing gene in the MHC class III region (like the XMIV), which then could have been the first substrate of the rearrangement. Another set of molecules with distal VJC1 segments, the signal-regulatory proteins (VJ C1 C1), and the poliovirus receptor (VJ C1 C2) could represent another group linked to the history of the Ig and TCR (see the following).

TREM1 and TREM2, receptors on monocytes/neutrophils involved in inflammatory responses, are composed of single VJ domains whose genes are MHC-linked. Myelin oligodendrocyte protein (MOG) and P0, two single V domains

involved in the synthesis of myelin sheath, are encoded in the MHC paralogous region on chromosome 1. Chicken BG, which is related to MOG but probably has a different function, is encoded in the chicken MHC. Butyrophilin, CD83, and tapasin all have VJ domains, and butyrophilin also has a C1-type domain. More distant relatives with VJC2-based architectures are also found in MHC (receptor for advanced glycosylation end products, CTX, lectin-related genes; see Fig. 4.12), and some of these genes related to the rearranging receptor ancestors are found on several paralogs (whether the MHC paralogs or other), suggesting that the V-C1 core was generated early in vertebrate evolution subsequent to the emergence of the chordate superphylum (see Fig. 4.13). Among all these molecules, butyrophilin is perhaps not on the direct track to antigen-specific receptors. Its C domain, although proven to be C1 through its crystal structure, is more like a C2 at the primary sequence level, and belongs to the CD80/86 family, rather than the TCR. Finally, tracing the VJ NITR gene family previously described in evolution may lead us to an understanding of the original NKC/LRC/MHC, as well as identifying more candidate genes related to the ancestral gene invaded by the RAG transposon.

Many invertebrate molecules not involved in immune responses are present as a distal V

domain associated with one or more C2-type domains. In the vertebrates many molecules have retained this feature such as CD2 and CTX. Some members resemble “primitive” antigen receptors and several of them map, for instance in humans, to at least two tetrads of paralogous genes, the MHC on chromosomes 1, 6. 9 (12), 19 and the LRC on chromosomes 1, 3, 11, 19 (21) (see Fig. 4.13).[160,442] Many form dimers and are expressed in lymphocytes, where they form a family of adhesion molecules. The crystal structure analysis of a CTX-related molecule (JAM) revealed a unique form of dimerization, suggesting that the diversity of ligand binding and domain-interactions used by different IgSF domain is extensive. Two JAM molecules form a U-shaped dimer with highly complementary interactions between the N-terminal domains. Two salt bridges are formed in a complementary manner by a novel dimerization motif, R (V, I, L) E. The receptor for advanced glycosylation end products gene has a rather “generic” receptor function as it recognizes aged cells exposing particular carbohydrate motifs. CD47, another conserved IgSF member with a CTX-like V domain, suggests an ancient function.[488] Perhaps such nonrearranging VJC1 genes that regulated cytotoxicity/phagocytosis were predecessors of the antigen receptors. Some molecules with VJ/C1 cores involved in cell-cell interactions often serve as ports of entry for viruses. In a move from “property to function,” an arms race consequence could result in a virus receptor developing into an immune receptor. The best examples of such molecules are in the CTX JAM family, in which receptor interactions with viruses may trigger an apoptosis, a primitive form of antiviral immunity.[33,489]

Emergence of T and B Cells

As described previously, agnathans have now been shown to have cells in the T and B lineages, similar to what is found in gnathostomes.[291] Because the jawless and jawed vertebrates have antigen receptors derived from different gene families, at first glance it seemed that the T-B split occurred twice in evolution. However, the gene expression profiles for the lamprey T and B cells are too similar to the patterns in gnathostome lymphocyte populations to be derived by convergent evolution; furthermore, the development of lamprey T cells in a thymus-like structure also suggests evolution from a common ancestor. Thus, it seems most likely that both the LRR and IgSF receptor families were present in the common ancestor,[2,13] with the VLR system predominating early in vertebrate evolution (see Fig. 4.10). Such a scenario exists today with NKRs in mammals, with different gene families (C-type lectin or IgSF) predominating in different species.[12]

Because APOBEC family members are most likely involved in VLR assembly and perhaps in mutation, there may have been a primordial IgSF receptor that was also modified somatically by an AID-like molecule, which functioned side-by-side with VLRs. The rearrangement break caused by the RAG transposon in a primordial IgSF gene offered a great advantage, as was detailed previously, and the IgSF receptors then could have supplanted VLRs in gnathostomes, while maintaining the AID-dependent machinery to diversify it further. It is difficult to imagine how a rearrangement break in an antigen receptor gene generated by LRR insertion could be advantageous; conversely, as mentioned previously, a break in the CDR3 loop in the center of the binding site is in perfect position to interact with peptide bound to MHC. While lampreys have a thymoid for development of their “T cells,” as described previously, there was a great leap in complexity of thymus structure in the gnathostomes, consistent with a new TCR/MHC system in which positive and negative

selection became a requirement for a functioning adaptive immune system. In addition, the general transcriptional and cytokine/chemokine networks for T-cell (and B-cell) development would have also been in place in the jawless vertebrates; in gnathostomes, this network became more complex in the Big Bang (eg, see the chemokine section in which the leap in sophistication can be examined with precision).

In summary, a working hypothesis proposes that the divergence of lymphocytes into T and B cells occurred early in vertebrate evolution (see Fig. 4.10). LRR- and IgSF-based antigen receptors existed simultaneously as well at this time (in the same organism or organisms in the same epoch), with VLR perhaps predominating in early vertebrates. The RAG transposon insertion into an IgSF receptor (perhaps one already diversifying by mutation or conversion), along with a genomewide duplication, resulted in the Ig/TCR/MHC-based system of gnathostomes, with all of its accompanying sophistication in all aspects of adaptive immunity, including development of the thymus and spleen, complexity of cytokine and chemokine networks, and intimate interactions of cells with primary and secondary lymphoid tissues.

CONCLUSION

Since the last edition of *Fundamental Immunology* was published[5] years ago, there have been several astonishing findings, as well as other interesting discoveries and integrations, regarding the evolution of the structure and function of the

immune system. Furthermore, there have been many genome and EST projects that have allowed us to determine whether or not particular genes or gene families are present in different taxa. Here, we briefly describe these findings and discuss their broad relevance and relationship to future studies.

A new system of defense in bacteria and archaebacteria against bacteriophage, CRISPR, has been elucidated.[490] Short phage DNA sequences have been acquired by prokaryotic genomes to direct sequence-specific protection against phages. These elements are transcribed into small RNAs that recruit endonucleases to cleave the phage nucleic acid. This system is widespread and its study is in its infancy. The discovery of this system fits well with studies of plants and animals over the last decade uncovering the plethora of mechanisms used to detect foreign nucleic acids (eg, TLR, NLR, RIG, APOBEC, etc.), as described previously. It should be clear to all immunologists by now that *all* living things must distinguish self from nonself, and have developed intricate mechanisms to achieve this end.

Cytokines such as IFNγ, IL-2, and IL-4, and other adaptive cytokines (and type I/III IFNs) and their receptors are not present outside of jawed vertebrates, nor is the vast array of chemokines seen in gnathostomes. However, at the moment it appears that (almost) all of the cytokines/chemokines discovered in mammals are also present in basal jawed vertebrates: Big Bang indeed! IL-17, a cytokine garnering great attention in basic immunology, and TNF, a central cytokine in both innate and adaptive immunity, seem to be the first cytokines to have emerged in evolution based on studies of lower deuterostomes. If, as suggested from studies in mammals, IL-17 is important for responses to extracellular bacteria, nonvertebrate deuterostomes may hold the key to understanding the physiology of the entire system (ie, in the absence of the competing TH1, TH2, and regulatory T cells), and one may be able to study the dynamics of IL-17 development and function in lower deuterostomes and even protostomes.

Additionally, over the past few years a new type of cell, the ILC, has come to prominence.[491] These cells are predominantly found in epithelia and mucosa and are involved in homeostasis and a first line of defense. As they do not bear antigen receptors, ILCs respond via cytokine receptors or PRRs. ILCs express cytokines consistent with T-cell subsets, and it is tempting to propose that they preceded adaptive T cells in evolution, and the cytokine-production profiles were coopted by the antigen receptor-bearing cells. However, as mentioned, it appears that "adaptive" cytokines arose late in evolution, coincident with adaptive immunity. Thus, it seems more like that ILCs arose simultaneously with the adaptive cells in the immunologic Big Bang, and there has been adaptation over time. However, as IL-17 and TGF-β are old cytokines, it has been proposed that their opposing functions arose before adaptive immunity.[492] TGF-β belongs to an ancient family of cytokines, and at least one of its functions in mammals is to antagonize proinflammatory responses (regulatory T differentiation, regulation of IgA synthesis, etc.). One model suggests that sophisticated innate immunity arose in mucosal tissues, regulated by the pro- and anti-inflammatory properties of IL-17 and TGF-β, respectively, by their expression in gut epithelia or by infiltrating hematopoietic cells; later, this was superimposed onto adaptive lymphocytes in the vertebrate lineage. Consistent with this idea, sea urchins have an expanded family of IL-17 genes,[48] suggestive of a very important function for this cytokine. So, such a system may have been the forerunner of both the ILCs and adaptive lymphocytes, perhaps found in tissues directly exposed to the environment.

Additionally, we are poised for more seminal studies of mucosal immunity. Mammals have dedicated secondary lymphoid tissues in their mucosa, and thus it is often difficult to tease apart the innate from adaptive responses in these tissues, except in contrived knockout or transgenic models. By contrast, ectothermic vertebrates have no Peyer patches or mesenteric lymph nodes, and thus are excellent models to examine responses in the lamina propria, which are predominantly T-independent.[493]

Lastly, studies of how the microbiota interact with the immune system have filled journals to the gills over the past 5 years. McFall-Ngai suggested that the driving force for adaptive immunity was not so much to fight off invaders, but rather to tolerate commensals,[494] perhaps not so different from Weaver's proposal.[492] This framework of interactions between leukocytes, and between leukocytes and commensals/pathogens, may be the key to understanding the genesis of adaptive immunity.

A new defense system in *Drosophila*, important for viral defense, has been uncovered. Previously, the recognition of pathogens by TLRs in the invertebrates was believed to be indirect, interacting with self-molecules similar to a cytokine interaction. However, *Drosophila* Tol7 has now been shown to interact directly with viruses, similar to TLRs in vertebrates,[153] but, as expected, the effector phase is different from the canonical (historical) toll pathway. There are several other tolls in the protostomes without a described function that can be studied in a new light.

One of the great triumphs in the field of comparative immunology was the discovery that similar mechanisms are used to recognize extracellular pathogens and initiate immune responses. It has been approximately 15 years since the *Drosophila* toll/IMD systems and their relationship to vertebrate TLRs and TNF receptors has been uncovered. Over the past few years, the intracellular defense mechanism such as NOD/NLR, RIG, helicase, etc., have

been elucidated in vertebrates, and we are beginning to piece together their evolutionary histories. The amazing similarities between the deuterostome and plant NOD/NLR systems will challenge us to understand their recognition events for years to come.[14]

The VLR system continues to amaze us.[13] Most comparative immunologists never expected a unique antigen receptor system to be uncovered in jawless fish. To then realize that the divergence of lymphocytes into two lineages occurred in the ancestor of jawed and jawless fish was astonishing. Now to have uncovered a primitive type of thymus candidate in jawless fish is a total shock. All of these discoveries force us to acknowledge that we should not be surprised by future discoveries in the evolution of immunity, such as a "convergent MHC," or an antigen presentation system not based on peptide presentation, or even a primordial type of adaptive immune system in lower deuterostomes or protostomes.

P.128

Furthermore, from comparative studies, Boehm and colleagues have proposed a simple model for the most fundamental elements required for thymocyte differentiation, which has been superimposed onto the lamprey thymus-like structures.[375,495] Further study of this minimal network of transcription factors, chemokines, and cytokines could uncover the origins of thymus differentiation in lower deuterostomes that clearly have no T/B cells.

Certain groups of organisms are interesting to study for different reasons. The genome projects in cnidarians demonstrated that certain gene families were more ancient than previously believed (from studies of the classical models *Drosophila* and *C. elegans*).[35] Thus, this taxonomic group has become the new rock stars of comparative immunology, not only for their immune complexity in the absence of a mesodermal germ layer, but also for elucidation of a histocompatibility reaction that has fascinated us for decades.[496]

Teleost fish have been shown again and again to have rapidly evolving immune systems, often expanding gene families in unprecedented ways (eg, NLR, tripartite motifcontaining), generating specific paralogs and losing others (eg, cytokines, chemokines, etc.), losing canonical syntenies found in all other vertebrates (eg, MHC class I and class II), and having unique forms of ancient molecules (eg, tetrameric IgM with no J chain). The third genomewide duplication (3R) is believed to have been a major force in this instability and rapid evolution.[20] This group provides an opportunity to study the plasticity of immune systems in related organisms over a short period of evolutionary time. With the cod story, they even offer a natural class II knockout system[395]!

Amphibians with metamorphosis offer models to study two modalities of self-tolerance, metamorphosis, and polyploidy. The larval immune system must somehow be suppressed with the appearance of adult self-determinants during metamorphosis and the refurbishing of the immune system. The amphibian *Xenopus* speciates by polyploidy, allowing an experimental system to examine the effects of whole-genome duplications on immune system loci (silencing, deletion, gene conversion, conservation), a key issue given the importance attributed to the genome-wide duplications in the evolution of immune systems in vertebrates.[328,399]

Birds offer another case of rapid evolution, probably because of attack by viruses. For the MHC, birds have lost immunoproteasomes and the thymic-specific proteasome, and have modified their class I groove to be more promiscuous in peptide binding. Chickens (but not

ducks) have lost the RIG-1 gene, apparently making them susceptible to influenza.[497] Clearly, birds have something fundamental and unique to teach us about how pathogens (most likely viruses in this case) can force a remodeling of innate and adaptive immunity.

The genomewide duplications early in the evolution of the vertebrates (the 2R hypothesis) have been confirmed in a variety of studies, and they were indeed important in the Big Bang emergence of the adaptive immune system. The 2R paradigm is useful for studying *any* gene family found on multiple chromosomes in the vertebrates; good examples of how it has aided in our understanding of immunity were the study of IgSF members involved in cell-cell interaction/costimulation, and the evolution/emergence of chemokines and TNF family members. An emerging paradigm is the possibility that genes encoding NKC, LRC, MHC, as well as the antigen receptors and costimulatory molecules (and other immune genes) were all linked at an early point in evolution.[2,498] In addition, while the agnathan adaptive system is similar to the Ig/TCR/MHC system of gnathostomes, the great sophistication that we see in the latter is not present in lampreys and hagfish. Our best guess at the moment is that the RAG transposon, in combination with the genomewide duplications, both superimposed onto an already existing adaptive framework, resulted in the Big Bang of adaptive immunity (see Fig. 4.10).

With the genome projects and advances in molecular biology, we have made strides in understanding old problems in vertebrate adaptive immunity, such as 1) when the L chains emerged and what the significance of more than one isotype is; 2) which antigen receptor (if any of the extant ones) came first, and all of them came to evolve to their present state; 3) when IgD emerged and what its function is in different vertebrate phyla, especially the transmembrane form; and 4) how γ/δ T cells recognize antigen. We propose that are two arms of the γ/δ T-cell lineage, one innate and the other adaptive, similar to B cells and α/β T cells.

The long-awaited molecular mechanisms of histocompatibility in nonvertebrates have been at least partially uncovered in plants, *Botryllus*, and *Hydractinia*. The common themes thus far are that the genes encoding the polymorphic receptors/ligands are closely linked and that the genes all appear to be unrelated to the vertebrate MHC. However, there are tantalizing links to immune gene clusters found throughout the animal kingdom that suggest there may be an underlying fundamental similarity in recognition, perhaps related to 1) the paucity of surface receptors available because of multiple constraints resulting in sharing of receptor/ligands, and 2) the signaling cascades.

Despite the great variation in mechanisms of allorecognition across phyla, are there commonalities? Whether in cnidarians or in tunicates, the polymorphic genetic regions involved contains from one to many IgSF members resembling members of the nectin PVR/CD155 family. In *Ciona*, these genes are not only closely linked in a single region but also are homologs found in the LRC. Could this region be the conserved and link aspects of immunity between vertebrates and invertebrates? The frequent presence of ITIM and ITAM indeed suggest the conservation of receptors interacting among these molecules.[160] It is clearly of ancient origin. With paralogs on four different chromosome regions in gnathostomes as well as an ancient connection to MHC and NKC, this region was present before 2R. It is not surprising now to detect very different molecular families involved in immune recognition events: LRR, lectins, IgSF. The comparison of allorecogniton in invertebrates has perhaps helped to focus our attention on genetic regions that may have

provided the “context” for leukocyte interactions.

Chapter 5

Immunoglobulins: Structure and Function

Harry W. Schroeder Jr
David Wald
Neil S. Greenspan

INTRODUCTION

Immunoglobulins (Igs) are marked by a duality of structure and function.[1] In common with other members of the Ig superfamily,[2] they provide the immune system with a conserved set of effector molecules. These effectors can activate and fix complement and they can bind to Fc receptors on the surfaces of granulocytes, monocytes, platelets, and other components of the immune response. Both activation of complement and binding to Fc receptors can contribute to the induction or maintenance of inflammation. They also provide the immune system with a polyclonal set of diverse ligand binding sites, which allow Igs, as a population, to recognize an almost unlimited array of self- and non-self-antigens, which may range from compounds as fundamental to life as deoxyribonucleic acid to manmade molecules that could not have played a role in the evolution of the immune system.

Differential splicing allows individual Ig molecules to serve as either membrane-bound receptors for the B cell that allow antigen-specific activation or as soluble effectors, which act at a distance. In vivo, proper effector function requires more than just antigen-specific binding; it requires successful neutralization of the offending antigen while avoiding potentially pathogenic self-reactivity.

The receptor and effector functions of each individual Ig can be localized to a separate region or domain of the molecule. Each variable (V) or constant (C) domain consists of approximately 110 to 130 amino acids, averaging 12,000 to 13,000 kD. A typical light (L) chain will thus mass approximately 25 kD, and a three C domain Cγ H chain with its hinge will mass approximately 55 kD.

Immunoglobulins are Heterodimers

Igs are heterodimeric proteins, consisting of two H and two L chains (Figs. 5.1 and 5.2). The eponymous Ig domain serves as the basic building block for both chains. Each of the chains contains a single amino-terminal V Ig domain and one, three, or four carboxy-terminal C Ig domains. H chains contain three or four C domains, whereas L chains contain only one. H chains with three C domains tend to include a spacer hinge region between the first (C_H1) and second (C_H2).[3]

At the primary sequence level, Igs are marked by the interspersion of regions of impressive sequence variability with regions of equally impressive sequence conservation. The V domains demonstrate the greatest molecular heterogeneity, with some regions including non-germline-encoded variability and others exhibiting extensive germline conservation across 500 million years of evolution.[4] The molecular heterogeneity of the V domains permits the creation of binding sites, or *paratopes*, which can discriminate between antigens that may differ by as little as one atom. Thus it is the V domains that encode the receptor function and define the monovalent specificity of the antibody. The H chain C_H1 domain, which is immediately adjacent to the V, associates with the single L chain C domain. Together, the C_H1 and C_L domains provide a stable platform for the paired set of V_H and V_L domains,

which create the antigen binding site. The distal C_H2 and C_H3 domains, for those antibodies with a hinge, or the C_H3 and C_H4 domains, for those with an extra (C_H2) domain, typically encode the effector functions of soluble antibody. Each of these Ig C_H domains is encoded by a separate exon. Although the sequences of the individual C_H domains are constant within the individual (and nearly constant within a species), they can vary greatly across species boundaries. The carboxy-terminal C_H domain encodes a secretory tail, which permits the antibody to exit the cell.

Also encoded within the germline sequence of each C_H gene are two membrane/cytoplasmic tail domain exons, termed M1 and M2. Alternative splicing removes the secretory sequence typically encoded by the terminal C_H3 or C_H4 domain and replaces it with the peptides encoded by the M1 and M2 exons, converting a secretory antibody to a

membrane-embedded receptor.[5] Between species, the membrane/cytoplasmic tail region is the most highly conserved portion of the C_H domains, which befits its role as a link to the intracellular signal transduction pathways that ultimately regulate B-cell function.

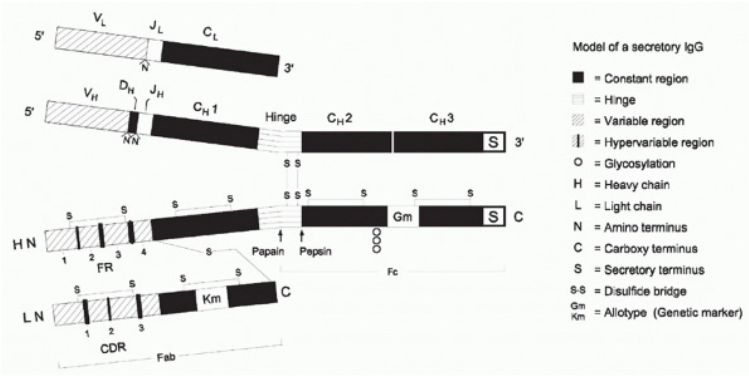

FIG. 5.1. Model of a Secreted Immunoglobulin (Ig)G. The germline exonic derivation of the sequence is shown at the *top*, and the protein structure is shown at the *bottom*. The location of the various cysteine residues that help hold both the individual domains and the various Ig subunits together are illustrated. Papain digests IgG molecules above the cysteine residues in the hinge that holds the two H chains together yielding two Fab molecules and an Fc, whereas pepsin digests below releasing an (Fab)'2 fragment and two individual Fcs (which are typically degraded to smaller peptide fragments). The location of some allotypic variants is illustrated. C_H2 domains can be variably glycosylated, which can also affect Ig structure and effector function.

Paratopes and Epitopes

The immunoglobulin-antigen interaction takes place between the paratope, the site on the Ig at which the antigen binds, and the *epitope*, which is the site on the antigen that is bound. It is important to appreciate that antibodies do not recognize antigens; they recognize epitopes borne on antigens.[6] This makes it possible for Igs to discriminate between two closely related antigens, each of which can be viewed as a collection of epitopes. It also is one scenario that permits the same antibody to bind divergent antigens that share equivalent epitopes, a phenomenon referred to as *cross-reactivity*.

It has been estimated that triggering of effector functions in solution typically requires aggregation of three or more effector domains, and thus tends to involve the binding of three or more epitopes.[6] For antigens encoding repeating epitope structures, such as polysaccharides or antigen aggregates, binding of a single polymeric Ig molecule carrying multiple effector domains, such as pentameric IgM, can be sufficient to induce effector function. For antigens encoding diverse epitopes, which is more typical of monodisperse

single-domain molecules in solution, triggering of inflammatory effector functions may require the binding of a diverse set of Ig molecules, all binding the same antigen, but at different epitopes.[7]

Membrane and Secretory Immunoglobulin

Alternative splicing allows Igs to serve either as soluble antibodies or as membrane-bound antigen receptors. In their role as antibodies, Igs are released into the circulation from where they may traffic into the tissues and across mucosal surfaces. In their role as the B-cell antigen receptor, they are anchored to the membrane by means of their M1:M2 transmembrane domain. Soluble antibodies can also be pressed into service as heterologous cell surface antigen receptors by means of their attachment to membrane-bound Fc receptors.[8] This permits the power of antibody recognition to be extended to nonlymphoid cells, such as Fc-expressing granulocytes, macrophages, and mast cells. The major difference between these two forms of cell surface receptors is that Igs as B-cell antigen receptors provide a monoclonal receptor for each B cell, whereas antibodies bound to Fc receptors endow the cell with a polyclonal set of antigen recognition molecules. This gives greater flexibility and increases the power of the effector cells to recognize antigens with multiple non-self-epitopes.

Isotypes and Idiotypes

Igs can also serve as antigens for other Igs. Immunization of heterologous species with monoclonal antibodies (or a restricted set of Igs) has shown that Igs contain both common

and individual antigenic determinants. Epitopes recognized within the V portion of the antibodies used for immunization that identify individual determinants are termed *idiotypes* (Fig. 5.3), whereas epitopes specific for the constant portion are termed *isotypes*. Recognition of these isotypes first allowed grouping of Igs into recognized classes. Each class of Ig defines an individual set of C domains that corresponds to a single H chain constant region gene. For example, IgM utilizes μ H chain C domains and IgE utilizes ε C domains.

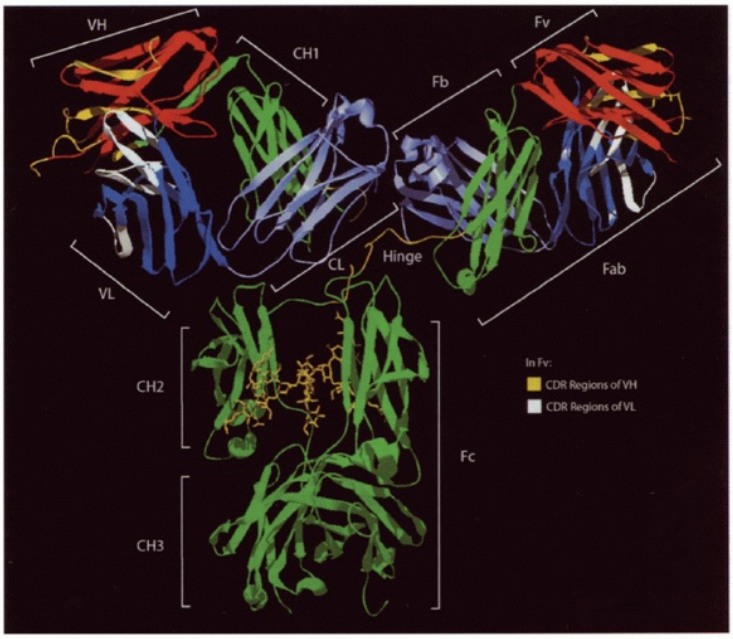

FIG. 5.2. Ribbon Diagram of a Complete Immunoglobulin (Ig)G1 Crystal (1 hzh in the protein data bank [PDB] from Data of Harris et al.[202]). The major regions of the Ig are illustrated. The heavy-chain constant regions (*green*) also include the hinge (*yellow*) between the first two domains. Cγ2 is glycosylated (also seen in *yellow*). The

heavy- and light-chain variable regions (*red* and *dark blue*, respectively) are N terminal to the heavy- (*green*) and light-chain (*light blue*) constant regions. Complementarity determining region loops in the heavy- and light-chain variable regions (*yellow* and *white*) are illustrated as well.

Some V domain epitopes derive from the germline sequence of V gene exons. These shared epitopes, commonly referred to as *public idiotopes* or *cross-reactive idiotypes* (see Fig. 5.3), are, from a genetic perspective, isotypic because they can be found on many Igs of different antigen-binding specificities that derive from the same germline V region. Examples include the cross-reactive idiotypes found on monoclonal IgM rheumatoid factors derived from individuals with mixed cryoglobulinemia, each of which can be linked to the use of individual V gene segments.[9]

Classes and Allotypes

Each of the various classes and subclasses of Igs has its own unique role to play in the immunologic defense of the individual. For example, IgA is the major class of Ig present in all external secretions. It is primarily responsible for protecting mucosal surfaces. IgG subclasses bind Fc receptors differently, and thus vary in effector function.[10] Determinants common to subsets of individuals within a species, yet differing between other members of that species, are termed *allotypes* and define inherited polymorphisms that result from allelic forms of immunoglobulin C (less commonly, V) genes.[11]

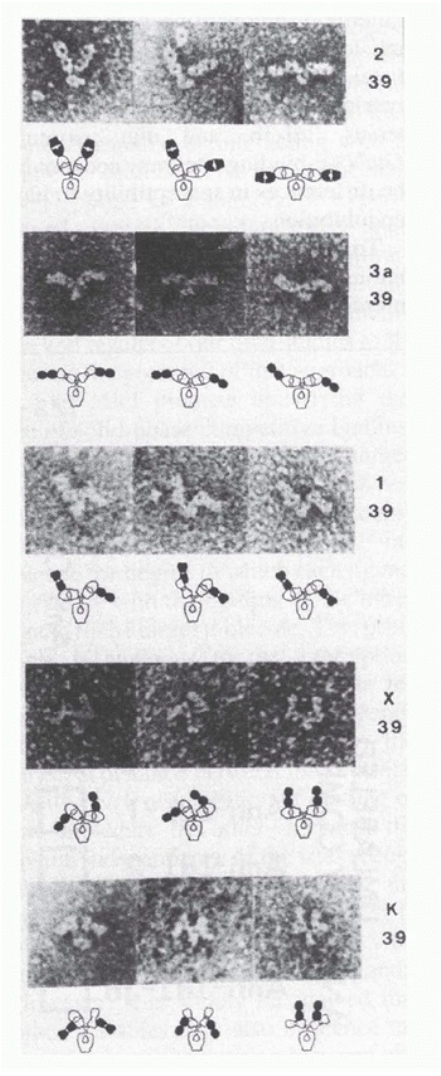

FIG. 5.3. Electron micrographs (*top*; ×350,000) and interpretive diagrams (*below*) of murine mAb hybridoma group A carbohydrate (HGAC) 39 (specific for the cell wall polysaccharide of *Streptococcus pyogenes*) in complex with anti-idiotypic mAb Fab fragments. HGAC 39 is represented in the diagrams as an open figure, and the Fab anti-Id probes are represented as solid figures. The Fab arms of the antibody targets and probes are drawn to indicate their rotational orientation as planar (oval with open center), intermediate (bone shape with or without central opening), or perpendicular ("dumbbell shaped"). Different complexes illustrate the range of Fab-Fab angles made possible by segmental flexibility. 1, anti-Id1-1 Fab; 2, anti-Id1-2 Fab; 39, HGAC 39; 3a, anti-Id1-3a Fab; K, anti-Cκ Fab; X, anti-IdX Fab. Id1 designates an individual idiotope, and IdX, a crossreactive idiotope. Antibody complexes were stained with 2% uranyl formate as described by Roux et al.[108] Reproduced from Proceedings of the National Academy of Sciences (from Roux et al.[108] with permission).

Glycosylation

N-linked carbohydrates can be found in all constant domains as well as in some variable domains.[12] The structure of the attached N-linked carbohydrate can vary greatly, depending on the degree of processing. These carbohydrates can play a major role in Ig function.[13] For example, human IgG molecules contain a conserved glycosylation site at Asn 297, which is buried between the C_H2 domains.[14] This oligosaccharide structure is almost as large as the C_H2 domain itself. O-linked sugars are also present in some Igs.[12] Human IgA1, but not IgA2, possesses a 13 amino acid hinge region that contains three to five O-linked carbohydrate moieties.[15] A deficiency in proper processing of these O-glycans can contribute to IgA nephropathy, which is a disease that is characterized by the presence of IgA1-containing immune complexes in the glomerular mesangium.[16]

A HISTORICAL PERSPECTIVE

The identification of Ig as a key component of the immune response began in the 19th century. This section describes the history of the identification of Ig and introduces fundamental terminology.

Antibodies and Antigens

Aristotle and his contemporaries attributed disease to an imbalance of the four vital humors: the blood, the phlegm, and the yellow and black biles.[17] In 1890, Behring (later, von Behring) and Kitasato reported the existence of an activity in the blood that could neutralize diphtheria toxin.[18] They showed that sera containing this humoral antitoxin activity would protect other animals exposed to the same toxin. Ehrlich, who was the first to describe how diphtheria toxin and antitoxin interact,[19] made glancing reference to "Antikörper" in a 1891 paper describing discrimination between two immune bodies, or substances.[20] The term antigen was first introduced by Deutsch in 1899. He later explained that antigen is a contraction of "Antisomatogen+- Immunkörperbildner," or that which induces the production of immune bodies (antibodies). Thus, the operational definition of antibody and antigen is a classic tautology.

Gamma Globulins

In 1939, Tiselius and Kabat immunized rabbits with ovalbumin and fractionated the immune serum by electrophoresis into albumin, alpha-goblulin, beta-globulin, and gamma-globulin fractions.[21] Absorption of the serum against ovalbumin depleted the gamma-globulin fraction, hence the terms immunoglobulin and IgG. "Sizing" columns were used to separate Igs into those that were "heavy" (IgM), "regular" (IgA, IgE, IgD, IgG), and "light" (light chain dimers). Immunoelectrophoresis subsequently permitted identification of the various Ig classes and

subclasses.

Fab and Fc

In 1949, Porter first used papain to digest IgG molecules into two types of fragments, termed Fab and Fc (Table 5.1).[22]

Papain digested IgG into two Fab fragments, each of which could bind antigen, and a single Fc fragment. Nisonoff developed the use of pepsin to split IgG into an Fc fragment and a single dimeric $F(ab)_2$ that could cross-link antigens.[23] Edelman broke disulfide bonds in IgG and was the first to show that IgG consisted of two H and two L chains.[24]

TABLE 5.1 Definitions of Key Immunoglobulin Structure Nomenclature

Fc	A constant region dimer lacking C_H1
Fab	A light chain dimerized to V_H-C_H1 resulting from papain cleavage; this is monomeric because papain cuts above the hinge disulfide bond(s)
F(ab)′2	A dimer of Fab′ resulting from pepsin cleavage below the hinge disulfides; this is bivalent and can precipitate antigen
Fab′	A monomer resulting from mild reduction of F(ab)′2: an Fab with part of the hinge
Fd	The heavy chain portion of Fab (V_H-C_H1) obtained following reductive denaturation of Fab
Fv	The variable part of Fab: a V_H-V_L dimer
Fb	The constant part of Fab: a C_H1-C_L dimer
pFc′	A C_H3 dimer

Two Genes, One Polypeptide

The portion of the constant domain encoded by the Fc fragment was the first to be sequenced and then analyzed at the structural level. It could be readily crystallized when chilled. The heterogeneity of the V domain precluded sequence and crystallographic analysis of an intact Ig chain until Bence-Jones myeloma proteins were identified as clonal, isolated Ig light chains. These intact chains could be purified and obtained in large quantities, which finally permitted rational analysis of antibody structure and function.[25] Recognition of the unique nature of a molecule consisting of one extremely variable V domain and one highly conserved C domain led to the then-heretical Dreyer-Bennett proposal of “two genes, one polypeptide,”[26] which was subsequently and spectacularly confirmed by Tonegawa.[27]

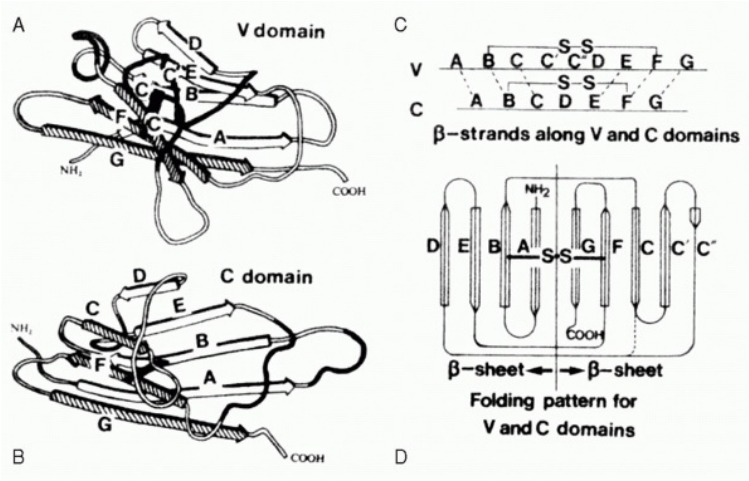

FIG. 5.4. The Immunoglobulin Domain. A: A typical variable domain structure. Note the projection of the C-C′ strands and loop away from the core. **B:** A typical compact constant domain structure. **C:** The cysteines used to pin the two b-sheets together are found in the B and F strands. **D:** The folding pattern for variable and constant domains.[2]

THE IMMUNOGLOBULIN DOMAIN

The Ig domain is the core unit that defines members of the Ig superfamily (reviewed in Williams and Barclay[2] and Harpaz and Chothia[28]). This section describes the Ig domain in detail.

The Immunoglobulin Superfamily

Each Ig domain consists of two sandwiched β-pleated sheets “pinned” together by a disulfide bridge between two conserved cysteine residues (Fig. 5.4). The structure of the β-pleated sheets in an Ig domain varies depending on the number and conformation of strands in each sheet. Two such structures, V and C, are typically found in Igs. C-type domains, which are the most compact, have seven antiparallel strands distributed as three strands in the first sheet and four strands in the second. Each of these strands has been given an alphabetical designation ranging from amino terminal A to carboxy-terminal G. Side chains positioned to lie sandwiched between the two strands tend to be nonpolar in nature. This hydrophobic core helps maintain the stability of the structure to the point that V domains engineered to replace the conserved cysteines with serine residues retain their ability to bind antigen. The residues that populate the external surface of the Ig domain and the residues that form the loops that link strands can vary greatly in sequence. These solvent exposed residues offer multiple targets for docking with other molecules.

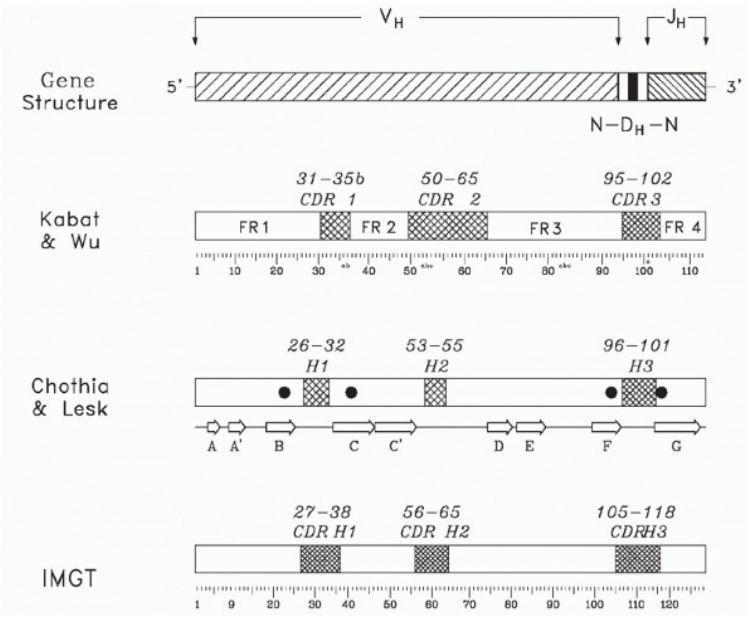

FIG. 5.5. Sequence Conservation and Hypervariability within a Heavy Chain Variable (V) Domain. The primary sequence the V domain can be divided into four regions of sequence conservation, termed framework regions (FRs), and three regions of hypervariability, termed complementarity determining regions (CDRs). A schematic of the genomic origin of the variable domain is shown at the top of the figure. The classic separation of the sequence into FR and CDR by Kabat et al.[31] is shown below the gene structure. The letter designation for individual β strands is given beneath the Chothia and Lesk nomenclature,[32] which focused more on structure. The positions of each of the four invariant residues of the V_H chain (FR1 Cys22, FR2 Trp36, FR3 Cys92, and FR4 Trp103) are shown as *darkened circles* on the Chothia and Lesk model. The ImMunoGeneTics information system® designation has attempted to rationalize sequence variability with structure and is the current nomenclature of choice.[33]

The V Domain

V-type domains add two additional antiparallel strands to the first sheet, creating a five strand-four strand distribution. Domain stability results from the tight packing of alternately inward-pointing residue side chains enriched for the presence of hydrophobic moieties to create a hydrophobic domain core. The H and L variable domains are held together primarily through noncovalent interaction between the inner faces of the β sheets.[29,30]

Early comparisons of the primary sequences of the V domains of different antibodies identified four intervals of relative sequence stability, termed framework regions (FRs), which were separated by three hypervariable intervals, termed complementarity determining regions (CDRs) (Figs. 5.5 and 5.6).[31] The exact location of these intervals has been adjusted over the years, first by a focus on the primary sequence,[31] then by a focus on the three-dimensional structure,[32] and, more recently, by a consensus integration of the two approaches by the international ImMunoGeneTics information system® (IMGT)[33] (see Fig. 5.5). (For students of the Ig repertoire, IMGT maintains an extremely useful website, http://www.imgt.org, which contains a large database of sequences as well as a multiplicity of software tools.)

The C and C′ strands that define a V domain form FR2. These strands project away from the core of the molecule (see Figs. 5.4 and 5.6) where they take on a conserved structure that is parallel and opposite to the FR2 of the companion V and adjacent to the FR4 of the complementary chain. Approximately 50% of the interdomain contacts in the hydrophobic

core of the V domain are formed by contacts between the FR2 of one chain and the FR4 of the complementary chain.[30] Another 30% to 45% is contributed by contacts between the CDR3 and the FR2 or CDR3 of the complementary domain. The overall interdomain contact includes between 12 and 21 residues from the L chain V domain and 16 to 22 residues from H chain V domain, most of which are contributed by the FR2, CDR3, and FR4 regions.

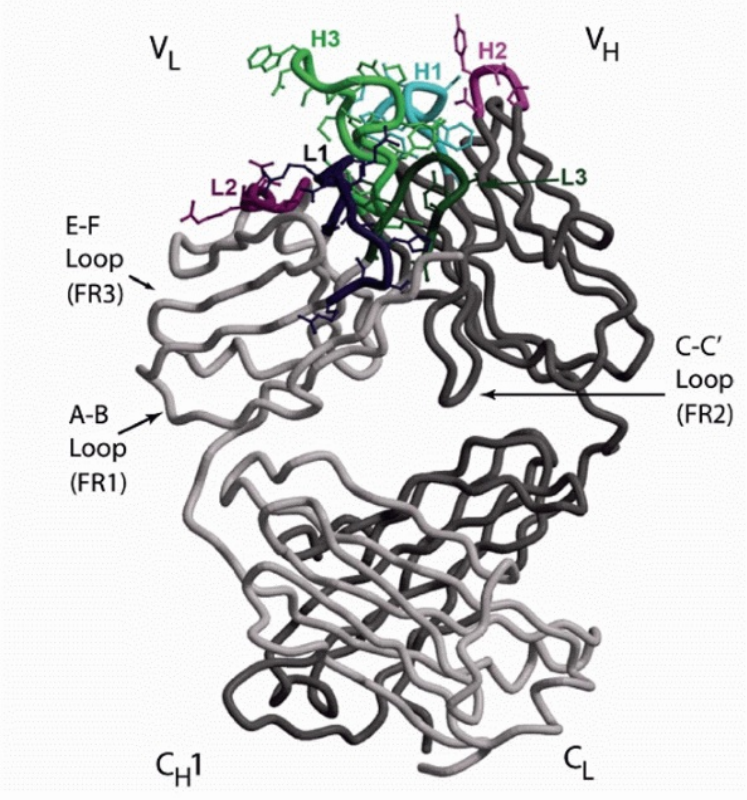

FIG. 5.6. The Structure of an Fab. The antigen-binding site is formed by the heavy (H) and light (L) chain B-C, C′-C″, and F-G loops. Each loop encodes a separate complementarity determining region (CDR). The location of CDRs H1, H2, H3, L1, L2, and L3 are shown. The opposing H and L chain C-C′ strands and loop help stabilize the interaction between VH and VL. This C-C′ structure is encoded by the second V framework region, FR2. The inclusion of this structure permits the variable (V) domains to interact in a head-to-head fashion. The E-F strands and loop are encoded by the FR3 region and lie directly below the antigen-binding site. The A-B strands and loop encode FR1 and lie between the CH1 and CL domains and the rest of the Vs. The beta sheet strands of the CH1 and CL domains rest crosswise to each other. The illustration is modified.[203]

There are approximately 40 crucial sequence sites that influence variable domain inter- and intradomain interactions.[32,34] Four of these sites are relatively invariant: the two cysteines that form the disulphide bridge between the beta sheets and two tryptophan (phenylalanine in Jκ) residues, one near the beginning of the C strand and the second near the beginning of the G strand, that pack against the bridge to add stability. Beyond these and other common core residues, Ig domains can vary widely in their primary amino acid sequences. However, a common secondary and tertiary structure characteristic of the core Ig V domain tends to be preserved.

FAB STRUCTURE AND FUNCTION

Introduction

It is the Fab domain that allows Ig to discriminate between antigens. The Fab is individually manufactured to precise specifications by individual developing B cells. It shows an amazing array of binding capabilities while maintaining a highly homologous scaffold. This section describes the characteristics of the Fab domain, its component V domains, and the *paratope*, which is the part of the Fab that actually binds antigen.

Fab, Fv, and Fb

The antigen-binding fragment (Fab) is a heterodimer that contains an L chain in its entirety and the V and C_H1 portions of the H chain (see Figs. 5.1 and 5.6). The Fab in turn can be divided into a variable fragment (Fv) composed of the V_H and V_L domains, and a constant fragment (Fb) composed of the C_L and C_H1 domains (see Table 5.1). Single Fv fragments can be produced in the laboratory through genetic engineering techniques.[35] They recapitulate the monovalent antigen binding characteristics of the original, parent antibody. Other than minor allotypic differences, the sequences of the constant domains do not vary for a given H chain or L chain isotype. The eponymous V domain, however, is quite variable.

Generation of Immunoglobulin Variable Domains by Recombination

Ig V domain genes are assembled in an ordered fashion by a series of recombination events.[27,36,37,38,39] The elegant mechanisms used for the assembly of these genes and the Fvs they create are fully discussed in Chapter 6. However, in order to understand the relationship between antibody structure and function, a brief review is in order.

In BALB/c mice, Ig V assembly begins with the joining of one of 13 diversity (D_H) gene segments to one of four joining (J_H) gene segments. This is followed by the joining of one of 110 functional variable (V_H) gene segments.[40,41,42] Each D_H gene segment has the potential to rearrange in any one of six reading frames (RFs), three by deletion and three by inversion. Thus, these 127 gene segments can come together in 3.4×10^4 combinations. The numbers of gene segments can vary quite widely between different mouse strains, but the process of assembly and the multiplicative effect of combinatorial diversity is the same.

In the final assembled V domain, the V_H gene segment encodes FRs H1 to H3 and CDRs H1 and H2 in their entirety (see Figs. 5.1 and 5.5), and the J_H encodes FR-H4. CDR-H3 is created de novo in developing B cells by the joining process. CDR-H3 contains the D_H gene segment in its entirety, as well as portions of the V_H and J_H gene segments.

After a functional H chain has been created, L chain assembly begins. Mice contain two L chain loci, κ and λ. In C57BL/6 mice, the κ locus includes five Jκ gene segments and 140 Vκ gene segments, of which 4 and 73 have been shown to be functional, respectively.[43,44,45] This provides 292 combinations. There is only one Cκ.[46] The BALB/c λ locus contains three Vλ, three functional Jλ, and two or three functional Cλ chains.[47,48] The λ constant domains are functionally indistinguishable from each other. Due to gene organization, the λ repertoire provides at most seven combinations. Each V_L encodes FRs L1 to L3, CDR L1 and L2, and two thirds of CDR-L3 (see Fig. 5.1). Each J_L encodes one-third of CDR-L3 and FR4 in its entirety. Any one

H chain can combine with any one L chain, thus 211 V, D, and J gene segments can provide approximately 1×10^7 different H:L combinations.

At the V→D and D→J junctions, the potential for CDRH3 diversity is amplified by imprecision in the site of joining, allowing exonucleolytic loss as well as palindromic (P junction) gain of terminal V_H, D_H, or J_H germline sequence. B cells that develop after birth express the enzyme terminal deoxynucleotidyl transferase (TdT) during the H chain rearrangement process.[27,36] TdT catalyzes the relatively random incorporation of non-germline-encoded nucleotides between V_H and D_H, and between D_H and J_H. Each three nucleotides of N

addition increase the potential diversity of CDR-H3 20-fold. Thus sequences with nine nucleotides of N addition each between the V→D and D→J junctions would enhance the potential for diversity by $(20)^6$, or by 6×10^7; six-fold greater than the potential diversity provided by VDJ gene segment combinations. These genomic gymnastics permit the length of CDR-H3 to vary from 5 to 20 amino acids among developing B cells in BALB/c bone marrow.[49] Together, imprecision in the site of VDJ joining and N addition provides the opportunity to create nearly random CDR-H3 sequence, potentially freeing the CDR-H3 repertoire from germline sequence constraints. Although a limited amount of N addition is observed between V_L and J_L in human,[50,51] N addition in murine L chains is distinctly uncommon. Moreover, the length of CDR-L3 appears to be under relatively strict control, greatly limiting the potential for somatic L chain junctional diversity. [48,50] Thus, CDR-H3 represents the greatest focus for the initial somatic diversification of the antibody repertoire.

Segmental Conservation and Diversity within the V Domain

Although the large numbers of V gene segments might give the impression of a smooth incremental range of available diversity, multigene families are thought to evolve in concert through mechanisms of gene conversion, and V gene segments are no exception. Sequence relationships allow grouping them into families and clans of sequences that share nucleotide homology,[52] as well as structural features. Close inspection of the V_H gene repertoire has shown that these family relationships reflect segmental gene conversion coupled with selection for function.[4,53,54]

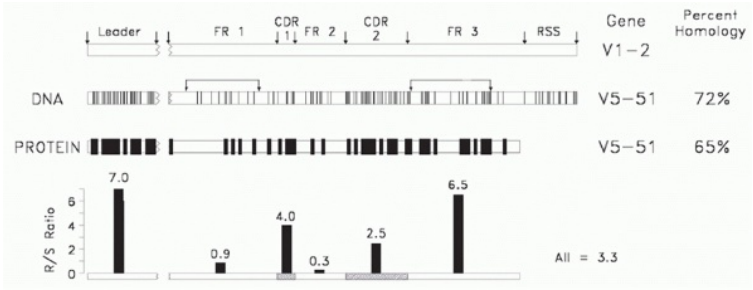

FIG. 5.7. A comparison of two human Clan I V_H sequences that belong to different V_H families (modified[4]). Shown is a comparison of the deoxyribonucleic acid and amino acid sequences of the V5-51 and V1-2 gene segments. Each line depicts a divergence in a nucleotide or amino acid at that position. Shown at the bottom is a replacement/silent site substitution analysis by interval. Random mutation tends to exhibit an R/S ratio of 2.9. The smaller the ratio, the greater the preservation of sequence. The intervals identified by the arrows predict the family and clan of origin.

Due to the need to maintain a common secondary and tertiary core Ig V domain structure capable of associating randomly with a complementary V chain to form a stable Fv, the core sequence of FR2, which is encoded by the V_H gene segment, and the core sequence of FR4, which is encoded by the J_H gene segment, are highly conserved among all Ig V domains. Conversely, the need to generate a diverse repertoire of antigen-binding sites has led to extensive diversity in the CDR-1 and CDR-2 intervals. One might presume that the FR1 and FR3 intervals, which form the external surface of the antibody, would not be under any particular constraints, but sequence comparisons suggest otherwise.

Given the need to diversify the CDRs and the need to preserve FR2, it is not surprising that family identity, which might reflect ancestral relationships, can be assigned by the extent of FR1 and FR3 similarity.[55] Of these, FR1 appears to be under the greatest constraints, with V_H gene segments belonging to different families both within and across species barriers

exhibiting extensive similarities in FR1 sequence (Fig. 5.7). Sequence similarities in FR1 and, to a lesser extent, FR3 allow grouping of human and murine V_H families into three clans of related sequences, presumably reflecting an early divergence in sequence from a primordial V_H gene sequence (Fig. 5.8).

Constraints on the Sequence and Structure of Variable-Encoded Complemenatarity Determining Regions

The antigen-binding site of an Ig is formed by the juxtaposition of the six hypervariable H and L chain V domain

intervals: CDRs-H1, -H2, and -H3; and CDRs-L1, -L2, and -L3.[31] The CDR sequences of V gene segments tend to be enriched for codons where mutations maximize replacement substitutions.[56] This includes the RGYW motif that facilitates somatic hypermutation.[57,58] While evolution appears to favor CDR1 and CDR2 sequences that facilitate codon diversity, it also appears to preserve specific loop structures.

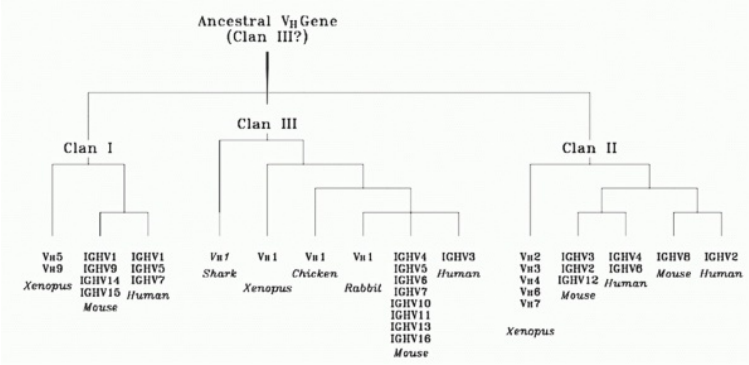

FIG. 5.8. Evolutionary Relationships among Vertebrate V_H Families. The sizes or relative placements of the evolutionary connecting lines are not to scale. V_H sequences from all mammalian species analyzed to date can be placed into one of these three clans (modified[4]).

Although there is great variation in the sequence and size of these CDRs, it has been shown that five of them, CDR-H3 being the notable exception, possess one of a small set of main-chain conformations termed canonical structures.[32,34,59,60,61,62] Each canonical structure is determined by the loop size and by the presence of certain residues at key positions in both the loop and framework regions. It can be calculated that the total number of possible combinations of canonical structures, or structure classes, is 300.[63] However, only 10 of these combinations, or classes, are sufficient to describe the majority of human and mouse Fab sequences. Among specific classes, the lengths of CDR-H3 and -L1 appear to correlate with the type of recognized antigen. Antibodies with short loops in -H2 and -L1 appear to be preferentially specific for large antigens (proteins), whereas antibodies with long loops in -H2 and -L1 appear to be preferentially specific for small molecules (haptens).[63]

Given that the sequence and structure of the framework regions, which define families, influences the canonical structure of V_H-encoded CDRs, it is not surprising that the structure repertoire of canonical structures is strongly associated with family and clan identity.[64] This implies restrictions to the random diversification of the hypervariable loop structures (canonical structures) and their combinations within the same V_H gene segment (canonical structure classes). It further suggests evolutionarily and structurally imposed restrictions operating to counteract the random diversification of these CDRs.

Diversity and Constraints on the Sequence and Structure of CDR-H3

The combination of VDJ assortment, variation in the site of gene segment rearrangement, and N nucleotide addition makes CDR-H3 the most variable of the six hypervariable regions. In some cases, the sequence of CDR-H3 appears designed to provide optimal flexibility.[65] Correspondingly, it has been more difficult to assign canonical structures to the CDR-H3 loops similar to those observed for the V-encoded CDRs. However, insight into a gradient of possible structures has been gained.

CDR-H3 can be separated into a base, which is adjacent to the frameworks, and a loop. The base tends to be stabilized by two common residues, an arginine at Kabat position 94 (IMGT 106) and an aspartic acid at Kabat 101 (IMGT 116).[32,33] These form a salt bridge which, together with the adjacent residues, tends to create one of three backbone conformations, termed kinked, extrakinked, and extended.[66] In some sequences with kinked or extrakinked bases, it is possible to predict whether an intact hydrogen-bond ladder may be formed within the loop of the CDR-H3 region, or whether the hydrogen-bond ladder is likely to be broken.[67,68] However, for many CDR-H3 sequences, especially those that are longer, current tools provide less than optimal predictions for the structures of individual CDR-H3s.

Despite the potential for totally random sequence provided by the introduction of N nucleotides, close inspection has shown that the distribution of amino acids in the

CDR-H3 loop is enriched for tyrosine and glycine,[31,69] and relatively depleted of highly polar (charged) or nonpolar (hydrophobic) amino acids, although the precise pattern depends on the species of origin.[70] This pattern of amino acid utilization is established early in B-cell development, prior to the expression of Ig on the surface of the cell (Fig. 5.9)[49,71,72,73] and reflects evolutionary conservation of J_H and D_H gene segment sequences. In particular, although the absolute sequence of the D_H is not the same, the pattern of amino acid usage by RF is highly conserved. Of the six potential RFs, RF1 by deletion is enriched for tyrosine and glycine. RF2 and RF3 by deletion are enriched for hydrophobic amino acids, as they are by inversion. RF1 by inversion tends to encode highly polar, often positively charged, amino acids.[69] Various species use different mechanisms to bias for use of RF1 by deletion, to limit use of hydrophobic RFs, and to restrict or prevent use of RFs enriched for charged amino acids. Forced rearrangement into RFs with charged amino acids yields an altered repertoire enriched for charge and depleted of tyrosine and glycine.[71]

The distribution of CDR-H3 lengths can also be regulated both as a function of differentiation and as a function of ontogeny.[49,74] In association with long V-encoded CDRs, short CDR-H3s create an antigen-binding cavity at the center of the antigen-binding site, and CDRs of intermediate length can create an antigen-binding groove. Each species appears to prefer a specific range of CDR-H3 lengths.[75] Long CDR-H3s, which can create “knobs” at the center of the antigen-binding site, are unevenly distributed between species and reflect both divergence in germline sequence and somatic selection.

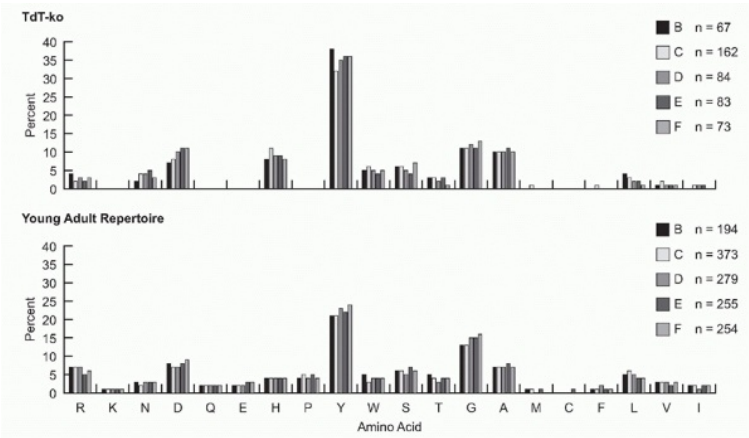

FIG. 5.9. Both in the absence or presence of N-addition, the preference for tyrosine and glycine in complementarity determining region-H3 begins early and intensifies with B-cell development. V_H 7183DJCμ transcripts were cloned and isolated from fractions B (pro-B cells) through F (mature B cells) from the bone marrow of 8- to 10-week-old terminal deoxynucleotidyl transferase-sufficient and terminal deoxynucleotidyl transferase-knockout BALB/c mice.[73] The amino acids are arranged by relative hydrophobicity, as assessed by a normalized Kyte-Doolittle scale.[204,205] Use is reported as the percent of the sequenced population. The number of unique sequences per fraction is shown.

The Antigen-Binding Site is the Product of a Nested Gradient of Regulated Diversity

The tension between the need to conserve essential structure and the need to emphasize diversity in an environment subject to unpredictable antigen challenge appears to create a gradient of regulated diversity in the Fv. The most highly conserved components of the Fv are FR2 and FR4, which form the hydrophobic core of the V_H:V_L dimer (see Figs. 5.4 and 5.5). FR1, which in the H chain presents with three conserved structures, helps form the ball and socket joint between the V_H and C_H1. FR3, which in the H chain defines the family and provides 7 different structures in human versus 16 different structures in mouse, frames the antigen-binding site (Fig. 5.10). The V-encoded CDRs, -H1, -H2, -L1, -L2, and most of -L3, are programmed for diversity. However, conserved residues within these CDRs, which interact with V family-associated FR3 residues, constrain diversity within a

preferred range of canonical structures. CDR-H3, the focus of junctional diversity, lies at the center of the antigen-binding site. The conformation of its base tends to fit within three basic structures. The loop varies greatly in sequence, yet still maintains a bias for the use of tyrosine and glycine. Thus, diversity increases with proximity to the tip of the antigenbinding site but appears to be held within regulated limits.

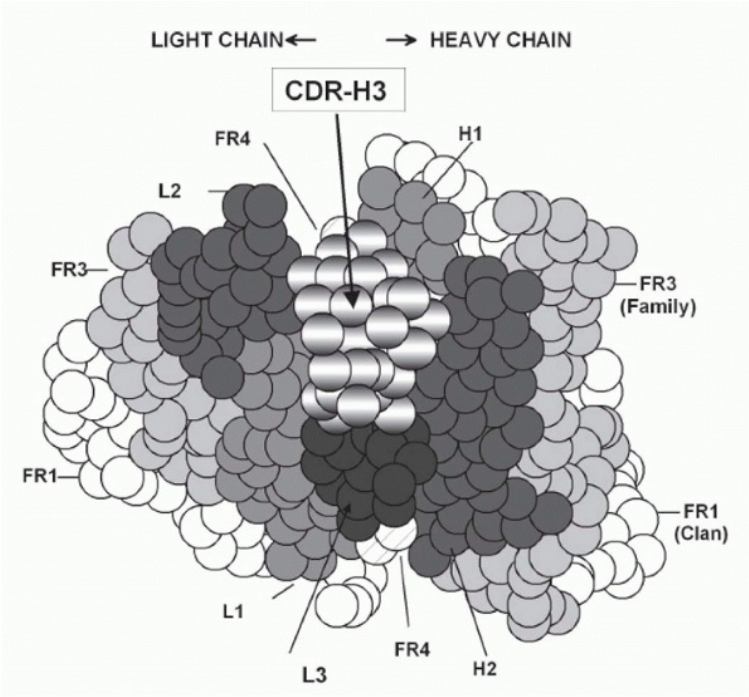

FIG. 5.10. Location and Generation of Complementarity Determining Region-H3.

A: A cartoon of the classic antigen-binding site (modified [4]). Due to its central location, most antigens bound to the antibody will interact with complementarity determining region-H3.

The extent and pattern of diversity in CDR-H3 can have a critical effect in the biologic function of Ig as a soluble effector molecule. Absence of N addition, with its enhancement of tyrosine and glycine usage (see Fig. 5.9) facilitates B-cell development, whereas enrichment for charged amino acids impairs it.[71,76,77] However, both the absence of N addition and enrichment for charged amino acids impair immune responses and protection in vivo.[71,76,78]

Somatic Hypermutation and Affinity Maturation

Following exposure to antigen and T-cell help, the V domain genes of germinal center lymphocytes can undergo mutation at a rate of up to 10^{-3} changes per base pair per cell cycle,[79] a process termed *somatic hypermutation*. Somatic hypermutation allows *affinity maturation* of the antibody repertoire in response to repeated immunization or exposure to antigen. Although affinity maturation often preserves the canonical structure of the CDR loops, the distribution of diversity appears to differ between the primary and antigenselected repertoire.[80] In the primary repertoire, diversity is focused at the center of the binding site in CDR-H3. With hypermutation, somatic diversity appears to spread to the V-encoded CDRs in the next ring of the binding site (see Fig. 5.10), enabling a more custom-tailored fit.

Binding of "Superantigens" to Nonclassic Variable Domain Antigen-Binding Sites

Not all antigens bind to the paratope created by the classic antigen-binding site. Antigens that can bind to public idiotopes on V domain frameworks[81] and recognize large portions of the available repertoire are termed superantigens. There are indications that B cell superantigens influence the pathogenesis of some common infections, such as those caused by *Staphylococcus aureus*.

ANTIGEN-ANTIBODY INTERACTIONS

Technological advances in biomolecular structure determination, analysis of molecular

dynamics, protein expression and mutagenesis, and biophysical investigation of receptor-ligand complex formation have facilitated significant advances in the understanding of antigen-antibody interactions. Particularly valuable has been the integration of high-resolution structural data with thermodynamic and kinetic analyses on a number of antigen-monoclonal antibody complexes. In this section, some of the key insights arising from these studies will be reviewed.

Molecular Flexibility

Like many other protein domains, V domains exhibit varying degrees and modes of molecular flexibility. Evidence suggests that some V modules (ie, V_L-V_H pairs) can adopt two or more conformations with meaningful frequencies in the unbound state. Because these different conformational states can exhibit distinguishable binding proclivities, molecular flexibility provides monoclonal antibodies with a mechanism for polyspecificity.[82] Molecular flexibility can also play a role in binding a single ligand, which, in such instances, may be better understood as a process of binding rather than as a simple event.[83,84] The extent of conformational adjustment by antibody or antigen required for complex formation can influence both the thermodynamics and kinetics of that process.

Role of Water

A significant role for water molecules has become clear from the study of high-resolution structures and thermodynamic analyses of antigen-antibody complexes. Water molecules exhibit a broad range of association times with protein surfaces. Thus some of the more tightly protein-associated of these solvent molecules effectively behave as parts of the protein.[85] Water molecules found in the antigen-antibody interface, whether constitutively bound or newly recruited, can make important contributions to both the intrinsic (ie, monovalent) affinity of the complex and to the differential affinities for different ligands (ie, specificity).[86] Amino acid residues of antigen and antibody can interact, indirectly, through hydrogen bonds to one or more water molecules.[86]

Thermodynamics and Antigen-Antibody Interactions

Specific residues in the antibody V domains or the antigen can contribute to complex formation in different ways, and some residues can contribute in multiple ways.[87] In addition

to making van der Waals contact, residues can be important due to contributions to the free energy of complex formation or to the differential free energy of complex formation for two or more different ligands. Some residues may contribute primarily to modulation of the association rate, the “relaxation” of the forming complex, or the dissociation rate.[83,88] Other contact residues contribute minimally to the energetics of complex formation, and yet other noncontact residues can be significant thermodynamic contributors.[89,90]

Structural and thermodynamic/kinetic comparisons of antibodies with germline V domain sequences and with somatically mutated V domain sequences have provided new insights into the structural and energetic bases for affinity maturation.[89,90] Mutations in both contact and noncontact residues can have major consequences, positive or negative, for the affinity with which an antibody binds an antigen. They can also favor tighter binding by enhancing V domain rigidity, thereby reducing the entropic penalty associated with complex formation.[90] Antibodies derived from secondary or later responses that have incorporated somatic mutations have been shown to exhibit less than absolute specificity. Even these “mature” antibodies can bind multiple ligands when screened on libraries of peptides or proteins,[91,92] a lesson likely to be relevant to most biomolecules.

It has been routine to distinguish between interactions in which antibodies bind to protein antigens versus those in which antibodies bind to carbohydrate antigens. Recent studies of antibodies that bind to human immunodeficiency virus-1 gp120 with high affinity and that exhibit potent and broad neutralizing activity suggest that antibodies can bind to epitopes

composed of both peptide and glycan elements.[93,94]

IMMUNOGLOBULIN "ELBOW JOINTS" AND "HINGES"

The structure of the constant domains can affect antibodyantigen interactions by influencing the range of molecular flexibility permitted between the two Fabs. In this section, the role of the Ig hinge will be discussed.

Elbow Joints

Individual Ig V and C domains tend to create rather rigid dimers. However, the antibody molecule as a whole, which consists of four or more such dimeric modules linked like beads on a string, can be viewed as a paradigm of molecular flexibility.[95] Flexibility begins between the Fv and the Fb of the Fab at what is termed the elbow bend or elbow angle.[96] This reflects both a ball and socket interaction between the FR1 of the H chain and the C_H1 domain,[97] and the identity of the L chain.[96] Five residues (three in V_H and two in C_H1) that are highly conserved in both antibodies and T-cell receptors make the key contacts that constitute this "joint." Elbow angles, assessed from crystal structures of homogeneous Fab fragments, range from 130 degrees to 180 degrees. λ light chains appear to permit an Fv to adopt a wider range of elbow angles than their κ chain counterparts.

Hinges

Some Ig isotypes contain a structural element that does not strictly correspond to the canonical structural motifs of Ig superfamily V and C domains, which is termed the hinge. Where it occurs, it is located between the C-terminus of the C^H1 and the N-terminus of the C^H2 domains. In isotypes such as IgG and IgA, the hinge is encoded by one (or more) separate exon(s). In isotypes with four C^H domains (ie, IgM and IgE), the C^H2 domain serves in place of a classical hinge.

The hinge, or the C^H2 domain in Igs that lack a hinge, permits an Fab arm to engage in an angular motion relative both to the other Fab arm and to its Fc stem (Figs. 5.3 and 5.11). This permits the two Fab arms to cover a range from maximal extension to an almost parallel alignment. The range of motion of the Fab arms reflects the nature of the hinge region, which in some C genes is rigid and in others, such as human IgA1, functions more as a tether for each individual Fab than as a support. This flexibility has major implications for antibody function, because it enables a bivalent antibody molecule to bind epitopes in a variety of relative spatial arrangements.

Among human IgG subclasses, the most unusual hinge region is that of IgG3. Unlike other human IgG hinge regions, the IgG3 hinge is encoded by a quadruplicated hinge exon, making it the longest hinge (62 amino acids) by far (Table 5.2). The primary structure of this hinge has been divided into upper, core (or middle), and lower hinge regions with somewhat different functional associations. The upper hinge in particular has been associated with the magnitude of segmental flexibility as assessed by fluorescence emission anisotropy kinetics[98]

and with the magnitude of Fab-Fab flexibility by immunoelectron microscopy.[99] The core or middle hinge appears to serve, at least in part, a spacer function. The lower hinge functions primarily to facilitate C_H2-C_H2 interactions.

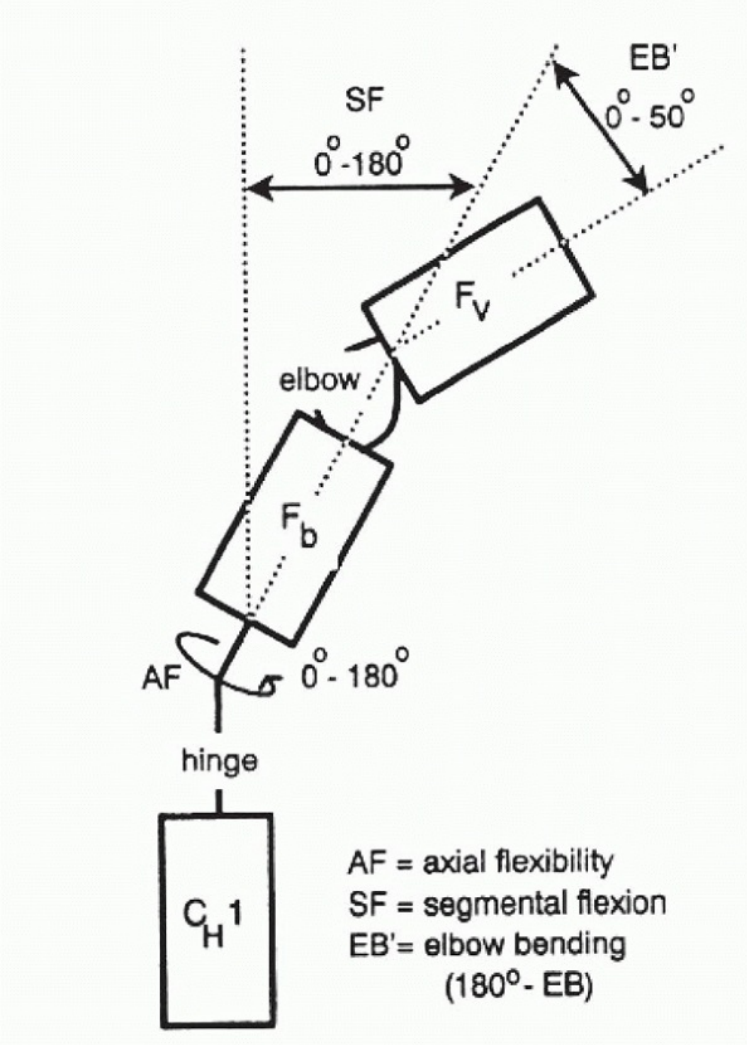

FIG. 5.11. Illustration of the Motions and Flexibility of the Immunoglobulin. Axial and segmental flexibility are determined by the hinge. The switch peptide (elbow) also contributes flexibility to the Fab. The measure of the elbow angle is defined with respect to the Fv and Fb axes of two-fold symmetry. From Carayannopoulos and Capra[206] with permission.

TABLE 5.2 Properties of Hinges in Immunoglobulin G, A, and D

Ig Type	Upper Hinge Length	Middle Hinge Length	Lower Hinge Length	Genetic Hinge Configuration (Amino Acids/Exon)	Susceptibility to Proteolysis	Special Features
IgG1	4	10	6	15		
IgG2	3	8	6	12		
IgG3	12	49	6	17-15-15-15		
IgG4	7	4	6	12		

IgA1	1	23	2	19	High	Heavy O-linked glycosylation
IgD				34-24	High	Extensive charged amino acids; heavy O-linked glycosylation at N terminus

Segmental flexibility of the Ig molecule, conferred mainly by the hinge, permits or facilitates simultaneous binding through two or more Fab arms. Such monogamous bivalency or multivalency, which enhances overall binding,[100,101] is a crucial factor permitting biosynthetically feasible antibody concentrations to offer adequate immunity against replicating pathogens. While it is more speculative why the Fab-Fc geometry needs to vary, it may have to do with optimizing effector function activation when antigen is bound, such as maintaining antigen binding when Fc receptors are simultaneously engaged.

The attribution of flexibility control to the hinge is supported by protein engineering studies in which V domain- identical IgGs of different subclasses were analyzed.[98,102] This basic conclusion is also supported by studies in which hinge regions have been selectively mutated or swapped among human or mouse IgG subclasses.[103,104,105] One of these studies indicated that structural variation among subclasses in the C_H1 domain also influenced segmental flexibility as assessed by nanosecond fluorescence polarization measurements.[103] Early suggestions that IgG subclass-related differences in activating the classical pathway of complement were explained by differences in segmental flexibility[98] were not confirmed by the studies in which mutant hinge regions were created.[103,104,105]

There are several types of molecular motion attributable to the hinge region that contribute to overall segmental flexibility (see Fig. 5.11). These include flexing between Fab arms (motion toward or away from one another in the same plane), Fab arms moving in and out of the same plane, Fab arms rotating along their long axes, and Fab arms moving in or out of the same plane as the Fc region.[106,107] The inter-Fab angles observed by electron microscopy range from O degrees to 180 degrees.[108,109] Similarly, Fab arm long-axis rotations can extend up to 180 degrees.[110]

Another key role of the hinge is the maintenance of the C_H2-C_H2 interaction (ie, effectively constraining molecular mobility within the Fc region itself). The lower hinge stabilizes C_H2-C_H2 contacts by providing the key cysteine residues involved in inter-H chain disulfide bonds. Experiments in which IgG molecules were modified to eliminate the hinge region demonstrate that covalent linkage between the hinge regions just “upstream” of the two C_H2 domains is critical for the preservation of IgG effector function.[111]

HEAVY CHAIN STRUCTURE AND FUNCTION

What might be termed the **fundamental strategy of humoral immunity** is a two-step process that begins with the identification by antibodies (of appropriate binding specificity) of the molecules or molecular complexes that should be eliminated. Following such identification (ie, noncovalent complex formation), antibodies can then trigger other molecular systems (eg, complement) or cells (eg, phagocytes) to destroy or remove the antigenic material—guilt by association at the molecular level. Thus, antigen specificity, determined primarily by the V

domains in the Fab arms, is physically and functionally linked to effector function, the activation of which is primarily attributable to the C domains of the Fc region. The effector functions associated with the humoral immune response primarily involve either complement or Fc receptor-bearing cells, such as neutrophils, macrophages, and mast cells. As might be expected, therefore, the Fc contains sites for noncovalently interacting with complement components, such as C1q, and with Fc receptors. This section focuses on the structure and function of the Fc regions of the various Ig classes and subclasses.

Structure and Function of the Fc

The necessity for interacting effectively with relatively conserved molecules such as C1q and Fc receptors provides a selective basis for maintaining the primary structures of the Fc region, at least where changes would undermine such intermolecular contacts. The degeneracy possible in noncovalent molecular recognition events permits selected primary sequence variations without catastrophic alterations in function. However, there are allotypic differences in the H chain constant domains among both human and mouse Igs. In some cases, these allotypic differences are associated with variation in function, at least in vitro. For example, two recombinant V domain-identical IgG3 antibodies, of

different allotypes, exhibited differential abilities to bind C1q or initiate antibody-dependent cell-mediated cytotoxicity.[112] Nevertheless, the H chains of the human IgG subclasses are particularly well conserved, with > 90% identity of amino acid sequences. In other mammalian species that have two or more IgG subclasses, they tend to exhibit less amino acid sequence identity than the human IgG subclasses.

By convention, the H chain constant domains are numbered from N-terminal to C-terminal, with C_H1 residing in the Fab arm and the remaining two (IgG, IgA, IgD) or three (IgM, IgE) C domains (C_H2, C_H3, and, if relevant, C_H4) residing in the Fc. In IgM and IgE, the C_H2 domain largely plays the role of the hinge region. The C domains of different isotypes and from different species share several key structural features. In distinction from V domains, which consist of four- and five-stranded β-pleated sheets linked through an intrachain disulfide bond, C domains consist of three- and four-stranded β-pleated sheets linked through an intrachain disulfide bond (see Fig. 5.4). Across isotypes, amino acid sequence identity for C_H domains is approximately 30%, while for subclasses (within an isotype) the amino acid sequence identity for CH domains is in the range of 60% to 90%. Important physical and biological properties of the human Ig isotypes are summarized in Table 5.3.

As noted previously, the traditional and accepted functional anatomy of Igs attributes antigen binding (both specificity and affinity) to the V modules in the Fab arms and effector function activation to the Fc region. While this scheme is both well supported and appealing, there is considerable (perhaps not widely appreciated) evidence that in some cases structural variations in H chain domains (ie, C_H domains and hinge) can influence both the affinity of the antibody for antigen and the discrimination among antigens.[113,114,115,116,117,118] Although these instances of C domain influence on ligand binding (through the V domains) primarily involve multivalent antigens, there are also reports that suggest C domain influence in instances of monovalent recognition.[119,120,121] Mechanisms for these effects in the context of binding multivalent antigens include isotype-related differences in segmental flexibility as well as the tendency for self-association. Results from a study comparing resistance to pneumococcal infection for IgG3-deficient and IgG3-producing mice are consistent with the notion that the cooperative binding permitted by murine IgG3 antibodies contributes to the effectiveness of humoral immunity.[122]

Fc Glycosylation

All Igs contain N-linked oligosaccharides, and it is becoming increasingly clear that this glycosylation plays significant roles in Ig structure and function. Though the type and extent of glycosylation varies among isotypes, an N-linked oligosaccharide on Asn 297 in the C_H2 domain is conserved on all mammalian IgGs and homologous portions of IgM, IgD, and IgE.

As the average serum IgG contains 2.8 oligosaccharides, there is often glycosylation present in the V domain as well.[123] The consensus sequence for the V domain N-linked oligosaccharides is not present in the germline, but it can be created during somatic hypermutation.[124] Glycosylation in the Fc region has been shown to be important for antibody half-life and effector functions.[125,126,127] Glycosylation of the Fc domain influences complement activation as Ig hypoglycosylation influences affinity for C1q as well as Ig binding to the FcR, possibly due to its effects on Ig structure.[128] Differential sialylation of the core Fc polysaccharide has recently been shown to have dramatic effects on the proinflammatory versus anti-inflammatory activity of IgG.[129,130] Furthermore, IgD N-linked glycans are necessary for IgD to bind to the IgD receptor on T cells.[131]

V domain glycosylation potentially affects the affinity for antigen, antibody half-life, antibody secretion, and organ targeting. Interestingly, glycosylation has been shown to be capable of both positively and negatively affecting antigen binding.[132,133,134,135] The biologic significance of Ig glycosylation can be seen from studies demonstrating that IgG from patients with rheumatoid arthritis is galactosylated to a lesser extent (termed IgG G0) than IgG from normal controls. In some cases, hypogalactosylation correlates with disease activity.[136] Hypogalactosylation of IgG has also been found to occur in other chronic inflammatory diseases such as Crohn's disease and systemic lupus erythematosus.[137]

Immunoglobulin M

IgM is an isotype of firsts. It is ontogenetically primary, being expressed first on developing B lineage cells. IgM is also the isotype that initially dominates the primary humoral immune response. It is probably, along with IgD, a phylogenetically primitive isotype in jawed vertebrates (an almost first) and may be the most phylogenetically stable isotype.[138]

IgM serves important immunological functions both on the surfaces of B-lymphocytes and in the fluid phase in the blood and in the mucosal secretions. On the cell surface, IgM consists of two identical μ H chains and two identical L chains (μ_2L_2). It is initially expressed on B lineage cells in noncovalent association with surrogate L chains, and subsequently, following successful L chain gene rearrangement, with κ or λ light chains. On the mature B-cell surface, IgM is noncovalently associated with two other polypeptide chains, Ig-α (CD79a) and Ig-β (CD79b).[139,140,141] These integral membrane proteins serve to transduce signals when surface IgM binds to and is cross-linked by cognate antigen.

In the secreted form, IgM can consist of either pentamers $(\mu_2L_2)_5$ or, less often, hexamers $(\mu_2L_2)_6$.[142] The μ_2L_2 monomers of the pentameric form are linked one to another by disulfide bonds in the C_H4 domains. Two of these monomers are, on one side, disulfide bonded not to another μ chain but to a 15,000 Da-polypeptide, called J chain. J chain is also found in polymeric IgA. There may be multiple patterns of such disulfide bonding, such that different cysteines participate in different monomeric units.[143]

Application of electron microscopy to polymeric IgM molecules has suggested that IgM can adopt two different quaternary arrangements: star and staple.[144,145] All of the antigen-binding sites are arrayed in radial fashion, in the same plane as one another and the Fc regions, in the star arrangement. In the staple form, the Fab arms bend out of the plane of the Fc regions. It has been conjectured that the staple form is utilized in binding simultaneously to two or more epitopes on multivalent antigens, such as bacterial or viral surfaces.

TABLE 5.3 Properties of Immunoglobulin Isotypes

Class or subclass	IgM	IgD	IgG1	IgG2	IgG3	IgG4	IgA1	IgA2	IgE

properties									
Molecular weight of secreted form (kDa)[a]	950(p)	175	150	150	160	150	160(m), 300(d)	160(m), 350(d)	190

Compiled from Carayannopoulos and Capra,206 Lefranc and Lefranc,209 Kuby,210 and Janeway et al.211

A major pathway through which soluble IgM mediates immunity or immunopathology is the activation of the classical pathway of complement. On a per molecule basis, relative to other isotypes, IgM is highly active in activating the classical pathway and can thereby effectively opsonize bacterial pathogens. In select cases (eg, *Neisseria meningitidis*), binding of IgM to bacterial surfaces, followed by complement activation, can cause direct lysis of the bacteria through the insertion of the membrane attack complex into the bacterial membrane.[146] IgM, like polymeric IgA, can reduce the effective number of colony- or plaque-forming units for, respectively, bacteria and viruses, through agglutination. Significant physical and biological properties of IgM and the other Ig isotypes are shown in Table 5.3.

Immunoglobulin D

IgD is primarily of interest in its membrane form, as the soluble form of IgD is found in relatively modest concentrations in the blood and other body fluids. The cell surface form of IgD is found along with IgM on all mature, naïve B cells, where it appears capable of

transducing activating and tolerizing signals.[147] As is true for IgM, the membrane form of IgD associates noncovalently with Ig-α (CD79a) and Ig-β (CD79b). Simultaneous cell surface expression of two H chain isotypes expressing the same V_H domains and the same L chains occurs via differential ribonucleic acid splicing.[148]

IgD exhibits greater sensitivity to proteolytic cleavage than IgM, which is consistent with a relatively short serum half-life of only 2.8 days. The relatively long hinge region is a primary target for proteolysis. Relatively modest efforts have historically been devoted to investigating of the functional roles of IgD antibodies, especially in the secreted form, in comparison to the other isotypes. However, new information suggests that IgD antibodies are produced in the upper respiratory mucosa by an unanticipated mechanism of class switch recombination and that these antibodies participate in host defense against pathogens relevant to this anatomical environment. In addition, secreted IgD antibodies can bind to basophils, through a receptor that is yet to be identified, and when these antibodies are crosslinked by cognate antigen, the basophils release potent mediators that influence immune reactivity, inflammation, and pathogen viability.[149]

Immunoglobulin G

IgG is the predominant isotype (approximately 70% to 75% of the total Ig) in the blood and extravascular compartments. The four human IgG subclasses (IgG1, IgG2, IgG3, and IgG4) are named in order of their relative serum concentrations, with IgG1 the most prevalent and IgG4 the least. There are differences in effector functions (eg, complement activation and Fc receptor binding) and other biological properties (such as serum half-life) among these subclasses. However, there are also crucial functional commonalities, such as placental passage (see Table 5.3).

IgG antibodies are the hallmark of immunological memory in the humoral immune response. In addition to the isotype switch from IgM to IgG in a secondary antibody response, somatic hypermutation can lead to affinity maturation, a process by which the average affinity of antibody for the antigen eliciting the immune response can increase.

IgG antibodies contribute to immunity directly and through the activation of complement or FcR-bearing cells. Important examples of immunity mediated directly through antibody binding include neutralization of toxins (eg, diphtheria toxin) and viruses (eg, poliovirus). Medically important examples of IgG-induced complement activation include immunity to encapsulated bacterial pathogens leading either to opsonization and destruction within phagocytes (eg., *Streptococcus pneumoniae*) or to direct complementmediated lysis (eg, *Neisseria meningitidis*). Activation of FcR-bearing cells by IgG antibodies has also been implicated in immunity to pathogens (eg, *Cryptococcus neoformans*).[150] The consensus view is that human IgG1 and IgG3 isotypes are effective activators of the classical complement pathway. While some older sources state that IgG2 and IgG4 are weak or nonactivators of the classical complement pathway, more recent evidence suggests that when epitope density is high, IgG2 is effective in activating complement.[151,152] One possible source for the isotype-related variation in complementactivating ability is variation in affinity for C1q (IgG3>IgG1> IgG2>IgG4), the portion of the first component in the classical pathway that physically contacts the C_H2 domains of antibodies. However, isotype-associated differences in complement activation have also been found to occur at steps of the cascade subsequent to the binding of C1q to antibody.[112,153] For example, in one study of chimeric monoclonal antibodies engineered to express identical V domains and representing all four human IgG subclasses, the IgG3 antibody fixed C1q better than the IgG1 antibody, but the IgG1 molecule was more effective in mediating complement-dependent cell lysis than the IgG3 molecule.[153] Thus, it is probably not possible to rank the relative abilities of the IgG subclasses to activate complement in a single absolute hierarchy.

The affinities of IgG subclasses for Fc receptors vary from about 5×10^5 M^{-1} to about 10^8 M^{-1}. Recent studies in the mouse suggest that the relative contributions of IgG subclasses to various immunopathological processes depend on their relative affinities for the activating

versus inhibiting isoforms of FcR.[154]

A remarkable attribute of IgG (for three of the four subclasses) is its serum half-life of about 23 days. This property, attributable to the Fc region and its interaction with the neonatal Fc receptor (FcγRn), has been exploited for therapeutics through the genetic fusion of solubilized receptors, (eg, cytotoxic T-lymphocyte antigen 4) to IgG Fc regions.[155]

A recently derived insight into the function of IgG4 antibodies relates to their apparently unique ability to spontaneously dissociate into half-molecules and to form antibodies composed of different half-molecules with distinct antigen

specificities (ie, bispecific antibodies that cannot cross-link antigen and thus have anti-inflammatory activity).[156] This phenomenon may be of particular relevance to specific immunotherapy in the setting of allergy.[157]

Immunoglobulin A

While IgG is the clearly predominant isotype in the blood, IgA is the dominant Ig isotype in the mucosal secretions as well as in breast milk and colostrum.[158]

In the blood, 10% to 15% of the Ig is IgA (vs. 65% to 75% IgG). Moreover, IgA has a shorter half-life than IgG in serum. The predominant form of IgA in human serum or plasma is monomeric (ie, α_2L_2), but there are small quantities of dimers [$(\alpha_2L_2)_2$] and fewer still trimers and tetramers. Secretory IgA consists of dimers and lesser amounts of trimers and tetramers associated with one joining (J) chain (distinct from the J region in the heavy chain V domain) and one SC chain (see following discussion). The latter is the extracellular portion of the polymeric Ig receptor (pIgR), which is expressed by mucosal epithelial cells and transfers polymeric IgA or IgM from basolateral to apical surfaces, thereby providing most of the Ig content of the mucosal secretions. The J chain is disulfide bonded to the tail pieces, short C-terminal extensions of the C_H3 domains, of the two IgA monomers of a dimer, while SC forms a disulfide bond to a cysteine in one C_H2 domain of one monomer.

The two α H chain C region genes correspond to two IgA subclasses, IgA1 and IgA2. IgA1 is the predominant (> 80%) IgA subclass in the serum. While IgA2 is the major form in some human mucosal secretions, such as those in the large intestine and the female genital tract, there is variation in the relative proportion of IgA1 and IgA2 in different secretions. The shorter hinge region of IgA2 confers increased resistance to bacterial proteases that might be encountered in the mucosal environment. The extended hinge region of IgA1 is believed to permit molecules of this isotype to accommodate variable epitope spacings on multivalent antigens. While the long hinge region of IgA1 molecules might be expected to confer relatively high susceptibility to proteolysis, relative protection against the activity of bacterial proteases is provided by heavy O-linked glycosylation in the hinge (Fig. 5.12). Nevertheless, the IgA1 hinge is uniquely susceptible to IgA proteases produced by certain pathogenic bacteria.[159]

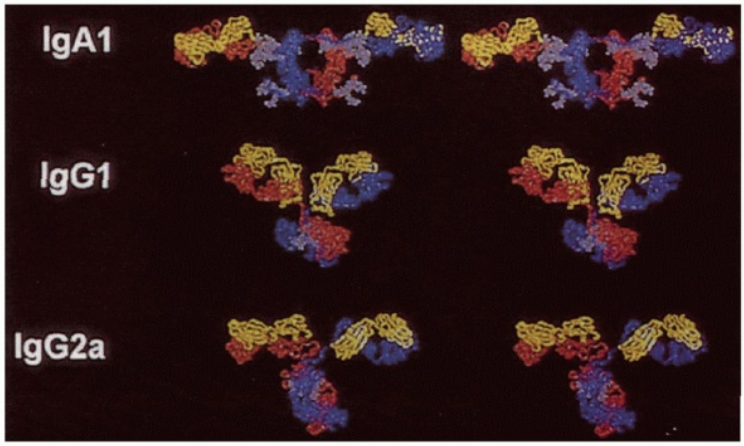

FIG. 5.12. A comparison of an x-ray and neutron-solution-scattering theoretical model (human immunoglobulin (Ig)A1) and x-ray crystal (murine IgG1 and IgG2a) structures. Light chains (*yellow*), heavy chains (*red* and *dark blue*), and glycosylation (*light blue*) are illustrated. The extended length of IgA1 over that of IgG can be seen along with extensive glycosylation that characterizes this isotype. From Boehm et al.[207] with permission.

Secretory IgA (S-IgA) has been shown to participate in immunity against a range of viral, bacterial, and parasitic pathogens at mucosal surfaces. The relative absence of functional complement and phagocytes in mucosal secretions is consistent with a different mix of mechanisms for mediating immune effects associated with S-IgA versus, for example, serum IgG. Mechanisms associated with IgA are less dependent on inflammation-producing molecules or cells, such as inhibition of microbial adherence through V module-mediated specific binding to microbial adhesins, agglutination of microbes, blocking of microbial receptors for cell surface carbohydrates with IgA-associated glycans, and mucus trapping (in which binding of S-IgA to bacteria makes them more adherent to host-generated mucus). There is also evidence that polymeric IgA can neutralize viruses

in some circumstances by interfering with steps postattachment, such as internalization. In some cases, posttranslational modifications of viral surface molecules, related to proteolytic events associated with epithelial cell transit, lead to IgA antibodies expressing protection-related antigen specificities that have no parallel in the IgG pool.[160,161] Some of the contributions of IgA to immunity are mediated through binding to FcαRI (CD89) on human neutrophils, monocytes/macrophages, and eosinophils. For example, cells bearing FcαRI on their plasma membranes can phagocytose IgA-antigen complexes. FcαRI binds to the IgA Fc region between the Cα2 and the Cα3 domains.[162] Amino acid residues in the IgA Fc region critically involved in the interaction with CD89 are indicated in Figure 5.13.

The ability of IgA to activate complement is controversial. At present, the preponderance of evidence suggests that IgA does not activate the classical complement pathway and only weakly, and under some pathophysiological circumstances, activates the alternative complement pathway. However, there is evidence suggesting that, in vitro at least, polymeric, but not monomeric, IgA can activate the complement pathway dependent on mannose-binding lectin.[163]

Additional properties of the polymeric forms of IgM and IgA are considered in the following section.

Immunoglobulin E

IgE is best known for its association with hypersensitivity reactions and allergy, but this isotype is also of interest in the context of immunity to parasites. In the blood, IgE is present

at the lowest concentration of any of the Ig isotypes (with roughly five orders of magnitude less IgE than IgG) and has the shortest half-life. The unimpressive quantitative representation of IgE in the blood is related to the high affinity of IgE antibodies for FcεRI, often referred to as the high-affinity Fc receptor for IgE. FcεRI is expressed on mast cells, basophils, Langerhans cells, and eosinophils. Due to the high affinity of FcεRI for its IgE ligand, mast cells and basophils are covered with relatively long-lived FcεRI-IgE complexes.

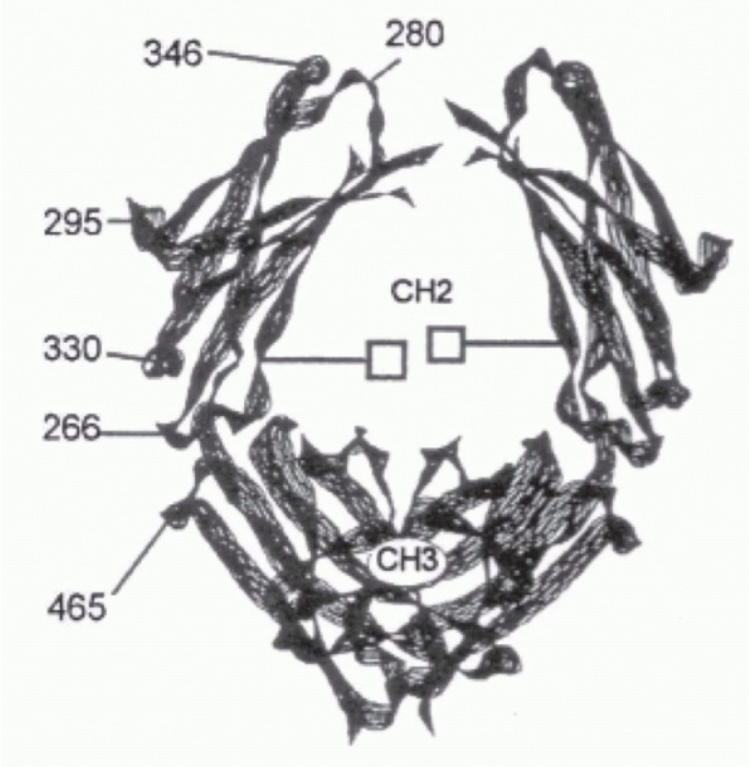

FIG. 5.13. Illustration of the Residues Essential for the Binding of immunoglobulin (Ig)A to FcαR (CD89). Residues represent mutations made in IgA C_H regions as mapped on an Fcy fragment. Of the residues mutated, L465 and L266 were found to be important for binding to CD89. From Carayannopoulos et al.[162] with permission.

The interaction between IgE and FcεRI has an affinity of ~10^{10} L/M. It primarily involves contacts between FcεRI and amino acids in the C_H3 domains, with some contributions from amino acids in the C_H2 domains. Although each IgE potentially has two sites for interacting with the FcεRI, the stoichiometry has been shown to be 1:1. Furthermore, it has been suggested that IgE binds to FcεRI in a kinked conformation.[164]

Upon ligation with bivalent or multivalent antigens specifically recognized by the bound IgE molecules, the FcεRI molecules transduce signals that activate the mast cells or basophils to secrete potent mediators of inflammation, such as histamine. These mediators are responsible for the symptoms associated with asthma, allergic rhinitis, and anaphylaxis.

There is a second receptor for IgE. FcεRII (CD23), a type II membrane protein, is expressed on monocytes/macrophages, B-lymphocytes, natural killer cells, follicular dendritic cells, Langerhans cells, eosinophils, activated epithelial cells, and platelets. It binds monomeric IgE with an affinity of ∽10^7 L/M, roughly three orders of magnitude lower than the affinity of FcεRI for IgE. Functional consequences of FcεRII-IgE interaction on macrophages include secretion of mediators of immediate hypersensitivity as well as cytokines and chemokines. There is also evidence suggesting that the FcεRII-IgE interaction can contribute to antigen capture and presentation to both B and T cells.

Fc Receptor Immunoglobulin Interactions

There are four receptors that bind the Fc regions of IgG molecules in humans and five such receptors in mice. Three of the human receptors are expressed primarily on hematopoietic cells directly involved in immune responses: FcγRI, FcγRII, and FcγRIII. Among the FcγR involved in antibody effector functions, there is important variation in affinity for IgG molecules. FcγRI binds IgG with relatively high affinity, permitting the binding of monomeric IgG. In contrast, FcγRII and FcγRIII bind to IgG with relatively low affinity. Consequently, these latter two receptors do not bind significant quantities of monomeric IgG but preferentially interact with IgG that has been effectively aggregated through interaction with bivalent or multivalent antigens (ie, immune complexes). Key amino acid residues involved in the binding FcγRs and FcεR1 with their corresponding Ig can be seen in Figure 5.14. Allotypic variations in FcγRIIA can also influence affinity for IgG ligands and subsequent effector function.[165]

There are different isoforms of FcγRII and FcγRIII. Of particular functional relevance, FcγRIIA is activating,

whereas FcγRIIB is inhibiting. In mouse models, deficiency of FcγRIIB can be associated with an autoimmune syndrome similar to human lupus.[166] Studies in mice have also suggested that the effectiveness of antibodies of the various murine IgG subclasses in mediating FcγR-dependent effector functions are correlated with the ratio of affinities of antibodies of those subclasses for activating versus inhibiting FcγR.[154]

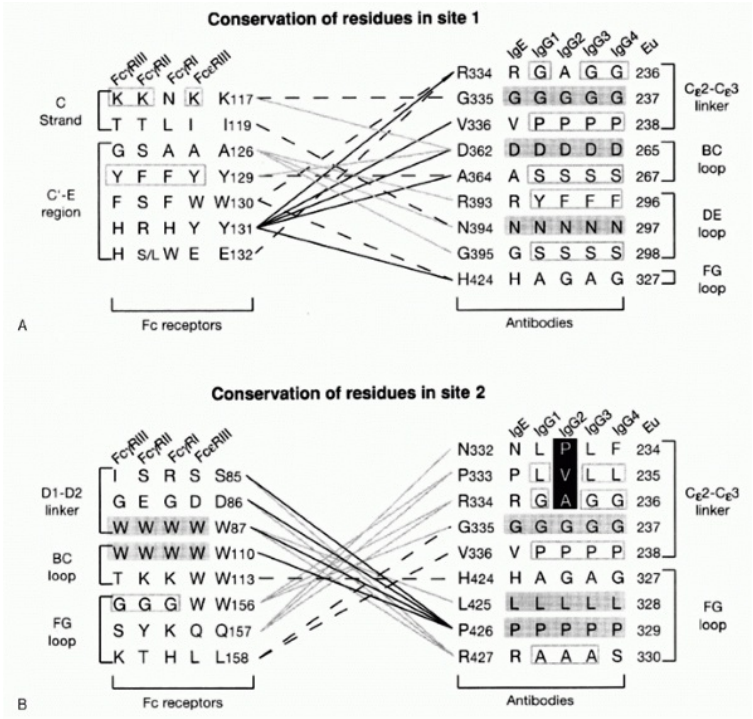

FIG. 5.14. Certain residues are conserved between FcγRs and FcεRI as well as between immunoglobulin (Ig)G and IgE that facilitate binding. Two sites participate: site 1 in **(A)** and site 2 in **(B)**. *Heavy lines* indicate the highest number of contacts and *dashed lines* indicate the least. Of considerable note are residues W87 and W110 in site 2 of the receptors and P426 in the Ig that form a core "praline sandwich" in the interaction between Ig and receptor. From Garman et al.[208] with permission.

FcγRIIIA is expressed on natural killer cells, whereas FcγRIIIB is expressed on neutrophils. The former receptor is attached to the membrane by a standard transmembrane polypeptide,

whereas the latter is attached via a glycophospholipid tail.

The fourth human receptor, the neonatal FcγR, or FcγRn (sometimes referred to as the Brambell receptor), transports IgG across the placenta. It also plays a crucial role in protecting IgG from proteolytic degradation, thereby prolonging serum half-life. While FcγRI, FcγRII, and FcγRIII are members of the immunoglobulin superfamily, FcγRn is structurally similar to major histocompatibility complex class I molecules, including noncovalent association with β2-microglobulin. The interaction between FcγRn and IgG involves amino acid residues in the C_H2-C_H3 interface[167] and is pH-sensitive. This latter property is consistent with the ability of FcγRn to bind IgG in acidic vesicular compartments and then release it into the neutral-pH environment of the blood. A crystallographic structure of the rat FcγRn in a 1:1 complex with a heterodimeric Fc (containing only one FcγRn-binding site) reveals that there are conformational changes in the Fc on binding to FcγRn.[168] The investigators also identified three titratable

salt bridges that confer pH-dependent binding of the IgG Fc to the FcγRn.

There are other FcR that interact with the non-IgG isotypes: IgM, IgD, IgA, and IgE. The FcR for IgA and IgE are covered in the respective sections devoted to the corresponding isotypes. In mice, an additional Fcα/μR binds both IgA and IgM, whereas in human these receptors are distinct.[169,170] Functional attributes of these receptors and the FcδR are continuing to be studied.

There are functional as well as structural parallels among FcR for IgG and non-IgG isotypes. Some of the features of Fc-FcR interaction that are conserved across isotypes are illustrated in Figure 5.14.

Transmembrane and Cytoplasmic Domains

Igs are expressed in both membrane and secreted forms. In contrast to the secreted form, the membrane Ig contains a transmembrane and a cytoplasmic domain. The transmembrane domain is a typical single-pass polypeptide segment consisting of 26 hydrophobic residues, extending from the C-terminus end of the C-terminal C^H domain and which forms an alphahelix followed by a variable number of basic amino acids. The cytoplasmic portion of the Ig H chain ranges in length from 3 amino acids for IgG to 30 amino acids for IgE.

Both membrane expression of Ig and the integrity of the cytoplasmic domain are important in antibody function. As the cytoplasmic domain is rather short, membrane-bound IgM is not thought to "signal" directly, but through the associated Igα and Igβ molecules.[171] However, disruption of either membrane expression of IgG1 in mice or the cytoplasmic tail results in the failure to generate an effective IgG1 response and IgG1 memory.[172] Mice lacking IgE membrane expression exhibit significant impairment in IgE responses and have extremely low levels of secreted IgE.[173] For those Igs with longer membrane:cytoplasmic tails, membrane Ig affects signaling beyond its association with Igα and Igβ. Specific residues in the transmembrane domain have been identified that are crucial for signal transduction while having no effect on the association with Igα and Igβ.[174]

HIGHER ORDER STRUCTURE

Many of the biological functions of IgA and IgM are dependent on their ability to form multimeric structures. This section will discuss the role of multimeric Ig in immune function.

Dimers, Pentamers, and Hexamers

The majority of multimeric IgA exists as dimers and, less commonly, trimers and tetramers, while IgM forms pentamers and occasionally hexamers. The polymeric structures of these antibodies enhances their functional affinity (avidity) for antigen, is essential for their active transport (both IgA and IgM) across epithelial cells to mucosal secretions, and in the case of IgM, enhances the activation of the classical pathway of complement. Once multimerized, IgA or IgM in a complex with J chain can bind to pIgR and cross mucosal epithelial cells.[175,176]

Though IgM can undergo transcytosis to the mucosal secretions, its principal action is in the serum.

The ability of IgA and IgM to multimerize is due to a tailpiece, an additional C-terminal segment of 18 amino acids in the secreted forms of the μ and α heavy chains. Tailpieces of both IgM and IgA contain a penultimate cysteine (residue 575 in IgM and 495 in IgA) that forms two different disulfide bonds important for multimer formation. In an Ig monomeric unit containing two identical H chains, one cysteine residue forms intermonomeric subunit bonds, whereas the remaining cysteine residue on the other heavy chain bonds to a cysteine on the J chain.[177,178,179,180]

Another cysteine residue, Cys414, also forms intermonomeric subunit disulfide bonds in IgM, and this bond is important in hexamer formation.[181] Besides disulfide bonds, the highly conserved glycan linked to Asn563 in IgM (and the homologous region in IgA) is also important for multimerization.[182]

Domain-swapping experiments demonstrate that the tailpiece regulates multimerization in the context of the specific H c hain. While addition of the α tailpiece to IgM has little effect on IgM polymerization, the introduction of the μ tailpiece to IgA leads to higher-order IgA polymers.[183] Based on this finding, it has been proposed that IgM polymerization is more efficient than IgA polymerization.

The J Chain

The J chain, an evolutionarily conserved 137 amino acid polypeptide produced by B-lymphocytes, functions to regulate multimer formation and to promote linkage of multimeric Ig to pIgR on epithelial cells. The J chain consists of a single domain in a beta barrel conformation and does not show sequence similarity to Ig domains.[184] It contains eight cysteine residues that participate in disulfide bonds with two tailpiece cysteines, as described previously, as well as function to stabilize its own structure through intramolecular bonds.[183,185] The J chain influences the polymerization of the multimers, as in the absence of J chain, IgA forms fewer dimers and IgM forms fewer pentamers.[186]

The J chain exists in all polymeric forms of IgA and is important in IgA polymerization and secretion across the mucosa. J chain is not required for IgM polymers but is required for external secretion. While IgM pentamers contain J chain, hexamers almost always lack it. The makeup of IgM is biologically significant because IgM hexamers have about 20-fold greater complement-activating activity than IgM pentamers. The presence of increased levels of hexameric IgM has been postulated to play a role in the pathogenesis of Waldenström macroglobulinemia and cold agglutinin disease.[187]

Immunoglobulin Transport

Transport of dimeric IgA and pentameric IgM to the mucosal secretions occurs after binding to pIgR that is present on the basolateral surface of the lining epithelial cells. The J chain is essential for the secretion of IgA and IgM and,

as described previously, influences the polymeric structure of the Ig.[175] pIgR is a transmembrane receptor synthesized by mucosal epithelial cells that contains seven domains including five extracellular V-like domains, a transmembrane domain, and a cytoplasmic domain.[188] Once bound to pIgR, polymeric Ig is endocytosed and transported to the apical surface of the cell. pIgR is then proteolytically cleaved between the fifth and sixth domains to release a complex (termed secretory Ig) containing the H, L, and J chains, and the SC, which represents the cleaved extracellular portion of pIgR.[189,190] As pIgR undergoes constitutive transcytosis in the absence of polymeric Ig, free SC is also released into the mucosal secretions. SC has several biological functions, including protecting the Ig from degradation by proteases and binding bacterial antigens such as the *Clostridium difficile* toxin A.[191,192] SC also functions to localize sIgA to the mucus layer to help protect against invasion by

pathogens.[193] Results from pIgR-null mice demonstrate that alternate pathways exist to transport polymeric Ig to the mucosal secretions as some secretory Ig still crosses the epithelial cells in the absence of pIgR.[194] Results from pIgR-null mice also demonstrate the importance of high levels of secretory antibodies as these mice are more susceptible to mucosal infections with pathogens such as *Salmonella typhimurium and Streptococcus pneumoniae*.[195,196]

The epithelial transcytosis of polymeric Ig has several biological implications. First by delivering the Ig to the mucosal surface, it enables antibodies to bind to pathogenic agents and prevent them from penetrating the mucosa, a process termed immune exclusion. Second, transcytosing antibody can neutralize viruses intracellularly.[197,198] Finally, polymeric Ig can bind to antigens in the mucosal lamina propria and excrete them to the mucosal lumen (where they can be removed from the body) by the same pIgR-mediated transcytosis process.[199,200] Some pathogens can exploit the pIgR-mediated transcytosis process in reverse to penetrate the mucosa. For example, the pneumococcal adhesin, CbpA, can bind pIgR at the epithelial apical surface, leading to bacterial penetration of the mucosa.[201]

CONCLUSION

Igs are extremely versatile molecules that can carry out many biological activities at the same time. The need to be able to recognize unique antigen structures prior to any previous exposure coupled with the need to maintain host cell receptor or complement recognition properties presents a truly unique challenge for the system. As has been described, the system incorporates diversity within specific constraints. The precise biological niches may differ, but the overall design for these molecules is the same.

The flexibility and biologic properties of Igs have made them a major focus of molecular engineering. Igs are being used as therapeutic agents, as well as for biotechnology applications. These opportunities have led to a resurgence of interest in the structure-function aspects of antibodies as we approach “designer antibodies.” Both the variable and constant portions of these molecules are current substrates for engineering purposes, offering the potential for altering both receptor and effector function. The study of antibodies began with the need to understand how sera could neutralize toxins. It is likely that antibodies will continue to be a major focus for those who seek to take fundamental principles of protein chemistry to the bedside.

Chapter 6

Immunoglobulins: Molecular Genetics

Edward E. Max

Sebastian Fugmann

INTRODUCTION

To respond to a foreign molecule (antigen) on an invading pathogen, the “humoral” immune system generates antibodies, or immunoglobulins (Igs), that can bind specifically to the offending antigen. Each antibody molecule is composed of two identical light (L) chains and two identical heavy (H) chains, all linked by disulfide bonds to form a symmetric Y-shaped tetramer. The ability of the immune system to generate an antigenspecific antibody depends on the fact that, before exposure to antigen, millions of naïve resting B cells circulate in the individual, each cell displaying on its membrane several thousand identical copies of a single unique species of antibody; these serve as B-cell receptors (BCRs) for that lymphocyte. Only a tiny fraction of the B cells express a BCR capable of binding to any particular antigen. When these B cells bind their antigen, they become activated to proliferate and mature into antibodysecreting plasma cells, which manufacture large amounts of antibody specific for the activating antigen. To be able to generate antibodies against a universe of diverse pathogens, this “clonal selection” mechanism for specific antibody secretion requires an enormous diversity of Ig species expressed on naïve B cells prior to antigen exposure. Indeed, in the 1960s the number of different antibody sequences in the repertoire of typical mouse was estimated in the millions. To encode this many sequences seemed to require an unreasonably high percentage of the mammalian genome (now estimated to contain only about 30,000 genes). Understanding the genetic source of Ig diversity—Ig gene assembly —was the first major challenge and achievement of the molecular biologic investigations of antibody genes, and this will be discussed first in this chapter.

A week or so after antigen administration, the B-cell response changes in two ways that generally improve the protective functions of antibodies. B cells initially express antibodies of the IgM isotype, but cells that migrate into germinal centers receive T-cell-derived stimuli that can induce them to switch to production of IgG, IgA, or IgE without changing their antigen specificity; this switch results from a deoxyribonucleic acid (DNA) recombination event known as class switch recombination (CSR). In addition, over the course of an immune response, the affinity of antibody for antigen gradually improves as a result of somatic hypermutation (SHM) of antibody genes, coupled to selection for B cells expressing high-affinity antibodies. CSR and SHM are discussed later in this chapter.

In this chapter, well-established facts about Ig genes are summarized concisely, while areas currently under investigation are considered in more detail, with particular attention to topics expected to interest immunologists.

OVERVIEW OF IMMUNOGLOBULIN GENE ASSEMBLY

In the 1960s, investigators determined the amino acid sequences of Igs secreted by several mouse myelomas (clonal tumors of B-lymphocytes that secrete a single pure species of Ig). The N-terminal domains of the L and H chains— each roughly 100 amino acids—were highly diverse between different myeloma proteins and were designated variable (V) regions. In contrast, sequences of the remaining domains of the proteins were essentially identical for every myeloma Ig of a given class (and so they were designated constant [C] region domains). The advent of recombinant DNA technology allowed comparisons of V region genes expressed in different myelomas with the corresponding sequences in nonlymphoid

DNA (commonly referred to as “germline” DNA). It was found that each myeloma V gene is composed of several segments that are separated in germline DNA; these germline segments must undergo one or more DNA recombination events to assemble a complete V region.[1] For example, each complete Vκ gene from a myeloma or B-lymphocyte encodes roughly 108 amino acids and is assembled by linking one of about 40 germline Vκ segments (encoding amino acids 1 through 95) to one (of five) “joining” or Jκ segments encoding residues 96 to 108. Similarly, a complete Vλ gene is assembled from one germline Vλ segment and one Jλ segment. H chains are assembled from three segments; a diversity (D) segment is interposed between V_H and J_H. In developing B cells, the germline gene segments are assembled into functional V exons by a process named V(D)J recombination (Fig. 6.1).

V(D)J recombination is a “cut and paste” process in which the DNA between two recombining V, D, or J gene segments is excised from the chromosome, and the two remaining DNA segments are joined together to reseal the DNA break. The two principal proteins executing the “cut” phase of this process are encoded by the recombination activating genes (RAG)1 and 2. These proteins recognize unique sequences, known as recombination signal sequences (RSSs), that flank and mark each eligible V, D, and J gene segment (RSSs are described further in the following). After the RAG proteins cut the DNA, the subsequent “joining” of the gene segments relies largely on ubiquitous DNA repair factors.

How Recombination Contributes to Diversity

V(D)J recombination contributes in several distinct ways to the diversity of antigen-binding specificities. First, there is

combinatorial diversity, as each Ig locus contains multiple V, D (in case of the IgH locus), and J segments that can be combined in many ways. The total number of theoretically possible combinations of V_H, D_H, J_H, V_L, and J_L, is the multiplication product of the numbers of possible H chains— about 40 (V_H) × 27 (D_H) × 6 (J_H) or 6480 combinations in humans —times the number of possible L chain combinations (about 290), or almost 2 million. This repertoire is vastly larger than could be achieved by devoting the same total lengths of DNA sequence to preassembled variable region exons. Second, there is junctional diversity generated by flexibility in the position of joining between gene segments. This was initially recognized by comparisons of nucleotide sequences of various myeloma Vκ genes to their germline Vκ and Jκ precursors. As shown in Figure 6.2A, these comparisons revealed that the crossover point between sequence derived from a germline Vκ region and a Jκ region could vary in different myelomas, increasing the diversity of amino acids around codons 95 and 96. H chain VDJ exons exhibit this flexibility at both V-D and D-J junctions, yielding striking variation in the lengths D regionderived segments, from zero to about 14 amino acids. And additional junctional diversity is produced by the addition of nucleotides not present in any germline elements: “N” and “P” nucleotides, discussed below. Importantly, the three-dimensional structures of Igs established by X-ray crystallography reveal that the VL-JL junction and the V_H-D_H-J_H junction each encode one of the three “complementarity determining region” loops of L or H chain that can contact antigen; thus, this junctional diversity is directly functionally relevant for diversifying antigen binding.

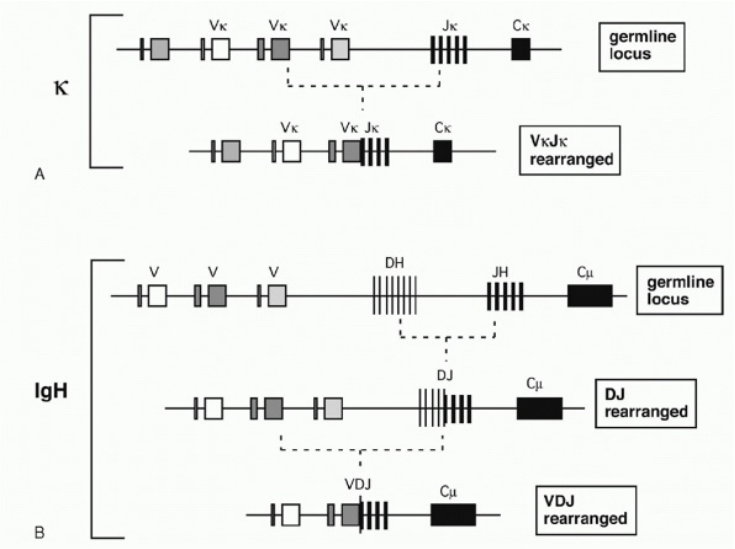

FIG. 6.1. Variable Assembly Recombination. A: In the κ locus, a single recombination event joins a germline Vκ region with one of the Jκ segments. **B:** In the immunoglobulin H locus, an initial recombination joins a diversity segment to a J_H segment. A second recombination completes the variable assembly by joining a V_H to DJ_H.

The imprecision of V(D)J recombination increases Ig diversity, but at a cost. Because the precise boundaries between V, D, and J result from independent stochastic events, only about one-third of all recombination events maintain the correct reading frame through the J segments. Gene rearrangements leading to functional Ig genes are often referred to as "productive," while out-of-frame rearrangements are labeled "nonproductive."

Function of Recombination Signal Sequences

Analysis of DNA sequences flanking the germline V, D, and J gene segments revealed highly similar sequence motifs that have subsequently been shown to define targets for V(D)J recombination: the RSSs, which serve as the recognition sequences for the V(D)J recombinase proteins RAG1 and RAG2, as mentioned previously. Notably, RSSs lie adjacent to L- and H-chain Ig gene segments and to T-cell-receptor (TCR) gene elements throughout phylogeny. RSSs consist of a conserved seven base pairs (bps) long "heptamer" (consensus: CACAGTG) and a nine bp long "nonamer" sequences

(consensus: ACAAAAACC) that are separated by less wellconserved spacers of either approximately 12 or 23 bp in length (Fig. 6.3). Based on the spacer lengths, the two classes of RSSs are referred to as 12-RSSs and 23-RSSs, respectively. (Note that some laboratories use the term recombination signal instead of RSS in their publications.)

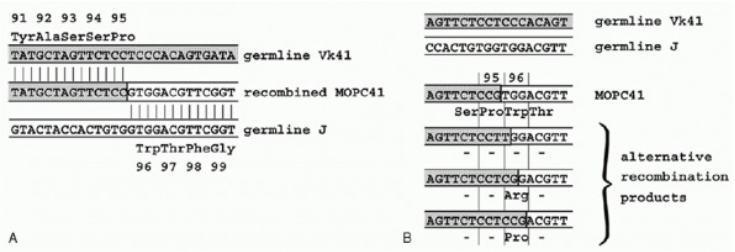

FIG. 6.2. Vκ-Jκ Recombination at Single Base Resolution. A: The sequence of the recombined MOPC41 κ gene around the VJ junction is shown (*center*) with the sequences of the two germline precursors (Vκ41 and Jκ1) shown above and below. The

germline origins of the recombined gene are indicated by the vertical lines and the shading of the V-derived sequence. **B:** The consequences of joining the same germline sequences (from part *A*) at four different positions are shown. Of the four alternative recombination products illustrated, the top one is that actually found in MOPC41. The second example has a single nucleotide difference but no change in encoded amino acid sequence. The third and fourth alternatives yield Arg or Pro at position 96; both of these amino acids have been found at this position in sequenced mouse κ chains.

Recombination occurs almost exclusively between coding sequences associated with RSSs of different spacer lengths, a requirement referred to as the "12/23-rule" (i.e., the recombination between two 12-RSSs [or two 23-RSSs] is "forbidden" and does not occur *in vivo*). Within each gene locus, all gene segments of one class (e.g., all Vs in the Igκlocus) carry RSSs with the same spacer length. Thus the 12/23 rule drives appropriate recombination events leading to functional VJ and VDJ products, and prevents futile recombination events, such as between two V or two J gene segments. While the heptamer and nonamer are the major determinants of RSS function necessary for V(D)J recombination, increasing evidence suggests that spacer sequences can modulate recombination efficiencies of compatible gene segments (e.g., they affect the non-random usage of human Vκ elements[2]).

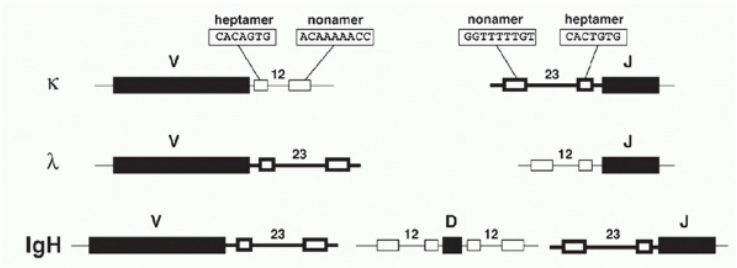

FIG. 6.3. Conserved Elements Flank Germline Variable (V), Diversity (D), and Joining (J) Region Genes. Conserved heptamer and nonamer recombination signal sequences (RSSs) lie adjacent to V, D, and J coding sequences and are important for targeting V(D)J recombination. The heptamer and nonamer elements are separated by spacer regions of about 12 basepairs (bp) (*thin lines*) or 23 bp (*thick lines*). Depending on the locus, V regions may be flanked by 12 bp or 23 bp RSS; and similarly for J regions. But one of each type of element must be present for recombination to occur, a requirement that prevents futile recombination events (e.g., J to J).

THE THREE IMMUNOGLOBULIN GENE LOCI

To understand the contribution of the germline V, D, J element repertoire to Ig diversity, several laboratories undertook cloning and sequence analysis of individual V region genes from the IgH, Igκ, and Igλ loci of human and mouse. More recently, the complete sequences of all human and mouse Ig loci have been determined as part of the genome sequencing projects for these two species (available online at www.ncbi.nlm.nih.gov, though annotation that describes

function and refers to earlier literature is incomplete). It is important to point out that Ig gene loci are not identical between individuals (humans) or between individual strains of inbred mice. Several Internet resources are devoted to providing convenient updated access to Ig germline gene sequences. The international ImMunoGeneTics database (http://imgt.org) includes a database for Ig and TCR genes from a variety of species, and includes maps, sequences, lists of chromosomal translocations, and multiple helpful links. IgBLAST (www.ncbi.nlm.nih.gov/igblast/) is a service of the National Center for Biotechnology Information and allows a submitted sequence to be searched against known annotated

germline V, D, and J sequences.

TABLE 6.1 Overview of the Number of Variable, Diversity, and Joining Segments in Each of the Three Immunoglobulin Loci in Humans and Mice

Locus	Species	V		D		J	
		Functional	*Pseudogenes*	*Functional*	*Pseudogenes*	*Functional*	*Pseudogenes*
IgH	Mouse	110	85	10		4	
	Human	40	83	24	3	6	3
Igκ	Mouse	95	45			4	1
	Human	46	87			5	
Igλ	Mouse	3				3	1
	Human	36	56			4-5	2-3

D, diversity; Ig, immunoglobulin; J, joining; V, variability.

Pseudogenes are recognized based on sequence defects that would preclude function (premature stop codons, defective recombination signal sequences, defective splice sites). The numbers in this table are approximate, owing to variation between mouse strains and between individual humans.

The Murine Immunoglobulin H Germline Variable, Diversity, and Joining Gene Segments

V_H Segments

The murine V_H region extends over about 2.5 megabases on chromosome 12 and includes roughly 100 functional segments (depending on mouse strain) plus additional V_H pseudogene segments (Table 6.1). All V_H elements are in the same transcriptional orientation as the D, J_H, and C_H regions.[3] The V_H segments are classified into 16 distinct families based on sequence similarity; V_H elements within a family show more than 80% nucleotide sequence identity. Elements of individual V_H families are largely clustered together, though some interdigitation occurs (Fig. 6.4). The V_H families can be grouped into three “clans” based on sequence conservation primarily of their framework regions (framework region 1, codons 6 to 24, and framework region 3, codons 67 to 85, respectively), which form the more conserved structural backbone of the Ig variable region. Importantly, these clans are conserved between man, mouse, and frog, suggesting that their emergence in the repertoire preceded the amphibian-reptile divergence.[4]

FIG. 6.4. Maps of the Murine and Human V_H Loci. The 15 known murine V_H gene families are shown in their approximate map positions. Each *rectangle* represents a cluster of V_H genes of the indicated family; the clan identification of the V_H families is indicated by the color of the rectangle: *black* for clan I, *gray* for clan II, and *white* for clan III. Although some interdigitation is shown by overlapping families (e.g., the Q52 and 7183 families), the murine V_H families are largely clustered. In contrast, all human V_H genes (*vertical lines*) of a prototypic haplotype are shown in the right panel; extensive interdigitation of families is apparent.

Diversity and J_H

About 50 kb downstream of the most 3′ V_H element resides the murine D cluster spanning about 80 kb, depending on

the mouse strain (see Table 6.1). Each D segment is flanked by 12 RSSs on both sides, so that the 12/23 rule ensures that all assembled V genes carry a D element between their V and J segments (which are both flanked by 23 RSSs that prevent direct V to J rearrangements).

The murine D elements are classified into four families: DSP2, DFL16, DST4, and DQ52. Although D regions could theoretically contribute to Ig diversity by being read in all three frames, the mouse has evolved mechanisms that strongly favor one of them.[5] Four functional germline J_H sequences reside about 0.7 kb downstream of the most 3′ D region, DQ52.

The Human Immunoglobulin H Germline Variable, Diversity, and Joining Gene Segments

V_H Segments

The human V_H locus spans 1.1 Mb at the telomeric end of chromosome 14 (14q32.33) (see Table 6.1). The human germline V_H segments—numbering roughly 40 to 45—fall into seven families that, in contrast to the family clusters characteristic of the murine locus, are extensively interdigitated (see Fig. 6.4). Some human V_H sequences are polymorphic owing to V_H insertions or deletions in different allelic chromosomes. Twenty-four additional germline V_H sequences have been mapped to chromosome 15 and 16 and represent nonfunctional "orphans" that were apparently duplicated from the IgH locus on chromosome 14.[6]

Diversity and J_H Regions

Twenty-six human D elements are located in an ˜40 kb region about 20 kb downstream of VH6, the most 3′ of the V_H genes.[7] This D cluster is comprised of four tandem duplications of a 9.5 kb segment containing a representative of each of six D families. The twenty-seventh D element—DHQ52— is the only one showing sequence similarity to a mouse segment (DQ52) and shares a homologous location just 5′ to J_H1. In contrast to mice, humans use all reading frames of D elements.[7] One reading frame encodes primarily hydrophilic residues, one encodes hydrophobic residues, and one includes frequent stop codons. Some D

elements contain stop codons that can be removed by nuclease trimming during VDJ assembly. As in mice, the human J_H cluster is immediately downstream of DHQ52.

Heavy Chain Constant Regions

Murine and human genomic clones containing C region H-chain (C_H) genes include separate exons encoding the ˜100 to 110 amino acid Ig domains. These domains were independently identified by internal homologies of amino acid sequences and by three-dimensional structural analysis (X-ray crystallography). The exons are separated from each other by introns of roughly 0.1 to 0.3 kb. Thus, for example, the mouse γ2b protein has three major domains (CH1, CH2, and CH3) with a small hinge domain between CH1 and CH2. The gene structure may be summarized as follows:

CH1 - intron - **hinge** - intron - **CH2** - intron - **CH3**

(292) (314) (64) (106) (328) (119) (322)

where the numbers in parentheses represent the number of nucleotides in each segment. As an interesting contrast, the hinge region of the α gene is encoded contiguously with the CH2 domain with no intervening intron, while the unusually long human γ3 hinge is encoded by three or four hinge exons.

Genomic Organization of the C_H Region

Each B-lymphocyte initially produces IgM by expressing an assembled variable region linked to Cμ, but may use CSR (discussed later in this chapter) to replace Cμ with one of the several C_H regions lying downstream, thereby allowing expression of IgG, IgA, or IgE (Fig. 6.5A). Eight murine C_H genes span about 200 kb of DNA on chromosome 12; these genes were linked by contiguous clones in 1982.[8] Several γ pseudogenes lie within the clustered γ functional genes[9] (Fig. 6.5B). The coding sequences of all C_H genes are oriented in the same direction.

The human C_H genes were similarly cloned, and then eventually completely linked by the Human Genome Project. The human IgH locus contains a large duplication, with two copies of a γ-γ-ε-α unit separated by a γ pseudogene (see Fig. 6.5B). One of the duplicated ε sequences is also a pseudogene, and a third closely homologous ε-related sequence—a "processed" pseudogene—is present on chromosome 9.

The IgH locus has also been examined in several other species besides mouse and human, and several notable differences have been observed. Rabbits, for example, have 13 Cα sequences and only a single Cγ gene[10]; this unusual expansion of genes contributing to mucosal immunity may be related to the peculiar habit of coprophagy in these animals. In contrast to the multiplicity of rabbit Cα genes, pigs have only one Cα gene and eight Cγ genes. Camels are unusual in having H chains that function in the absence of L chains.[11]

Membrane versus Secreted Immunoglobulin

Igs are found either as secreted molecules in the serum or as membrane-bound receptors. The membrane-bound μ chains contain a C-terminal hydrophobic transmembrane domain consisting of 26 uncharged hydrophobic amino acids encoded by additional membrane exons, and these residues anchor the protein in the cell membrane lipid bilayer. The membrane (μ_m) and secreted (μ_s) forms are derived from the same gene by alternative splicing (Fig. 6.6). The same general gene structure has been found for other C_H genes, suggesting that differential splicing accounts for the two forms of all Ig isotypes.

Early B cells make roughly similar quantities of both μm and μ_s, whereas maturation to the plasma cell stage is associated with strong predominance of μ_s production, facilitating high-level secretion of circulating Ig. The balance between the two ribonucleic acid (RNA) splice forms of μ has been interpreted as a competition between splicing of the CH4 and M1 exons versus the cleavage/polyadenylation at the upstream μ_s poly(A) site. These processes are mutually exclusive because CH4-M1 splice removes the μ_s poly(A) site, while cleavage at the μ_s poly(A) site removes the membrane exons.

Cis-regulatory elements (and corresponding transacting RNA binding proteins) control the balance between these

processes. They include a GU-rich element downstream of the μs poly(A) site,[12] the polyadenylation factor cleavage stimulator factor 64,[13] and the U1A protein.[14] These factors likely function downstream of B-lymphocyte-induced maturation protein-1 (BLIMP-1) whose expression in Ig-secreting plasma cells was also found to be critical for μ_S poly(A) site utilization.[15] *Cis*-acting sequences affecting the ratio of alternative splice forms have been described for other isotypes besides Cμ, particularly Cα.[16]

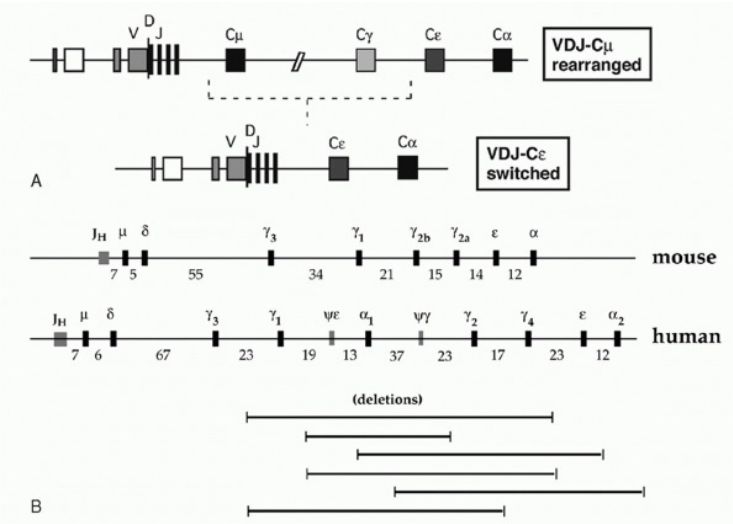

FIG. 6.5. Deletional Isotype Switch Recombination. A: The expression of "downstream" heavy chain genes is accomplished by a recombination event that replaces the Cμ gene with the appropriate heavy chain constant gene (Cε is shown as an example), deleting the deoxyribonucleic acid between the recombination breakpoints. **B:** The murine and human heavy chain constant region genes are diagrammed with the approximate intergene distance indicated below (in kb); various literature values for these distances differ somewhat, possibly due to allelic polymorphisms. The human locus shows a large duplication of γγεα sequences.

Membrane Ig serves as the antigen-recognition component of the BCR that is critical for initiating the signal for lymphocyte activation following contact with antigen. Transduction is mediated by an associated protein dimer composed of the BCR components Igα and Igβ (CD79a and CD79b) whose cytoplasmic domains contain immunoreceptor tyrosine-based activation motifs similar to those found in the CD3 chains mediating TCR signaling. Additional signaling is mediated by conserved tyrosines in the cytoplasmic tails of the IgG and IgE H chains, which serve as a phosphorylation-dependent docking sites for the signaling adapter Grb2.[17] Binding of Grb2 enhances BCR signaling and subsequent B-cell proliferation.

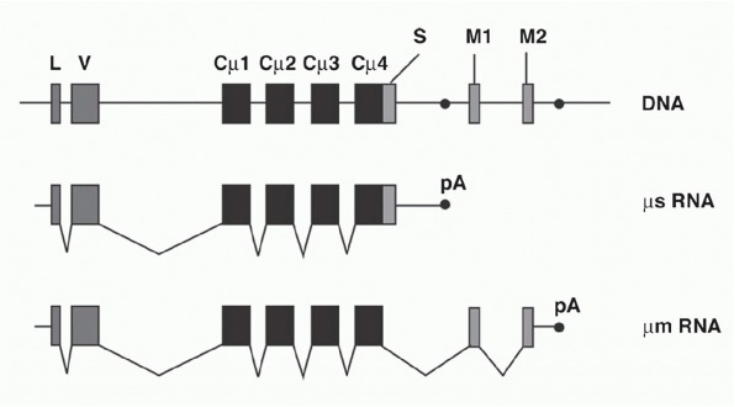

FIG. 6.6. Two Ribonucleic Acids (RNAs) Generated from the μ Gene by Alternative Processing. The *top line* illustrates the exons of the μ gene (*black rectangles*) in an expressed, rearranged μ gene. A primary transcript including all the exons present in the deoxyribonucleic acid can be processed as shown to yield either μ_S RNA (containing a C-terminal "secreted" sequence) or μ_m RNA (containing the two membrane exons).

Kappa Light Chain Genes

Murine Germline Vκ Locus

The murine Vκ locus spans about 3.2 mb on chromosome 6[18] and contains 20 Vκ families, some of which are shared by human and mouse (see Table 6.1). Vκ sequences within a single family are largely clustered together. Some Vκ elements lie in the opposite orientation to that of the Jκ and Cκ elements, and these Vκ segments undergo VJ recombination by an inversion rather than deletion (Fig. 6.7). A few Vκ sequences have been localized to chromosome 16 and 19 and are considered orphan genes.

Human Germline Vκ Locus

The human Vκ locus (see Table 6.1) lies on the short arm of chromosome 2 (2p11-2) spanning ~2 mb of DNA.[19] The locus includes a large inverted duplication, so that most Vκ sequences exist in pairs with one copy lying in the cluster proximal to Jκ (and in the same orientation) and a second copy (inverted) in the distal cluster. The average sequence similarity between duplicates is 98.9%, suggesting the duplication occurred less than 5 million years ago. This is consistent with the absence of such duplication in chimpanzees, which diverged from the human lineage approximately 6 million years ago. Interestingly, about 5% of human alleles also lack the distal duplication.

Outside the Igκ locus, at least 25 orphan Vκ segments have been identified in clusters on chromosome 1, 2, and 22. The orphan cluster located in the long arm of chromosome 2 was probably separated from the major locus—on the short arm of this chromosome—by a pericentric inversion (which must have occurred rather recently in evolution as it is absent from chimpanzee and gorilla).

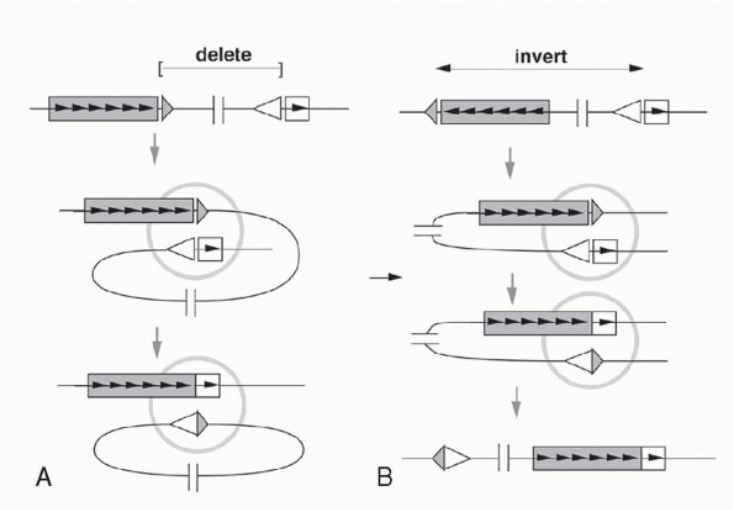

FIG. 6.7. The Same "Micro" Mechanism of Recombination can Join Vκ and Jκ by Deletion or Inversion, Depending on the Relative Orientation of the Two Precursors in Germline DNA. A: When V coding sequence (*shaded rectangle*) and J coding sequence (*white rectangle*) are oriented in the same 5′ → 3′ direction in germline DNA (as indicated by the *internal arrowheads*), the recombination yields a VJ coding joint plus a DNA circle containing the signal joint (*apposed triangles*). **B:** If V is oriented in the opposite direction in germline DNA, an identical recombination reaction at the "micro" level (*inside shaded circle*) leaves the signal joint linked to the recombined VJ coding joint.

Jκ and Cκ Elements

In comparison to the H chain genes, the organization of the C region segments in the κ locus is relatively simple (see Table 6.1). A single Cκ gene with a single exon and with no reported alternative splice products is found in both mouse and human. While all five Jκ elements are functional in humans, the third J element in mice has not been observed in functional κ L chains.

Apart from the typical Vκ-Jκ rearrangements, an additional recombination event occurs uniquely in the κ locus. The event is mediated by V(D)J recombination utilizing a 23-RSS element—designated Recombining Sequence in the mouse[20] and Kappa Deleting Element in the human[21]—that is positioned in an intergenic region downstream of Cκ; the recombination results in the deletion of the Cκ exon. Hence, Cκ fragments are undetectable on Southern blots of DNA from λ-expressing human lymphoid cells,[22] as in most B cells the Cκ genes are apparently deleted from both chromosomes before Igλ gene rearrangement begins.

Lambda Light Chain Genes

Murine λ Locus

In laboratory mouse strains, only about 5% of the B-lymphocytes utilize Igλ L chain, and the diversity of these L chains is meager due to the very small number of V region genes (Fig. 6.8). Complete sequence analysis[23] of the murine locus revealed two V-J-C clusters (Vλ2-Vλx-Jλ2Cλ2-Jλ4Cλ4 and Vλ1-Jλ3Cλ3-Jλ1Cλ1) separated by about 110 kb. Each Jλ is linked to its own Cλ region gene, but Jλ4 is nonfunctional. Recombination occurs largely within each cluster, although Vλ2Cλ1 products are occasionally observed. The ancestry of the Vλx element is uncertain, as it is rather dissimilar to the other Vλ segments; indeed, it resembles Vκ as much as Vλ. In contrast to the Igκ locus, the Vλ segments are flanked by 23-RSS and the Jλ gene segments by 12-RSS (see Fig 6.3).

Human λ Locus

The human Vλ region was characterized by intensive cloning, sequencing, and mapping of Vλ elements and ultimately by the complete sequence analysis of 1 Mb covering the entire locus[24] (see Table 6.1). Within the Vλ cluster lies the human VpreB gene (discussed below), as well as several genes and pseudogenes unrelated to the Igλ system.

λ L chains are much more abundant in man than in mouse (about 40% of human L chains are λ versus about 5% in mouse). Four forms of human λ chains have been classified serologically, with differences residing in a small number of amino acids in the C region. The serologic classification of Kern+ corresponds to a glycine at position 152 versus a serine in Kern-. The Oz+ designation corresponds to a lysine at position 190 versus an arginine in the Oz- variant. Similarly, Mcg+ λ chains (versus Mcg-) contain asparagine 112 (versus alanine), threonine 114 (versus serine) and lysine 163 (versus threonine).

Four functional human Jλ-Cλ segments and three pseudogenes are clustered within an approximately 33 kb region of DNA (see Fig. 6.8) and the four major expressed human λ isotypes correspond to the functional JCλ1, JCλ2, JCλ3, and

JCλ7, with the latter encoding an isotype provisionally designated Mcp.[25] JCλ6 may be functional in some individuals, and the common allele—which has a 4 bp insertion leading to a deletion of the C-terminal third of the Cλ region— can nevertheless undergo Vλ-Jλ recombination, encoding a truncated protein that can associate with H chains. A variety of polymorphic variants of the human λ locus have been detected, apparently the result of gene duplication, as shown in Figure 6.8.[26] Lastly, three Cλ-related sequences have been discovered near the major Jλ-Cλ cluster. One of these, designated λ14.1, represents the human homolog of the murine "surrogate" L chain λ5 (see following discussion).

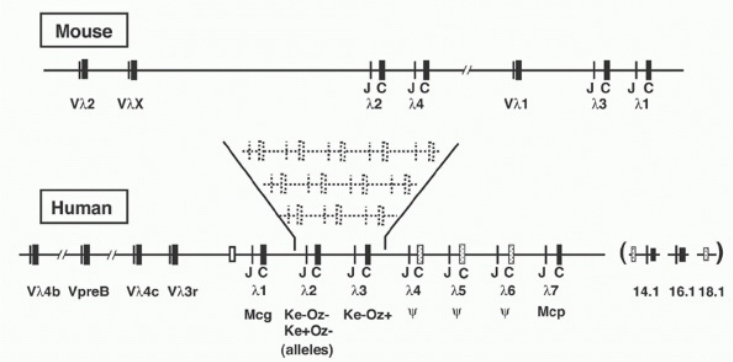

FIG. 6.8. Germline λ Genes. The maps in this figure are schematic (i.e., not to scale). **A:** The murine λ gene system includes four JC complexes and three V genes, as shown. **B:** The human λ locus includes multiple V genes, of which only three are shown. The human VpreB "surrogate" light chain gene is located within the Vλ cluster. The Cλ locus includes a segment of seven JC complexes plus three additional unlinked sequences. The hatched JC complexes diagrammed above the seven linked λ sequences represent polymorphic variants with additional duplications of the JC unit. The 14.1 sequence—the human λ5 "surrogate" light chain homolog—lies downstream of the JC cluster. Exon 1 of the 14.1 gene is homologous to an exon upstream of Jλ1 (as indicated by the *unlabeled white rectangle*).

λ-Related "Surrogate" Light Chains

Ig H chains cannot reach the cell surface without pairing with Ig L chains. However, Ig μ H chains can be detected on the surface of pre-B cells whose Igκ and Igλ loci are still in their germline configuration and thus do not produce L chains. In these cells, a "surrogate L chain" (SLC) composed of two smaller proteins, VpreB and λ5, facilitates the surface expression of the μ H chain protein. The first component (λ5) was identified as the product of a gene expressed exclusively in pre-B cells that showed high sequence similarity to the J and C

regions of the λ locus,[27] As four murine Cλ genes were already known, it was designated λ5. The second component of the SLC was identified as a gene residing about 4.7 kb upstream of λ5 in the mouse genome. Based on its similarities to both Vλ and Vκ (and its expression in pre-B cells), it was called VpreB1. A second, nearly identical sequence in the mouse genome is named VpreB2 and appears to be functional,[28] and a less similar VpreB3 has also been described. Neither λ5 nor VpreB genes show evidence of gene rearrangement in B or pre-B cells, and homologs have been found in every mammalian species examined.

The two SLC proteins form a L chain-like heterodimer that is able to fulfill some functions of a true L chain, including association with μ H chains to permit surface μ expression prior to the availability of κ or λ L chains. Thus, when a μ H chain gene was transfected into an Ig-negative myeloma line, no surface μ expression was observed unless λ5 and VpreB genes were also transfected.[29] Surface μ chains are covalently linked to the λ5 protein, while the VpreB1 protein is noncovalently associated. The expression of μ-SLC on the surface of pre-B cells triggers the onset of Vκ-Jκ rearrangement, as discussed below.

In humans, three λ5-like sequences are located downstream of the human Cλ cluster on chromosome 22 (see Fig. 6.8), but only one—designated 14.1—appears to be functional. The human VpreB homolog lies within the Vλ cluster[30] in contrast to murine VpreB, which lies close upstream of λ5.

V(D)J RECOMBINATION

The mechanism by which germline variable region segments (V_L and J_L, or V_H, D, and J_H) are assembled in the DNA to form a complete active V region has been pursued ever since Ig gene recombination was first discovered. In this section we will address 1) the molecular mechanism of the reaction, 2) the topology of the recombination events, 3) the components of the recombinase machinery, and 4) the regulation of that machinery during B-cell development.

Molecular Mechanism of V(D)J Recombination

Recombination Model Overview

A model for the detailed mechanism of the V(D)J recombination event must account for the observed features of the recombination *products* and of their germline *precursors*. In the germline *precursors*, the RSSs with their heptamer, nonamer, and appropriate 12 or 23 bp spacers are necessary and sufficient to create efficient recombination targets; model substrates in which RSSs flank DNA sequences completely unrelated to Ig genes are competent to undergo recombination. The model shown in Figure 6.9 will serve as a framework for discussion of the recombination mechanism. The recombination is thought to begin with binding of the RAG1-RAG2 complex to the RSSs that flank the two gene segments to be recombined. Simultaneous DNA cleavage occurs precisely between the RSSs and the gene segments. The two ends of the RSSs (frequently named “signal ends”) are joined directly, forming “signal joints.” In contrast, the ends of the gene segments (also referred to as “coding ends”) are processed prior to joining and are ultimately ligated together, giving rise to “coding joints” and completing the recombination event.

Recombination Products: Coding Joints and Signal Joints

In the recombination *products*, signal joints are typically direct ligation products of the signal ends: the RSSs are joined directly at the heptamers (“back-to-back”), and nucleotide additions or deletions at these junctions are quite rare. The properties of the coding joints, however, are more complex, as the joining reaction at these DNA ends is “imprecise.” The following features are frequently present:

1. Deletions: variable number of bases are deleted from the ends of the coding regions (in comparison to the “complete” sequence in the germline precursor)
2. Nongermline (“N”) nucleotides: random nucleotides (with a bias toward G and C) are added by a templateindependent DNA polymerase (discussed below). The sequence of

these N nucleotides has no relationship to the germline V, D, or J sequences.

3. Palindromic ("P") nucleotides: the ends of the coding gene segments are sealed by a DNA hairpin structure (see Fig. 6.9, and discussed in the following). "Opening" of these hairpins frequently occurs by nicking at some distance away from the hairpin tip leading to single-stranded overhangs. Filling in of such overhangs by DNA polymerases generates DNA palindromes that mirror the nucleotides at the end of the V, D, or J segment.[31] P nucleotides are generally only one or two bps, but they can be longer, especially in mice with the severe combined immunodeficiency defect (SCID) disorder in which the opening of the hairpins occurs in an aberrant manner.

Recombination Intermediates: Blunt Signal Ends and Hairpin Coding Ends

To study broken DNA ends as intermediates in V(D)J recombination, several laboratories employed ligation-mediatedpolymerase chain reaction (LM-PCR) to detect signal ends. This technique involves ligating blunt double-stranded oligonucleotide linkers to blunt genomic DNA breaks, and then amplifying the ligation junctions between a primer in the ligated oligonucleotide and a primer based on known sequence from the ligated genomic DNA; amplification products can

then be cloned and sequenced. LM-PCR analyses of both TCR and Ig genes undergoing V(D)J recombination showed the signal ends to be blunt double strand breaks (dsbs), usually exactly at the heptamer border.[32] Similar LM-PCR experiments failed to detect the coding ends unless they were pretreated with mung bean nuclease, a single-strandspecific endonuclease that recognizes the distortion of DNA at a hairpin structure. Sequences of these LM-PCR products from coding ends suggested that the hairpins are precisely at the end of the coding elements, usually without loss or gain of a single nucleotide.[33] By Southern blot analyses, coding ends were found to have two properties suggestive of a hairpin-like structure: 1) resistance to exonuclease treatment, and 2) doubling of the apparent length of restriction fragments under denaturing electrophoresis conditions.[34]

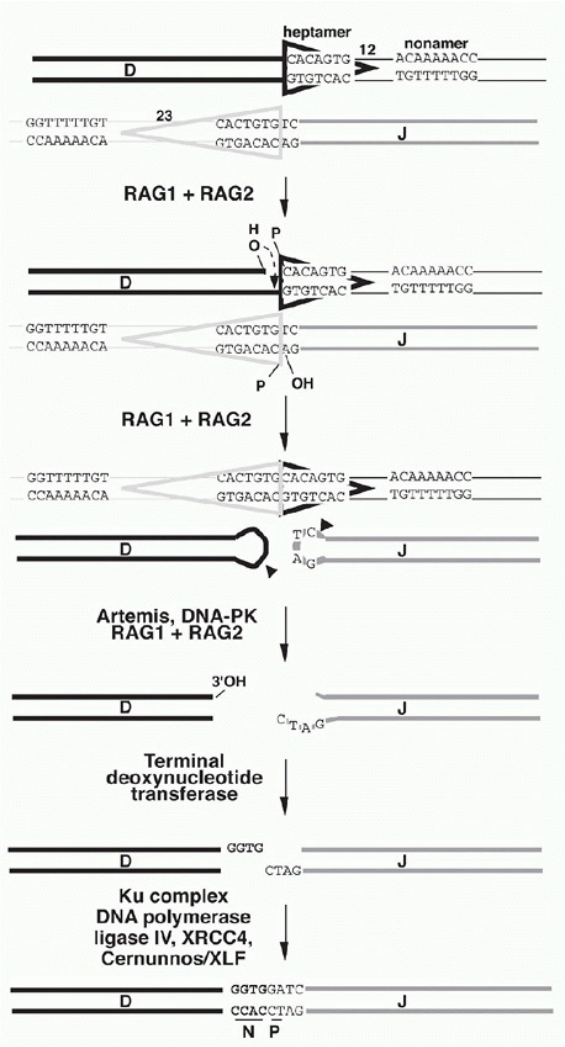

FIG. 6.9. Model for V Assembly Recombinations. All V assembly recombination reactions (in immunoglobulin and T-cell receptor genes) may proceed by a common mechanism, illustrated here by D-J recombination. The recombination signal sequences (RSSs) are included in *triangles*, which is the conventionally used RSS graphic. Hairpin loops are created on coding ends dependent on the action of the two Recombination Activating Genes: RAG1 and RAG2. After the opening of the hairpin loops, the pictured diversity coding sequence shows the effects of "nibbling" by exonuclease, but the joining coding sequence is spared and shows P nucleotide generation; N region addition is pictured in this example as occurring only on the diversity region end. In reality, exonuclease digestion and N nucleotide addition can occur on either (or both) ends. The steps in the proposed mechanism are discussed in the text.

Hairpin ends represent V(D)J recombination intermediates that, in wild-type cells, are opened at the hairpin tip (or a few nucleotides away from it) by the Artemis nuclease (discussed below). P nucleotides result from opening the loop at an asymmetric position (see Fig. 6.9); this model would explain why P nucleotides are never observed at coding ends that have been "nibbled" after opening of the hairpin. P nucleotide segments in the rare coding joints observed in SCID mice are unusually long and likely result from resolution of hairpins by nicking enzymes that, unlike Artemis, do not focus on the area near the tip of hairpin loops but instead nick in variable positions in the double-stranded hairpin "stem."[34]

Topology of V(D)J Recombination

Deletion versus Inversion

If a V segment and a J segment are both oriented in the same direction, they can recombine by excising the DNA between the coding sequences and ligating the two coding ends. Ligation of the two signal ends produces a DNA circle that generally lacks replication origins and therefore fails to replicate as cells divide after V(D)J recombination. Such excision circles are therefore generally absent in mature B-lymphocytes that have already undergone several rounds of proliferation after completing the Ig gene assembly. By isolating circular DNA from cells actively undergoing Vκ-Jκ rearrangement, it is possible to isolate and characterize the circular molecules bearing signal joints.[35]

As mentioned previously, some germline Vκ genes are oriented in the opposite direction from the Jκ-Cκ region. In these cases, VJ recombination occurs by an inversion of the DNA between the recombining V and J segments, leaving both the VκJκ coding joint and the signal joint (formed by ligating the RSSs) retained in the chromosome (see Fig. 6.7). This demonstrates that the enzymatic machinery "sees" only the DNA in the immediate vicinity of the recombination site and is insensitive to the topology of the DNA strands far from this site.

Nonstandard Joints

In addition to the canonical coding and signal joints, several "nonstandard" recombination joints have been documented, that, though not contributing to physiologic Ig gene assembly, represent tell-tale signs of a recombination event.[36] In the first phase of V(D)J recombination, the DNA is cut at both gene segment-RSS boundaries that participate in the reaction, thereby generating four DNA ends. In principle, there are three possible topologies in which these DNA ends can be rejoined:

1. "Signal and coding joints": the standard reaction product in which the two coding ends get joined generating the assembled VJ gene and the 12-RSS/23-RSS signal joint.
2. "Open and shut joints": the RSSs get ligated back to the gene segments from which they were released. These joints are topologically identical to the starting DNAs, but can be distinguished from them if nucleotides have been added or deleted at the junctions.
3. "Hybrid joints": joints in which the RSSs have traded places so that the 23-RSS that was flanking the Vκ segment is now linked to the Jκ segment, and vice versa.

"Hybrid" and "open and shut" joints have been observed in transfected plasmids bearing artificial recombination substrates[36] as well as in endogenous Ig loci *in vivo*.[37]

Secondary V(D)J Recombination

As discussed previously, imprecise joining of gene segments causes about two-thirds of all recombination products to be out-of-frame. Thus, a B-lymphocyte could end up with nonproductively rearranged Igκ genes on both alleles. However, germline Vκ segments lying upstream of an initial Vκ-Jκ recombination junction can recombine with Jκ segments lying downstream of the junction, producing a "secondary" recombination event, as shown in Figure 6.10A.

Such secondary recombination also occurs in cells that have assembled a productive Vκ-Jκ joint if the encoded antigen binding domain recognizes an autoantigen. This type of secondary recombination, known as "receptor editing," is considered in more detail later in this chapter.

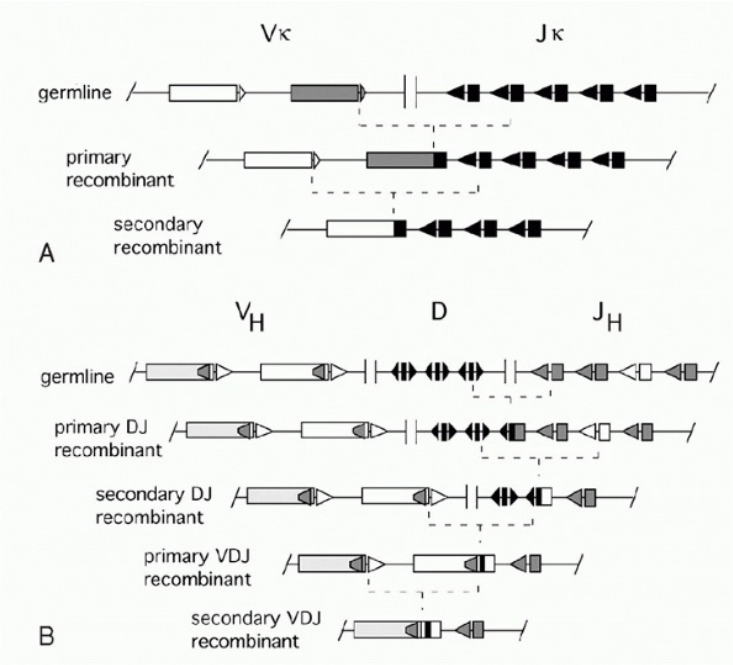

FIG. 6.10. Secondary Recombinations. A: In the κ light chain system, a primary recombination can be followed by recombination between an upstream V and a downstream J. **B:** Analogous secondary recombinations can occur in the heavy chain system between upstream D and downstream J segments. After V(D)J recombination eliminates all 12-RSS signal elements from the chromosome, secondary recombination can still occur between VH (23-RSS) and an internal heptamer within the VH coding sequence of the VDJ unit.

In the IgH locus, secondary D-J rearrangements sometimes occur, but only until V_H-DJ_H recombination removes all unused upstream D_H segments (Fig. 6.10B). VDJ rearrangement eliminates all the 12-RSSs from the IgH locus that could pair with the 23-RSSs flanking the upstream V_H elements. Sometimes, these V_H segments do, however, recombine with an established VDJ unit, displacing most of the originally assembled V_H element,[38] a process sometimes called V_H replacement. Such events are mediated by cryptic RSSs (mainly a heptamer sequence) that is present near the 3′ end of about 70% of all V_H genes (see Fig. 6.10B). Such internal cryptic RSSs are not generally found in L chain genes. As discussed previously for the L chain, secondary recombination represents a rescue mechanism for cells with nonproductive rearrangements on both H chain chromosomes, and for cells whose encoded antibody recognizes an autoantigen.

The V(D)J Machinery

Since the discovery of V(D)J recombination as the process that assembles the germline antigen receptor gene segments into functional genes, one major question was the identity of the enzymatic machinery catalyzing this complex set of reactions. Genetic and biochemical work by a large number of laboratories led to identification of a total of 13 different proteins that have been shown to be directly involved in V(D)J recombination: RAG1, RAG2, HMG1, Ku70, Ku80, DNA-PKcs, Artemis, pol μ, pol λ, TdT, XRCC4, Cernunnos/XRCC4-like factor (XLF), and DNA ligase IV. The only lymphoid-specific factors are RAG1, RAG2, and TdT; all others are ubiquitously expressed in all cell types, and this feature allows investigators to study aspects of V(D)J recombination by ectopically expressing the RAG proteins in nonlymphoid cells. A recent biochemical tour de force study showed that coding joint formation could be recapitulated *in vitro* using artificial recombination substrates and highly purified preparations of all 13 proteins.[39] The respective coding joints showed all of the features typically observed *in vivo* (nucleotide deletion, N nucleotide, and P nucleotide

addition), suggesting that most, if not all, of the factors involved in the coding end processing steps of V(D)J recombination have been identified. In contrast, signal joint formation was not observed. This step seems to require the removal of the RAG proteins after the cleavage reaction and is likely to require additional factors as yet unidentified.

Recombination Activating Gene Proteins: Mediators of Early Steps in V(D)J Recombination

A major advance in the investigation of V(D)J recombination was the identification of two genes whose products are critical for this process in the B and T cell lineages. In the pioneering experiments, Schatz and Baltimore[40] stably transfected fibroblasts with a construct containing a selectable marker whose expression was dependent on V(D)J recombination; as expected, no measurable recombination occurred in this nonlymphoid cell. However, when either human or murine genomic DNA was transfected into these fibroblasts, a small fraction of recipient cells stably expressed recombinase activity, activating the selectable marker. This suggested that a single transfected genomic DNA fragment was able confer recombinase activity in a fibroblast. (Presumably the fibroblast contained endogenous copies of the same genes, but their expression was repressed by mechanisms that could not repress the transfected genes.) This active fragment was cloned and turned out to contain two closely linked genes, designated RAG1 and RAG2, respectively. Both RAG1 and RAG2 are essential for recombination; therefore, these genes would not have been discovered by this transfection technique if they had not been closely linked in the genome. The genes are notable for having no introns splitting up their open reading frame in most species, and for their opposite transcriptional orientation in all species examined.

A crucial role for the RAG genes in V(D)J recombination was supported by the conservation of these genes in all jawed vertebrate species analyzed thus far, from shark through man. RAG1 and RAG2 are expressed together in developing B and T cells, specifically at the stages at which V(D)J recombinase activity is required for the assembly of Ig and TCR genes. Moreover, mouse strains in which either gene has been eliminated by homologous recombination (gene “knockouts”) have no mature B or T cells, as the result of their inability to initiate V(D)J recombination.[41,42] Similarly, a subset of human patients with SCID syndrome characterized by the complete absence of T- or B-lymphocytes have been found to have null mutations in RAG genes.[43] Patients with hypomorphic alleles often have a complex set of features (oligoclonal T cells, hepatosplenomegaly, eosinophilia, decreased serum Ig but elevated IgE) known as the Omenn syndrome, which can also be caused by defects in other genes involved in V(D)J recombination. Interestingly, the same RAG mutation in different patients can cause either Omenn syndrome or SCID, depending on unknown factors.[44]

RAG1 shows intrinsic binding affinity for the RSS nonamer sequence via its nonamer binding domain even in the absence of RAG2. Exhaustive mutational analysis has revealed that RAG1 contains the catalytic center of the RAG complex, composed of three amino acids critical for all enzymatic activity: D600, D708, and E962.[45,46] RAG2, on the other hand, serves as a regulatory cofactor; it has no intrinsic binding affinity for RSSs, but once bound to RAG1 improves the strength and specificity of RAG1 RSS contacts.[47,48] It is also enhances RAG activity on chromosomal substrates and it restricts V(D)J recombination to the G0/G1 stage of the cell cycle (both features are discussed below).

Attempts to determine the molecular role of the RAG proteins in cell-free recombination assays were initially hampered by poor solubility of the proteins, but functional analyses of truncated RAG genes (using RAG expression vectors cotransfected into fibroblasts along with recombination substrate plasmids) revealed that surprisingly large segments of both proteins could be deleted without eliminating recombinase activity, and some of the remaining core regions were

soluble and could be handled relatively easily in experiments. This work allowed the demonstration that in a cell-free *in vitro* system, core regions of the two RAG proteins together are capable of carrying out cleavage of substrate DNAs as well as hairpin formation

on the coding end.[49]

The RAG-mediated cleavage occurs in two steps: first a nick is introduced on the top strand between a gene segment and the adjacent heptamer (see Fig. 6.9), then the 3′-hydroxyl group participates as the nucleophile in a direct transesterification reaction to attack the phosphodiester bond adjacent to the heptamer on the bottom strand (see Fig. 6.9), yielding a DNA hairpin structure on the coding end and a new 3′-hydroxyl group on the 3′ end of the bottom heptamer strand.[50] After DNA cleavage, the RAG proteins remain in a complex with the DNA ends and facilitate aspects of the joining phase. Mutant forms of RAG1 or RAG2 have been reported that are competent for cleavage but show impairment in coding or signal joint formation.[51]

While nicking can occur asynchronously at the 12-RSS and 23-RSS, hairpin formation is "coupled" and occurs synchronously at both RSSs. *In vitro*, coupled cleavage requires only the RAG proteins, HMG1/2 (discussed below) and Mg^{2+} as the divalent metal ion in the reaction buffer. *In vivo*, DNA dsb formation at an individual RSS is dangerous as it could give rise to translocations, and it is thought that Mg^{2+} promotes an optimal molecular "architecture" for controlled V(D)J recombination. *In vivo* experiments indeed suggest that RAG proteins may bind to and introduce a nick at a single 12-RSS, but do not complete DNA cleavage until a matching 23-RSS is captured into the RAG-RSS complex.[52]

In addition to the "classical" activities of RAG proteins on DNA segments containing RSSs, these proteins can also catalyze DNA strand cleavage on "nonstandard" substrates.

1. Transposition. *In vitro*, purified recombinant core RAG proteins can catalyze the excision and insertion of a DNA fragment with signal ends into foreign DNA, acting as a transposase.[53,54] This property provides additional support for the early speculation that the V(D)J recombination system may have originated by insertion of transposon-like DNA fragment encoding RAG genes (and bearing RSSs at its ends) into a primordial antigen receptor gene, thereby generating a pair of separated V and J gene segments. This model of the origin of V(D)J recombination is consistent with the many mechanistic similarities at the molecular level between Ig gene rearrangements and transposition,[55] and the recent identification of the Transib transposase family that shows striking sequence similarity to RAG1 and is widespread in insect, echinoderm, helminth, coelenterate, and fungal genomes.[56] The recent finding of an apparent homolog of the entire RAG1 and RAG2 gene locus in a sea urchin genome suggests that the two RAG genes may have entered the genome of a common ancestor of all deuterostomes far earlier than the Ig-/TCR-based adaptive immune system developed.[57] It remains unclear whether the primordial RAG transposon encoded solely RAG1 (which would then have integrated next to the primordial RAG2 gene) or both RAG1 and RAG2. The transposase activity of RAGs, however, seems to be almost completely suppressed *in vivo*, and the C-terminus of RAG2 may have evolved to control this potentially deleterious activity.[51,58,59,60]
2. V_H replacement. As mentioned previously, recombination events can occur between a V_H 23-RSS and cryptic RSS within rearranged V_H coding sequences. An *in vitro* model suggests that in V_H replacement, the RAG proteins nick both DNA strands without forming a hairpin coding end.[61] Whether this is indeed a completely different activity is unclear.
3. Translocations at non-RSS sequences. The RAG complex also generates two nicks to cleave within the major breakpoint region of the *Bcl2* gene. This 150-bp segment is the target of a common RAG-catalyzed translocation between the IgH locus and the *Bcl2* gene occurring in most follicular lymphomas. In this segment, there are no RSSs, and the RAG proteins recognize an unusual sequence-dependent DNA conformation different from the normal B-form double helix.[62]

Although the "core" RAG proteins have been useful for elucidating the molecular mechanism of the cleavage step of V(D)J recombination in biochemical studies, it is clear that the "noncore" portions of each protein confer important functions, as expected from their sequence conservation across species. Broadly speaking, the "noncore" regions ensure

regulated and efficient recombination on the physiological substrates (i.e., imperfect RSSs deviating from the perfect consensus heptamer and nonamer) in the context of chromatin. The functions of the “noncore” regions have largely been inferred by comparing V(D)J recombination products from cells expressing core RAG proteins versus full-length versions, and more recently by *in vitro* studies using full-length RAG proteins that are now available for such analyses.

The C-terminal region of RAG2 has multiple functions and is important for achieving normal numbers of B- and T-lymphocytes *in vivo*,[63] for the formation of precise signal joints during IgH recombination,[64] and for protecting against RAG-mediated DNA transposition.[51,65] These functions are thought to be conferred at least in part, by a plant homeo domain (PHD) zinc finger fold that is formed by amino acids 414 to 487 in murine RAG2. This PHD domain binds specifically to the tails of histone H3 that are trimethylated at lysine 4 (H3K4Me3),[66,67,68] a histone modification that is associated with “open” chromatin and that is uniquely present on “accessible” RSSs in Ig loci (discussed below). *In vitro* studies suggest that the binding of the RAG2 PHD domain to histone tails causes a conformational change that increases the catalytic activity of the RAG complex.[69]

Furthermore, the RAG2 C terminus regulates RAG2 protein levels—and hence V(D)J recombinase activity—across the cell cycle to prevent dsbs during DNA synthesis or mitosis, when such breaks could lead to chromosomal deletions.[32] RAG1 protein and messenger RNA (mRNA) transcript levels of both RAG genes vary little across the cell cycle, but phosphorylation of RAG2 at Thr490 by the cyclin-dependent

kinase cdk2 mediates its destruction via ubiquitination and proteasomal degradation during S phase.[70] Mice expressing RAG2 with a T490A mutation (which cannot be phosphorylated) showed RAG2 protein and dsbs throughout the cell cycle, demonstrating the importance of the RAG2 degradation signal in cell-cycle control of V(D)J recombination.[71,72]

The N-terminal noncore region of RAG1 is required *in vivo* for optimal RAG1 activity and for the formation of precise signal joints in D-J recombination.[64] This region of RAG1 contains a RING finger domain that seems to be required for ubiquitination of several proteins, including histone H3.[73]

Apart from the obvious importance of the RAG proteins in understanding the initial steps of V(D)J recombination, knowledge of these proteins and their genes has allowed two major technical advances that have opened the way to many additional experiments. First, various nonlymphoid cell lines with known defects in various DNA repair genes have been transfected with the RAG genes to identify genes involved V(D)J recombination (these factors are described below). Second, availability of the RAG1 and RAG2 knockout mice has been instrumental in a large number of immunology studies. These mice completely lack functional B cells or T cells, and are not “leaky” like SCID mice, which develop some functional B and T cells, especially as the animals age. Thus the RAG-deficient mice can be used to study the importance of the “innate” immune system (i.e., responses that occur in the absence of antigen-specific lymphocytes) in particular immune responses. They can also be used as recipients for various lymphocyte populations to explore the roles of different cell types. They can also be used as recipients for various lymphocyte populations to explore the roles of different cell types. They can be transfected with transgenes encoding specific Ig genes to study the roles of specific antibodies in B cell development and in immune responses. Finally, they can be used in “RAG complementation” experiments designed to assess the phenotype —in lymphocytes—of various other gene knockouts.[74] In RAG complementation, embryonic stem cells in which the gene of interest has been knocked out by homologous recombination are injected into homozygous RAG2 knockout (RAG2-/-) blastocysts. This procedure yields chimeric mice in which all B and T cells derive from the embryonic stem cells deleted for the gene of interest, as these are the only source of intact RAG genes to support lymphocyte development. Such animals can be made more easily than a knockout mouse line, and can be used to study the effect of gene deletion in lymphocytes independent of effects the deletion may have in other cells. In particular, for cases where the gene knockout causes

embryonic lethality due to effects on nonlymphoid cells, RAG complementation allows the selective knockout in lymphocytes to be studied in the background normal gene expression in nonlymphoid cells.

High Mobility Group Proteins

The search for RAG cofactors that stimulate cleavage activity in biochemical assays led to the identification of HMG1.[75] HMG1 (and the closely related HMG2) are abundant and ubiquitous proteins that bind DNA in a non-sequence-specific manner and to cause a local bend in DNA. The two RAG proteins can form a stable signal complex with a 12-RSS, but efficient complex formation with a 23-RSS requires the addition of either HMG1 or HMG2.[76] HMG1/2 apparently stabilizes the bending of the 23-RSS that is induced by the RAG proteins themselves.[77]

Nonhomologous End Joining Components

The RAG proteins are the essential lymphocyte-specific factors in the DNA cleavage phase of V(D)J recombination, but DNA repair factors that are part of a DNA repair pathway known as nonhomologous end joining (NHEJ) are essential for the joining phase. NHEJ is the major pathway for repair of dsbs (such as those induced by ionizing radiation or reactive oxygen species) during the G0-G1 phases of the cell cycle. (In the S and G2 phases, the additional chromatid genome copy enables breaks to be repaired by homologous recombination.) The six classical core components of NHEJ are Ku70, Ku80, DNA-PKcs, XRCC4, DNA Ligase IV, Artemis, and Cernnunos/XLF, but additional proteins play a role in some models of NHEJ.

The DNA-PK Complex. The first gene for an NHEJ component to be recognized as participating in V(D)J recombination was the SCID gene. This gene was originally identified as being mutated in the *scid* mouse strain that is immunodeficient due to a marked impairment in V(D)J recombination of both Ig and TCR genes. Lymphocytes from *scid* mice are able to perform the RAG-mediated cleavage reaction, and can also form signal joints, but are markedly defective in coding joint formation. Subsequently, it was found that the *scid* mutation also impairs NHEJ, causing radiosensitivity.

The gene mutated in the *scid* mouse strain encodes DNAPKcs, a large protein (460 kD) with a kinase domain near its C terminus that is related to phosophoinositide-3-kinase (PI3K). This kinase is DNA-dependent and represents the catalytic subunit (hence “cs”) of a heterotrimer known as the DNA-PK complex. The other components are Ku70 and Ku80 (also referred to as Ku86), which were originally identified as the autoantigens recognized by a patient antiserum (Ku was the coded name of the patient, and the numbers refer to the approximate size of the proteins, 70 kD and 80 to 86 kD, respectively). Together, these two very abundant proteins form a heterodimer that binds to the ends of double-stranded DNA independent of the nucleotide sequence of the DNA. The DNA-Ku complex can then recruit DNAPKcs and activate autophosphorylation of this protein.[78] *In vitro* activation of DNA-PKcs was found to be efficient when DNA ends either were at high concentration or, if at low concentration, were on DNA fragments long enough to circularize readily. In contrast, when the DNA-PKcs was located on the ends of DNA fragments too short to circularize (and too dilute for efficient intermolecular interactions with other DNA ends), the DNA-PKcs activation was much reduced. These observations suggest that kinase activation can occur only after two DNA ends are brought together by DNA-PKcs in “synapsis.”[79,80] Further phosphorylation of

DNA-PKcs inactivates the protein and may prepare it for removal once DNA ends have been sealed.

Ku genes are highly conserved through evolution, and homologs are even found encoded in the genome of some bacteria, consistent with a function in general NHEJ not restricted to V(D)J recombination. While mice with a targeted deletion of DNA-PKcs resemble the original *scid* mutation (i.e., defective coding but functional signal joint formation[81,82]), Ku70 and Ku80 mutant cell lines are defective in both signal and coding joint formation, and Ku70- and Ku80-deficient mice exhibit a complete block in B- and T-cell development due to their inability to undergo V(D)J recombination.[83,84,85]

DNA Ligase IV and XRCC4. An important role of activated Ku-DNA-PKcs complex is to recruit the additional components of NHEJ. One such component is DNA ligase IV, which is recruited to the Ku complex and activated by the protein XRCC4.[86,87] The evidence suggests that DNA ligase IV is the essential ligase that joins DNA ends in V(D)J recombination and NHEJ. Human patients with ligase IV deficiency (characterized by hypomorphic alleles) have a severe phenotype including chromosomal instability, developmental and growth retardation, radiosensitivity, and immunodeficiency with a T-B-NK+ phenotype.[88] The rare D_H-J_H junctions detected show extensive nucleotide deletion consistent with delayed ligation and prolonged exonuclease digestion.[89] In mice, disruption of either the XRCC4 or the DNA ligase IV gene causes embryonic lethality associated with neuronal apoptosis. Crossing these mice with p53 mutants does not improve V(D)J recombination, but rescues the mice from embryonic lethality, suggesting that neuronal cells may be unusually susceptible to p53-triggered apoptosis induced by normal low-level DNA damage during brain development; a similar mechanism may explain the severe human phenotype.[90] DNA ligase IV is the only NHEJ component absolutely required to join compatible sticky DNA ends *in vitro*, though XRCC4 can stimulate this activity significantly.[87]

Cernunnos/XRCC4-like Factor. The next NHEJ component was independently discovered by two laboratories. One group used yeast two-hybrid screening to search for proteins interacting with XRCC4.[91] The other group searched for the gene causing a syndrome of T+ B lymphocytopenia, increased radiosensitivity, and microcephaly in a Turkish family; these investigators used functional cDNA rescue of a patient's cell line from a radiomimetic drug to identify the gene.[92] The protein identified by both groups is a 299 amino acid nuclear protein, which was named Cernunnos or XLF. The protein has a predicted secondary structure similar to that of XRCC4, to which it binds in cells[93] as expected from its isolation via two-hybrid screen. When Cernunnos/XLF-deficient fibroblasts were transfected with RAG genes and a recombination substrate, imprecise signal joining was observed, similar to the defect in patients with hypomorphic DNA ligase IV mutations. These experiments all suggest a role for Cernunnos/XLF linked to the function of XRCC4 and ligase IV.

Artemis. The coding ends generated by RAG cleavage cannot be directly ligated because of their hairpin structure, and therefore V(D)J recombination requires a single-strand endonuclease activity to cleave the hairpins. This activity is conferred by the protein named Artemis, which was discovered through positional cloning of the genetic defect in a group of human SCID patients with defects in V(D)J recombination and increased radiation sensitivity.[94] Patients with homozygous null mutations of Artemis survive (no embryonic lethality) and show sensitivity to γ irradiation as well as defects in coding joints, while signal joint formation is normal. Hypomorphic Artemis mutations can cause features of the Omenn syndrome similar to those observed with hypomorphic RAG gene mutations.[95] Purified recombinant Artemis protein has an intrinsic exonuclease activity *in vitro*; however, when complexed with DNA-PKcs in the presence of DNA ends, it gains a single-strand endonuclease activity and, in an ATP-dependent step, becomes phosphorylated at multiple sites in the C-terminal region of the protein.[96,97] The Artemis endonuclease can cleave synthetic and RAG-generated hairpin ends as well as other singlestranded DNA near a transition to double-strand DNA.[98]

DNA Polymerase X Family Members. If a hairpin opening leaves blunt ends or complementary sticky ends (like the ends generated by many restriction enzymes), *in vitro* joining experiments suggest that these ends can be joined by ligase IV without any additional processing.[99] However, as Artemis probably opens most hairpins noncomplementary DNA overhangs, further processing of DNA ends generally occurs before ligation completes the recombination. This processing may include further nuclease digestion (by Artemis or exonucleases) and apparently also involves variable DNA extension by three DNA polymerases—polymerase λ, polymerase μ, and terminal deoxynucleotidyl transferase (TdT)—all of which are members of the polymerase X family. Interestingly, all three proteins contain a Brca1-C-terminus domain, which is thought to confer binding to Ku.[100]

Terminal Deoxynucleotidyl Transferase and N Regions. TdT, the primary source of untemplated "N region" additions in VDJ junctions, is an enzyme uniquely expressed in the thymus and bone marrow; in the B lineage, it is expressed almost exclusively in pro-B cells. It catalyzes the nontemplated addition of nucleotides to the 3′ end of DNA strands. Though no template determines the nucleotides added, the enzyme adds dG residues preferentially, consistent with N region sequences observed in VDJ joints. Both TdT expression and N nucleotide addition are characteristically absent from fetal lymphocytes.[101] N region addition is common in H chain genes (recombined in pro-B cells) but rare in murine L chain genes (recombined in pre-B cells), though perhaps somewhat less rare in human.[102] This is consistent with the observation that in mice the expression of a μ H chain may downregulate TdT expression,[103] contributing to the reduced level during the stage of L chain recombination.

Lymphocytes with engineered defects in their TdT genes produced rearranged Ig V regions with almost no N additions. Conversely, when TdT expression was engineered in cells undergoing κ or λ L chain rearrangement, the level of

N nucleotide addition to these coding joints was dramatically increased. Furthermore, mice engineered to undergo premature Vκ-Jκ joining in pro-B cells show an increased frequency of N region nucleotides in their recombined Vκ genes.[104] These results suggest that the low frequency of N region sequences in normal κ or λ recombinations is caused by the reduced levels of TdT at this stage of B-cell development (see following discussion).

The absence of N region addition in TdT mutant mice, as well as in normal fetal lymphocytes, is associated with an increase in the frequency of recombination junctions with microhomologies. These are short stretches of nucleotides that are present close to the end of both germline gene segments involved in the recombination event. These junctions suggest a joining intermediate in which the complementary single-stranded regions from the two coding ends hybridize to each other, much as "sticky ends" generated by restriction endonucleases can facilitate ligation of DNA fragments. This alternative joining pathway may restrict the diversity of neonatal antibodies; the resulting antibodies are possibly enriched in specificities for commonly encountered pathogens, or have broadened specificity, as has been reported for TCRs lacking N regions.[105] Decreased N region nucleotides and a high incidence of homology-mediated recombination have also been found in the rare coding joints formed in Ku80-/- mice, consistent with a role for Ku in recruiting TdT or supporting its action.[106]

Polymerase μ and Polymerase λ. Polymerase μ and polymerase λ are ubiquitously expressed polymerases. Both readily fill in single-strand gaps in DNA and apparently participate in V(D)J recombination by filling in single-strand 3′ overhangs generated by asymmetric hairpin opening. Without this filling in, such overhangs might be resected by nucleases. Indeed, when *in vitro* NHEJ reconstitution experiments are performed using purified proteins and DNA fragments with overhanging ends, the omission of polymerase μ or polymerase λ increases the deletional trimming at junctions.[100] Similar excessive deletions at VDJ junctions are observed in mice lacking polymerase μ or polymerase λ. Remarkably, however, polymerase μ knockout mice show abnormalities only in their L chains,[107] whereas the deletions in polymerase λ knockouts are restricted to their H chains.[108] This selectivity may be explained by corresponding changes in the relative mRNA levels for these two polymerases at different stages of B-cell development.

Other Participants in V(D)J Recombination

DNA Damage Response Factors. In eukaryotic cells, DNA breaks initiate signals that halt cell division, induce DNA repair, and in some cases trigger apoptosis. Several proteins apart from NHEJ components can be detected at DNA breaks induced by V(D)J recombination or irradiation, including γ-H2AX, a phosphorylated form of the histone H2AX; ATM, the product of the gene mutated in the disease ataxia telangiectasia; Nbs1 (or nibrin), the product of the gene mutated in Nijmegen breakage syndrome; and 53BP1, p53 binding protein 1. The importance of these proteins in V(D)J recombination is not clear because defects in all three

are compatible with near normal V(D)J recombination. Possibly, they participate in backup mechanisms to prevent aberrant V(D)J recombination and thus translocations.

Pax5/B-Cell-Specific Activator Protein. Pax5 (also known as B-cell-specific activator protein; BSAP) is a transcription factor required for normal B-cell development. Pax5-deficient mice are able to complete DJH recombination, but V_H to DJ_H recombination is impaired except for certain V_H genes located proximal to the D regions. Interestingly, 94% of human and mouse V_H coding genes were found to have potential Pax5 binding sites. Surprisingly, Pax5 was found to coimmunoprecipitate with RAG proteins, to potentiate *in vitro* cleavage of a V_H gene RSS, and to enhance V_H to DJ_H recombination in RAG-transfected fibroblasts; the latter enhancement required intact Pax5 binding sites in the V_H sequence.[109]

REGULATION OF V(D)J RECOMBINATION IN B-CELL DEVELOPMENT

The expression of only one antigen binding specificity by each B-lymphocyte is a crucial requirement of the clonal selection model of the humoral immune response. Thus, the recombination events that occur between Ig gene segments are carefully regulated so that most B cells express only one L chain isotype, either Igκ or Igλ (isotype exclusion), and use only one of the two alleles of H and L chain genes (allelic exclusion). These constraints ensure that each B cell expresses a single H_2L_2 combination. Current evidence suggests that V(D)J recombination is controlled largely at two levels: regulation of the RAG protein activity and regulation of accessibility of the germline V, D, and J elements to the recombinase machinery. Both of these are controlled by the stage of B-cell development; conversely, the expression of Ig provides a signal critical for regulating maturation of B cells. A brief scheme of B-cell development is presented in the following as background.

B- and T-lymphocytes differentiate from pluripotent hematopoietic stem cells in the fetal liver and bone marrow (Fig. 6.11). The primordial lymphoid progenitor has the potential to differentiate into B- or T-lymphocytes or natural killer cells. Among the earliest markers that indicate B-lineage specificity are the non-Ig components of the pre-BCR: Igα, Igβ, and λ5. CD19, which functions as a coreceptor in signal transduction, first appears in large proliferating “pro-B” cells, which also express several other distinguishing surface markers including c-kit, B220, TdT, and CD43. RAG gene expression in pro-B cells initiates D to J rearrangements on both alleles. Subsequently, recombination with germline V_H elements occurs; if the recombination is “productive” (i.e., yielding an “in-frame” VDJ junction), a μ H chain protein can be produced. This protein appears on the B-cell surface along with SLC in a pre-BCR (also named μ-SLC) complex that also includes Igα and Igβ. As the resulting large pre-B cells proliferate, RAG gene expression declines. After several rounds of division, the cells become smaller, stop dividing, turn up RAG gene expression once more, undergo L chain recombination, and express surface

IgM. These “immature B cells” again turn down RAG expression. In these IgM+IgD- immature B cells, contact with autoantigens may upregulate RAG expression again to facilitate receptor editing (discussed in more detail below). When immature B cells eventually also express surface IgD, they become “mature B cells” and migrate into the periphery, ready to be triggered by antigen exposure.

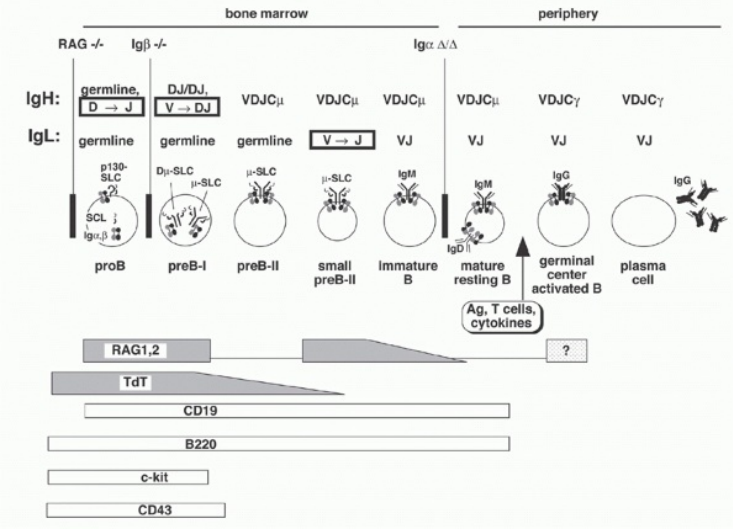

FIG. 6.11. Immunoglobulin (Ig) Gene Recombination in B-Cell Development. A simplified scheme of B-cell development is presented as a background for discussion of Ig gene recombination. The stages occurring in the bone marrow versus in the periphery (e.g., lymph nodes, spleen) are shown, along with the status of IgH and IgL genes at each stage. A graphic depicting the Ig-related proteins displayed on the surface at each stage is presented; at the bottom, the stage-dependent expression of recombination activating genes and terminal deoxynucleotidyl transferase—both important in V(D)J recombination—is schematically depicted.

Allelic Exclusion and Regulated V(D)J Recombination

The previous description of B-cell development serves as a background to understand an explanation of allelic exclusion that was first proposed by Alt and colleagues[110] and has been supported by subsequent experiments. According to this model the functional rearrangement of an L (or H) chain gene in a particular B cell would inhibit further L (or H) chain gene rearrangement in the same cell. If the inhibition occurred promptly after the first functional rearrangement, then two functional Igs could never be produced in the same cell. An initial nonproductive rearrangement would have no inhibitory effect, so recombination could continue until a functional product resulted or until the cell used up all its germline precursors.

In pro-B cells, the first Ig gene rearrangements join D to J_H segments (commonly on both chromosomes), and this is followed by V_H to DJ_H recombination. If the first V_H to DJ_H recombination in a pro-B cell produces a functional VDJ gene, a functional μ H chain will be expressed on the cell surface paired with the SLCs. The expression of this pre-BCR complex has been shown to have two consequences. First, it blocks further H chain recombination by decreasing RAG gene expression[111] and by reducing target accessibility, as reflected in decreased V_H gene transcription.[112] The latter is important for rendering the IgH locus inaccessible during subsequent rearrangement of the Igκ and Igλ loci. If the initial V_H to DJ_H rearrangement is nonfunctional (e.g., out of frame), subsequent V_H to DJ_H recombination occurs on the other allele. If the VDJ recombination product on the

second chromosome is also nonproductive, then the cell has reached a dead end and is eliminated by apoptosis.[113]

The second consequence of pre-BCR expression is the initiation of Ig L chain recombination. This effect was originally deduced from the rarity of κ-expressing cells without H chain gene rearrangement, suggesting that H chain expression is required for κ recombination. As additional evidence, a functional μ gene introduced into early B-lineage cells can cause RAG gene expression and turn on transcription of unrearranged Vκ genes. These are designated

"sterile" transcripts because they cannot encode a κ protein, but they are required for Vκ-Jκ recombination. When this recombination ensues, the possibilities for functional and nonproductive Vκ-Jκ rearrangements resemble those discussed previously for the H chain. Expression of a functional κ chain that can associate with μ to form a surface-expressed IgM molecule results in the downregulation of RAG gene expression and suppression of further κ rearrangements. By this mechanism, functional rearranged VκJ-Cκ transgenes can suppress rearrangement of endogenous κ genes.[114]

Most B cells show isotypic exclusion (i.e., they express either κ or λ but not both). Furthermore, κ rearrangement seems to occur before λ. Thus in normal and malignant human B-lymphoid cells, κ-expressing cells generally have their λ genes in germline configuration, while in λ-expressing cells, κ genes are either rearranged (rarely) or deleted (most commonly) by recombination signal recombination events discussed previously in this chapter.[22] The mechanisms that dictate the order of L chain recombination remain unknown. Plausible models include either the selective suppression of λ recombination until all options on the Igκ locus are exhausted or differences in the timing of the developmental programs controlling κ and λ accessibility.

Regulation of RAG Expression

A complete explanation of RAG gene expression would explain its lymphoid specificity, the two waves of RAG expression (during IgH and IgL rearrangements) and the autoantigen-induced upregulation associated with receptor editing. Although our current knowledge is still incomplete, several *cis*-regulatory elements that regulate RAG expression have been characterized. Surprisingly, the elements and mechanism for regulating expression during B- and T-cell development are distinct. RAG1 and RAG2 are transcribed toward each other in opposite directions, driven by promoters near the respective transcription start sites. Three B-cell-specific enhancers—designated Erag, D3, and Ep—have been reported, lying about 23 kb, 8 kb, and 1.6 kb, respectively, upstream of RAG2.[115,116,117] The B-cell-specific function of these regulatory regions is likely explained by the intersecting specificities of transcription factors that interact with them, including Pax5, E2A, FoxP1, FoxO1, NFATc1, and Ikaros. NFκB, which binds at several locations in the RAG enhancers, and FoxO1 (binding to Erag) were found to be important mediators of the upregulation of RAG expression in cells undergoing receptor editing.[118,119] Regulation of RAG2 protein across the cell cycle has been discussed previously in this chapter.

Parameters Affecting Recombinational Accessibility and Transcription

V(D)J recombination is triggered by RAG expression in the development of both B and T cells, yet Ig gene recombination is largely confined to B cells (exception: early T cells typically show D-J_H recombination); TCR gene recombination is exclusive to T cells. A widely accepted explanation for this locus specificity is provided by the "accessibility" model.[120] This model proposes that only those gene segments programmed for recombination at a given stage of B- and T-cell development are "accessible" to the RAG recombinase. One clue suggesting this model was that susceptibility to recombination and transcription of germline gene elements seem to be tightly correlated.[120] For example, many germline V_H genes are transcribed at the pre-B cell stage, just at the time when these genes are targets for recombination; these transcripts— designated "sterile" like the Vκ transcripts mentioned previously —are not seen in more mature B cells in which H chain recombination has been terminated. In support of the accessibility model, recombinant RAG proteins incubated with nuclei purified from pro-B cells (which generate sterile transcripts in the IgH locus) were found to cleave DNA at Ig J_H RSSs, but not at TCRδ RSSs; conversely, in pro-T nuclei the TCRδ RSS was cleaved, but not an Ig gene RSS.[121]

One molecular correlate of accessibility is the epigenetic state of DNA in the nuclear chromatin. The minimal repeat unit of chromatin is the nucleosome, which consists of eight core histones (two copies each of H2A, H2B, H3, and H4) with 146 bp DNA wrapped around it. *In vitro*, RAG proteins are unable to bind to and cut DNA wrapped around nucleosomes,[122,123] and hence nucleosomes have to be shifted or removed (a process

called chromatin remodeling) to allow access. An alternative but not mutually exclusive approach to gain access is posttranslational modification of the histone tails, which regulates the tightness of DNA-nucleosome contacts. The following section provides an overview of how accessibility of the Ig gene loci for RAG activity is regulated by several distinct but interconnected epigenetic mechanisms. We discuss a few important examples for each mechanism and refer to comprehensive review articles for an in-depth discussion.

Subnuclear Localization

In general, inactive genes tend to be located in the periphery of nuclei, while active genes are recruited to a more central nuclear location.[124] It is unclear whether the location per se dictates the chromatin state of a locus or whether the movement is a consequence of a locus being "opened." Fluorescence in situ hybridization (FISH) with large (~100 kb) probes specific for Ig loci is routinely used to reveal the position of Ig gene loci and control genes in the nucleus. The IgH and Igκ loci are located at the nuclear periphery in hematopoietic progenitors and pro-T cells, but move to central areas of the nucleus in pro-B cells.[125] As only the IgH locus gets rearranged at this stage, the correlation of position with accessibility is not perfect.

Transcription

Transcription typically occurs in "open" chromatin, and an emerging theme suggests that while some locus "opening" has

to precede transcription, transcription per se also positively reinforces this chromatin state. As mentioned previously, transcription of individual elements within Ig gene loci correlates well with their availability for V(D)J recombination at that stage. In early pro-B cells when D to J_H recombination takes places a "μo" transcript starts upstream of DQ52 and proceeds all the way through the J_H elements[126,127]; and only after DJ_H rearrangement do V_H sterile transcripts appear.[120] It is currently unclear whether transcription per se is directly linked to recombination or whether the correlation is largely mediated by similar requirements for gaining access to chromatinized DNA.

Histone Modifications

Posttranslational modifications of histone tails are important epigenetic marks of the chromatin state (also referred to as the "histone code"). Distinct marks correlate well with actively transcribed and inactive (or repressed) gene loci. As these patterns hold true for Ig loci as well, active marks (e.g., histone acetylation) and inactive marks (e.g., the methylation of lysine 9 on histone H3, H3K9Me2) correlate well with both transcription and recombination accessibility.[128] Importantly, one particular mark for open chromatin, H3K4Me3, is directly linked to the RAG recombinase. As discussed previously, histone tails with this modification are recognized by the PHD domain of RAG2; strikingly, the distribution of RAG2 in Ig loci matches exactly the pattern of H3K4Me3 (which mark accessible gene segments).[129] Beyond facilitating the recruitment of the recombinase, this histone modification also increases cleavage activity *in vitro*.[69]

Methylation

Most cytosine residues within CpG dinucleotides are methylated in mammalian DNA, but genes that are actively expressed in a particular cell are generally relatively hypomethylated in that cell type, implying that DNA methylation inhibits transcription. DNA methylation also seems to inhibit V(D)J recombination. The developmental maturation from pro-B to pre-B cells is associated with progression from a κ locus that is largely methylated, nontranscribed, and nonrearranging to one that is hypomethylated, transcribed, and rearranging.[130,131] Furthermore, methylation of artificial recombination substrates blocked V(D)J recombination when transfected into a recombination competent B-cell line[132]; V(D)J recombination of a transgenic construct occurred only when it was unmethylated.[133] Methylation and histone acetylation are interrelated; for example, the methyl-CpG-binding protein MeCP2 recruits

histone deacetylases, which reduce acetylation of histones.

Gene Localization in the Nucleus

While accessibility allows the RAG proteins to selectively bind to appropriate sets of RSSs at each developmental stage, V(D)J recombination also requires that a pair of compatible gene segments (and their RSSs) are in close physical proximity. This becomes a particularly daunting requirement for gene segments > 1 mb apart in linear DNA sequence. Such distant segments are apparently brought close together in the nucleus, a process of "locus compaction" that loops out large regions of intervening DNA. Evidence for this model derives from FISH experiments showing greater compaction of the IgH locus in pro-B cells poised to undergo V(D)J recombination than in their earlier hematopoietic progenitors.[125] B cells deficient in Pax5 are impaired in recombination of the most distal V_H regions and show less movement of these regions towards the J_H-C locus than normal cells.[134] Data from a recently developed high-resolution FISH method provide a detailed model of the three-dimensional structure of the IgH locus, revealing rosette-like structures with central hubs from which several loops extend.[135]

cis Mediators of Accessibility and Looping

All previously described properties are dependent on *cis*-regulatory elements within the Ig loci, including classic promoters and enhancers. Individual promoters are present upstream of all V elements in all Ig loci, while the downstream D and J elements share a smaller number of promoters. Enhancers are present in each Ig locus, and they are thought to confer the transcriptional activation of each locus at the appropriate stage of B-cell development. Murine κ and IgH loci have intronic enhancers in the intron between J and C (iEκ and Eμ, respectively), and all three loci have enhancers downstream of C coding regions. (For example, downstream of the murine IgH locus is a complex of four enhancers, collectively known as the 3′ regulatory region.) Promoters and enhancers were originally defined based on their role in regulating transcription, but these and other recently reported elements appear to play additional roles in Ig gene recombination. Transcriptional activation and the correlated locus "opening" is mediated by the recruitment of transcription factors that in turn recruit histone modifying and chromatin-remodeling enzymes. In addition, promoters and enhancers regulate transcription through the formation of DNA loops, some of which are critical determinants of the three-dimensional structure of Ig loci, thereby affecting V(D)J recombination as well as CSR (as discussed below).

An enhancer may activate transcription of several genes within a given gene locus, but its effects may be deleterious if it can activate other nearby genes requiring different patterns of expression. To prevent enhancer function beyond appropriate domains, boundary elements known as insulators establish borders between gene loci that are differentially regulated. The protein CCCTC binding factor (CTCF) is commonly found at insulators and also functions by creating DNA loops. One such insulator apparently lies downstream of a complex of enhancers at the 3′ end of the IgH locus, the 3′-regulatory region, where it may protect genes further downstream from being regulated by the Ig enhancer elements.[136] A recently discovered regulatory element with insulator properties is the intergenic control region-1 (IGCR1), which participates in CTCF-dependent looping between the Eμ and 3′ regulatory region enhancers.[137,138,139] Based on results of deletion of this region, the IGCR1 element suppresses recombination of V_H to D segments not already joined to J_H, prevents V_H to DJ_H recombination in T cells, and mediates the BCR-induced signal that terminates sterile V_H transcription and recombinational accessibility of V_H segments after a productive VDJ recombination leads to expression of a μ protein.

Late RAG Expression: Receptor Editing and Receptor Revision

Although the RAG genes are generally downregulated by a signal mediated by the appearance of membrane IgM at the end of the pre-B-cell stage, RAG gene expression and V(D)J recombination can recur later during "receptor editing" of autoreactive B cells in the

bone marrow. One estimate suggests that about 25% of Igs are products of receptor editing.[140] After production of an initial Igκ. protein, receptor editing by L chain rearrangement can occur three ways: an initial VκJκ junction could be deleted by recombination between an upstream V and downstream J on the same chromosome ("secondary recombination," as discussed previously), VκJκ recombination could occur on the other (allelic) copy of the κ locus, or Vλ-Jλ recombination could be activated.

Most replacement of productively rearranged L or H chain genes likely serves to extinguish an antibody that was autoreactive, thus complementing two other mechanisms to silence autoantibodies: anergization and cell deletion by apoptosis. Early studies with transgenic autoantibodies suggested that anergy or deletion were the main fates of self-reactive B cells, but these conclusions may have depended on the nonphysiologic inability of the cells to silence the transgenic autoantibody by receptor editing. More recent studies involving autoantibody "knockin" genes—i.e., productive V[D]J recombined genes swapped into the physiologic positions within the IgH or Igκ gene loci using homologous recombination —have shown that receptor editing is the major mechanism for B cell tolerance.[141,142] This conclusion was also supported by a study of mice expressing a transgenic antibody against the murine Cκ constant region, a model of a self-superantigen; these mice provided evidence of receptor editing leading to virtually 100% λ L chain expression.[143]

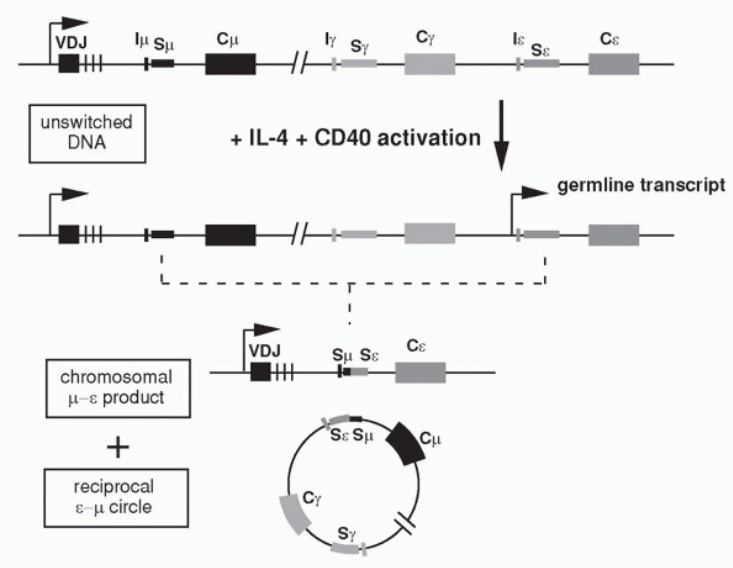

FIG. 6.12. Switch Regions and Composite Switch Junctions. The recombination breakpoints in isotype switch recombination fall within repetitive "switch" (S) regions. Stimuli that activate switch recombination (IL-4 and CD40 activation in the example shown) generally promote transcription across the target S region, initiating just upstream at the "I" exon. Recombination between Sμ and Sε produces two composite switch junctions: an Sμ-Sε junction retained in chromosomal DNA, and a reciprocal Sε-Sμ junction found in fractions of circular DNA. Polymerase chain reaction amplification across either composite junction can be used to study switch recombination.

IMMUNOGLOBULIN GENE ALTERATIONS IN GERMINAL CENTERS

Several days after exposure to an antigen, B cells accumulate in local lymph nodes, gut-associated lymphoid tissue, and spleen, and begin additional maturation steps in germinal centers (GCs). During the GC response, antigen-driven B cells undergo cycles of proliferation and their Ig genes undergo two unique alterations. 1) Lymphocytes switch from making IgM to making a new H chain isotype by the process of CSR. This process introduces dsbs upstream of Cμ in a specific repetitive noncoding DNA segment—the "switch region" —and in a similar switch region upstream of the new target Cx region; the DNA between the breaks is then deleted, and the ends of the remaining chromosomal DNA are rejoined so that

the assembled VDJ region now lies upstream of the new Cx gene (Fig. 6.12). 2) In the other GC-associated gene alteration, the affinity of the antibody for its antigen increases by a process that introduces random mutations in VH and VL—somatic hypermutation (SHM)—and then selects for B cells producing higher-affinity antibodies. For many years, CSR and SHM were considered to be unrelated processes, but several lines of evidence provided hints that they might share some mechanistic features. First, while dsbs are expected intermediates for the DNA recombination underlying class switching, DNA breaks in V regions were also detected accompanying SHM. Second (and conversely), in addition to the mutations occurring in V regions associated with SHM, mutations were also observed surrounding the recombination junctions of CSR. Third, RNA transcription was found to be required for both processes.

Activation-Induced Deaminase

A fourth and dramatic link between CSR and SHM was the discovery that both processes require the protein known as activation-induced deaminase (AID). The gene encoding AID (known as *Aicda*, for *a*ctivation *i*nduced *c*ytosine *dea*minase) was discovered[144] by a subtractive strategy designed to screen for transcripts that were expressed in a murine B-cell line when induced to undergo CSR, but that were not expressed in uninduced cells. AID is expressed almost exclusively in GC B cells and in B cells activated *in vitro*, though exceptions to this generalization will be discussed later. Mice engineered with a targeted defect in the *Aicda* gene are completely deficient in CSR and SHM. The same defects are seen in patients with a homozygous defect in the human *Aicda* gene, a condition known as the hyper-IgM syndrome-2.[145] These patients have elevated serum levels of IgM because their B cells cannot undergo efficient CSR. AID is not only necessary for CSR and SHM, but apparently sufficient (in a mammalian cell at least), as overexpression of AID in fibroblasts can confer transcription-dependent CSR of an artificial switch construct[146] and transcriptiondependent SHM of a transfected model mutation target DNA.[147] These experiments suggest that AID is the only B-cell-specific protein required for SHM and CSR. AID is also required for somatic Ig gene conversion in those species (e.g., rabbit and chicken) that use that process to somatically diversify Ig genes.

As translated from the cDNA, AID is a ˜24 kD 198 amino acid protein that forms homodimers. AID shows 34% amino acid identity with the RNA editing enzyme APOBEC1, which catalyzes the deamination of a cytosine residue to uracil in a specific position in the mRNA encoding apolipoprotein B. The human *Apobec1* and *Aicda* genes are genetically linked, both lying at chromosome 12p13. Three other APOBEC1-related genes on other chromosomes have also been identified, but are not thought to participate in SHM or CSR.

Like APOBEC1, recombinant AID protein has a cytidine deaminase activity *in vitro*; it was initially proposed that, by analogy with APOBEC1, AID functions by deaminating cytidines in specific RNAs to produce novel edited transcripts encoding one or more proteins required for CSR and SHM. However, no evidence of AID-dependent edited RNAs has been reported, nor does AID deaminate RNA cytidines *in vitro.* Instead, current evidence indicates that AID acts on DNA, deaminating cytidines to uracil—in V regions for SHM, and in switch regions for CSR. The resulting uracils would be then recognized as both Watson-Crick mismatches and abnormal DNA bases by the cell's genetic surveillance machinery, triggering error-prone repair of V regions to produce SHM, or DNA cleavage to mediate CSR.

This DNA-deamination model for AID is consistent with various properties reported for this protein *in vitro* or in cells.

1. In transfected *Escherichia coli* cells, AID mutates cytidine to uracil in DNA, a result that would be unexpected by the RNA-deamination model, as bacteria presumably lack the specific mammalian RNA targets predicted by that model.[148,149]
2. Defective SHM and CSR are observed with inhibition or genetic inactivation of uracil-N-glycosylase (UNG), an enzyme that removes uracil residues from DNA,[150,151] consistent with the idea that CSR and SHM involve a step in which AID-produced uracil in DNA is

removed by UNG. Moreover, B cells from *Ung*-/- mice accumulate uracils in V and in switch regions in an AID-dependent manner.[152]

3. AID isolated from B-lymphocytes can deaminate cytidine to uracil in single-strand DNA *in vitro*[153,154,155] or in doublestrand DNA that is being transcribed *in vitro*, presumably because transcription causes localized regions of singlestrandedness.[155,156,157]
4. 4. AID is found to be associated with IgH genes *in vivo* in B cells undergoing CSR,[158,159,160] as assessed by Chromatin ImmunoPrecipitation (ChIP) using an anti-AID antibody.
5. A DNA sequence motif WRC—where W is A or T (*w*eak Watson-Crick pairs) and R (pu*r*ine) is A or G—that has been recognized as a hotspot target of SHM is also a preferred target for AID deamination *in vitro*,[154,157] and the hotspot preference can be altered by engineering amino acid changes in the segment of the AID protein thought to recognize the hotspot target in DNA.[161,162,163]

In light of these and other observations, the DNA deamination model for AID action is now almost universally accepted. The AID protein is highly conserved from fish to human, with all species having approximately 200 amino acids and sharing sequence similarities throughout the protein. In all species, AID contains a motif common to the active site of all cytidine deaminases: H[A/V]E - $X_{(24-36)}$ - PCXXC. This motif is also found in other members of the AID-APOBEC gene family, including APOBEC2, APOBEC3 (with several distinct paralogs in human), and APOBEC4.[164] AID is encoded in the five exons of the *Aicda* gene.

Structure-function relationships of AID have been probed by examining cross-species sequence comparisons and the effects of natural and engineered mutations in the protein. Remarkably, mutations in the N-terminus of AID impaired SHM but not CSR, whereas mutations or deletion in the C-terminus selectively impaired CSR,[165,166,167] suggesting the possibility that the N- and C-terminal regions of the protein contact specific cofactors required (respectively) for SHM and CSR function. Other functional features of the protein include a dimerization domain, several phosphorylatable residues, segments affecting nuclear localization, and target sequences for association with other proteins.

Although AID was initially recognized for its participation in SHM and CSR in GC cells, more recent reports have reported several other roles for this protein, both beneficial and deleterious.

1. *Epigenetic methylation.* Selective DNA methylation of cytidines is an epigenetic mechanism that participates in the regulation of transcription, and the methylation pattern of DNA is normally replicated when DNA is replicated prior to cell division. In primordial germ cells of

early embryogenesis, a global erasure of methylation occurs as part of the reprogramming to pluripotency, and AID apparently participates in this process.[168,169]

2. *Germline mutation.* AID can deaminate methylcytosine to thymine, which unlike uracil is a natural DNA base. This reaction in germ cells may contribute to the most frequent germline point mutation observed in mammals: the transition from CpG to TpG.[170]
3. *Genomic protection.* AID and other APOBEC family members protect cells against retroviral infections and against the spread of endogenous retroviruses.[171,172,173]
4. *Tolerance, apoptosis.* AID appears to be important for the establishment of B-cell tolerance in humans and mice, in that the low levels of AID expression observed in immature and transitional B cells appear to be necessary for suppressing the appearance of autoantibodies.[174,175,176] This effect may be related to the apparent requirement of AID for normal levels of apoptosis, which contribute to the elimination of B cells expressing autoantibodies.
5. *Oncogenic mutations and translocations.* Soon after AID was discovered, it was observed

that overexpression of the protein caused tumors in transgenic mice,[177] and even normal expression of AID in B cells contributes to tumorigenic translocations and oncogenic mutations.[178] A notable example of AID-stimulated translocation is the recurrent *c-myc/Ig* translocation seen in Burkitt lymphoma and murine myelomas. Other cancers where AID plays a role through mutation include intestinal and lung cancer.

Based on studies of AID+/- heterozygous mice expressing roughly 50% of normal AID, the level of AID activity seems to be the limiting factor for both SHM and CSR, but is also limiting for oncogenic translocations and mutations.[179,180] Therefore, AID activity must be regulated robustly to balance between its multiple beneficial and deleterious actions. The regulation of AID activity is extremely complex, involving multiple levels of control, and is still incompletely understood.

Transcriptional and Posttranscriptional Regulation of AID Expression

Early studies showed that AID expression in B cells is upregulated by IL-4 and CD40 engagement. In more recent investigations, four DNA regions that regulate *Aicda* gene expression have been identified. They include an upstream enhancer responsive to T-cell signals, a promoter, a regulatory region just downstream of exon 1, and an additional enhancer downstream of the *Aicda* gene.[181,182,183,184,185,186]

The microRNA miR-155 has been shown to suppress AID expression.[187,188] MicroRNAs are short (21 to 23 nt) RNAs that hybridize to complementary sites in numerous target RNAs, triggering their degradation or inhibiting their translation. A target for miR-155 lies in the 3′ untranslated region of the AID transcript. AID expression was increased in miR-155-deficient mice and in mice whose *Aicda* gene was mutated to disrupt the 3′UTR target sequence. In both cases, consequences of the increase in AID expression included increased off-target mutations and increased *c-myc-IgH* translocations. Perhaps to protect against such effects, miR-155 is itself upregulated by the same signals that induce *Aicda* transcription in B cells.

Posttranslational Regulation

The level of AID activity in the nucleus is affected by its distribution between cytoplasm and nucleus, by the protein half-life, and by phosphorylation at various positions in the protein.

AID was found to shuttle between nucleus and cytoplasm.[189] Most of the protein is cytoplasmic and only a small fraction is in the nucleus, where it can act on DNA to cause CSR and SHM as well as “off-target” deleterious effects. Movement between cytoplasm and nucleus is controlled by at least three independent mechanisms: active nuclear import mediated by an N-terminal nuclear localization signal,[190] active nuclear export mediated by a C-terminal nuclear export signal,[189,191] and a cytoplasmic retention mechanism apparent when active import and export mechanisms are both blocked. Two proteins that may facilitate AID import independently of the nuclear localization signal are GANP[192] and CTNNBL1.[193] Nuclear-cytoplasmic distribution affects AID stability, because in the nucleus AID is targeted for ubiquitination and proteasomal degradation, shortening its halflife.[194] Conversely, in the cytoplasm, the chaperone protein Hsp90 protects AID from proteasomal degradation.[195]

In addition to ubiquitination, AID is also subject to posttranslational phosphorylation at several distinct residues in the protein, including Ser3, Thr27, Ser38, Thr140, and Tyr184. Of these, the functional relevance of the Ser38 site is best understood. Phosphorylation of AID Ser38 is essential to recruit replication protein A (RPA), a trimeric singlestrand DNA binding protein[159,196] that may be required to stabilize a single-strand DNA target for AID. Preparations of AID purified from transfected *E. coli* or from nonlymphoid eukaryotic cells lack Ser38 phosphorylation; they can deaminate single-strand DNA *in vitro*, but are inactive in an assay for deamination of double-strand DNA transcribed *in vitro* by T7 polymerase. Activity in the latter assay requires AID that is phosphorylated at Ser38 and associated with RPA. In the AID protein, Ser38 lies within a conserved phosphorylation site [RRXX(T/S)] for the cyclic-AMP dependent protein kinase A (PKA), and multiple experiments have confirmed that PKA phosphorylates AID at Ser38 *in vitro* and physiologically *in vivo*.[196,197] The physiologic

importance of Ser38 phosphorylation is strongly supported by observations of the effect of mutating this serine to alanine. The AID^{S38A} protein has essentially normal activity in deaminating single-stranded DNA *in vitro*, but severely reduced activity in deaminating transcribed double-strand DNA *in vitro*.

Less is known about the other sites of AID phosphorylation. At Thr140, alanine replacement causes more modest inhibition of AID activity than Ser38Ala, preferentially affecting SHM *in vivo*, but without significant effect on *in vitro* catalytic activity.[198] In contrast to Ser38 and Thr140, phosphorylation of Ser3 apparently suppresses *in vivo* AID activity; alanine replacement at this position increases SHM,

CSR, and oncogenic translocation, also without affecting *in vitro* catalytic activity.[199]

Clearly, multiple mechanisms regulate the level of activity of AID in B-cell nuclei, but these mechanisms cannot explain how—within nuclei—AID acts on Ig V genes and switch regions at a much higher frequency than on the rest of the genome. Targeting mechanisms differ somewhat between SHM and CSR, and will be discussed in the context of those processes.

Somatic Hypermutation

The hypothesis that antibody genes inherited in the germline might be subject to somatic mutation in lymphocytes during the life of an individual was suggested as an explanation for the diversity of antibodies several years before recombinant DNA technology became available to clarify the role of V(D)J recombination. Persuasive evidence for somatic mutation was reported in the 1970s: analyses of Vλ1 amino acid sequences of murine myeloma antibodies showed many instances of a particular prototype sequence, plus several variants containing unique single amino acid substitutions that could be explained by single nucleotide changes. The prototype was interpreted as reflecting the germline sequence, with the variants arising by somatic mutation.[200] Subsequent investigations at the DNA level revealed myeloma V region sequences that deviated from their germline counterparts, verifying the principle of somatic mutation.

Somatic mutations are much rarer in IgM than in antibodies with "switched" isotypes (IgG, IgA, and IgE) made by B cells that have been exposed to AID in GCs, but they do occur; antibodies with "switched" isotypes without mutations are also found. These observations suggest that though both SHM and CSR normally occur in GC B cells, the two processes are unlinked.

Role of Hypermutation in Immune Responses

To understand the role of SHM in the antibody response, several groups have studied the extent of Ig gene mutation at different times after the immunization of mice. Studies of the responses to p-azophenylarsonate (Ars), phosphorylcholine, influenza hemagglutinin, oxazalone, and several other antigens have all indicated that the initial response after primary immunization is established by antibodies showing no somatic mutation. About 1 week after immunization, mutated sequences begin to be observed, increasing during the next week or so. Booster immunizations yield sequences showing additional mutations.

Many hybridomas made late in the immune response produce mutated antibodies with a higher antigen affinity than the unmutated (sometimes loosely called "germline") antibodies made early after immunization. The shift to higher affinity is a phenomenon long recognized at the level of (polyclonal) antisera and has been termed "affinity maturation." This phenomenon can now be explained as the result of an "evolutionary" mechanism selecting antibodies of progressively higher affinity from the pool of randomly mutated V sequences.

According to this model, at the time of initial antigen exposure an animal has a set of naïve B-lymphocytes expressing IgM with germline (unmutated) versions of Ig variable regions resulting from gene rearrangements that occurred prior to immunization. Because of the diversity of available V_H, D,J_H, V_L, and J_L sequences as well as the impressive recombinational potential described previously, some B cells will express Ig molecules capable of binding the antigen with modest affinity. Antigen binding stimulates these B cells to proliferate and to move to lymphoid follicles, where they form GCs. In the GC environment,

AID is expressed and SHM machinery is activated, generating random mutations in the Ig genes of stimulated GC B cells. Many of these mutations reduce the affinity of the encoded antibody for antigen,[201] and some may induce autoantibody specificities (i.e., the ability to bind to self-molecules[202]). As clearance of the antigen lowers the antigen concentrations, only the cells displaying high affinity for antigen will be stimulated effectively; cells displaying lower-affinity antibodies or antibodies with affinity for self-antigens are subjected to programmed cell death ("apoptosis").[203,204] The preferential proliferation of the high-affinity cells and their maturation to secreting plasma cells causes an increase in the average affinity of the antibodies in the serum. Some high-affinity cells become memory cells, persisting long after the initial antigen exposure, ready to respond to a subsequent antigen exposure with rapid production of high-affinity antibody. In this model, the driving force for affinity maturation— analogous to natural selection in the evolution of species—is selection for high-antibody affinity in the face of falling antigen concentration. The importance of this selective force is suggested by the observation that affinity maturation can be inhibited by repeated injection of antigen (which removes the selective pressure for high affinity)[205] or by overexpression of the antiapoptotic protein Bcl-XL (which allows survival of B cells expressing low affinity antibody).[206]

Cellular Context of Somatic Mutation

Each GC appears to be populated by a small number of antigen-specific founder B cells[207] and an unusual Thy-1 negative T-cell population, also antigen-specific,[208] The GC environment promotes contact between the B cell and follicular dendritic cells— which store, process, and present antigen—and T-lymphocytes, which activate somatic mutation in part via CD40-CD40Ligand interaction.[209] In a widely accepted model of GC function, SHM occurs in a subpopulation of B cells known as centroblasts. These cells proliferate in the "dark zone" of the GC and bear characteristic surface markers including IgD, CD38, and the receptor for peanut agglutinin. Proliferating GC centroblasts give rise to nondividing centrocytes in the "light zone" of the GC; there centrocytes are programmed for apoptosis unless they are rescued by follicular dendritic cell-presented antigen and T-cell activation via CD40 engagement. Selection for high-affinity antibodies occurs because cells expressing high-affinity antibodies are most efficiently rescued from apoptosis. Surviving centrocytes may return to the dark zone to undergo several successive cycles of mutation and proliferation followed by selection. This model is supported by direct observation (by two-photon microscopy) of B cells moving between light zone and dark zone.[210] Migration of

B cells to follicles or GC zones is thought to be controlled by a complex system of chemotactic receptor /ligand pairs including CXCR5/CXCL13, CXCR4/SDF1, CCR7/CCL9 (or CCL21), S1P1/sphingosine-1-phosphate, and EBI2/its lipid ligand.[211] Although certain features of this classical model have been challenged, the broad outlines have received strong support from studies in which cells in the dark zone or light zone of individual GCs can be marked by a photo-activatable green fluorescent protein (GFP) and then followed for several hours using two-photon imaging as the cells migrate through a mounted lymph node.[212]

The notion that GC B cells compete to avoid apoptosis on the basis of antigen affinity of their BCR has been has been supported by a study that directly compared caspase activation (an apoptosis marker) in B cells expressing transgenic antibodies with higher versus lower affinity for the same antigen; the lower-affinity cells were found to undergo a significantly higher rate of apoptosis.[213] The mechanism by which high-affinity antigen binding selects for survival is not fully understood. One possibility is that a higher-affinity BCR directly delivers a stronger activation signal to the B cell, inhibiting apoptosis. However, a second possibility is that a higher-affinity BCR could capture antigen more efficiently, enabling stronger antigen presentation to GC T cells, which could then deliver stronger survival signals to the B cell via secreted or surface protein interactions. Consistent with the second model, experiments using two-photon microscopy have documented that that B cells from mice immunized with a

fluorescent antigen can capture that antigen from follicular dendritic cells in the GC.[214] To test whether B-cell antigen capture might confer survival independently of the BCR, investigators engineered B cells in ovalbumin-primed mice to deliver ovalbumin via a surface lectin instead of via the BCR; they observed that the internalized ovalbumin antigen was capable of conferring a B-cell survival advantage in the GC in the absence of BCR engagement.[212] However, effective BCR signaling can enhance antigen processing and presentation,[215] so internalization/presentation and BCR signaling may work together to promote GC B-cell survival and mediate selection for high affinity.

Most experiments on SHM have focused on GC cells, as does the discussion in this chapter. However, T-cell-independent SHM may also occur in a population of less mature cells, which may populate the splenic marginal zone and which may increase the repertoire of circulating lymphocytes prior to antigen exposure, especially in young individuals,[216,217] or perhaps function in tolerance induction, as discussed previously. Also, mice lacking histologically detectable GCs as a result of lymphotoxin-α deficiency are capable of SHM and affinity maturation.[218] T-cell-independent antigens can induce a low level of SHM in B cells.[219]

Molecular Mechanism of Hypermutation

AID deaminates cytidine to uracil, an analog of thymine. Thus, if replicated before repair, an original C:G base pair would, in the daughter cell receiving the uracil-bearing DNA strand, mutate to a T:A. But it was initially not clear how cytidine deamination could affect A:T base pairs, which are targeted in 50% to 60% of mutations observed in SHM. By analyzing abnormalities in SHM that are observed in various mutant B cells, Di Noia and Neuberger[150] formulated a model for SHM that has explained this question and has gained wide acceptance (Fig. 6.13). The model proposes that after AID-catalyzed deamination creates a uracil residue in the target DNA, the possible outcomes depend on how the resulting mismatch is resolved. 1) The U:G mismatch may be replicated as described above, resulting in what are known as phase 1A mutations. 2) The uracil base may, before replication, be excised by UNG, creating an abasic site. Normally, the creation of such abasic sites is the first step of the base excision repair pathway, in which subsequent steps remove the sugar-phosphate backbone, leaving a single nucleotide gap that is then restored to a C:G bp by DNA polymerase β and DNA ligase. If the DNA replicates before the abasic site is repaired, the strand with the abasic site may directly engage translesional polymerases (which are error-prone, as discussed below) to insert an unpaired nucleotide (i.e., any nucleotide) opposite the abasic lesion, leading to phase 1B mutations (see Fig. 6.13). 3) The original U:G mismatch— or possibly the abasic site created by UNG action—may be recognized by the mismatch repair (MMR) system of the cell. MMR triggers excision of the DNA strand for several nucleotides surrounding the mismatch, and this strand is then resynthesized by polymerase β, in the case of faithful repair, or by error-prone polymerases, in the case of SHM. Error-prone repair inserts mispaired bases, which may become fixed on one strand by replication, creating mutations (designated phase 2) from both A:T and G:C bps at some distance from the position of the original U:G mismatch. If a mispaired base is recognized by MMR before replication, a new cycle of MMR may be initiated, extending mutation even farther from the initial deamination event.

Role of Uracil-N-Glycosylase in Somatic Hypermutation. The UNG gene encodes two proteins that differ in their N termini as a result of alternative promoters that generate different initial coding exons. UNG1 is expressed in mitochondria, whereas UNG2 is nuclear. Hydrolytic deamination of cytosines to uracil occurs at a significant rate in all eukaryotic and prokaryotic cells, and misincorporation of dUTP during replication further contributes to the load of uracil in DNA. UNG2 plays a major role in mitigating this load by initiating faithful base excision repair.

In SHM, the faithful repair of uracil is somehow subverted to introduce mutations. *Ung*-/- mice and human patients with a rare form of HyperIgM immunodeficiency due to *UNG* mutations have similar immunologic phenotypes. First, as discussed in the following, *Ung*-/- individuals are profoundly defective in CSR, as expected if this process requires AID-catalyzed deamination of cytidine followed by *UNG*-catalyzed removal of uracil. Although the frequency

of mutation is roughly normal in *UNG*-deficient individuals, mutations at C are almost exclusively transitions of C to T (phase IA). As suggested by Figure 6.13, *Ung*-/- individuals would not create the abasic sites that lead to C → G and C → A mutations by replication, though some mutations of these kinds could be produced by MMR. Indeed, the frequencies of mutations

from A, T, and G in *Ung*-/- individuals are normal, apparently resulting from MMR activated by the U:G mismatch in many cells.

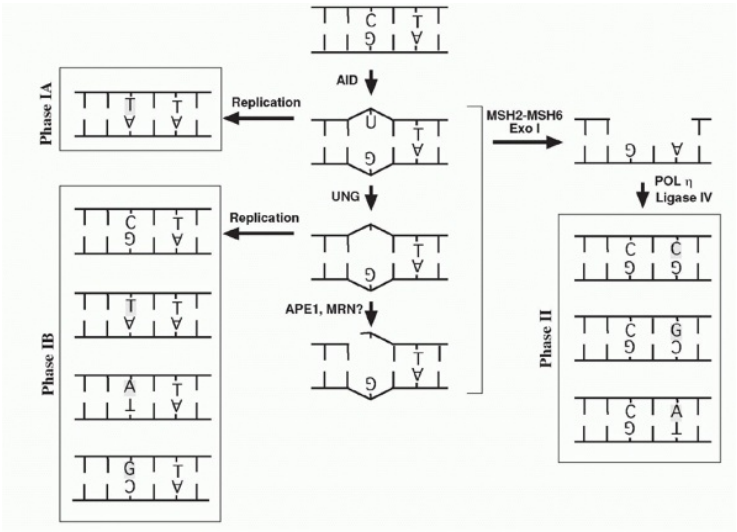

FIG. 6.13. Mechanistic Model of Reactions Triggered by Activation-Induced Deaminase (AID) in Somatic Hypermutation and Class Switch Recombination (CSR). The graphic at the top depicts a small region in a VH gene showing a targeted C:G basepair and a nearby T:A pair. After AID-catalyzed deamination of a C residue, the DNA may be subjected to various modifications as shown, leading to mutations indicated by nucleotides in gray rectangles. The model is described in the text. The Phase II mutations occur when mismatched bases incorporated by an errorprone polymerase are replicated before they can be corrected by MMR. The same mechanism explains two switchregion -associated events occurring during CSR: DNA strand breaks (see center panel at bottom) and mutations.

Mismatch Repair in Somatic Hypermutation. MMR is a highly conserved mechanism that detects abnormalities in DNA, including mispaired nucleotides and abnormal bases, and repairs them. The eukaryotic MMR system has two main components. MutS binds tightly and specifically to DNA defects and recruits MutL. The Mut complex then activates a latent nuclease activity to remove a segment of the DNA strand including the mismatched base; this gapped strand is then resynthesized by a DNA polymerase. Mammals have several MutS homologs, including three reported in somatic cells—MSH2, MSH3, and MSH6—which exist in the cell as heterodimers. MSH2-MSH6 (also known as MutSα) is the most abundant form and is specialized for recognizing single base gaps or mismatches, while MSH2-MSH3 (MutSβ) recognizes larger gaps and insertion/deletion loops. The mammalian MutL proteins are heterodimers consisting of MLH1 paired with PMS1, PMS2, or MLH3. Apart from their effects on SHM and CSR, mutations in MMR genes, especially MSH2 and MLH1, underly hereditary nonpolyposis colorectal cancer. Recent efforts in several laboratories have led to *in vitro* reconstitution of mammalian MMR with purified components, enabling powerful analysis of this complex mechanism.[220] In addition to the MutS and MutL proteins, the system requires the following components: Exo1 to excise the gap; replication protein A, which binds to the single strand DNA in the gapped region (and is known to bind to phosphorylated AID, as discussed previously); proliferating cell nuclear antigen (PCNA), which promotes processivity by encircling DNA in a sliding ring clamp and by recruiting other

components; DNA polymerase δ; DNA ligase I; and several other proteins.

Knockouts of MSH2, MSH6, and Exo1 have been studied by several laboratories and show consistent decrease in B-cell SHM from A:T bps (with a corresponding increase in the percentage of mutations from G:C bps).[221,222] These results, in the context of the model of Figure 6.13, suggest that MMR triggered by the MSH2-MSH6 heterodimer primarily introduces mutation at A:T bps. The predilection for

mutating A:T bps matches the activity of polymerase η, as discussed in the next section, implying that this polymerase may be the one most frequently engaged by the MMR machinery in repairing AID-generated lesions. Indeed, MSH2-MSH6 is capable of binding to a U:G mismatch, MSH2 can bind to polymerase η in cell extracts, and MSH2-MSH6 can stimulate the activity of polymerase η *in vitro*.[223]

Error-Prone Polymerases. Although avoidance of error is a high priority for most DNA replication, error-prone DNA synthesis served an important function long before SHM evolved to mutate Ig genes; indeed, error-prone polymerases have been most thoroughly studied in *E. coli* and yeast. These polymerases are useful in all cells for replication of DNA containing focal lesions that would block replication by stringent high-fidelity polymerases. However, the tolerance of these error-prone polymerases to abnormalities in DNA structure is accompanied by tolerance of non-Watson-Crick basepairing in the replication of normal DNA and by absence of DNA proofreading activity. More than a dozen of these polymerases have evolved in eukaryotes, each specializing in different aspects of "translesion DNA synthesis" (TLS) and showing differing spectra of infidelity in replication of normal DNA. Clear evidence for participation of several TLS polymerases in SHM has come from comparing the known *in vitro* activities of a particular polymerase with the SHM abnormalities seen in mice or humans with mutations in the corresponding polymerase gene.

Polymerase η characteristically inserts mismatched bases opposite T nucleotides, and individuals lacking this polymerase show the predicted abnormality: decreased mutations at A:T base pairs. This was first demonstrated in patients with xeroderma pigmentosum variant disease, whose defects in polymerase η subject them to sunlight-induced skin cancers in addition to their abnormal SHM; a similar defect in mutations from A:T bps was subsequently shown for polymerase η knockout mice.[224,225] Polymerase η binds to MSH2-MSH6, as mentioned previously, and is upregulated in cells undergoing SHM.

In addition to polymerase η, the TLS polymerase REV1 has been shown to participate in SHM. REV1 is known to preferentially insert cytosine residues opposite uracil or abasic sites, and *Rev1* knockout B cells were found to be impaired in C to G mutations, especially in the nontranscribed (coding) strand.[226] Polymerase ζ,[227,228] polymerase κ,[229] and polymerase θ[230,231,232] knockouts have also been reported to show altered SHM patterns, but these effects are smaller or not seen in all circumstances.

Error-prone repair apparently operates in competition with faithful repair carried out by DNA polymerase β. The human B-cell line BL2 is known to undergo SHM, but in subclones of this line with higher SHM proficiency, polymerase β levels were very low; overexpression of polymerase β in a proficient subclone suppressed SHM activity.[233] Compared to wild-type B cells, polymerase β-deficient B cells (developing in a wild-type recipient) showed increased switch region mutation after induction of CSR *in vitro*.[234]

A fundamental question about the action of error-prone polymerases is how they are specifically engaged for SHM of Ig genes, given that most spontaneous cytosine deamination in nonlymphoid cells is accurately repaired. One apparent clue is that some TLS polymerases are upregulated in B cells undergoing SHM. In addition, when the sliding clamp protein PCNA is monoubiquitinated at lysine residue K164, it is known to bind and activate TLS polymerases including polymerase η. When this ubiquitination is prevented, either by knockout of the specific E3 ubiquitin ligase of PCNA or by a K164R mutation at the ubiquitination site in PCNA, SHM is abnormal. $PCNA^{K164P}$ mice were found to have a dramatically decreased ability to mutate A:T sites during SHM, similar to the phenotype of the polymerase η knockout, as though polymerase η requires monoubiquinated PCNA in order to

participate in SHM.[235] However, these clues do not fully explain why Ig genes in GC B cells are less faithfully repaired than other genes in the same cells. This question is part of the larger issue of mutational targeting, as discussed below.

Targeting and Distribution of Mutations

The mutation rate of Ig genes in GC B cells undergoing SHM may reach as high as 10^{-3} mutations/bp/generation, or about 10^6 times higher than the normal genomic mutation rate;[236] this elevated rate could be lethal to B cells if mutations were not carefully targeted specifically to Ig genes. Several other genes highly expressed in GC B cells were also found to be mutated at lower levels (e.g., *Bcl6* and *Cd95*[237]), though several other genes expressed in GC B cells at comparable levels are not mutated. Apparently, some of the features that target SHM to Ig genes may be shared by other genes.

Recently, a genome-wide analysis has made it clear that AID binds much more widely to the genome than was previously appreciated. When chromatin from mouse B cells incubated with lipopolysaccharide (LPS) and IL-4 was analyzed by ChIP with an anti-AID antibody, 5910 genes were found by deep sequencing of the immunoprecipitated DNA (ChIP-seq),[160] including many previously described AID targets. Although this is a large number, it is still a small minority of the genome. As judged by the number of sequence tags recovered, AID binding to the IgH locus was substantially higher than binding to any other region. A sample of genes identified as AID-binding by ChIP-seq showed significant mutation frequency, whereas control genes did not. The AID-binding genes were associated with high levels of mRNA transcription (by RNA-seq), by a chromatin mark commonly associated with transcription—histone H3 trimethylated on Lys4 (H3K4me3)—and by density of Pol II binding. However, only the IgH locus, with its uniquely high levels of AID occupancy and mutations, bound to RPA; this binding was AID-dependent and was diminished in the S38A and T140A mutants of AID described previously.

The difference between AID-targeting and SHM frequency has been reinforced by analysis of SHM in panels of non-Ig genes isolated from murine Peyer patch B cells.[238] All the non-Ig genes were mutated at levels much lower than the 2.2×10^{-2} mutations per bp detected near J_H4, but substantial numbers of mutations were found at *Bcl6*, *Pim1*, *CD79B*, and several other previously reported targets of SHM. The mutations were almost completely AID-dependent, as in cells from *Aicda*-/- mice, all genes showed very low mutation

frequencies that were barely above the sequencing error rate. However, different genes varied widely in the way their mutation rates were affected by the double knockout *Ung-/- Msh2-/-,* in which only phase 1A mutations should be possible. At one extreme, *c-myc*, which is known to mutate at a very low rate in GC B cells, showed a mutation rate in the *Ung-/- Msh2-/-* cells almost 17-fold higher than in the wild-type, as though almost all AID-induced deamination in the wild-type B cells had been faithfully repaired by UNG- and Msh2-dependent mechanisms. In contrast, *Bcl6* mutations were only 1.3-fold higher in the double knockout, suggesting that faithful repair of this gene was dramatically less active.

Thus SHM susceptibility depends not only on differential AID targeting across the genome but also on differential ratios of error-prone versus faithful repair. The distinction between these two variables (deamination and repair) has only recently been recognized, so it was not taken into account in many earlier studies described in the following.

RNA Transcription. A relationship between SHM and RNA transcription is suggested by the observation that unrearranged V_H and Vκ genes are generally neither transcribed nor mutated, but become susceptible to both processes when V(D)J recombination moves them close to their (respective) intronic enhancers, Eμ and iEκ. In contrast, the λ locus lacks an enhancer between J and C; unrearranged Vλ regions are transcribed in B cells[239] and can be mutated.[240] The Ig coding sequences are apparently not specifically required to target SHM, as transgenic V coding sequence can be replaced by a human β-globin gene or prokaryotic *neo* or *gpt* gene without affecting the hypermutation rate downstream of the promoter.

Mutations around a given V region are distributed in a domain that begins roughly 100 to 200 bps downstream of the promoter, extends for ~1.5 to 2 kb downstream, and then tapers off long before the RNA transcriptional termination. This distribution led to the hypothesis that after transcriptional initiation, a "mutator factor" attaches to the transcriptional machinery, attacks DNA as the transcription complex moves downstream, and eventually falls off, so that further transcription proceeds without mutations.[241] Consistent with this model, a VκJκ-Cκ transgene bearing a second Vκ promoter engineered upstream of the Cκ region was found to incur mutations over a second domain extending into the Cκ region, in addition to the usual V region mutations.[242] Conversely, the insertion of an irrelevant 2 kb DNA fragment between a Vκ promoter and the leader (signal peptide) exon prevented mutation within the Vκ transgene, which now apparently lay downstream of the mutational domain.[243] (Mutations also occur in domains surrounding repetitive switch regions upstream of C_H genes. The frequency of these mutations is similar to that in V regions, but the domains are larger, correlating to some extent with the length of the switch region, as discussed in the following.) The key mutator factor is apparently AID, which can deaminate double-strand DNA *in vitro* only when the DNA is transcribed. One hypothesis suggests that DNA near the advancing RNA polymerase complex becomes negatively supercoiled or partially single-stranded, which might facilitate access of the DNA to AID.[244] Another explanation, involving R loops, is described below. Evidence for patches of single-stranded DNA in transcribed V regions undergoing SHM has been obtained using a bisulfite technique.[245]

In vivo dependence of SHM frequency on transcriptional activity has been confirmed by several findings. In one study, SHM was studied in knockin mice with a prerecombined V_HDJ_H region driven by either of two V region promoters; SHM rates in these knockin strains were highly correlated with transcription driven by the different promoters.[246] In another study, a tetracycline-inducible GFP reporter gene engineered with a stop codon was stably transfected into a B-cell line. The rate of reversion of the stop codon by SHM (allowing GFP expression) was found to be directly related to the transcription rate, as regulated by a tetracycline analog.[247] Other studies examining SHM in models where transcription was altered by mutating enhancers have supported the relationship between SHM and enhancer-induced transcription. Some non-Ig enhancers could support SHM in a stably transfected cell line,[248] but others could not, leading to the suggestion that specific elements in enhancers might confer susceptibility to SHM. One candidate element is the sequence CAGGTG, which is a target for E-box transcription factors and which is found in several Ig enhancers. When a murine κ enhancer containing CAGGTG was linked to a GFP gene inactivated by a premature stop codon, stable transfectants of chicken B-cell line DT40 were found to produce mutants that expressed GFP, but a single mutation in the CAGGTG motif prevented SHM without changing transcription.[249] Inactivation of the E-box transcription factor E2A in DT40 cells was found to reduce SHM of endogenous Ig genes without significant effects on Ig gene (or AID) transcription.[250]

However, some conflicting conclusions have been drawn about enhancer-dependence of SHM depending on whether experiments investigated transgenes versus constructs created in the endogenous context using homologous recombination (i.e., knockouts or knockins). For example, the downstream IgH enhancers HS3b and HS4 were found important for SHM in transgenes[251] but dispensable in the context of endogenous genes.[252]

In one case, transcriptional enhancer activity has been clearly separated from an associated SHM stimulating activity. Just downstream of the chicken Ig λ 3′ enhancer lies a DNA segment whose deletion in the DT40 B-cell line severely impaired SHM without dramatically affecting transcription; this segment could confer SHM when inserted into a non-Ig locus.[253,254]

To summarize, it appears that transcription is necessary but not sufficient for targeting hypermutation, but the additional elements required for SHM have not been defined as of this writing (though E2A function may be among them).

Chromatin Marks. A parameter related to transcription of Ig genes (i.e., their context in chromatin) has also been studied in relation to SHM targeting. Culture of a B-cell line under conditions that upregulate SHM (in the presence of T cells and anti-IgM) led to increased acetylation of histone H3 and H4 at V region but not C region DNA, as assessed by ChIP analysis[255] paralleling the distribution of mutations. The increased histone acetylation was not a consequence of AID action as it occurred when AID expression (and SHM) was inhibited by antisense treatment; moreover, when cells were treated with the deacetylase inhibitor trichostatin A, the C region was both acetylated and subjected to SHM. Other histone modifications that may be correlated with SHM are phosphorylation or monoubiquitination of histone H2B.[256,257]

Hotspot Focusing. Mutations occurring within V region genes expressed *in vivo* in B cells may be highly selected for antigen-binding function of the expressed antibody. To analyze the spectrum of mutations produced by SHM unbiased by selection, investigators have studied nonproductively rearranged VDJ alleles or "passenger" transgenes engineered with stop codons to prevent expression as a protein. In these genes, mutational "hot spots" as well as "cold spots" have been recognized, apparently due to local sequence features that may promote or suppress somatic mutation. The consensus sequence WRC (i.e., [A/T][G/A][C]) is the most consistent hotspot for mutation, presumably reflecting the predilection of AID for *in vitro* deamination of this sequence. It is possible that evolution has concentrated mutational hot spot frequencies in CDR regions to enhance the potential for diversity generation in the parts of the protein critical for antigen contact.[258]

The previous discussion has identified several factors influencing the targeting of SHM, a process in which a unique triggering event—AID-dependent deamination of DNA—is followed by a cascade of other events that depend on mechanisms common to most cells. All of these steps, including the AID-dependent trigger, can be affected by biologic parameters common to all cells, such as transcription, enhancers, epigenetic state, DNA repair mechanisms, etc. Many of these same mechanisms affect CSR as well as SHM. Recently, three additional biologic parameters have been found to influence AID-triggered events in CSR: RNA polymerase stalling, the RNA splicing in spliceosomes, and RNA degradation by exosomes. It is possible that these three processes impinge on both SHM and CSR, but because they were discovered in the context of CSR, they are discussed in the following section.

Heavy Chain Switch

Switch Regions and Switch Junctions

As briefly mentioned previously in this chapter, isotype switching involves removal of Cμ from downstream of the rearranged H chain VDJ gene and its replacement by a new downstream C_H region. This occurs by a deletional recombination—CSR—in which the recombinational breakpoints generally occur within G-rich repetitive DNA sequences known as switch (or S) regions lying 5′ of each C_H region (except Cδ). While most switch breakpoints fall in the S regions, some are in nearby nonrepetitive DNA. The S region of the mouse μ gene, Sμ, is located about 1 to 2 kb 5′ to the Cμ coding sequence and is composed of numerous tandem repeats of sequences of the form (GAGCT) n(GGGGT), where n is usually 2 to 5 but can range as high as 17. All of the S regions of downstream isotypes include pentamers similar to GAGCT and GGGGT embedded in larger repeat units rather than precisely tandemly repeated as in Sμ. In support of the critical role of S regions for CSR, knockout of Sγ1 by homologous recombination essentially abolished expression of IgG1 from that allele,[259] and mice with a deletion of Sμ were also dramatically impaired in CSR.[260,261]

A switch recombination between, for example, μ and ε genes produces a composite Sμ-Sε sequence (see Fig. 6.12). From a comparison between the sequence of an Sμ-Sε composite switch region and the sequences of the germline Sμ and Sε, one can localize the exact recombination sites between Sμ and Sε that occurred in each allele. Such comparisons have indicated that there is no specific site, either in Sμ or in any other S region, where the recombination always occurs, although clusters of recombination sites have been reported at

two specific regions within the tandem repeats of murine Sγ3 region.[262] Thus, unlike the enzymatic machinery of V-J recombination, the switch machinery can break and join sequences in a broad target region, and as the recombination targets are in intronic DNA, there are no reading frame complications. Often both IgH alleles in a single cell undergo switching to the same downstream isotype. Some alleles undergo sequential switching events; for example, a common pathway to IgE expression is an initial μ → γ1 switch, followed by a CSR between the composite Sμ-Sγ1 switch region and the Sε region.[263] Sγ1- Sε switching may even occur independently of Sμ.[264] Although most CSR occurs as a deletion within a single IgH allele, switching between two allelic chromosomes was detected at a frequency of roughly 7% to 10% in mouse and rabbit.[265,266]

DNA fragments excised by switch recombination have been cloned from fractions of circular DNA isolated from cells actively undergoing isotype switch recombination. Thus, at least some of the excised DNA segments ligate their ends to form "switch circles"; these contain composite switch junctions that are in theory reciprocal to the composite switch junction retained on chromosomal DNA (see Fig. 6.12). Because switch circles are not linked to centromeres and do not apparently contain origins of replication, they are not efficiently replicated. Therefore, they are not found in cells that have divided many times after switching (e.g., in myelomas or hybridomas).

Many composite switch junction sequences show mutations near the recombination breakpoint when compared to the corresponding germline switch sequences. Indeed, many features of CSR are shared by SHM (as indicated previously in this chapter), including the requirements for transcription, AID, UNG2, and MMR components for normal CSR and SHM. However, CSR is more complex in that it involves simultaneous targeting to two DNA regions (i.e., switch

regions of Cμ and the target Cx), it requires dsbs, and it consequently requires mechanisms to repair the breaks. AID can theoretically trigger single-strand breaks on both DNA strands by the mechanisms discussed for SHM, including cleavage by APE-1. If these breaks are close enough together, they can effectively form a dsb with staggered ends, and if dsbs occur in two switch regions, the DNA repair mechanisms common to all cells may rejoin the broken ends to complete a CSR event. Indeed, B cells in which Sμ and Sγ1 were deleted and replaced by recognition sites for the yeast homing endonuclease I-SceI were capable of mediating some μ → γ1 CSR in the absence of AID if I-SceI was expressed,[267] highlighting the participation of ubiquitous AID-independent repair mechanisms for CSR. These mechanisms depend on the NHEJ components described previously in this chapter plus backup participation by alternative end-joining mechanisms discussed below.

Regulation of Isotype Switching: Proliferation and AID Expression

Isotype switching occurs physiologically in animals about 1 week after immunization with T-dependent antigens, at about the same time that somatic mutation of Ig genes begins. Both processes normally occur in GCs of lymphoid organs, a location that facilitates interactions between B cells, T cells, and follicular dendritic cells presenting antigen. As demonstrated by *in vitro* switching experiments, T cells promote switching by secretion of cytokines (especially IL-4 and transforming growth factor β) as well as by cell-to-cell contact.

A major component of the cell contact signal is mediated by an interaction between the B-cell surface marker CD40 and its ligand—designated CD40L, CD154, or gp39—which is expressed on activated T cells (primarily CD4+). CD40 is a member of the TNF-receptor family, while CD40L belongs to the TNF-ligand family. The dependence of switching on the CD40-CD40L interaction is highlighted by the genetic disease known as the X-linked hyper-IgM syndrome-1, which was found to be caused by a defect in the human gene encoding the CD40L/gp39.[268] Like AID-deficient patients with hyper-IgM syndrome-2 described previously, patients with X-linked hyper-IgM syndrome-1 have elevated concentrations of IgM in their serum and almost no Igs of other isotypes. In addition, their antibodies fail to show affinity maturation or evidence of B-cell memory responses. Similar defects are seen in humans with mutations in their CD40 gene, an autosomal recessive disease designated hyper-IgM 3.[269]

CSR impairment may also be caused by abnormal function of CD40 signaling pathway components including IKKγ (also known as NEMO), NFκB proteins, and C-Jun N-terminal kinase. Mouse strains with engineered defects in CD40 are defective in SHM and T-dependent CSR, but respond with normal isotype switching to T-independent antigens. The T-independent switching pathway may be especially important for gut-associated switching to IgA.[270] One role of the CD40 engagement is to induce B-cell proliferation. Indeed, other proliferative stimuli (e.g., LPS or IgM or IgD crosslinking) can support cytokine-induced isotype switching *in vitro* in the absence of T cells and CD40 activation. The relationship of CSR to cell division is supported by evidence that switching is linked to the cell cycle[271] and to the number of cell divisions after stimulation,[272] a phenomenon which may reflect cell division-related regulation of AID expression.[273] However, apart from activating proliferation, CD40 has additional effects that may facilitate switching, including upregulation of IL-4 responsiveness and IL-4 receptor number,[274] upregulation of sterile "switch transcripts" (discussed below), and upregulation of AID expression. Activated B cells also express CD40L, which can not only trigger CD40 signaling but also transduce a "reverse" signal affecting B-cell function.[275] Independent of CD40, B-cell activation can independently be stimulated by TLR ligands and cytokines such as APRIL, another member of the TNF family.[276]

Regulation of Class Switch Recombination to Specific Isotypes: Promoters, Enhancers, and Chromatin

Different isotypes are known to predominate in different immune responses depending on the antigen, route of antigen administration, and several other parameters. These different parameters act in part by influencing the cytokine milieu of the B cells. IL-4, for example, promotes the expression of IgE and IgG1, whereas TNF-β promotes switching to IgA. These lymphokines have been proposed to act by making the targetisotype "accessible" to switch recombinase machinery that may be largely non-isotype-specific. The accessibility is associated with expression of a "sterile" or "germline" RNA transcript that initiates upstream of a target S region (see Fig. 6.12) and extends through the target C region. The germline transcript is spliced so that a noncoding upstream exon known as an I ("intron") region is joined to the first coding exon of the C region. (This contrasts with the "productive" transcript containing VDJ spliced to the C region.) The same experimental conditions—particularly the same cytokines—that favor the accumulation of germline transcripts from a particular isotype generally also stimulate switch recombination to the same isotype. In many cases, the signals transduced by the cytokine receptor have been elucidated. For example, IL-4 stimulates germline transcription by activating the transcription factor STAT6, which binds to one of several IL-4 response motifs in the promoter region upstream of Iε and Iγ1. CD40 engagement also acts in part through NFκB-mediated binding to I region promoters.[277]

Gene targeting experiments have shown that mouse strains lacking the I region (and its promoter) of a particular isotype do not switch to that isotype, reinforcing the idea that sterile transcription is necessary for CSR.[278] The low extent of sequence conservation of the I exons and the lack of consistent open reading frames suggest that these transcripts do not encode a functional protein. Indeed, the exact sequence of the I region may be irrelevant as an I region can be replaced by an unrelated sequence and still support CSR.[279] However, the transcribed exon upstream of the S region apparently needs a splice donor site allowing splicing to the downstream C region, as a targeted construct lacking such a splice donor site was reportedly unable to support CSR even though transcription through the S region occurred.[280]

Apart from I region promoters, germline transcription and isotype switching are also regulated by IgH enhancers. A combined deletion of the murine 3′-regulatory region enhancers HS3b and HS4 was found to cause a significant impairment in switching to most isotypes, although switching to IgG1 was unaffected (and IgA only moderately decreased).[281] The diminished switching was associated with diminished germline transcription of the same isotypes,

suggesting that an important function of the enhancers in CSR is to increase germline transcription. The relative independence of γ1 from regulation by enhancers may be related to the putative locus control region associated with that gene.[282]

Enhancers are believed to function via physical interactions between enhancer-bound proteins and promoterbound proteins, creating a DNA loop that brings enhancers into close proximity to promoters. Such looping may have special significance in promoting DNA recombination between segments of DNA lying great linear distances apart in the chromosome, as has been discussed in the context of V(D)J recombination. Chromosome conformation capture experiments have shown that Eμ and 3′-regulatory region enhancers are in close proximity in mature resting B cells, and that when B cells are stimulated to switch to γ1 by LPS + IL4 (or to γ3 by LPS alone), the corresponding I region promoter moves close to the two enhancers.[283,284] This looping would bring Sμ, which lies just downstream of Eμ, close to the Iγ1 (or Iγ3) promoter, presumably facilitating recombination between Sμ and the Sγ region.

Another parameter correlated with regional transcriptional regulation is the chromatin context of the genes, including specific modifications of histone proteins, as discussed previously in this chapter. For example, acetylation of histone H3 (H3Ac) is associated with DNA regions of increased "accessibility" to transcription (as well as to experimental digestion by restriction enzymes), while transcriptional promoters tend to be marked with trimethylation of H3 at lysine4 (H3K4me3). In B cells stimulated to switch to γ1 by LPS + IL4 (or to γ3 by LPS alone), the corresponding I region and switch regions show increased H3Ac and H3K4me3 marks.[285,286] The importance of the H3K4me3 mark for transcription and CSR is highlighted by evidence that preventing this mark—by B cell-specific knockout of PTIP, a component of the machinery that catalyzes this modification—leads to impaired germline γ transcription and defective CSR to γ isotypes.[287] PTIP knockout B cells show decreased DNA looping between the 3′ enhancer region and Iγ region promoters, suggesting that PTIP contributes to this looping.[288] Knockdown of other factors that are necessary to maintain H3K4me3 also reduce CSR efficiency, including the components of the complex known as FACT (*fa*cilitates *c*hromatin *t*ranscription).[289]

Surprisingly, a histone modification generally associated with gene silencing—trimethylation of H3 lysine 9 (H3K9me3)—has also been reported to mark switch regions targeted for CSR in both mouse and human B cells.[290,291] Recently, a screen for nuclear proteins associating with AID *in vitro* identified KAP1 (KRAB domain-associated protein 1),[292] a transcriptional repressor that associates with heterochromatin protein 1, as binding to H3K9me-modified chromatin. By coimmunoprecipitation, KAP1 was confirmed to bind to AID *in vivo*, and B-cell-specific conditional knockout of KAP1 was found to diminish AID binding to Sμ and to impair CSR efficiency by about 50%.

Switch Region Targeting of AID in Class Switch Recombination: R Loops, Paused Polymerase II, and AGCT

A model in which AID loads onto an RNA polymerase complex and acts on DNA as the transcription complex travels downstream was discussed previously in the context of AID function in SHM, and a similar model apparently applies in the context of CSR. The domain of AID susceptibility in switch regions can be deduced from the distribution of C:G → T:A mutations in B cells that are defective for both UNG and MMR, because (as shown in Fig 6.13) in these cells the only AID-dependent mutations would be U:G mismatches resolved by replication to T:A. A study of the distribution of such mutations in clones from *Ung*-/-, *Msh2*-/- B cells found that a domain of mutations began about 150 bp 3′ of the Iμ transcription start site and extended 4 to 5 kb downstream, with diminishing mutation frequency near Cμ.[293] The location of AID binding in B-cell DNA can also be directly determined by ChIP-seq analysis, as discussed previously. AID was found to bind to many loci that are transcribed in B cells; indeed, the patterns of AID and RNA polymerase II binding detected by ChIP are very similar.[160] RPA, however, was efficiently bound only at IgH switch regions, and this binding was inhibited by the Ser38Ala mutation that blocks the critical Ser38 phosphorylation

discussed previously.

One likely consequence of germline transcription in facilitating CSR involves the formation of a stable RNA:DNA complex known as an R-loop. In this structure, RNA transcribed from the template strand of a DNA molecule binds tightly to that strand with Watson-Crick basepairing, displacing the other DNA strand, which forms a single-stranded loop. In support of the R-loop model, cell-free transcription across G-rich switch regions was found to generate a stable association of the transcript RNA with the template DNA[294]; significantly, no substantial association occurred when the switch region was transcribed in reverse orientation, leading to a C-rich transcript, or when the transcribed template was a DNA fragment other than a switch region. The displaced DNA strand in S region R loops was susceptible to deamination by AID.[155] Evidence that such R-loops form *in vivo* over S regions has been obtained from bisulfite analysis of singlestrand DNA regions in B cells.[295,296]

The tightly bound RNA-DNA complex on the template strand of an R-loop may explain both the high level of polymerase II accumulation and the AID-induced mutations in the vicinity of switch region DNA.[297] Progression of the polymerase II complex transcribing through the switch region might be impeded by the RNA bound to the template strand, leading to an accumulation of "stalled" polymerase II molecules; the "stalling" of AID molecules associated with the transcription complex might prolong exposure of the DNA to deamination by AID. Some support for this scheme was reported from an *in vitro* model in which AIDtriggered mutations in a transcribed DNA substrate were

increased when transcription was slowed by reducing the nucleotide triphosphate concentration.[298] The importance of stalled polymerase II for CSR was reinforced by the results of a screen for factors whose knockdown by specific shRNAs would inhibit CSR[299]: one protein recovered in this screen was the murine homolog of suppressor of Ty 5 (Spt5), a transcription elongation factor known to be associated with stalled polymerase II. Spt5 knockdown decreased both CSR and switch region hypermutation, as well as AID occupancy of the Sμ region, without affecting cellular levels of AID protein or germline transcripts. By coimmunoprecipitation experiments, AID and Spt5 were found to associate. And genes with high Spt5 occupancy by ChIP analysis were found to be most susceptible to mutations induced by AID overexpression. Polymerase II stalling has been extensively studied in yeast and drosophila, and is found in many genes that require more rapid changes in expression than can be achieved by modulating transcriptional initiation.[300] Apparently, the complex of proteins mediating polymerase II stalling has been adapted in B cells for the special function of regulating CSR of IgH genes.

The R-loop model explains how the "upper" nontranscribed DNA strand would become single-stranded and accessible to AID, but it raises the question of how AID might gain access to the "lower" template DNA strand, held in a tight RNA-DNA hybrid. This strand is known to be accessible to AID because it undergoes C → T mutations in *Ung*-/- Msh2-/- double knockout B cells.[293] A likely answer to this question has come from an analysis of proteins bound to AID when mixed with a B cell extract plus *in vitro*-transcribed switch region DNA.[301] The complex of AID and transcribed DNA was found to bind to components of the multisubunit RNA exosome. The exosome is an evolutionarily conserved structure containing nine core proteins that can associate with RNA nucleases, leading to degradation of RNA from template DNA; the exosome could thus potentially expose the template DNA strand to AID. Indeed, shRNA knockdown of one exosome component in the murine B cell line CH12F3 inhibited CSR. Moreover, exosome components were found to associate with AID *in vivo* by immunoprecipitation experiments and were detected (by ChIP) bound to switch region DNA in cells activated for CSR. Finally, in a deamination assay of a model switch region DNA transcribed *in vitro* by T7 polymerase, the addition of AID + RPA + PKA led to deamination of only the nontemplate strand, but the further addition of exosome components led to deamination on the template strand as well. These experiments highlight the exosome as a likely candidate for explaining AID action on the template strand of R-loops, though an unhybridized "lower strand" may also be produced as a result of transcription-dependent supercoiling or antisense transcription.

However, the propensity for R-loop formation is not the only property of switch regions that facilitates CSR. When the Sγ1 region was inverted, it retained about 25% of the wildtype CSR activity.[302] As this inverted, and now C-rich, DNA segment could not form an R-loop, this result suggests that while the R-loop contributes to CSR, other features of the S region that are preserved in the inverted sequence also play a role. Replacement of a natural murine Sμ sequence with the AT-rich frog Sμ sequence, which cannot form an R-loop, supported somewhat reduced but still substantial frequencies of CSR, and it functioned equally well in either orientation. Significantly, in either orientation, the recombination junctions were clustered in a portion of the S region that is rich in repeats of the sequence AGCT, which is a special case of the WRC consensus sequence for AID targeting, being present on both strands as a self-complementary palindrome. Indeed, the AGCT-rich region was a good substrate for *in vitro* deamination by AID when transcribed in association with RPA. The AGCT motif is enriched in all mammalian S regions and may be particularly effective as a target for CSR because its presence in clusters on both strands promotes closely spaced nicks on opposite strands, or even a dsb with a single base overhang if the cytosines in both strands of the same AGCT motif are targeted.[303] The density of AGCT in S regions correlates with the location of switch junctions better than the density of WRC or the boundaries of G-richness or R-loops.[296] These results all suggest that clusters of AGCT may represent a target for CSR that evolved in amphibians, with R-loop formation evolving later in mammals to further enhance AID accessibility to S region DNA.

DNA Breaks as Intermediates in Class Switch Recombination

The recombination event that underlies isotype switching includes DNA breaks and rejoining events that must involve both strands of DNA. Although the RAG-induced DNA breaks that initiate V(D)J recombination occur at the corresponding position on the two strands (yielding a blunt end and a hairpin), the nature of the ends in the initial CSR cleavage is not so clear. An early compilation of switch junctions[304] found only infrequent instances of microhomology at the junction (i.e., short sequence segments that are identical in the unrearranged S sequences near the recombination breakpoint). As these microhomology examples would be consistent with invasion of one DNA strand from Sμ targeting a short homologous region in a downstream S region (or vice versa), the rarity of such junctions has been interpreted as an indication that CSR only rarely occurs by strand invasion and instead usually proceeds by ligation of blunt DNA ends. However, dsbs with staggered ends would generally be the result of the widely accepted mechanism shown in Figure 6.14 (bottom left): a DNA break on one strand might result from AID-catalyzed cytosine deamination, removal of the resulting uracil by UNG, and singlestrand cleavage 5′ to the abasic site by an endonuclease, probably apurinic-apyridinic endonuclease 1 (APE1). The initial staggered ends could be converted to blunt ends through exonuclease trimming of a 5′ or 3′ single strand overhang, through filling in of a shorter 3′ end by a DNA polymerase, or through a combination of both processes. Filling in by error-prone polymerases could explain the mutations commonly observed around the switch junction, as mentioned previously.

Evidence supporting initially staggered DNA breaks in CSR was reported from occasional switch junctions observed in a model CSR substrate designed with two oppositely

oriented S regions such that CSR would occur by inversion, preserving both recombination junctions on the same chromosome. Several duplications at the ends of inverted DNA after CSR suggested that complementary overhangs at dsbs had been filled in before joining.[305] Additional evidence for staggered breaks has come from several investigators using ligation-mediated-polymerase chain reaction (LM-PCR) to detect double-strand DNA ends at switch regions in cells undergoing CSR.[306,307,308] LM-PCR protocols involving ligation of a blunt linker directly to blunt ends from genomic DNA were successful in amplifying blunt ends from DNA of B cells activated for CSR, but when the DNA was pretreated with T4 polymerase, which would convert staggered end cuts to blunt, the yield of amplified LM-PCR products was significantly increased, suggesting that most of the ends in the isolated genomic DNA (before T4 polymerase treatment) were staggered.

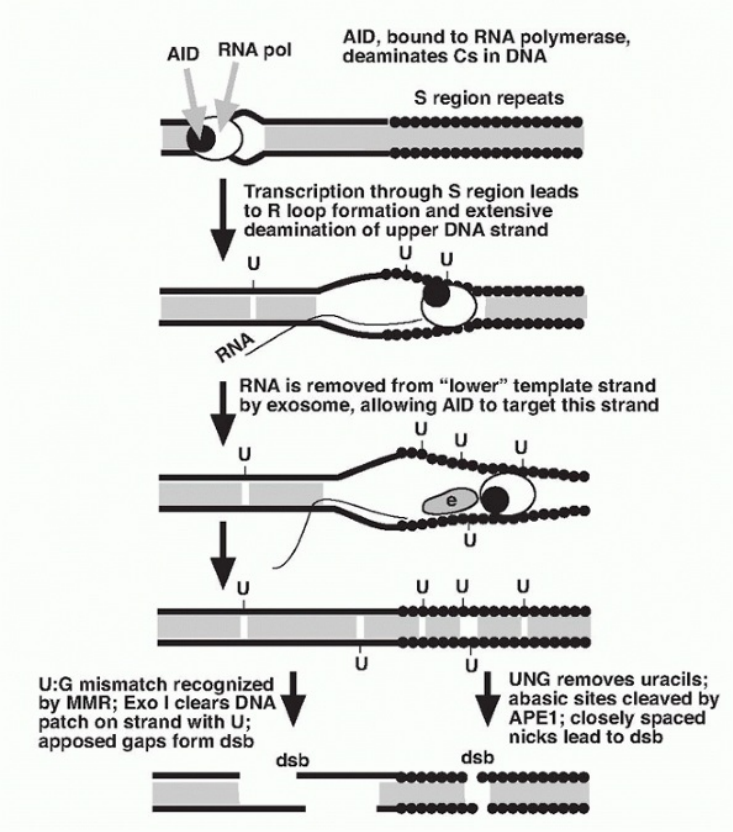

FIG 6.14. Mechanistic Model of Class Switch Recombination. This figure incorporates features of the most widely accepted models, but some aspects are uncertain at present. Two strands of deoxyribonucleic acid (DNA) near the 5′ boundary of a switch region are shown in *black*, with the S region repeats indicated by *dots*. DNA with normal Watson-Crick basepairing is indicated by the *gray shading* between the DNA strands. Ribonucleic acid (RNA) polymerase moves to the right, transcribing the sequence into an RNA strand; multiple other proteins accompany the RNA polymerase, but only activation-induced deaminase (AID) (*black circle*) is shown. AID can deaminate C residues to U in single-stranded R-looped DNA displaced by the RNA-DNA complex. The exosome complex (*e* in the drawing) degrades RNA in the RNA-DNA hybrid, leaving an unpaired lower strand where AID can deaminate C residues. DNA cleavage triggered by processing of uracils can lead to double-strand breaks in pathways dependent or independent of mismatch repair components as shown.

When the CSR-associated dsbs in Sμ were examined by LMPCR in B cells from normal and AID-/- individuals, the dsbs were significantly fewer in AID-/- B cells, though not completely absent. Furthermore, microscopic foci of the modified histone γH2AX (which rapidly accumulates at dsbs) were found at IgH genes (localized by FISH) in B cells undergoing CSR; these foci were strikingly diminished in AID-/- B cells, consistent with AID-dependence of dsbs in CSR.[309] These foci, as well as switch region dsbs, occur predominantly in the G1 phase of the cell cycle.[310] Like the off-target deamination by AID discussed previously in the context of SHM, off-target DNA breaks are another potential consequence of AID. B cells from mice overexpressing AID showed a high incidence of chromosomal translocations and DNA breaks compared with *Aicda*-/- mice; in the context of homozygous p53 deficiency (which allows cell growth despite DNA damage), many of the mice developed B-cell lymphomas.[311] In a study designed to systematically examine the locations of dsbs in mouse B cells stimulated to undergo CSR, ChIP was used to identify DNA associated with Nbs1, a protein that rapidly binds to dsbs *in vivo*, as discussed below.[312] This analysis detected hundreds of reproducible AIDdependent DNA break locations, some of which were syntenic

with DNA rearrangements found in human B-cell lymphomas. Many of the AID-dependent dsbs occurred in nontranscribed regions, unlike the CSR-related dsbs in IgH switch regions. Evidence indicates that AID-dependent off-target dsbs are normally repaired largely by homologous recombination: B cells defective for the homologous recombination component XRCC2 were found to harbor many more γ-H2AX foci than were found in *Xrcc2*+/+ cells or in *Aicda*-/- Xrcc2-/- cells.[313] B cells apparently protect against these breaks by upregulating *Xrcc2* transcription when activated for CSR.

Ubiquitously Expressed Components of Class Switch Recombination Machinery

UNG and Mismatch Repair. The model of Figure 6.13 suggests that after AID-catalyzed deamination of a cytidine residue, the resulting uracil is removed by *UNG*, creating an abasic site that is converted by APE1 to a single-strand DNA break (nick), which can become double-stranded if there is a nearby nick on the opposite strand. This model predicts that both CSR and the creation of dsbs would be severely impaired in the absence of *UNG*. Indeed, B cells from *Ung*-/- mice showed almost complete inability to switch *in vitro* to IgG1 or IgG3 secretion, and significant impairment in IgA secretion.[151] dsbs in *Ung*-/- B cells, as detected by LM-PCR, were also significantly reduced, but not abolished.[308] Human patients with homozygous *UNG* deficiency due to mutations in both *UNG* alleles showed a hyper-IgM phenotype, with a more profound defect than in *Ung*-/- mice: the patients showed essentially no IgG, IgE, or IgA secretion by stimulated B cells, and no dsbs (by LM-PCR) in Sμ.[314]

A role for APE1 or APE2 in CSR is supported by the observation that in mice with engineered deficiencies these genes, B cells induced for CSR show decreased switching and decreased induction of dsbs.[315]

The complementary pathways of UNG and MMR action in SHM were discussed previously (see Fig. 6.13); current evidence suggests a similar participation of MMR in CSR. Although

CSR was dramatically impaired in *Ung*-/- B cells (e.g., *in vitro* switching to IgG1 was reduced to about 6% of wild-type), the double knockout *Ung*-/- Msh2-/- caused significant further impairment (to 1.5% of wild-type IgG1 switching).[316] Evidence suggests that the C-terminal 10 amino acids of AID that are required for CSR but not SHM may function by stabilizing the interaction of UNG2 and the MSH2-MSH6 dimer to DNA.[317]

If a single-strand break created on one strand by UNG and APE1 is too far away from the the closest single-strand break on the opposite strand to create a dsb, then Exo1 engaged by MMR can chew from a nick on one strand toward a nick on the opposite strand, creating a dsb.[310,318] Consistent with this idea, mice engineered with a knockout of the MMR component Exo1 show a significantly decreased efficiency of CSR, to roughly 15% to 30% of normal.[319]

Thus, many of the same AID-triggered mechanisms that induce mutations in V_H regions operate in switch regions to induce dsbs. Once created, these dsbs are resolved by mechanisms distinct from the mechanisms resolving mismatches in SHM; however, as discussed in the following, some of the components that resolve dsbs generated in V(D)J recombination play a similar role in CSR.

End Joining Proteins in Class Switch Recombination. If AID triggers DNA cleavage at switch regions, ubiquitous DNA repair and ligation enzymes could participate in the subsequent DNA repair steps of CSR, as in V(D)J recombination. This possibility has been tested by engineered gene knockouts. However, as NHEJ knockouts would impair V(D)J recombination, thus blocking B-cell development prior to the stage of CSR, investigators have studied NHEJ in CSR using mouse strains with knockins of productive recombined H and L chain genes, which can undergo CSR. IgH/IgL knockin mice with intact Ku genes were able to switch to downstream isotypes, but the corresponding Ku-70- or Ku-80-deficient mice were reported to be dramatically impaired in CSR, although decreased cell proliferation could have contributed to this effect as more recent studies using different conditions report 30% to 50% residual CSR activity.[320]

The other “core” factors of NHEJ—XLF/Cernunnos, Ligase4, and XRCC4—catalyze the DNA ligation in NHEJ and have also been investigated for participation in CSR.[320,321,322,323,324] B cells deficient in any one of these genes show variably decreased CSR efficiency, with increased junctional microhomologies compared with normal B cells. This observation suggests that one or more fairly robust backup pathways—commonly called alternative NHEJ—can repair dsbs using microhomology-based ligation when “classic” NHEJ is inoperative. This conclusion is consistent with studies of alternative NHEJ repair of dsbs unrelated to CSR.[78] The proteins CtIP,[325] PARP1,[326,327] and XRCC1[328] apparently contribute to alternative NHEJ during CSR, as experimentally reduced expression of each protein decreases microhomology at CSR junctions.

Apart from these core NHEJ components, Artemis and DNA-PKcs are required for joining ends that require processing, like the hairpin coding ends produced in V(D)J recombination discussed previously in this chapter. Artemisdeficient murine B cells have no obvious impairment in CSR efficiency[329] but show several-fold increases (compared to wild-type) in the number of chromosome aberrations in the IgH locus detected by FISH assays[330]; these aberrations are AID-dependent and only observed after activation of B cells for CSR. In humans, Artemis deficiency results in a SCID syndrome with severe defects in B- and T-cell development, but rare Sμ-Sα recombination junctions amplified from patient B cells were found to show a high index of microhomologies,[331] suggesting that Artemis is required for normal classic-NHEJ resolution of dsbs in human CSR.

Studies on the role of DNA-PKcs in CSR have yielded somewhat conflicting conclusions on whether this protein is required for maximally efficient CSR, with the results of individual studies perhaps depending on the knocked-in Ig genes used, the specific mutations of DNA-PKcs, or the genetic background of mice studied.[332,333] However, *DNAPKcs-/-* B cells showed evidence of AID-dependent chromosome aberrations in the IgH locus, similar to those seen in *Artemis-/-* cells but more numerous.[330] Thus it appears that both Artemis and DNA-PKcs are required for efficient repair of at least a subset of the dsbs associated with CSR.

DNA Damage Response Proteins in Class Switch Recombination. NHEJ is one component of a larger mechanism for detecting and repairing dsbs, collectively known as the DNA damage response (DDR). Because DNA dsbs are potentially damaging to the cell, and occur in all cells through accidents of DNA metabolism, toxic chemicals, and radiation, DDR appeared early in evolution, and many components are conserved from yeast to mammals. Defects in DDR can cause developmental abnormalities, cancer predisposition, and sensitivity to radiation, as well as immunodeficiency resulting from impaired V(D)J recombination or CSR. DDR factors participate in a baroque cascade of interactions to cluster at dsbs and initiate repair. The complexities of the DDR are beyond the scope of this chapter, but are described in several recent reviews.[78,334]

Several DDR components have been documented to participate in CSR and are listed below; mutations in some of these cause specific genetic syndromes in humans, often associated with immunodeficiency.

1. Nbs1, product of the gene that is defective in the human disease Nijmegen breakage syndrome.[309,335,336] Nbs1 functions as part of a complex that also includes Mre11 and Rad50 (MRN complex). Mre11 has a nuclease activity, and may contribute to DNA cleavage in CSR; mice and humans with defective Mre11 also show impaired CSR.[337,338]
2. ATM, product of the gene *m*utated in the human disease *a*taxia *t*elengectasia and a member of the phosphatidylinositol-3′-kinase family.[339,340]
3. γ-H2AX—the phosphorylated form of histone H2AX— which rapidly accumulates in foci at dsbs, and helps to assemble other proteins at dsbs to prevent the breaks from progressing to chromosome translocations.[341]
4. The E3 ubiquitin ligase RNF8 (Ring Finger 8), which is known to monoubiquitinate

histones at dsbs.[342]

5. The E3 ubiquitin ligase RNF168, found to be mutated in the RIDDLE (*r*adiosensitivity, *i*mmuno*d*eficiency, *d*ysmorphic features, *l*earning difficulties) syndrome.[343]

6. 53BP1 (p53 binding protein 1) originally discovered as a protein binding to the tumor suppressor p53, but subsequently found to function in checkpoint control and to localize rapidly to DNA breaks *in vivo*. *53BP1*-/- murine B cells show dramatic impairment in CSR (to 55 to 25% of wild-type), but increases in the frequency of AID-triggered deletions within Sμ,[344] suggesting that formation of dsbs and repair of closely-spaced breaks does not require 53BP1, but joining of more distant dsbs depends on this protein.

Although the we currently lack a detailed model explaining the functions of all the DDR factors in dsb repair and specifically in CSR, the emerging evidence suggests that these proteins have mutual interactions and distinct but related roles, so that the elimination of any one protein reduces CSR efficiency but permits residual CSR to occur by pathways that remain intact.

Other Proteins that may Target AID for Class Switch Recombination. As discussed in the context of SHM, accurate targeting of AID is important since off-target activities of this protein can be deleterious, and off-target dsbs triggered by AID could be particularly dangerous. Several searches for proteins that might contribute to targeting of AID to switch regions have uncovered candidates for this function. In one study,[345] biotinylated AID was used as bait to fish for *in vitro* binding proteins, which were identified by mass spectrometry. One protein identified by this screen was PTBP2 (polypyrimidine tract-binding protein 2) which is considered to be a regulator of RNA splicing. Knockdown of PTBP2 by shRNA in CH12 B cells caused a substantial decrease in binding of AID to Sμ (determined by ChIP) and significant impairment of CSR. The possible role of a splicing regulator in CSR could be related to the puzzling observation that germline transcripts must be spliced in order for efficient CSR,[280] as mentioned previously.

A screen for proteins that could bind selectively *in vitro* to AGCT sequences—which are found clustered in many switch regions—identified another protein that might target AID in CSR: the 14-3-3 proteins, a family of seven members widely expressed and known to bind to many signaling proteins.[346] ChIP assays on B cells stimulated for CSR showed that 14-3-3 proteins bind to switch regions in an isotypespecific way (depending on stimulus conditions) in both normal and *Aicda*-/- cells, and reduction of 14-3-3 activity by either a peptide inhibitor or by genetic engineering decreased both CSR efficiency and AID binding to switch region DNA. Finally, a bimolecular fluorescence complementation assay revealed that in B-cell nuclei AID and 14-3-3 molecules form a complex that is dependent on the AID C-terminal amino acids required for CSR. These experiments suggest that 14-3-3 proteins are additional candidates for AID targeting molecules.

PKA, the cAMP-regulated protein kinase responsible for phosphorylation of AID Ser38 discussed previously, has also been suggested as a candidate that targets AID-dependent DNA cleavage to switch regions.[347] PKA was found by ChIP to bind to switch regions of stimulated B cells from normal and *Aicda*-/- mice, whereas the binding of RPA depended on Ser38-phosphorylated AID. Cellular concentrations of cAMP were found to rise rapidly after stimulation to CSR, and a genetic inactivation of PKA activity that prevented its activation by cAMP reduced both RPA binding and CSR. These data suggest a model in which CSR stimuli recruit both PKA and nonphosphorylated AID to switch regions, and AID gains the ability to recruit RPA and trigger dsbs efficiently only when cAMP-activated PKA phosphorylates Ser38.

Additional components of CSR may be discovered by analysis of patients with a hyper-IgM phenotype unexplained by defects in known components.[314]

CONCLUSION

Recombinant DNA technology has revolutionized the study of the antibody response. Initial

investigations used powerful cloning and sequencing methods to define the structure of the Ig genes as they exist in the germline and in actively secreting B-lymphocytes. Subsequent experiments have begun to shed light on the mechanisms of the processes unique to these genes: V(D)J recombination, CSR, and SHM.

The knowledge of Ig genes gained so far has answered some of the most puzzling mysteries about antibody diversity, as discussed previously, and has also led to many practical ramifications involving these genes that are beyond the scope of this chapter. As one example, cloned Ig genes have allowed the production of recombinant monoclonal antibodies and the bioengineering of Ig-fusion proteins that exploit the exquisite specificity of antibody V region binding (e.g., antibody-toxin fusions) or the ability of Ig C region domains to extend serum half-life or engage Fc receptors. Other engineered derivatives utilizing Ig genes include single-chain antibodies, bispecific antibodies, and “intrabodies” designed not to be secreted from a cell but rather to bind to intracellular targets.[348,349,350] Ig V gene fragments cloned into bacteriophage so as to express single-chain V regions on the phage surface (phage display libraries) can be used to obtain specific monoclonal antibodies without immunization or use of mammalian cells, and *in vitro* mutation and selection protocols can mimic affinity maturation to yield high-affinity antibodies.[351] Even Ig gene regulatory regions have been exploited to achieve B-cell-specific expression of oncogenes[352] and of intracellular toxins that could be used to target B lymphomas.[353] Apart from these biotechnology applications, Ig gene probes have led to the identification of numerous proto-oncogenes that become activated by translocation into Ig gene loci.[354] For instance, Bcl2 was initially discovered as the target of Ig H chain translocation in follicular lymphoma, and provided an entry into an entire family of apoptosis-related genes. A final example of medical benefit from Ig gene technology has been the use of patient-specific Ig gene rearrangements of leukemias or lymphomas to monitor disease status by PCR.[355,356]

Further practical applications of Ig genes can be anticipated in the future, as well as a deeper scientific understanding of their molecular biology and their contribution to the immune system.

Chapter 7

Antigen-Antibody Interactions and Monoclonal Antibodies

Jay A. Berzofsky

Ira J. Berkower

INTRODUCTION

The basic principles of antigen-antibody interaction are those of any bimolecular reaction. Moreover, the binding of antigen by antibody can, in general, be described by the same theories and studied by the same experimental approaches as the binding of a hormone by its receptor, of a substrate by enzyme, or of oxygen by hemoglobin. There are several major differences, however, between antigen-antibody interactions and these other situations. First, unlike most enzymes and many hormone-binding systems, antibodies do not irreversibly alter the antigen they bind. Thus, the reactions are, at least in principle, always reversible. Second, antibodies can be raised, by design of the investigator, with specificity for almost any substance known. In each case, one can find antibodies with affinities as high as and specificities as great as those of enzymes for their substrates and receptors for their hormones. The interaction of antibody with antigen can thus be taken as a prototype for interactions of macromolecules with ligands in general. In addition, these same features of reversibility and availability of a wide variety of specificities have made antibodies invaluable reagents for identifying, quantitating, and purifying a growing number of substances of biologic and medical importance.

One other feature of antibodies that in the past proved to be a difficulty in studying and using them, compared to, say, enzymes, is their enormous heterogeneity. Even “purified” antibodies from an immune antiserum, all specific for the same substance and sharing the same overall immunoglobulin (Ig) structure, will be a heterogeneous mixture of molecules of different subclass, different affinity, and different fine specificity and ability to discriminate among crossreacting antigens. The advent of hybridoma monoclonal antibodies[1,2,3] has made available a source of homogeneous antibodies to almost anything to which antisera can be raised. Nevertheless, heterogeneous antisera are still in widespread use and even have advantages for certain purposes, such as precipitation reactions. Therefore, it is critical to keep in mind throughout this chapter, and indeed much of the volume, that the principles derived for the interaction of one antibody with one antigen must be modified and extended to cover the case of heterogeneous components in the reaction.

In this chapter, we examine the theoretical principles necessary for analyzing, in a quantitative manner, the interaction of antibody with antigen and the experimental techniques that have been developed to study these interactions as well as to make use of antibodies as quantitative reagents. Furthermore, we discuss the derivation, use, and properties of

monoclonal antibodies.

THERMODYNAMICS AND KINETICS

The Thermodynamics of Affinity

The basic thermodynamic principles of antigen-antibody interactions, as we indicated previously, are the same as those for any reversible bimolecular binding reaction. We review these as they apply to this particular immunologic reaction.

Chemical Equilibrium in Solution

For this purpose, let S = antibody binding sites, L = ligand (antigen) sites, and SL = the complex of the two. Then for the reaction

$$S + L \rightleftharpoons SL \qquad (1)$$

the mass action law states

$$K_A = \frac{[SL]}{[S][L]} \qquad (2)$$

where K_A = association constant (or affinity) and square brackets = molar concentration of the reactants enclosed. The import of this equation is that for any given set of conditions such as temperature, pH, and salt concentration, the ratio of the concentration of the complex to the product of the concentrations of the reactants at equilibrium is always constant. Thus, changing the concentration of either antibody or ligand will invariably change the concentration of the complex, provided neither reactant is limiting, that is, neither has already been saturated, and provided sufficient time is allowed to reach a new state of equilibrium. Moreover, because the concentrations of antibody and ligand appear in this equation in a completely symmetrical fashion, doubling either the antibody concentration or the antigen concentration results in a doubling of the concentration of the antigen-antibody complex, provided the other reactant is in sufficient excess. This proviso, an echo of the one just discussed, is inherent in the fact that [S] and [L] refer to the concentrations of free S and free L, respectively, in solution, not the total concentration, which would include that of the complex. Thus, if L is not in great excess, doubling [S] results in a decrease in [L] as some of it is consumed in the complex, so the net result is less than a doubling of [SL]. Similarly, halving the volume results in a doubling of the total concentration of both antibody and

ligand. If the fraction of both reactants tied up in the complex is negligibly small (as might be the case for low-affinity binding), the concentration of the complex quadruples. However, in most practical cases, the concentration of complex is a significant fraction of the total concentration of antigen or antibody or both, so the net result is an increase in the concentration of complex but by a factor of <4. The other important, perhaps obvious, but often forgotten, principle to be gleaned from this example is that because it is concentration, not amount, of each reactant that enters into the mass action law (Equation 2), putting the same amount of antigen and antibody in a smaller volume will increase the amount of

complex formed, and diluting them in a larger volume will greatly decrease the amount of complex formed. Moreover, these changes go approximately as the square of the volume, so volumes are critical in the design of an experiment.

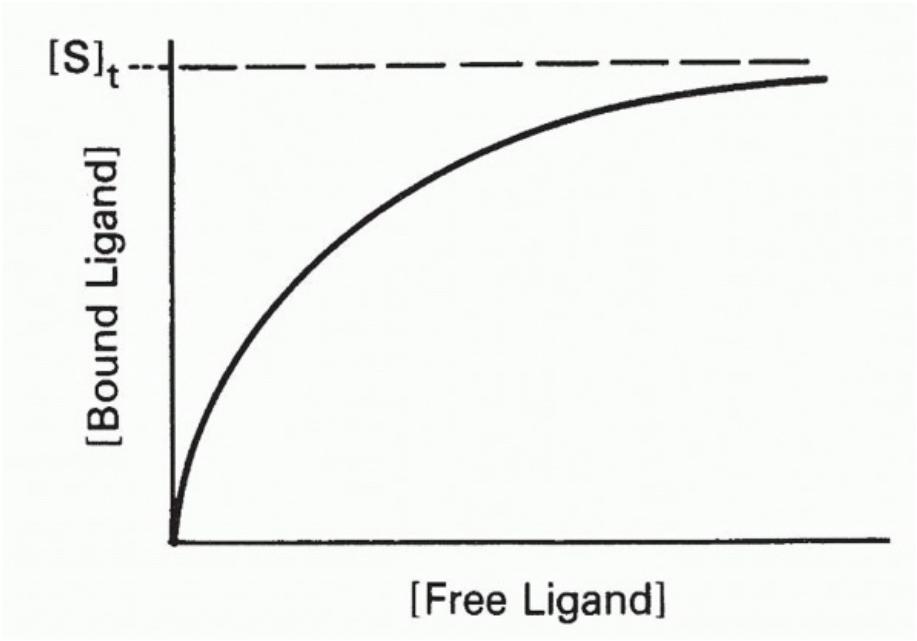

FIG. 7.1. Schematic Plot of Bound Ligand Concentration as a Function of Free Ligand Concentration at a Constant Total Concentration of Antibody-Combining Sites, $[S]_t$. The curve asymptotically approaches a plateau at which [bound ligand] =[S_t.]

The effect of increasing free ligand concentration [L], at constant total antibody concentration, on the concentration of complex, [SL], is illustrated in Figure 7.1. The mass action law (Equation 2) can be rewritten as

$$[SL] = K_A[S][L] = K_A([S]_t - [SL])[L] \qquad (3)$$

or

$$[SL] = \frac{K_A[S]_t[L]}{(1 + K_A[L])} \qquad (3')$$

where $[S]_t$ = total antibody site concentration; that is, [S] + [SL]. Initially, when the complex [SL] is a negligible fraction of the total antibody $[S]_t$, the concentration of complex increases nearly linearly with increasing ligand. However, as a larger fraction of antibody is consumed, the slope tapers off and the concentration of complex, [SL], asymptotically approaches a plateau value of $[S]_t$ as all the antibody becomes saturated. Thus, the concentration of antibody-binding sites can be determined from such a saturation binding curve (see Fig. 7.1), taking the concentration of (radioactively or otherwise labeled) ligand bound at saturation as a measure of the concentration of antibody sites.* This measurement is sometimes referred

to as antigen-binding capacity.

The total concentration of ligand at which the antibody begins to saturate is a function not only of the antibody concentration but also of the association constant, KA, also called the affinity. This constant has units of molar (M^{-1}) or L/mol, if all the concentrations in Equation 2 are molar. Thus the product $K_A[L]$ is unitless. It is the value of this product relative to 1 that determines how saturated the antibody is, as can be seen from Equation 3′. For example, an antibody with an affinity of 10^7 M^{-1} will not be saturated if the ligand concentration is 10^{-8} M (product $K_A[L] = 0.1$) even if the total amount of ligand is in great excess over the total amount of antibody. From Equation 3′ the fraction of antibody occupied would be only 0.1/1.1, or about 9%, in this example. These aspects of affinity and the methods for measuring affinity are analyzed in greater detail in the next section.

Free Energy

Regarding thermodynamics, the affinity, KA, is also the central quantity because it is directly related to the free energy, ΔF, of the reaction by the equations

$$\Delta F° = -RT \ln K_A \qquad (4)$$

$$K_A = e^{-\Delta F°/RT} \qquad (4')$$

where R = so-called gas constant (1.98717 cal/°K•mol), T = absolute temperature (in degrees Kelvin), ln = natural logarithm, and e = base of the natural logarithms. The minus sign is introduced because of the convention that a negative change in free energy corresponds to positive binding. The ΔF° is the standard free-energy change defined as the ΔF for 1 mol antigen + 1 mol antibody sites combining to form 1 mol of complex at unit concentration.

It is also instructive to note an apparent discrepancy in Equations 4 and 4′. As defined in Equation 2, K_A has dimensions of M^{-1} (ie, L/mol), whereas in Equation 4′, it is dimensionless. The reason is that for Equation 4′ to hold strictly, K_A must be expressed in terms of mole fractions rather than concentrations. The mole fraction of a solute is the ratio of moles of that solute to the total number of moles of all components in the solution. Because water (55 M) is by far the predominant component of most aqueous solutions, for practical purposes, one can convert K_A into a unitless ratio of mole fractions by dividing all concentrations in Equation 2 by 55 M. This transformation makes Equation 4′ strictly correct, but it introduces an additional term, -RT ln 55 (corresponding to the entropy of dilution), into Equation 4. This constant term cancels out when one is subtracting ΔF values but not when one discusses ratios of ΔF values.

An important rule of thumb can be extracted from these equations. Because ln 10 = 2.303, a 10-fold increase in affinity of binding corresponds to a free-energy change ΔF of only 1.42 kcal/mol at 37°C (310.15°K). (The corresponding values for 25 and 4°C are 1.36 and 1.27 kcal/mol, respectively.) This is less than one-third the energy of a single hydrogen bond (about 4.5 kcal/mol). Looked at another way, a very high affinity of 10^{10} M^{-1} corresponds to a ΔF of only 14.2 kcal/mol, approximately the bonding energy of three hydrogen bonds. (Of course, because hydrogen bonds with water are broken during the formation of hydrogen bonds between

antigen and antibody, the net energy per hydrogen bond is closer to 1 kcal/mol.) It is apparent from this example that of the many interactions (hydrophobic and ionic as well as hydrogen bonding) that occur between the contact residues in an antibody-combining site and the contacting residues of an antigen (such as a protein), almost as many are repulsive as attractive. It is this small difference of a few kilocalories between much larger numbers corresponding to the total of attractive and the total of repulsive interactions that leads to net "high-affinity" binding. If ΔF were any larger, binding reactions would be of such high affinity as to be essentially irreversible. Viewed in this way, it is not surprising that a small modification of the antigen can result in an enormous change in affinity. A single hydrogen bond can change the affinity manyfold, and similar arguments apply to hydrophobic interactions and other forms of bonding. This concept is important when we discuss specificity and antigen structure later.

Effects of Temperature, pH, Salt Concentration, and Conformational Flexibility

It was mentioned previously that K_A is constant for any given set of conditions such as temperature, pH, and salt concentration. However, it varies with each of these conditions. We have already seen that the conversion of free energy to affinity depends on temperature. However, the free energy itself is also a function of temperature

$$\Delta F^\circ = \Delta H^\circ - T\,\Delta S^\circ \qquad (5)$$

where ΔH = change in enthalpy (the heat of the reaction),† ΔS = entropy (a term related to the change in disorder produced by the reaction),[2] and T = absolute temperature (in degrees Kelvin).

It can be shown that the association constant KA will thus vary with temperature as follows:

$$\frac{d \ln K_A}{dT} = \frac{\Delta H^\circ}{RT^2} \qquad (6)$$

or equivalently,

$$\frac{d \ln K_A}{d(1/T)} = \frac{-\Delta H^\circ}{R} \qquad (6')$$

The derivation of these equations is beyond the scope of this book.[4] However, the practical implications are as follows. First, one can determine the standard ΔH° of the reaction from the slope of a plot of ln K_A versus 1/T. Second, for an interaction that is primarily exothermic (ie, driven by a large negative ΔH, such as the formation of hydrogen bonds and polar bonds), the affinity decreases with increasing temperature. Thus many antigen-antibody interactions have a higher affinity at 4°C than at 25°C or 37°C, so maximum binding for a given set of concentrations can be achieved in the cold. In contrast, apolar or hydrophobic interactions are driven largely by the entropy term T ΔS, and ΔH° is near zero. In this case, there is little effect of temperature on the affinity.

As for the effects of pH and salt concentration (or ionic strength) on the affinity, these vary depending on the nature of the interacting groups. Most antigen-antibody reactions are studied near neutral pH and at physiologic salt concentrations (0.15 M NaCl). If the interaction is dominated by ionic interactions, high salt concentration lowers the affinity.

Conformational flexibility of an antigen can also affect the affinity by affecting the entropy term in Equation 5. An outstanding example comes from the thermodynamics of binding of a series of broadly neutralizing monoclonal antibodies to the human immunodeficiency virus (HIV) envelope protein gp120. The energetics of binding between HIV gp120 and its cellular receptor cluster of differentiation (CD)4[5] or to a panel of monoclonal antibodies[6] has been studied in detail. The results provide insight into the ways protein flexibility can help the virus to evade antibody immunity. They may also explain part of the difficulty in eliciting antibodies of this type when immunizing with the native protein.

GP120 is a glycoprotein that exhibits at least two conformational states: one exists on the virus, and it changes to the other when it binds the CD4 receptor on the cell surface. Monoclonal antibodies F105 and b12 bind residues within the CD4 binding site on gp120 while monoclonal 2G12 binds the opposite surface. The CD4 binding site defines a neutralizing surface that is conserved among a broad range of HIV isolates.

As shown in Table 7.1, CD4 and each antibody demonstrated a strongly negative ΔF, corresponding to high affinity binding. However, as shown by microcalorimetry, they arrived at the affinity in different ways. The CD4 and F105 have a strong negative ΔH of binding, but they also have a large negative entropy due to the conformational change required, as shown by strongly positive values for -TΔS. This entropy effect greatly reduces the overall ΔF of binding, so they depend on a very large negative ΔH to bind. In contrast, monoclonal b12 has moderate levels of both ΔH and -TΔS, resulting in a nearly identical ΔF. Monoclonal 2G12 binds gp120 with a less favorable ΔH but no entropy cost.

The two discrete conformations of gp120 may be called the open and closed forms. The excursion between these two conformations affects the entropy of binding. CD4 and F105 only bind the open form, which reduces randomness and creates an entropy barrier. Monoclonal b12 is less dependent on one conformation, so it binds with less entropy cost, and 2G12 is indifferent to the two forms, so it has no entropy effect at all.

The strong entropy effect observed for these monoclonals may illustrate one way for the virus to evade antibody binding, through a mechanism called conformational masking.

The randomness of gp120, as found on the virus, means that it is rarely in the open conformation, making it difficult for most antibodies such as F105 to bind. Only the rare antibody that is b12-like can bind multiple forms and eventually pull gp120 into its most favorable conformation.

TABLE 7.1 Energetics of Antibody Binding to gp120 Core Structure

Ligand	ΔF	ΔH	-TΔS
CD4	-10.4	-48.4	38.2

F105	-11.4	-30.0	18.6
b12	-12.3	-18.0	5.7
2G12	-7.8	-6.2	-1.6

CD, cluster of differentiation. From Kwong, et al.6

The same effect may explain the difficulty in eliciting antibodies to this site using native gp120. If it is rarely in the open form, it will be unable to trigger B cells to make antibodies that require this form, and it will deliver only a weak antigenic stimulus to those that bind partially to different conformations, such as b12. These considerations suggest that a more favorable vaccine antigen could be made if gp120 could be anchored in the open conformation, so it could stimulate B cells to make antibodies that require this form. The hallmark of this structure would be its ability to bind F105 and b12 with a good ΔH and reduced values of -TΔS.

Kinetics of Antigen-Antibody Reactions

A fundamental connection between the thermodynamics and kinetics of antigen-antibody binding is expressed by the relationship

$$K_A = \frac{k_1}{k_{-1}} \qquad (7)$$

where k_1 and k_{-1} are the rate constants for the forward (association) and backward (dissociation) reactions.

The forward reaction is determined largely by diffusion rates (theoretical upper limit 10^9 L/mol/sec) and by the probability that a collision will result in binding, that is, largely the probability that both the antigen and the antibody will be oriented in the right way to produce a good fit as well as the activation energy for binding. The diffusive rate constant can be shown[7] to be approximated by the Smoluchowski equation

$$k_{dl} = 4\pi a D(6 \times 10^{20}) \qquad (7a)$$

where *a* = sum of the radii in centimeters of the two reactants, D = sum of the diffusion constants in cm^2/sec for the individual reactants, and the constant 6×10^{20} is necessary to convert the units to M^{-1}. • sec^{-1}. For example, if $a = 10^{-6}$ cm and $D = 10^{-7}$ cm^2/sec, then $k_{d1} \approx 7.5 \times 10^8$ M^{-1}. • sec^{-1}. Association rates will generally be slower for large protein antigens than for small haptens. This observation may be due to the smaller value of D, to the orientational effects in the collision, and to other nondiffusional aspects of protein-protein interactions. Therefore, association rates for protein antigens are more frequently on the

order of 10^5 to 10^6 M^{-1}. • sec^{-1} (see following discussion). However, this observation can also be partly understood from diffusion-limited rates alone. If the radii of hypothetically spherical reactants are r_1 and r_2, then in Equation 7a, $a = r_1 + r_2$, whereas D is proportional to $1/r_1 + 1/r_2$. The diffusive rate constant is therefore proportional to

$$(r_1 + r_2)\left(\frac{1}{r_1} + \frac{1}{r_2}\right) = \frac{(r_1 + r_2)^2}{r_1 r_2} \qquad (7b)$$

From this result, it can be seen that if $r_1 = r_2 = r$, then r cancels out and the whole term in Equation 7b is simply equal to 4. Thus, for the interaction between two molecules of equal size, the diffusive rate constant is the same regardless of whether those molecules are large or small.[8] However, if one molecule is large and the other small, the rate is greater than if both molecules are large. This difference occurs because reducing the radius r_1 while keeping r_2 constant (and larger than r_1) has a greater effect on increasing the diffusion constant term D, proportional to $(1/r_1 + 1/r_2)$, in which the smaller radius produces the larger term than it has on the term *a*, which is still dominated by the larger radius r_2. For example, if $r_2 = r$ as shown, but $r_1 = 0.1r$, then the numerator in Equation 7b is only reduced from $4r^2$ to $1.21r^2$, whereas the denominator is reduced from $1r^2$ to $0.1r^2$. Thus, the ratio is increased from 4 to 12.1. Viewed another way, the greater diffusive mobility of the small hapten outweighs its diminished target area relative to a large protein antigen because the larger target area of the antibody is available to both.

The dissociation rate (or "off rate") k_{-1} is determined by the strength of the bonds (as it affects the activation energy barriers for dissociation) and the thermal energy kT (where k is Boltzmann constant), which provides the energy to surmount this barrier. The activation energy for dissociation is the difference in energy between the starting state and the transition state of highest energy to which the system must be raised before dissociation can occur.

As pointed out by Eisen,[9] if one compares a series of related antigens, of similar size and other physical properties, for binding to an antibody, the association rates are all very similar. The differences in affinity largely correspond to the differences in dissociation rates.

A good example is that of antibodies to the protein antigen staphylococcal nuclease.[10] Antibodies to native nuclease were fractionated on affinity columns of peptide fragments to isolate a fraction specific for residues 99 through 126. The antibodies had an affinity of 8.3×10^8 M^{-1} for the native antigen and an association rate constant, k_{on}, of 4.1×10^5 M^{-1}. • sec^{-1}. This k_{on} was several orders of magnitude lower than had been observed for small haptens,[11] as discussed previously. A value of k_{off} of 4.9×10^{-4} sec^{-1} was calculated using these results in Equation 7. This is a first-order rate constant from which one can calculate a halftime for dissociation (based on $t_{1/2} = \ln 2/k_{off}$) of 23 minutes. These rates are probably typical for high-affinity ($K_A \approx 10^9$ M^{-1}) antibodies to small protein antigens such as nuclease (molecular weight [MW] ≈ 17,000). The dissociation rate is important to know in designing experiments to measure binding because if the act of measurement perturbs the equilibrium,

the time one has to make the measurement (eg, to separate bound and free) is determined by this halftime for dissociation. For instance, a 2-minute procedure that involves dilution of the antigen-antibody mixture can be completed before significant dissociation has occurred if the dissociation halftime is 23 minute. However, if the on rate is the same, but the affinity 10-fold lower, still a respectable $8 \times 10^7\ M^{-1}$, then the complex could be 50% dissociated in the time required to complete the procedure. This caution is relevant when we discuss methods of measuring binding and affinity in the following.

Because knowledge of the dissociation rate can be so important in the design of experiments, a word should be said about techniques to measure it. Perhaps the most widely applicable one is the use of radiolabeled antigen. After equilibrium is reached and the equilibrium concentration of bound radioactivity determined, a large excess of unlabeled antigen is added. Because any radioactive antigen molecule that dissociates is quickly replaced by an unlabeled one, the probability of a radioactive molecule associating again is very small. Therefore, one can measure the decrease in radioactivity bound to antibody with time to determine the dissociation rate.‡

AFFINITY

It is apparent from the previous discussion that a lot of information about an antigen-antibody reaction is packed into a single value, its affinity. In this section, we examine affinity more closely, including methods for measuring affinity and the heterogeneity thereof, the effects of multivalency of antibody and/or of antigen, and the special effects seen when the antigen-antibody interaction occurs on a solid surface (two-phase systems).

Interaction in Solution with Monovalent Ligand

The simplest case is that of the interaction of antibody with monovalent ligand. We may include in this category both antihapten antibodies reacting with truly monovalent haptens and antimacromolecule antibodies, which have been fractionated to obtain a population that reacts only with a single, nonrepeating site on the antigen.** In the latter case, the antigen behaves as if monovalent in its interaction with the particular antibody population under study. The proviso that the site recognized (antigenic determinant) be nonrepeating, that is, occur only once per antigen molecule, of course, is critical.

If the combining sites on the antibody are independent (ie, display no positive or negative cooperativity for antigen binding), then for many purposes one can treat these combining sites, reacting with monovalent ligands, as if they were separate molecules. Thus, many, but not all, of the properties we discuss can be analyzed in terms of the concentration of antibody-combining sites, independent of the number of such sites per antibody molecule (2 for IgG and IgA, 10 for IgM).

To determine the affinity of an antibody, one generally determines the equilibrium concentrations of bound and free ligand, at increasing total ligand concentrations, but at constant antibody concentration. Alternatively, one can vary the antibody concentration, but then, the analysis is slightly more complicated. Perhaps the theoretically most elegant experimental method to determine these quantities is equilibrium dialysis,[12,13] depicted and explained in Figure 7.2, in which ligand (antigen) is allowed to equilibrate between two

chambers, only one of which contains antibody, separated by a semipermeable membrane impermeable to antibody. The important feature of this method, as opposed to most others, is that the concentrations of ligand in each chamber can be determined without perturbing the equilibrium. The disadvantage of this method is that it is applicable only to antigens small enough to permeate freely a membrane that will exclude antibody. Another technical disadvantage is that bound antigen, determined as the difference between bound plus free antigen in one chamber and free antigen in the other, is not measured independently of free antigen.

Another category of method uses radiolabeled ligand in equilibrium with antibody and then physically separates free antigen bound to antibody and quantitates each separately. The methods used to separate bound and free antigen are discussed in the section on radioimmunoassay (RIA). These methods generally allow independent measurement of bound and free antigen but may perturb the equilibrium.

Scatchard Analysis

Once data are obtained, there are a number of methods of computing the affinity, of which we shall discuss two.

Perhaps the most widely used is that described by Scatchard[14] (Fig. 7.3[15]). The mass action equilibrium law is plotted in the form of Equation 3

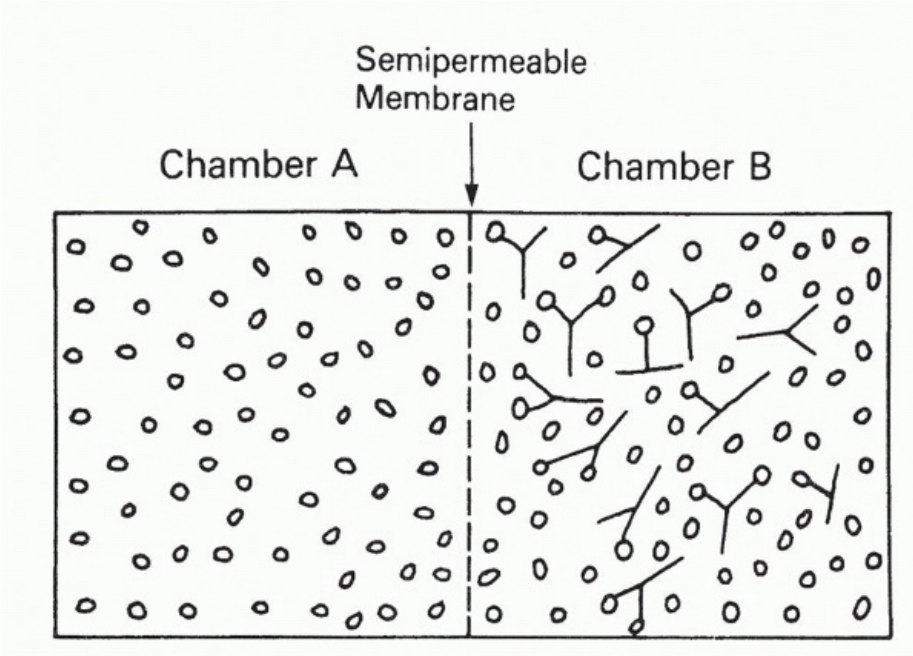

FIG. 7.2. Equilibrium Dialysis. Two chambers are separated by a semipermeable membrane that is freely permeable to ligand but not at all to antibody. Antibody is placed in one chamber (B) and ligand in one or both chambers. Regardless of how the ligand is distributed initially, after sufficient time to reach equilibrium, it will be distributed as follows. The concentration of free ligand will be identical in both chambers, but chamber B will have additional ligand bound to antibody. The concentration of bound ligand is thus the difference between the ligand concentration in the two chambers, whereas the

free concentration is the concentration in chamber A. Because these concentrations must obey the mass action law, Equation 2, they can be used to determine the affinity KA, from Equation 3 or 3′, by any of several graphical procedures, such as Scatchard analysis (described in the text).

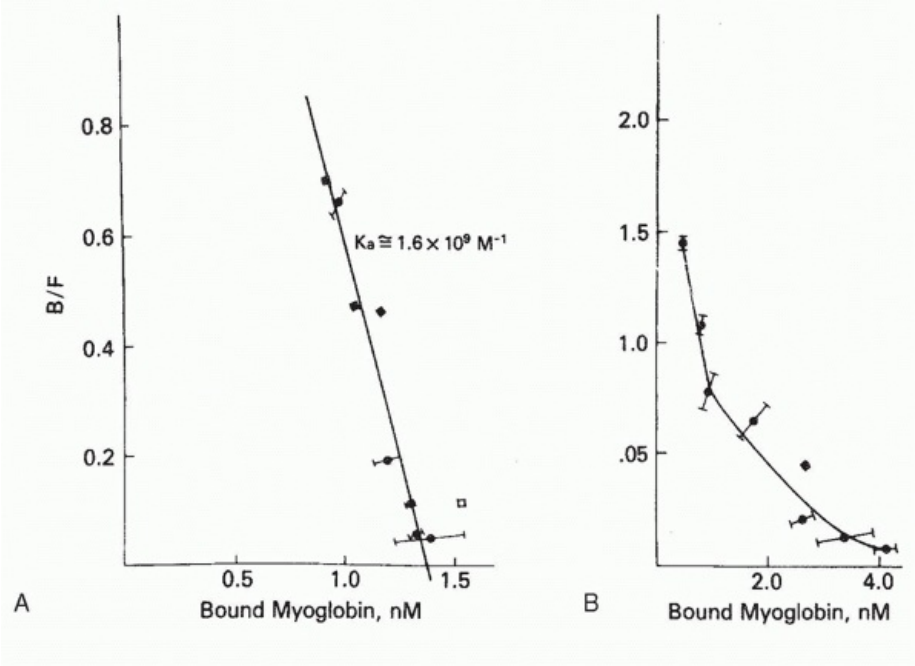

FIG. 7.3. Scatchard analysis of the binding of [3H]-sperm whale myoglobin by a monoclonal antibody to myoglobin **(A)** and by the serum antibodies from the same mouse whose spleen cells were fused to prepare the hybridoma **(B)**. The monoclonal antibody (clone HAL 43-201E11, clone 5) produces a linear Scatchard plot, whose slope, -1.6 × 10^9 M^{-1}, equals -K_A, and whose intercept on the abscissa gives the concentration of antibodybinding sites. In contrast, the serum antibodies produce a curved (concave up) Scatchard plot, indicative of heterogeneity of affinity. From Berzofsky et al.,[15] with permission.

$$[SL] = K_A([S]_t - [SL])[L] \qquad (3)$$

and B is substituted for [SL] and F for [L], referring to bound and free ligand, respectively. Then the Scatchard equation is

$$\frac{B}{F} = K_A([S]_t - B) \qquad (8)$$

Note that a very critical implicit assumption was made in this seemingly very simple conversion. The [SL] within the parentheses in Equation 3 was intended to be the concentration of bound antibody sites so that ($[S]_t$ - [SL]) = free [S]. However, in Equation 8,

we have substituted B, the concentration of bound ligand. If the ligand behaves as monovalent, then this substitution is legitimate, as every bound ligand molecule corresponds to an occupied antibody site. However, if the ligand is multivalent and can bind more than one antibody site, then Equation 8 is valid only in ligand excess where the frequency of ligands with more than one antibody bound is very low. In this section, we are discussing only monovalent ligands, but this proviso must be kept in mind when the Scatchard analysis is applied in other circumstances.

From Equation 8, we see that a plot of B/F versus B should yield a straight line (for a single affinity), with a slope of $-K_A$ and an intercept on the abscissa corresponding to antibody-binding site concentration (see Fig. 7.3). This is the so-called Scatchard plot. An alternative version that is normalized for antibody concentration is especially useful if the data were obtained at different values of total antibody concentration, $[A]_t$, instead of constant $[A]_t$. However, for this version, one requires an independent measure of total antibody concentration, other than the intercept of the plot. Then one divides Equation 8 by the total concentration of antibody molecules (making no assumptions about the number of sites per molecule) to obtain

$$\frac{R}{c} = K_A(n - r) \qquad (9)$$

where r = the number of occupied sites per antibody molecule, n = the total number of sites per antibody molecule, and c = free ligand concentration, that is, c = F. Thus,

$$r = \frac{B}{[\text{total antibody}]} = \frac{B}{[A]_t}$$

$$n = \frac{[\text{total sites}]}{[\text{total antibody}]} = \frac{[S]_t}{[A]_t}$$

where $[A]_t$ = total molar antibody concentration. In this form of the Scatchard plot, r/c versus r, the slope is still $-K_A$ and the intercept on the r axis is n. Thus one can determine the number of sites per molecule. Of course, if one determines $[S]_t$ from the intercept of Equation 8, one can also calculate the number of sites per molecule by dividing $[S]_t$ by any independent measure of antibody concentration. Thus, the only advantage of normalizing all the data points first to plot the r/c form arises when the data were obtained at varying antibody concentrations. If the antibody concentration is unknown but held constant, then the B/F form is more convenient and actually provides one measure of antibody (site) concentration. Because today we know the value of n for each class of antibody (2 for IgG and serum IgA, 10 for IgM), the concentration of sites and that of antibody are easily converted in many cases.

Heterogeneity of Affinity

The next level of complexity arises when one is dealing with a mixture of antibodies of

varying affinity for the ligand. This is the rule, rather than the exception, when one deals with antibodies from immune serum, even if they are fractionated to be monospecific, that is, all specific for the same site

on the antigen. Contrast, for example, the linear Scatchard plot for a homogeneous monoclonal antibody to myoglobin (see Fig. 7.3A), with the curved Scatchard plot for the serum antibodies from the same mouse used to prepare the hybridoma monoclonal antibody (see Fig. 7.3B). This concave up Scatchard plot is typical for heterogeneous antibodies. In a system such as hormone receptor-hormone interaction, in which negative cooperativity can occur between receptor sites (ie, occupation of one site lowers the affinity of its neighbor), a concave up Scatchard plot can be produced by negative cooperativity in the absence of any intrinsic heterogeneity in affinity. However, in the case of antibodies, where no such allosteric effect has been demonstrated, a concave up Scatchard plot indicates heterogeneity of affinity.

Ideally, one would like to imagine that the tangents all along the curve correspond (in slope) to the affinities of the many subpopulations of antibodies. Mathematically, this is not strictly correct, but it is true that the steeper part of the curve corresponds to the higher affinity antibodies and the shallower part of the curve to the lower affinity antibodies. Graphical methods have been developed to analyze more quantitatively the components of such curves,[16,17] and a very general and versatile computer program (LIGAND) has been developed by Munson and Rodbard[18] that can fit such curves using any number of subpopulations of different affinity. For purposes of this chapter, we discuss only the case of two affinities and then examine the types of average affinities that have been proposed when one is dealing with much greater heterogeneity. We also examine mathematical estimates of the degree of heterogeneity (analogous to a variance).

When an antibody population consists of only two subpopulations of different affinities, K_1 and K_2, then we can add the component Equations 3′ to obtain

$$r = r_1 + r_2 = \frac{n_1 K_1 c}{(1 + K_1 c)} + \frac{n_2 K_2 c}{(1 + K_2 c)} \qquad (10)$$

so that

$$\frac{r}{c} = \frac{n_1 K_1}{(1 + K_1 c)} + \frac{n_2 K_2}{(1 + K_2 c)} \qquad (10')$$

where the subscripts correspond to the two populations. Then the graph of r/c versus r can be shown to be a hyperbola whose asymptotes are, in fact, the linear Scatchard plots of the two components (Fig. 7.4). This situation has been analyzed graphically by Bright.19 Taking the limits as $c \rightarrow 0$ and as $c \rightarrow \infty$, it can easily be shown that the intercept on the abscissa is just $n_1 + n_2$ (or, in the form B/F versus B, the intercept is the total concentration of binding sites $[S]_t$), and the intercept on the ordinate is $n_1K_1 + n_2K_2$. Thus, one can still obtain the total value of n or $[S]_t$ from the intercept on the abscissa. The problem is in obtaining the two affinities, K_1 and K_2, and the concentrations of the individual antibody subpopulations (corresonding to n_1 and n_2). If K_1 is greater than K_2, one can approximate the affinities from

the slopes of the tangents at the two intercepts (see Fig. 7.4), but these will not, in general, be exactly parallel to the two asymptotes, which give the true affinities, so some error is always introduced, depending on the relative values of n_1 and n_2 and K_1 and K_2. A graphical method for solving for these exactly has been worked out by Bright[19] and computer methods by Munson and Rodbard.[18]

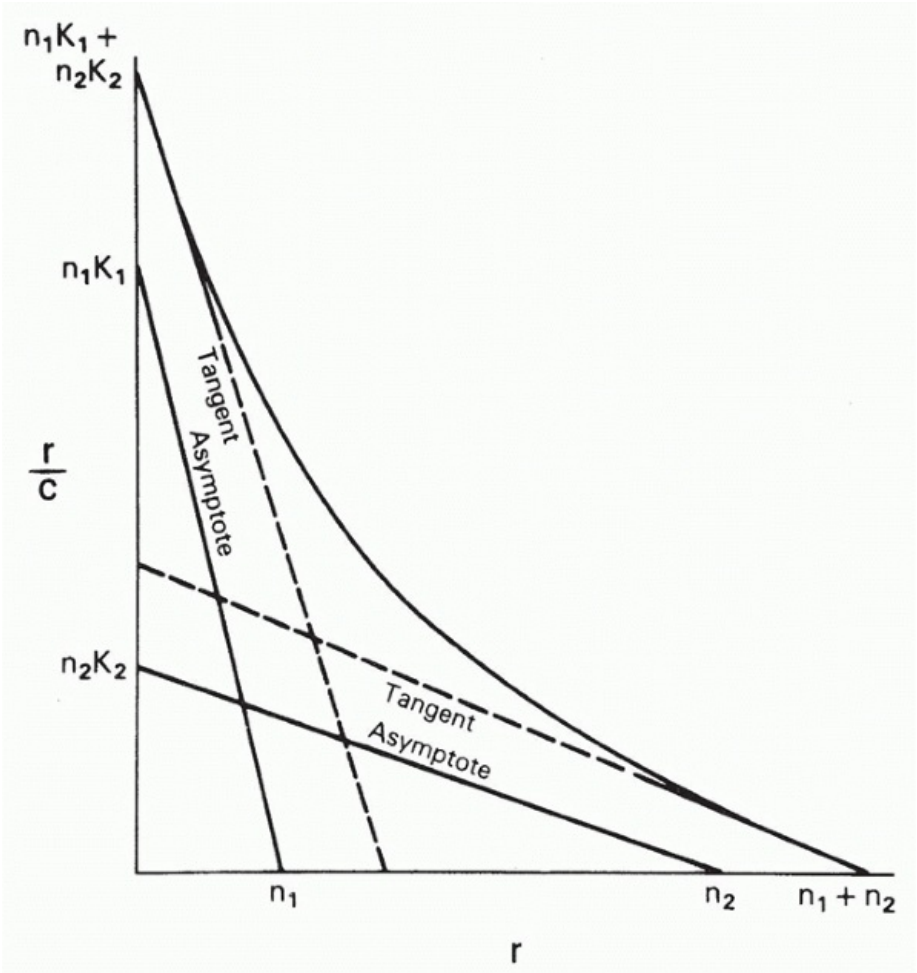

FIG. 7.4. Analysis of a Curved Scatchard Plot Produced by a Mixture of Two Antibodies with Different Affinities. The antibodies have affinities K_1 and K_2 and have n_1 and n_2 binding sites per molecule, respectively. The r is the concentration of bound antigen divided by the total antibody concentration (ie, bound sites per molecule), and c is the free antigen concentration. The curve is a hyperbola that can be decomposed into its two asymptotes, which correspond to the linear Scatchard plots of the two components in the antibody mixture. The tangents to the curve at its intercepts only approximate these asymptotes so that the slopes of the tangents estimate but do not accurately correspond to the affinities of the two antibodies. However, the intercept on the r axis corresponds to $n_1 + n_2$. Note that in this case n_1 and n_2 must be defined in terms of the total antibody concentration, not that of each component.

Average Affinities

In practice, of course, one rarely knows that one is dealing with exactly two subpopulations, and most antisera are significantly more heterogeneous than that. Therefore, the previously mentioned case is more illustrative of principles than of practical value. When faced with a curved Scatchard plot, one usually asks what the average affinity is, and perhaps some measure of the variance of the affinities, without being able to define exactly how many different affinity populations exist.

Suppose one has m populations each with site concentration $[S_i]$ and affinity K_i, so that at free ligand concentration [L], the fraction of each antibody that has ligand bound will be given by an equation of the form of Equation 3′:

$$B_i = \frac{K_i[S_i]_t[L]}{(1 + K_i[L])} \qquad (11)$$

Then the bound concentrations sum to give

$$B = \sum_{i=1}^{m} B_i = \sum_{i=1}^{m} \frac{K_i[S_i]_t[L]}{(1 + K_i[L])} \qquad (11')$$

Substituting F for [L] and dividing through by this quantity, one obtains

$$\frac{B}{F} = \sum_{i=1}^{m} \frac{K_i[S_i]_t}{(1 + K_iF)} \qquad (12)$$

or equivalently,

$$\frac{r}{c} = \sum_{i=1}^{m} \frac{K_in_i}{(1 + K_ic)} \qquad (12')$$

These can be seen to be generalizations of Equations 10 and 10′. Taking the limits as $F \rightarrow 0$ and $F \rightarrow \infty$, one again sees that the

$$\text{intercept on ordinate} = \sum_{i=1}^{m} K_i[S_i]_t \qquad (13)$$

and the

$$\text{intercept on abscissa} = \sum_{i=1}^{m} [S_i]_t = [S]_t \qquad (14)$$

Therefore, one can still obtain the total antibody site concentration from the intercept on the abscissa (Fig. 7.5).[20]

Two types of average affinity can be obtained graphically from the Scatchard plot.[20] Perhaps the more widely used K_0 is actually more accurately a median affinity rather than a mean affinity. It is defined as the slope of the tangent at the point on the curve where half the sites

are bound, that is, where B = $[S_t]/2$ (see Fig. 7.5). A second type of average affinity, which we call Kav, is a weighted mean of the affinities, each affinity weighted by its proportional representation in the antibody population. Thus, we take the ratio

$$K_{av} = \sum_{i=1}^{m} \frac{K_i[S_i]_t}{[S]_t} \qquad (15)$$

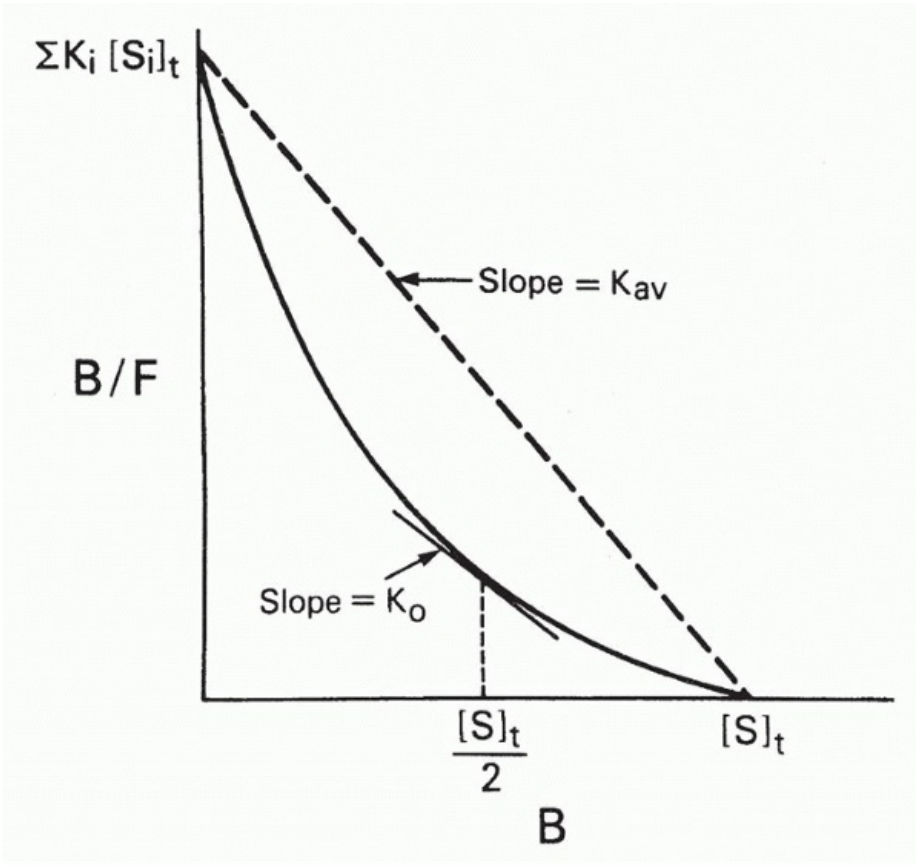

FIG. 7.5. Types of Average Affinities for a Heterogeneous Population of Antibodies, as Defined on a Scatchard Plot. K_0 is the slope of the tangent to the curve at a point where B = $[S]_t/2$, that is, where half the antibody sites are bound. Thus, K_0 corresponds to a median affinity. The K_{av} is the slope of the chord between the intercepts and corresponds to a weighted average of the affinities weighted by the concentrations of the antibodies with each affinity. Adapted from Berzofsky.[20]

From Equations 13 and 14, it is apparent that K_{av} is simply the ratio of the two intercepts on the B/F and B axes, that is, the slope of the chord (see Fig. 7.5). This type of weighted mean affinity, K_{av}, is therefore actually easier to obtain graphically in some cases than K_0, and we shall see that it is useful in other types of plots as well.

Indices of Heterogeneity: The Sips Plot

For a heterogeneous antiserum, one would also like to have some idea of the extent of heterogeneity of affinity. For instance, if the affinities were distributed according to a normal (Gaussian) distribution, one would like to know the variance.[21,22] More complex analyses have been developed that do not require as many assumptions about the shape of the distribution,[23,24,25] but the first and most widely used index of heterogeneity arbitrarily assumes that the affinities fit a distribution, first described by Sips,[26] which is similar in shape to a normal distribution. This was applied to the case of antibody heterogeneity by Nisonoff and Pressman,[27] and is summarized by Karush and Karush.[28] One fits the data to the assumed binding function

$$r = \frac{n(K_0 c)^a}{(1 + (K_0 c)^a)} \qquad (16)$$

which is analogous to Equations 3′ and 11 (the Langmuir adsorption isotherm) except for the exponent *a*, which is the index of heterogeneity. This index, *a*, is allowed to range from 0 to 1. For *a* = 1, Equation 16 is equivalent to Equation 3, and there is no heterogeneity. As *a* decreases toward 0, the heterogeneity increases. To obtain a value for a graphically, one plots the algebraic rearrangement of Equation 16:

$$\log\left(\frac{r}{n-r}\right) = a \log c + a \log K_0 \qquad (17)$$

so that the slope of log [r/(n - r)] versus log c is the heterogeneity index *a*.

C. DeLisi (personal communication) has derived the variance (second moment) of the Sips distribution in terms of the free energy RT ln K_0, about the mean of free energy. The result (normalized to RT) gives the dispersion or width of the distribution as a function of *a*:

$$\frac{\sigma^2_{Sips}}{R^2T^2} = \frac{\pi^2(1-a^2)}{3a^2} \qquad (18)$$

This is useful for determining a quantity, δ_{Sips}, which can be thought of as analogous to a standard deviation, if one keeps in mind that this is not a true Gaussian distribution. In addition, as noted previously, the use of the Sips distribution requires the assumption that the affinities (really the free energies) are continuously distributed symmetrically about a mean, approximating a Gaussian distribution. This assumption frequently is not valid.

The Plot of B/F versus F or T

Another graphical method that is useful for estimating affinities is the plot of bound/free versus free or total ligand concentration, denoted F and T, respectively[20] (Fig. 7.6). To simplify the discussion, let us define the bound/free ratio, B/F, as R, and define R_0 as the intercept, or limit, as free

ligand F → 0. First, for the case of a homogeneous antibody, from Equation 3′,

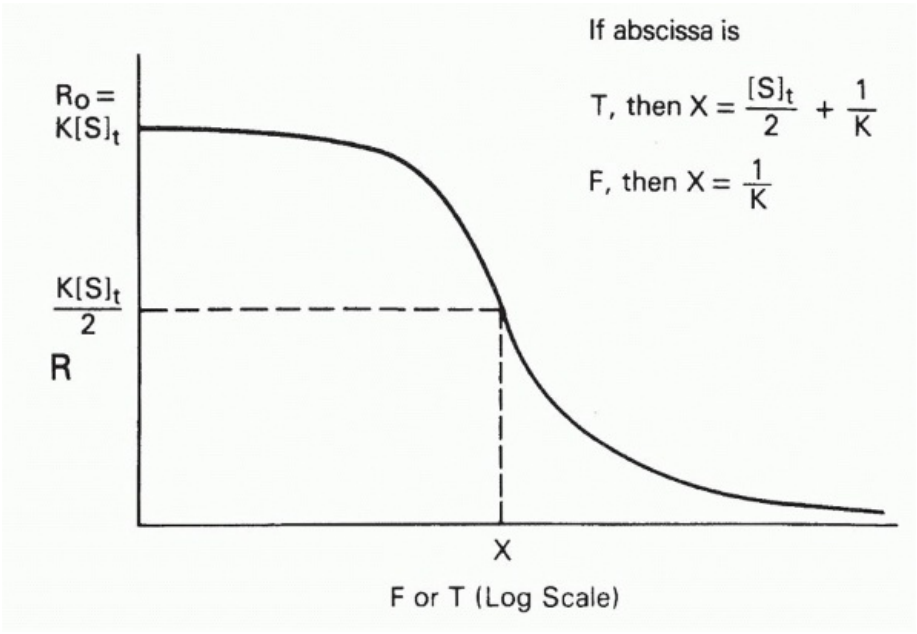

FIG. 7.6. Schematic Plot of R, the Bound/Free Ratio, as a Function of Free (F) or Total (T) Antigen Concentration. The curves have a similar sigmoidal shape, but the midpoint (where R = $R_0/2$) of the plot of R versus T has a term dependent on antibody site concentration ([S]t), whereas the midpoint of the plot of R versus F is exactly 1/K, independent of antibody concentration. Adapted from Berzofsky.[20]

$$R = \frac{B}{F} = \frac{K[S]_t}{(1 + KF)} \qquad (19)$$

and

$$R_0 = \lim_{F \to 0} \frac{B}{F} = K[S]_t \qquad (20)$$

Let us define the midpoint of the plot (see Fig. 7.6) as the point at which R decreases to half its initial value, R_0, that is, at which R = $K[S]_t/2$. For the case of homogeneous antibody (ie, a single affinity), simple algebraic manipulation,[20] substituting $K[S]_t/2$ (ie, $R_0/2$) for B/F in Equation 8, will show that at this midpoint††

$$F = \frac{1}{K} \qquad (21)$$

and

$$B = \frac{[S]_t}{2} \qquad (22)$$

so that the total concentration, T, is

$$T = B + F = \frac{[S]_t}{2} + \frac{1}{K} \qquad (23)$$

Thus, if one plots B/F versus F, the midpoint directly yields 1/K. However, it is frequently more convenient experimentally to plot B/F versus T. In this case, the midpoint is no longer simply the reciprocal of the affinity. As seen from Equation 23, the assumption that the midpoint is 1/K will result in an error equal to half the antibody-binding site concentration. Thus, in plots of B/F versus T, the midpoint will be a good estimate of the affinity only if $[S]_t/2 << 1/K$, that is, if the antibody concentration is low compared to the dissociation constant. In fact, if the affinity is so high that $1/K << [S]_t/2$, then one will merely be measuring the antibody concentration, not the affinity at all[20] (see Fig. 7.6).

In the case of a heterogeneous antiserum, we have already seen that

$$R_0 = \sum_i K_i[S_i]_t \qquad (13)$$

Therefore, at the midpoint, when $B/F = R_0/2$, it is easy to see that

$$K_{av} = \left(\frac{B}{F}\right)\left(\frac{2}{[S]_t}\right) = \frac{R_0}{[S]_t} \qquad (24)$$

Thus, one can still obtain the average affinity, as defined previously.[20]

Regardless of average affinities, the effect of affinity heterogeneity is to broaden the curve or to make the slope shallower. This can be seen by visualizing the curve of B/F versus F as a step function. Each antibody subpopulation of a given affinity, K_i, will be titrated to 50% of its microscopic B/F at a free ligand concentration $F = 1/K_i$. The high-affinity antibodies will be titrated at low F, but the low-affinity antibodies will require much higher F to be titrated. The resulting step function is analogous to the successive transitions corresponding to different pK values in a pH titration.

Intrinsic Affinity

The affinity, K_A, that we have been discussing so far is what has been termed the intrinsic affinity, that is, the affinity of each antibody-combining site treated in isolation. We have been able to do this, regardless of the valence of the antibodies, by using the concentration of combining sites, [S], in our equations rather than the concentration of antibody molecules, [A], which may have more than one site. Even without any cooperativity between combining sites, there is a statistical effect that makes the actual affinity different from the intrinsic

affinity if the antibody is multivalent and one uses whole antibody concentration rather than site concentration. The way this difference arises can best be seen by examining the case of a bivalent antibody, such as IgG. We assume that the two sites are equivalent and neither is affected by events at the other. The ligand, as in this whole section, is monovalent. Then there are two binding steps

$$A + L \overset{K_1}{\rightleftharpoons} AL, \qquad AL + L \overset{K_2}{\rightleftharpoons} AL_2 \tag{25}$$

and the corresponding actual affinities are

$$K_1 = \frac{[AL]}{[A][L]}, \qquad K_2 = \frac{[AL_2]}{[AL][L]} \tag{26}$$

If the intrinsic affinity of both equivalent sites is K, then K1 will actually be twice K because the concentration of available sites [S] will be twice the antibody concentration when the first ligand is about to bind in step 1. However,

once one site is bound, the reverse (dissociation) reaction of step 1 can occur from only one site, namely, that which is occupied. Conversely, for the second step, the forward reaction has only one remaining available site; however, in the reverse reaction, $AL_2 \rightarrow AL + L$, either site can dissociate to go back to the AL state. The second site bound need not be the first to dissociate, and because the sites are identical, one cannot tell the difference. Thus, for step 2, the apparent concentration of sites for the reverse reaction is twice that available for the forward reaction, so the affinity K_2 for the second step will be only half the intrinsic affinity, K.

It is easy to see how this statistical effect can be extrapolated to an antibody with n sites[29]:

$$K_1 = nK \quad \text{and} \quad K_n = \left(\frac{1}{n}\right) K \tag{27}$$

For the steps in between, two derivations are available,9,29 which yield

$$K_i = \frac{(n - i + 1)}{i} K \tag{28}$$

The actual affinity, rather than the intrinsic affinity, becomes important with monovalent ligands when one is interested in the effective affinity (based on a molar antibody concentration) under conditions where [L] is so low that only one site can bind antigen. Then for IgG or IgM (with 2 or 10 sites per molecule, respectively), the apparent affinity will be theoretically 2 or 10 times the intrinsic affinity. For most purposes, it is easier to use site concentrations and intrinsic affinities. The analyses given previously, such as B/F versus F or the Scatchard plot, whether B/F versus B or r/c versus r, will all yield intrinsic affinities. It is the intrinsic affinity that tells us something about the nature of the antibody-ligand interaction.

Once one enters the realm of multivalent ligands, the actual affinity or effective affinity involving multipoint binding between multivalent antibody molecule and multivalent ligand molecule can be much greater than the intrinsic affinity for binding at each site. This case is

the subject of the next section.

Interaction with Multivalent Ligands

So far, we have discussed only situations in which the ligand is monovalent or effectively monovalent with respect to the particular antibody under study. However, in many situations, the ligand molecule has multiple repeating identical determinants, each of which can bind independently to the several identical combining sites on a divalent or multivalent antibody.‡‡ Although the intrinsic affinity for the interaction of any single antibody-combining site with any single antigenic determinant may be the same as that discussed in the preceding section, the apparent or effective affinity may be much higher due to the ability of a single antibody molecule to bind more than one identical determinant of a multivalent antigen molecule. Karush[30] has termed this phenomenon "monogamous bivalency." Such monogamous binding can occur between two molecules in solution, or between a molecule in solution and one on a solid surface, such as a cell membrane or microtiter plate. We first discuss the situation in solution and then discuss the additional considerations that apply when one of the reactants is bound to a solid surface.

Monogamous Bivalency

Suppose a divalent antibody molecule reacts with antigen that has two identical determinants. This situation has been treated in detail by Crothers and Metzger,[31] and by Karush.[30] Let us call the two antibody sites S and S′, and the antigenic determinants D and D′, with the understanding that, in actuality, we cannot distinguish S from S′ or D from D′. The interaction can be broken up into two steps, a bimolecular reaction

$$\begin{array}{cccc} S & D & \overset{K_1}{\rightleftharpoons} & S-D \\ | & + & | & | \\ S' & D' & & S' \quad D' \end{array} \qquad (29)$$

followed by an intramolecular reaction

$$\begin{array}{cccc} S-D & & \overset{K_2}{\rightleftharpoons} & S-D \\ | & | & | & | \\ S' & D' & & S'-D' \end{array} \qquad (30)$$

The association constant for the first step, K_1, is related to the intrinsic affinity, K, simply by a statistical factor of 4 due to the degeneracy (equivalence) between S and S′ and between D and D′. This is a typical second-order reaction between antigen and antibody. However, the second step (Equation 30) is a first-order reaction because it is effectively an interconversion between two states of a single molecular complex, the reactants S′ and D′ being linked chemically (albeit noncovalently) through the S-D bond formed in the first step. Thus, the first-order equilibrium constant, K_2, is not a function of the concentrations of S-S and D-D in solution, as K_1 would be. Rather, the forward reaction depends on the geometry of the complex and the flexibility of the arms; in other words, the probability that S′ and D′ will encounter each other and be in the right orientation to react if they do come in contact

depends on the distances and freedom of motion along the chain S′-S-D-D′ rather than on the density of molecules in solution (ie, concentration).

The reverse reaction for step 2, on the other hand, will have a rate constant similar to that for the simple monovalent S-D → S + D reaction, as the dissociation reaction depends on the strength of the S′-D′ (or S-D) bond and is not influenced by the other S-D interaction unless there is strain introduced by the angles required for simultaneous bonds between S and D and S′ and D′. Note that K_2 will inherently have a statistical factor of 1/2 compared to the intrinsic K'_2 for the analogous reaction if the S′-S-D-D′ link were all covalent because in the forward reaction of Equation 30 only one pair can react, whereas in the reverse reaction either S′-D′ or S-D could dissociate to produce the equivalent result.

We would like to know the apparent or observed affinity for the overall reaction

$$\begin{array}{ccc} S & D & S-D \\ | & | & | \\ + & \overset{K_{obs}}{\rightleftharpoons} & \\ | & | & | \\ S & D & S-D \end{array} \qquad (31)$$

Because the free energies, ΔF_1 and ΔF_2, for the two steps are additive, the observed affinity will be the product of K_1 and K_2

$$K_{obs} = K_1 K_2 \qquad (32)$$

where we have defined K_1 and K_2 to include the statistical degeneracy factors.*** The equilibrium constants K_1 and K_2 are each the ratios of forward and reverse rate constants, as in Equation 7. Of these four rate constants, all are directly related to the corresponding terms for the intrinsic affinity between S and D except for the intramolecular forward reaction of step 2, as noted previously. Thus, the difficulty in predicting K_{obs} is largely a problem of analyzing the geometric (steric) aspects of K_2, assuming one already knows the intrinsic affinity, Crothers and Metzger[31] have analyzed this problem for particular situations. Qualitatively, we can say that whether K_2 will be larger or smaller than K will depend on factors such as the enforced proximity of S′ and D′ in step 2 and the distance between D and D′ compared to the possible distances accessible between S and S′, which in turn depends on the length of the antibody arms and the flexibility of the hinge between them. Thus, because K_1 can be approximated by K, except for statistical factors, the apparent affinity for this “monogamous bivalent” binding interaction, K_{obs}, may range from significantly less than to significantly greater than K^2. If K_2 is of the same order of magnitude as K, then K_{obs} will be of the order of K^2, which can be huge (eg, if $K \approx 10^9\ M^{-1}$, Kobs could be $\approx 10^{18}\ M^{-1}$). The halftime for dissociation would be thousands of years. It is easy to see how such monogamous bivalent interactions can appear to be irreversible, even though in practice the observed affinity is rarely more than a few orders of magnitude larger than the K for a single site, possibly due to structural constraints.[32]

If apparent affinities this high can be reached by monogamous bivalency, even greater ones

should be possible for the multipoint binding of an IgM molecule to a multivalent ligand. Although IgM is decavalent for small monovalent ligands, steric restrictions often make it behave as if pentavalent for binding to large multivalent ligands. However, even five-point binding can lead to enormously tight interactions. Therefore, even though the intrinsic affinity of IgM molecules tends to be lower than that of IgG molecules for the same antigen,[30] the apparent affinity of IgM can be quite high.

Two-Phase Systems

The same enhanced affinity seen for multipoint binding applies to two-phase systems. Examples include the reaction of multivalent antibodies with antigen attached to a cell surface or an artificial surface (such as Sepharose or the plastic walls of a microtiter plate), the reaction of a multivalent ligand with antibodies on the surface of a B cell, a Sepharose bead, or a plastic plate, and the reaction of either component with an antigen-antibody precipitate. For the reasons outlined previously, "monogamous" binding can make the apparent affinity of a multivalent antibody or antigen for multiple sites on a solid surface be quite large to the point of effective irreversibility.

However, another effect also increases the effective affinity in a two-phase system. This effect applies even for monovalent antibodies (Fab fragments) or monovalent ligands. The effect arises from the enormously high effective local concentration of binding sites at the surface, compared to the concentration if the same number of sites were distributed in bulk solution.[33] Looked at another way, the effect is due to the violation, at the liquid-solid interface, of the basic assumption in the association constants, K_A, discussed previously, that the reactants are all distributed randomly in the solution. (To some extent, the latter is involved in the enhanced affinity of multivalency as well.) This situation has been analyzed by DeLisi34 and DeLisi and Wiegel,[35] who break the reaction down into two steps: the diffusive process necessary to bring the antigen and antibody into the right proximity and orientation to react, and the reactive process itself. The complex between antigen and antibody, when positioned but not yet reacted, is called the encounter complex. The reaction can then be written

$$S + D \underset{k_-}{\overset{k_+}{\rightleftharpoons}} S \cdots D \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} SD \qquad (33)$$

where S = antibody site, D = antigenic determinant, k+ and k_ = forward and reverse diffusive rate constants, and k_1 and k_{-1} = forward and reverse reactive rate constants once the encounter complex is formed. If the encounter complex is in a steady state, the overall rate constants will be given by

$$k_f = \frac{k_1 k_+}{(k_1 + k_-)} \qquad (34)$$

$$k_r = \frac{k_{-1} k_-}{(k_1 + k_-)} \qquad (35)$$

where subscripts f and r = forward and reverse.[34] The association constant, according to Equation 7, is the ratio of these two, or

$$K_A = \frac{k_1 k_+}{k_{-1} k_-} \qquad (36)$$

The relative magnitudes of k_1 and k_- determine the probable fate of the encounter complex. Is it more likely to react to form SD or to break up as the reactants diffuse apart?

Now suppose that k is slow compared to k_1. Then the SD bound complex and the encounter complex, S … D, may interconvert many times before the encounter complex breaks up and one of the reactants diffuses off into bulk solution. If the surface has multiple antigenic sites, D, then even a monovalent antibody (Fab) may be much

more likely, when SD dissociates to S … D, to rereact with the same or nearby sites than to diffuse away into bulk solution, again depending on the relative magnitudes of these rate constants. This greater probability to rereact with the surface rather than diffuse away is the essence of the effect we are describing. A more extensive mathematical treatment of reactions with cells is given in DeLisi34 and DeLisi and Wiegel.[35]

A somewhat different, and very useful, analysis of the same or a very similar effect was given by Silhavy et al.[36] These authors studied the case of a ligand diffusing out of a dialysis bag containing a protein for which the ligand had a significant affinity. Once the ligand concentration became low enough that there was an excess of free protein sites, then the rate of exit of ligand from the dialysis bag was no longer simply its diffusion rate nor was it simply the rate of dissociation of protein-ligand complex. These authors showed that under these conditions the exit of ligand followed quasi-first-order kinetics, but with a half-life longer than the half-life in the absence of protein by a factor of $(1 + [P]K_A)$

$$t_+ = t_-(1 + [P]K_A) \qquad (37)$$

where [P] = protein site concentration, K_A = affinity, and t_+ and t_- = half-lives in the presence and absence of protein in the bag.

In this case, the protein was in solution, so the authors could use the actual protein concentration and the actual intrinsic affinity, K_A. In the case of protein on a two-dimensional surface, it is harder to know what to use as the effective concentration. However, the high local concentration of protein compartmentalized in the dialysis bag can be seen to be analogous to the high local concentration attached to the solid surface. The underlying mechanism of the two effects is essentially the same and so are the implications. For instance, in the case of dialysis, a modest 10 μM concentration of antibody sites with an affinity of 10^8 M^{-1} can reduce the rate of exit of a ligand 1000-fold. A dialysis that would otherwise take 3 hours would take 4 months. It is easy to see how this “retention effect” can make even modest affinities appear infinite (ie, the reactions appear irreversible). This retention effect applies not only to immunologic systems but also to other interactions at a cell surface or between cell compartments where the local concentration of a protein may be

high. In particular, these principles of two-phase systems should also govern the interaction between antigen specific receptors on the surface of T cells and antigen-major histocompatibility complex (MHC) molecule complexes on the surface of antigen-presenting cells, B cells, or target cells.

One final point is useful to note. Because these retention effects depend on a localized abundance of unoccupied sites, addition of a large excess of unlabeled ligand to saturate these sites will diminish or abolish the retention effect and greatly accelerate the dissociation or exit of labeled ligand. This effect of unlabeled ligand can be used as a test for the retention effect, although one must be aware that in certain cases the same result can be an indication of negative cooperativity among receptor sites.

RADIOIMMUNOASSAY AND RELATED METHODS

Since it was first suggested in 1960 by Yalow and Berson,[37] RIA has rapidly become one of the most widespread, widely applicable, and most sensitive techniques for assessing the concentration of a whole host of biologic molecules. Most of the basic principles necessary to understand and apply RIA have been covered previously in this chapter. In this section, we examine the concepts and methodologic approaches used in RIA. For a detailed methods book, we refer the reader to Chard,[38] Rodbard,[39] and Yalow.[40]

The central concept of RIA is that the binding of an infinitesimal concentration of highly radioactive tracer antigen to low concentrations of a high-affinity-specific antibody is very sensitive to competition by unlabeled antigen and is also very specific for that antigen. Thus, concentrations of antigen in unknown samples can be determined by their ability to compete with tracer for binding to antibody. The method can be used to measure very low concentrations of a molecule, even in the presence of the many impurities in biologic fluids. Accomplishment of this requires an appropriate high-affinity antibody and radiolabeled antigen, a method to distinguish bound from free-labeled antigen, optimization of concentrations of antibody and tracer-labeled antigen to maximize sensitivity, and generation of a standard curve, using known concentrations of competing unlabeled antigen, from which to read off the concentrations in unknown samples as well as the best method for representing the data. We review all these steps and pitfalls in this procedure except the preparation of antibodies and labeled antigens.

Separation of Bound and Free Antigen

Whatever parameter one uses to assess the amount of competition by the unlabeled antigen in the unknown sample to be tested, it will always be a function of bound versus free, radiolabeled antigen. Therefore, one of the most critical technical requirements is the ability to distinguish clearly between antibody-bound radioactive tracer and free radioactive tracer. This distinction usually requires physical separation of bound and free ligand. If the bound fraction is contaminated by free ligand, or vice versa, enormous errors can result, depending on the part of the binding curve on which the data fall.

Solution Methods

Solution RIA methods have the advantage that binding can be related to the intrinsic affinity of the antibody. However, bound and free antigen must be separated by a method that does not perturb the equilibrium. Three basic types of approaches have been used: precipitate the

antibody with bound antigen, leaving free antigen in solution; precipitate the free antigen, leaving antibody and bound antigen in solution; or separate free from antibody-bound antigen molecules in solution on the basis of size by gel filtration. This last method is too cumbersome to use for large numbers of samples and is too slow, in general, to be sure the equilibrium is not perturbed in the process. Therefore, gel filtration columns are not widely used for RIA. Methods that precipitate antibody are perhaps the most widely used. If the antigen is sufficiently smaller (<30,000 MW) than the antibody that it will remain in solution at

concentrations of either ammonium sulfate[41] or polyethylene glycol, 6000 MW (10% W:W),[42] which will precipitate essentially all the antibody, then these two reagents are frequently the most useful. Precipitation with polyethylene glycol and centrifugation can be accomplished before any significant dissociation has occurred due to dilutional effects.[43] However, if the antigen is much larger than about 30,000 to 40,000 MW, these methods will produce unacceptably high background control values in the absence of specific antibody. If the antibody is primarily of a subclass of IgG that binds to staphylococcal protein A or G, one can take advantage of the high affinity of protein A or G for IgG by using either protein A (or G)-Sepharose or formalinkilled staphylococcal organisms (Cowan I strain) to precipitate the antibody.[44] Finally, one can precipitate the antibody using a specific second antibody, an anti-Ig raised in another species. Maximal precipitation occurs not at antibody excess but at the "point of equivalence" in the middle of the titration curve where antigen (in this case, the first antibody) and the (second) antibody are approximately equal in concentration. Thus, one must add carrier Ig to keep the Ig concentration constant and determine the point of equivalence by titrating with the second antibody. Even worse, the precipitin reaction is much slower than the antigen-antibody reaction itself, allowing reequilibration of the antigen-antibody interaction after dilution by the second antibody. Some of these problems can be reduced by enhancing precipitation with low concentrations of polyethylene glycol.

The other type of separation method is adsorption of free antigen to an agent, such as activated charcoal or talc, which leaves antigen bound to antibody in solution. Binding of antigen by these agents depends on size and hydrophobicity. Although these methods are inexpensive and rapid, they require careful adjustment and monitoring of pH, ionic strength, and temperature to obtain reproducible results and to avoid adsorption of the antigen-antibody complex. Furthermore, because these agents have a high affinity for antigen, they can compete with a low-affinity antibody and alter the equilibrium. Also, as charcoal quenches beta scintillation counting, it can be used only with gamma-emitting isotopes such as ^{125}I.

Solid-Phase Methods

Solid-phase RIA methods have the advantages of high throughput and increased apparent affinity due to the effects at the solid-liquid interface noted previously. However, they have the concomitant disadvantage that one is not measuring the true intrinsic affinity because of these same effects. The method itself is fairly simple. One binds the antibody in advance to a solid surface such as a Sepharose bead or the walls of a microtiter plate well. To avoid competition from other serum proteins for the solid phase, one must use purified antibody in this coating step. Once the wells (or Sepharose beads) are coated, one can incubate them with labeled tracer antigen with or without unlabeled competitor, wash and count directly the radioactivity bound to the plastic wells or to the Sepharose. The microtiter plate method is

particularly useful for processing large numbers of samples. However, because the concentration, or even the amount, of antibody coating the surface is unknown and because the affinity is not the intrinsic affinity, one cannot use these methods for studying the chemistry of the antigen-antibody reaction itself. A detailed analysis of the optimum parameters in this method is given by Zollinger et al.[43]

A variation that does allow determination of affinity, based on the enzyme-linked immunosorbant assay (ELISA) described in the following, but equally applicable to RIA, was described by Friguet et al.[45] This uses antigen-coated microtiter wells and free antibody but measures competition by free antigen to prevent the antibody in solution from binding to the antibody on the plate (see Fig. 7.9B). Thus, the antibody bound to the plastic is antibody that was free in the solution equilibrium. The affinity measured is that between the antibody and antigen in solution, not that on the plastic, so it is not directly influenced by the multivalency of the surface. However, as pointed out by Stevens,46 the determination of affinity is strictly accurate only for monovalent Fab fragments because a bivalent antibody with only one arm bound to the plastic and one bound by antigen in solution will still be counted as free. Therefore, there will be an underestimate of the ligand occupancy of the antibody combining sites and thus an underestimate of affinity. Stevens also points out a method to correct for this error based on binomial analysis. Subsequently, Seligman[47] showed that the nature and density of the antigen on the solid surface can also influence the estimate of affinity.

Optimization of Antibody and Tracer Concentrations for Sensitivity

The primary limitations on the sensitivity of the assay are the antibody affinity and concentration, the tracer concentration, and the precision (reproducibility) of the data. In general, the higher the affinity of the antibody, the more sensitive the assay can be made. Once one prepares the highest affinity antibody available, this parameter limits the extent to which the other parameters can be manipulated. For instance, because the unlabeled antigen in the unknown sample is going to compete against labeled tracer antigen, the lower the tracer concentration, the lower the concentration of the unknown sample, which can be measured up to a point. That point is determined by the affinity, K_A, as can be seen from the theoretical considerations discussed previously.[38] The steepest part of the titration curve will occur in the range of concentrations around $1/K_A$. Concentrations of ligand much below $1/K_A$ will leave most of the antibody sites unoccupied so that competition will be less effective. Thus, there is no value in reducing the tracer concentration more than a few-fold lower than $1/K_A$. Therefore, although it is generally useful to increase the specific radioactivity of the tracer and reduce its concentration, it is important to be aware of this limit of $1/K_A$. Increasing the specific activity more than necessary can result in denaturation of antigen.

Similarly, lowering the antibody concentration will also increase sensitivity, up to a point. This limit also depends on $1/K_A$ and on the background “nonspecific binding.” Decreasing the antibody concentration to the point that binding of tracer is too close to background will result in

loss of sensitivity due to loss of precision. In general, the fraction of tracer bound in the absence of competitor should be kept greater than 0.2, and in general closer to 0.5.[48]

A convenient procedure to follow to optimize tracer and antibody concentrations is first to choose the lowest tracer concentration that results in convenient counting times and counting precision for bound values of only one-half to onetenth the total tracer. Then, keeping this tracer concentration constant, one dilutes out the antibody until the bound/free antigen ratio is close to 1.0 (bound/total = 0.5) in the absence of competitor. This antibody concentration in conjunction with this tracer concentration will generally give near-optimal sensitivities, within the limits noted previously. It is important to be aware that changing the tracer concentration will require readjusting the antibody concentration to optimize sensitivity.

Analysis of Data: Graphic and Numerical Representation

We have already examined the Scatchard plot (bound/free versus bound) and the plot of bound/free versus free or total antigen concentration as methods of determining affinity. The latter lends itself particularly to the type of competition curves that constitute an RIA. In fact, the independent variable must always be antigen concentration, as that is the known quantity one varies to generate the standard curve. Let us use B, F, and T to represent the concentrations of bound, free, and total antigen, respectively. We have seen that the plot of B/F versus F is more useful for determining the affinity, K_A, than the plot of B/F versus T. However, in RIA, the quantity one wants to determine is T, and correspondingly, the known independent variable in generating the standard curve is T. Another difference between the situation in RIA and that discussed previously is that, in RIA, one has both labeled and unlabeled antigen. The dependent variable, such as B/F, is the ratio of bound tracer over free tracer, as only radioactive antigen is counted. The B/F for the unlabeled antigen will be the same at equilibrium, assuming that labeled and unlabeled antigen bind the antibody equivalently, that is, with the same K_A. This assumption is not always valid and requires experimental testing.

The sigmoidal shape of B/F versus F or T, when F or T (the “dose”) is plotted on a log scale, has been seen in Figure 7.6. The shape for B/T versus F or T would be similar. Note that because B + F = T,

$$\frac{B}{F} = \frac{B}{(T - B)} = \frac{B/T}{(1 - B/T)} \qquad (38)$$

and

$$\frac{B}{T} = \frac{B/F}{(1 + B/F)} \qquad (39)$$

These transformations can be useful. If one plots B/F or B/T versus F or T on a linear scale, then the shape is approximately hyperbolic, as in Figure 7.7. The plot of B/F versus T (log scale) was one of the first methods used to plot RIA data and is still among the most useful. The most sensitive part of the curve is the part with the steepest slope.

It has been shown by probability analysis that if the antigen has multiple determinants, each capable of binding antibody molecules simultaneously and independently of one another, then the more such determinants capable of being recognized by the antibodies in use, the steeper will be the slope.[49] This effect of multideterminant binding on steepness arises

because, in RIA, an antigen molecule is scored as bound whether it has one antibody molecule attached or several. It is scored as free only if no antibody molecules are attached. Thus, the probability that an antigen molecule is scored as free is the product of the probabilities that each of its determinants is free. The effect can lead to quite steep slopes and has been confirmed experimentally.[49]

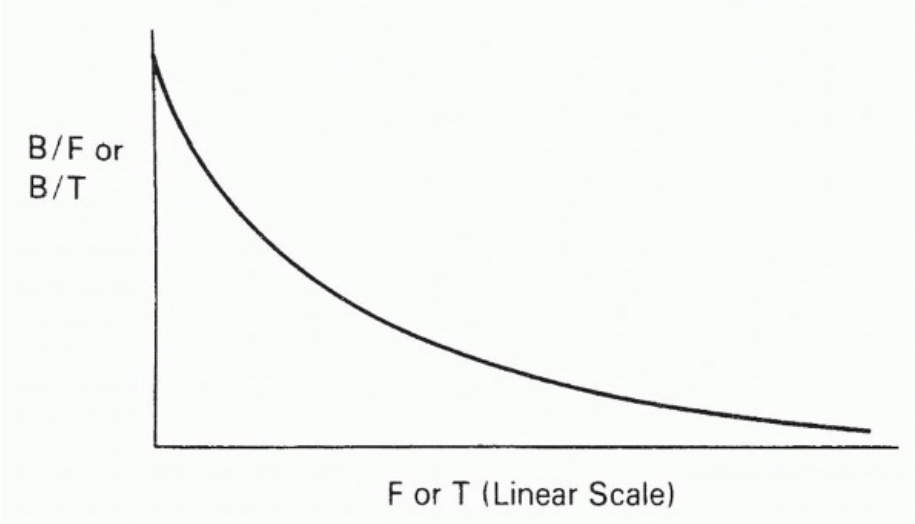

FIG. 7.7. Schematic Plot of B/F or B/T (the Bound Over Free or Total Antigen Concentration) as a Function of Free (F) or Total (T) Antigen Concentration, when Plotted on a Linear Scale. Contrast with similar plot on a log scale in Figure 7.6.

A transform that allows linearization of the data in most cases is the logit transform.[50,51] To use this, one first expresses the data as B/B_0, where B_0 is the concentration of bound tracer in the absence of competitor. One then takes the logit transform of this ratio, defined as

$$\text{logit}\,(Y) = \ln\left[\frac{Y}{(1-Y)}\right] \qquad (40)$$

where ln = the natural log (log to the base e). The plot of logit (B/B^0) versus ln T is usually a straight line (Fig. 7.8).

The slope is usually -1 for the simplest case of a monoclonal antibody binding a monovalent antigen. The linearity of this plot obviously makes it very useful for graphical interpolation, which one would like to do to read antigen concentration off a standard curve. One additional advantage is that linearity facilitates tests of parallelism. If the unknown understudy is identical to the antigen used to generate the standard curve, then a dilution curve of the unknown should be parallel to the standard curve in this logit-log coordinate system. If not, the assay is not valid.

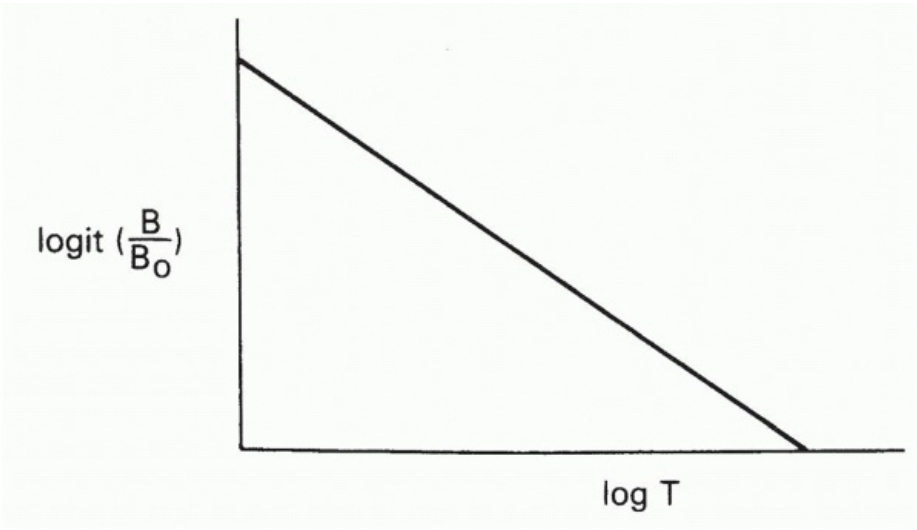

FIG. 7.8. Schematic Logit. Log plot used to linearize radioimmunoassay data. B and T are bound tracer and total antigen concentration, respectively, and B_0 is the value of B when no unlabeled antigen is added to tracer. The logit function is defined by Equation 40, logit (Y) = ln [Y/(1 - Y)].

These and other methods of analyzing the data are discussed further by Feldman and Rodbard[52] and Rodbard,[39] including statistical treatment of data. Although a number of computer programs have become available for rapid analysis of RIA data without using manual plots of standard curves, they are all based on these and similar methods, and their accurate interpretation depends on an understanding of these concepts.

Corrections for B, F, and T

Before we leave this section on analysis of RIA data, we must point out a few controls and corrections to the data without which the results may be fallacious.

First, in any method that precipitates antibody and bound antigen (or uses a solid-phase antibody), there may always be a fraction of antigen that precipitates or binds nonspecifically in the absence of specific antibody. Thus, one must always run controls with normal serum or Ig to determine this background. The nonspecific binding usually increases linearly with antigen dose, that is, it does not saturate. This control value should be subtracted from B but does not affect F when measured independently, only F determined as T minus B. The total antigen that is meaningful is the sum of that which is specifically bound and that which is free. Nonspecifically bound antigen should be deleted from any term in which it appears.

A second correction is that for immunologically inactive radiolabel, that is, either free radioisotope, or isotope coupled to an impurity or to denatured antigen. The fraction of radioactive material that is immunologically reactive with the antibodies in the assay can be determined by using a constant, low concentration of labeled antigen and adding increasing concentrations of antibody. If there is no contamination with inactive material, all the radioactivity should be able to be bound by sufficient antibody. If the fraction of tracer bound reaches a plateau at <100% bound, then only this fraction is active in the assay. The importance of this correction can be seen from the example in which the tracer is only 80%

active. Then, when the true B/F is 3 (B/T = 0.75), applying only to the active 80% of the tracer, the remaining 20%, which can never be bound, will mistakenly be included in the free tracer, doubling the amount that is measured as free. Thus, the measured B/F will be only 1.5 (ie, 0.6/0.4) instead of the true value of 3 (ie, 0.6/0.2). This factor of 2 will make a serious difference in the calculation of affinity, for instance, from a Scatchard plot. Also, it will result in a plateau in the Scatchard plot at high values of B/F, as with 20% of the tracer obligatorily free, B/F can never exceed 4 (ie, 0.8/0.2). To correct for this potentially serious problem, the inactive fraction must always be determined and subtracted from both F and T.

Nonequilibrium Radioimmunoassay

So far, we have assumed that tracer and unlabeled competitor are added simultaneously, and sufficient incubation time is allowed to achieve equilibrium. To measure the affinity, of course, equilibrium must be assured. However, suppose one's sole purpose is to measure the concentration of competitor by RIA. Then one can actually increase the sensitivity of the assay by adding the competitor first, allowing it to react with the antibody, and then intentionally adding the tracer for too short a time to reach a new equilibrium. One is essentially giving the competitor a competitive advantage. It can be shown that the slope of the dose-response curve, B/T versus total antigen added, is increased in the low-dose range —a mathematical measure of increased sensitivity. A detailed mathematical analysis of this procedure may be found in Rodbard et al.[53] Note, however, that use of such nonequilibrium conditions requires very careful control of time and temperature.

Enzyme-Linked Immunosorbent Assay

An alternative solid-phase readout system for the detection of antigen-antibody reactions is the ELISA.[54] In principle, the only difference from RIAs is that antibodies or antigen are covalently coupled to an enzyme instead of a radioisotope so that bound enzyme activity is measured instead of bound cpm. In practice, the safety and convenience of nonradioactive materials and the commercial availability of plate readers that can measure the absorbance of 96 wells in a few seconds account for ELISA's widespread use. Because both ELISA and RIA are governed by the same thermodynamic constraints, and the enzyme can be detected in the same concentration range as commonly used radioisotopes, the sensitivity and specificity are comparable. We consider three basic strategies for using ELISA assays to detect specific antibody or antigen.

As shown in Figure 7.9A, the indirect antibody method is the simplest way to detect and measure specific antibody in an unknown antiserum. Antigen is noncovalently attached to each well of a plastic microtiter dish. For this purpose, it is fortunate that most proteins bind nonspecifically to plastic. Excess free antigen is washed off, and the wells are incubated with an albumin solution to block the remaining nonspecific protein binding sites. The test antiserum is then added, and any specific antibody binds to the solid-phase antigen. Washing removes unbound antibodies. Enzyme-labeled anti-Ig is added. This binds to specific antibody already bound to antigen on the solid phase, bringing along covalently attached enzyme. Unbound antiglobulin-enzyme conjugate is washed off; substrate is then added. The action of bound enzyme on substrate produces a colored product, which is detected as increased absorbance in a spectrophotometer.

Although this method is quick and very sensitive, it is often difficult to quantitate. Within a

defined range, the increase in optical density is proportional to the amount of specific antibody added in the first step. However, the amount of antibody bound is not measured directly. Instead, the antibody concentration of the sample is estimated by comparing it with a standard curve for a known amount of antibody. It is also difficult to determine affinity by this method because the solid-phase antigen tends to

increase the apparent affinity. The sensitivity of this assay for detecting minute amounts of antibody is quite good, especially when affinity-purified antiglobulins are used as the enzyme-linked reagent. A single preparation of enzymelinked antiglobulin can be used to detect antibodies to many different antigens. Alternatively, class-specific antiglobulins can be used to detect how much of a specific antibody response is due to each Ig class. Obviously, reproducibility of the assay depends on uniform antigen coating of each well, and the specificity depends on using purified antigen to coat the wells.

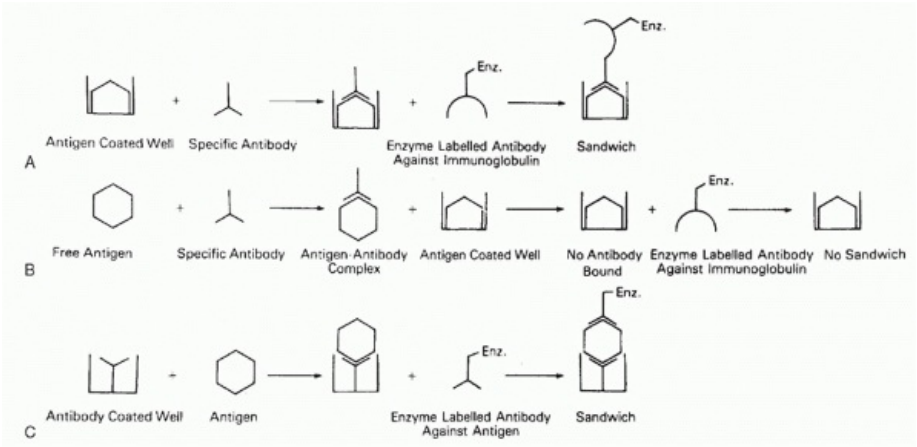

FIG. 7.9. Three Strategies for the Detection of Specific Antibody-Antigen Reactions Using the Enzyme-Linked Immunosorbant Assay Technique. A: Direct binding. **B:** Hapten inhibition. **C:** Antigen sandwich.

Figure 7.9B shows the competition technique for detecting antigen. Soluble antigen is mixed with limiting amounts of specific antibody in the first step. Then the mixture is added to antigen-coated wells and treated as described in Figure 7.9A. Any antigen-antibody complexes formed in the first step will reduce the amount of antibody bound to the plate, and hence will reduce the absorbance measured in the final step. This method permits the estimate of affinity for free antigen, which is related to the half-inhibitory concentration of antigen. Mathematical analysis of affinity by this approach was described by Friguet et al.[45] with modification by Stevens,[46] as discussed under RIA solid-phase methods. In addition, some estimate of cross-reactivity between the antigen in solution and that on the plate can be obtained.

Figure 7.9C shows the sandwich technique for detecting antigen. Microtiter plates are coated with specific antibody. Antigen is then captured by the solid-phase antibody. A second antibody specific for the antigen, and coupled to enzyme, is added. This binds to the solid-phase antigen-antibody complex, carrying enzyme along with it. Excess second antibody is

washed off, and substrate is added. The absorbance produced is a function of the antigen concentration of the test solution, which can be determined from a standard curve. Specificity of the assay depends on the specificity of the antibodies used to coat the plate and detect antigen. Sensitivity depends on the affinity as well as amount of the first antibody coating the well, which can be increased by using affinity-purified antibodies or monoclonal antibodies in this step. The sandwich method depends on divalency of the antigen or else the two antibodies must be specific for different antigenic determinants on the same antigen molecule. When comparing two monoclonal antibodies to the same antigen, this technique can be used to ascertain whether they can bind simultaneously to the same molecule or whether they compete for the same site or sites close enough to cause steric hindrance.[55]

When antibodies are serially diluted across a plate, the last colored well indicates the titer. Specificity of binding can be demonstrated by coating wells with albumin and measuring antibody binding in parallel with the antigen-coated wells. Because it can be used to test many samples in a short time, ELISA is often used to screen culture supernatants in the production of hybridoma antibodies. The sensitivity of the method allows detection of clones producing specific antibodies at an early stage in cell growth.

An important caution when using native protein antigens to coat solid-phase surfaces (see Fig. 7.9A) is that binding to a surface can alter the conformation of the protein. For instance, using conformation specific monoclonal antibodies to myoglobin, Darst et al.[56] found that binding of myoglobin to a surface altered the apparent affinity of some antibodies more than others. This problem may be avoided by using the solution phase methods of Figure 7.9B or 7.9C.

ELIspot Assay

The normal ELISA assay can be modified to measure antibody production at the single cell level. In this method, tissue culture plates are coated with antigen, and various cell populations are cultured on the plate for 4 hours. During that time, B cells settle to the bottom and secrete antibodies, which bind antigen nearby and produce a footprint of the antibody-secreting cell. The cells are then washed off, and a second antibody, such as enzyme-labeled goat antihuman IgG, is added. Finally, unbound antibody is washed off, and enzyme substrate is added in soft agar. Over the next 10 minutes, each footprint of enzyme activity converts the substrate to a dark spot of insoluble dye, corresponding to the localized zone where the B cell originally secreted its antibody.

Using this method, it is possible to detect as few as 10 to 20 antibody-producing B cells in the presence of 10^6 spleen cells, and typical results for immunized mice range from 200 to 500 spot-forming cells per 10^6 spleen cells.[57,58] Clearly, to work at all, this assay must be capable of detecting the amount of antibody secreted by a single immune B cell and specific enough to exclude nonspecific antibodies produced by most nonimmune B cells. Sensitivity depends on the affinity and amount of antibodies secreted and may be optimized by titering the amount of antigen on the plate.

This type of assay is useful in analyzing the cellular requirements for antibody production in vitro, as the number of responding B cells is measured directly. It can also be used to detect antibodies made in the presence of excess antigen. For example, during acute infections[59]

and in autoimmunity,[60] when antigen may be in excess over antibody, this assay makes it possible to measure antibody-producing B cells, even though free antibody may not be detectable in circulation. It can also be used to measure local production of self-reactive antibodies in a specific tissue, such as synovium. By using two detecting antibodies, each specific for a different Ig class and coupled to a different enzyme, and two substrates producing different colored dyes, cells secreting IgA and IgG simultaneously can be detected.[61] Recently, ELIspot was used to show that bacterial deoxyribonucleic acid (DNA)-containing CpG sequences is a polyclonal B-cell mitogen.[62]

ELIspot can also detect secreted cytokines, as opposed to antibodies, by coating the plate with a capture antibody and detecting antigen with an enzyme-coupled second antibody (as in a sandwich ELISA; see Fig. 7.9C). For example, using plates coated with monoclonal antibody to interleukin (IL)-4, T cells secreting IL-4 could be detected,[63] providing one measure of T helper 2 cells.

SPECIFICITY AND CROSS-REACTIVITY

The specificity of an antibody or antiserum is defined by its ability to discriminate between the antigen against which it was made (called the homologous antigen or immunogen) and any other antigen one might test. In practice, one cannot test the whole universe of antigens but only selected antigens. In this sense, specificity can only be defined experimentally within that set of antigens one chooses to compare. Karush[30] has defined a related term, selectivity, as the ability of an antibody to discriminate, in an all-or-none fashion, between two related ligands. Thus, selectivity depends not only on the relative affinity of the antibody for the two ligands but also on the experimental lower limit for detection of reactivity. For instance, an anticarbohydrate antibody with an affinity of 10^5 M^{-1} for the immunogen may appear to be highly selective, as reaction with a related carbohydrate with a 100-fold lower affinity, 10^3 M^{-1}, may be undetectable. On the other hand, an antibody with an affinity of 10^9 M^{-1} for the homologous ligand may appear to be less selective because any reaction with a related ligand with a 100-fold lower affinity would still be quite easily detectable.

Conversely, cross-reactivity is defined as the ability to react with related ligands other than the immunogen. More usually, this is examined from the point of view of the ligand. Thus, one might say that antigen Y cross-reacts with antigen X because it binds to anti-X antibodies. Note that in this sense, it is the two antigens that are cross-reactive, not the antibody. However, the cross-reactivity of two antigens, X and Y, can be defined only with respect to a particular antibody or antiserum. For instance, a different group of anti-X antibodies may not react at all with Y so that with respect to these antibodies, Y would not be cross-reactive with X. One can also use the term in a different sense, saying that some anti-X antibodies cross-react with antigen Y.

In most cases, cross-reactive ligands have lower affinity than the immunogen for a particular antibody. However, exceptions can occur in which a cross-reactive antigen binds with a higher affinity than the homologous antigen itself. This phenomenon is called heterocliticity, and the antigen that has a higher affinity for the antibody than does the immunogen is said to be heteroclitic. Antibodies that manifest this behavior are also described as heteroclitic antibodies. A good example is the case of antibodies raised in C57BL/10 mice against the

hapten nitrophenyl acetyl. These antibodies have been shown by Mäkelä and Karjalainen[64] to bind with higher affinity to the cross-reactive hapten, nitroiodophenyl acetyl, than to the immunogen itself. Another example is the case of retro-inverso or retro-D peptides.[65,66,67,68,69] By reversing the chirality from L to D amino acids, and simultaneously reversing the sequence of amino acids, one can produce a peptide that is resistant to proteolysis and has its side chains approximately in the same position as the original L amino acid peptide, with the exception of some amino acids with secondary chiral centers such as Thr and Ile. However, the backbone NH_2 and COOH moieties are reversed. Antibodies that interact with only the side chains might not distinguish these peptides, whereas antibodies that interact with the main chain as well as side chains might distinguish them and have potentially higher or lower affinity. In a study of monoclonal antibodies to a hexapeptide from histone H3, some bound the retro-D form with higher affinity than the native sequence and some did not.[67,68] The former are examples of heterocliticity. In addition to greater binding affinity, the retro-D peptides may have even greater activity in vivo because of their resistance to proteolysis.[65,66,67,68,69] This stability makes them more useful as drugs as well.[65,66,70]

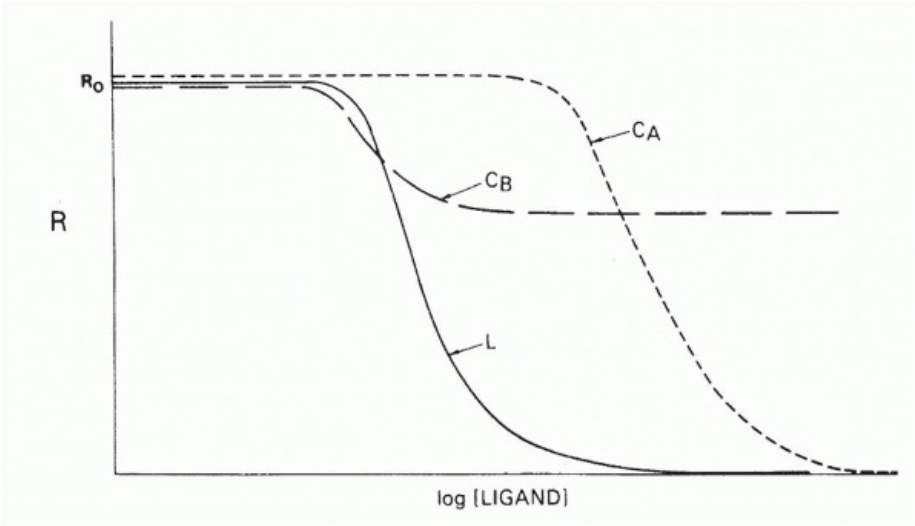

FIG. 7.10. Schematic Radioimmunoassay Binding Curves for Homologous Ligand L and Cross-Reacting Ligands. Cross-reacting ligand C_A manifests type 1 or true cross-reactivity demonstrated by complete inhibition of tracer ligand binding and a lower affinity. Ligand C_B displays type 2 cross-reactivity or determinant sharing, as recognized from the plateau at less than 100% inhibition, but not necessarily a lower affinity. The ordinate R is the ratio of bound/free radiolabeled tracer ligand, and R_0 is the limit of R as the concentration of all ligands, including tracer, approaches zero. From Berzofsky and Schechter,[71] with permission.

Cross-reactivity has often been detected by methods such as the Ouchterlony test, or hemagglutination (see the following for descriptions of both of these) or similar methods,

which have in common the fact that they do not distinguish well between differences in affinity and differences in concentration. This practical aspect, coupled with the heterogeneity of immune antisera, has led to ambiguities in the usage of the terms “cross-reactivity” and “specificity.” With the advent of RIA and ELISA techniques, this ambiguity in the terminology, as well as in the interpretation of data, has become apparent.

For these reasons, Berzofsky and Schechter[71] have defined two forms of cross-reactivity and, correspondingly, two forms of specificity. These two forms of cross-reactivity are illustrated by the two prototype competition RIA curves in Figure 7.10. In reality, most antisera display both phenomena simultaneously.

Type 1 cross-reactivity, or true cross-reactivity, is defined as the ability of two ligands to react with the same site on the same antibody molecule, possibly with different affinities. For example, the related haptens dinitrophenyl and trinitrophenyl may react with different affinity for antibodies raised to dinitrophenyl hapten. In protein antigens, such differences could occur with small changes in primary sequence (eg, the conservative substitution of threonine for serine), or with changes in conformation, such as the cleavage of the protein into fragments (Fig. 7.11).[71,72,73,74,75] If a peptide fragment contained all the contact residues in an antigenic determinant (ie, those that contact the antibody-combining site), it might cross-react with the native determinant for antibodies against the native form but with lower affinity because the peptide would not retain the native conformation. This type of affinity difference is illustrated by competitor C_A in Figure 7.10, in which complete displacement of tracer can be achieved at high enough concentrations of C_A, but higher concentrations of C_A than of the homologous ligand, L, are required to produce any given degree of inhibition.

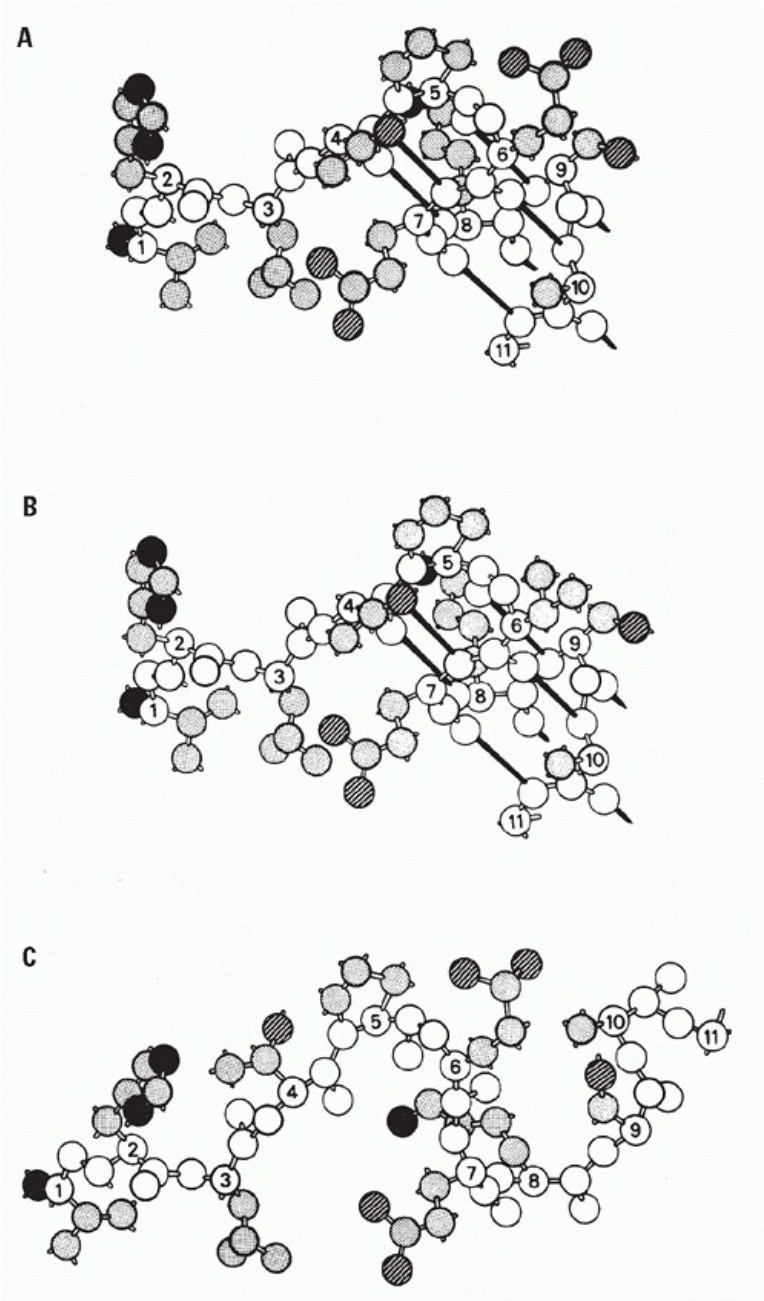

FIG. 7.11. An Artist's Drawing of the Amino Terminal Region of the β Chain of Hemoglobin. A: The first 11 residues of the β^A chain. **B:** The comparable regions of the β^S chain. The substitution of valine for the normal glutamic acid at position 6 makes a distinct antigenic determinant to which a subpopulation of antibodies may be isolated.[72,73] **C:** A schematic diagram of the sequence in (**A**) unfolded as occurs when the protein is denatured. This region may be cleaved from the protein, or the peptide synthesized,[74] resulting in changed antigenic reactivity. An antiserum prepared to hemoglobin (or the β chain thereof) might exhibit cross-reactivity with the structures shown in (**B**) and (**C**), but the molecular mechanisms would be different. Polypeptide backbone atoms are in *white* in the side chains, oxygen atoms are *hatched*, nitrogen atoms are *black*, and carbon atoms are *lightly stippled*. Adapted from Berxofsky and Schechter[71] and Dean and Schecter.[75]

A separate issue from affinity differences is the issue of whether the cross-reactive ligand reacts with all or only a subpopulation of the antibodies in a heterogeneous serum.

This second type of cross-reactivity, which we call type 2 cross-reactivity or shared reactivity, therefore can occur only when the antibody population is heterogeneous, as in most conventional antisera. In this case, the affinity of the cross-reactive ligand may be greater than, less than, or equal to that of the homologous ligand for those antibodies with which it interacts. Therefore, the competition curve is not necessarily displaced to the right, but the inhibition will reach a plateau at less than complete inhibition, as illustrated by competitor C_B in Figure 7.10. As an example, let us consider the case of a protein with determinants X and Y, and an antiserum against this protein containing both anti-X and anti-Y antibodies. Then a mutant protein in which determinant Y was so altered as to be unrecognizable by anti-Y, but determinant X was intact, would manifest type 2 crossreactivity.

It would compete with the wild-type protein only for anti-X antibodies (possibly even with equal affinity), but not for anti-Y antibodies.

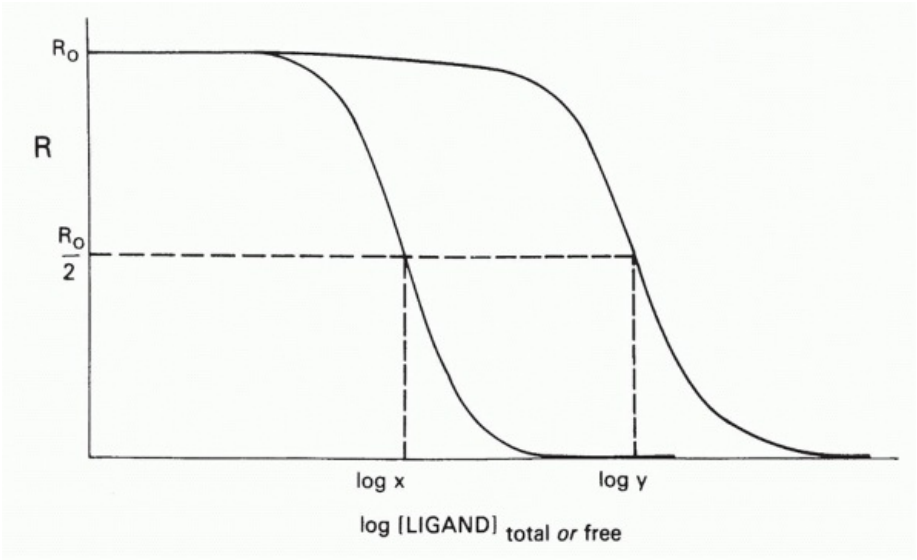

FIG. 7.12. Schematic Radioimmunoassay Binding Curves Showing the Effect of Affinity on the Midpoint and the Slope at the Midpoint and the Value of Using Free (Ligand) Rather than Total (Ligand). Ordinate R is the ratio of bound/free radiolabeled tracer ligand, and R_0 the limit of R as all ligand concentrations approach zero. If x and y are the concentrations of ligands X and Y that reduce R to exactly $R_0/2$, then if the abscissa is total ligand concentration, $x = 1/K_X + [S]_t/2$ and $y = 1/K_Y + [S]_t/2$, where $[S]_t$ is the concentration of antibody binding sites and K_X and K_Y the affinities of the antibody for the respective ligands. However, if the abscissa is free ligand concentration, $x = 1/K_X$ and $y = 1/K_Y$ so that the ratio x/y (or the difference log x - log y on a log plot) corresponds to the ratio of affinities K_Y/K_X. Note that the slopes at the midpoints are the same on a log scale, but that for Y would be only K_Y/K_X that for X on a linear scale. From Berxofsky and Schechter,[71] with permission.

Of course, both types of cross-reactivity could occur simultaneously. A classic example would be the peptide fragment previously discussed in the case of type I cross-reactivity. Suppose the fragment contained the residues of determinant X, albeit not in the native conformation, but did not contain the residues of a second determinant, Y, which was also expressed on the native protein. If the antiserum to the native protein consisted of anti-X and anti-Y, the peptide would compete only for anti-X antibodies (type 2 cross-reactivity) but would have a lower affinity than the native protein even for these antibodies. Thus, the competition curve would be shifted to the right and would plateau before reaching complete inhibition.†††

In the case of a homogeneous (eg, monoclonal) antibody in which only type 1 or true cross-reactivity can occur, one can quantitate the differences in affinity for different crossreactive ligands by a method analogous to the B/F versus F method described previously. Suppose that ligands X and Y cross-react with homologous ligand L for a monoclonal antibody. If one plots the bound/free (B/F = R) ratio for radiolabeled tracer ligand L as a function of the log of the concentration of competitors X and Y, one obtains two parallel competition curves (Fig. 7.12),[71] under the appropriate conditions (see subsequent discussion). The first condition is that the concentration of free tracer be less than $1/K_L$, the affinity for tracer. In this case, it can be shown[71] that

$$K_X \approx \frac{1}{[X]_{free}} \qquad (41)$$

at the midpoint where $R = R_0/2$, where K_X = affinity for X. This is analogous to Equation 21 for the case in which unlabeled homologous ligand is the competitor. Also, in

analogy with Equation 23, it can be shown that if the total concentration of competitor, $[X]_t$, is used instead of the free concentration, [X]free, an error term will arise, giving

$$[X]_t \text{ (at } R = R_0/2) = \frac{1}{K_X} + \frac{[S]_t}{2} \qquad (42)$$

Thus, with competitor on a linear scale, the difference in midpoint for competitors X and Y will correspond to the difference $1/K_X - 1/K_Y$ regardless of whether free or total competitor is plotted, but the ratio of midpoint concentrations will equal K_X/K_Y only if the free concentrations are used.

This last point is important if one plots the log of competitor concentration, as is usually done, as the horizontal displacement between the two curves on a log scale corresponds to the ratio [X] / [Y], not the difference.[71]

If a second condition also holds, namely, that the concentration of bound tracer is small compared to the antibody site concentration $[S]_t$, then the slopes (on a linear scale) of the curves at their respective midpoints (where $R = R_0/2$) will be proportional to the affinity for that competitor, K_X or K_Y (71). (Both conditions can be met by keeping tracer L small relative to both K_L and $[S]_t$.) When $[X]_{free}$ and $[Y]_{free}$ are plotted on a log scale, the slopes will

appear to be equal (ie, the curves will appear parallel) because a parallel line shifted m-fold to the right on a log scale will actually be 1/m as steep, at any point, in terms of the antilog as abscissa.

When the antibodies are heterogeneous in affinity, the curves will be broadened and in general will not be parallel. When heterogeneity of specificity is present, and type 2 cross-reactivity occurs, it should be pointed out that the fractional inhibition achieved at the plateau in a B/F versus free competitor plot will not be proportional to the fraction of antibodies reacting with that competitor but will be proportional to a weighted fraction, where the antibody concentrations are weighted by their affinity for the tracer.[71]

These two types of cross-reactivity lead naturally to two definitions of specificity.[71] The overall specificity of a heterogeneous antiserum is a composite of both of these facets of specificity. Type 1 specificity is based on the relative affinities of the antibody for the homologous ligand and any cross-reactive ligands. If the affinity is much higher for the homologous ligand than for any cross-reactive ligand tested, then the antibody is said to be highly specific for the homologous ligand (ie, it discriminates very well between this ligand and the others). If the affinity for cross-reactive ligands is below the threshold for detection in an experimental situation, then type 1 specificity gives rise to selectivity as was discussed previously.[30] The specificity can even be quantitated in terms of the ratio of affinities for the homologous ligand and a cross-reactive ligand.[76] It is this type 1 specificity that most immunochemists would call true specificity, just as we have called type 1 cross-reactivity true cross-reactivity.

The common use of the term “cross-reactivity” to include type 2 or partial reactivity leads to a second definition of specificity, which applies only to heterogeneous populations of antibodies such as antisera. We call this type 2 specificity. If all the antibodies in the mixture react with the immunogen, but only a small proportion react with any single cross-reactive antigen, then the antiserum would be said to be relatively specific for the immunogen. Note that it does not matter whether the affinity of a subpopulation that reacts with a cross-reactive antigen is high or low (type 1 cross-reactivity). As long as that subpopulation is a small fraction of the antibodies, the mixture is specific. Thus, type 2 specificity depends on the relative concentrations of antibodies in the heterogeneous antiserum, not just on their affinities. Also note that one can use these relative concentrations of antibody subpopulations to compare the specificity of a single antiserum for two cross-reactive ligands. However, it would not be meaningful to compare the specificity of two different antisera for the same ligand by comparing the fraction of antibodies in each serum which reacted with that ligand. Although type 2 specificity may appear to some a less classic concept of specificity than type 1, it is type 2 specificity that one primarily measures in such assays as the Ouchterlony double immunodiffusion test, and it carries equal weight with type 1 specificity in such assays as hemagglutination, discussed in the following section. Type 2 specificity also leads naturally to the concept of “multispecificity,” described in the following section.

Multispecificity

The theory of multispecificity, introduced and analyzed by Talmadge[77] and Inman,[78,79] and discussed on a structural level by Richards et al.,[80] suggests a mechanism by which the diversity and specificity of antisera can be expanded and also understood. The idea is that

each antibody may actually bind, with high affinity, a variety of diverse antigens. When one immunizes with immunogen A, one selects for many distinct antibodies, which have in common only that they all react with A. In fact, each antibody may react with other compounds, but if fewer than 1% of the antibodies bind B, and fewer than 1% bind C, and so on, then by type 2 specificity, the whole antiserum will appear to be highly specific for A. Note that the subpopulation that binds B may react with an affinity for B as high as or higher than that for A so that the population would not be type 1 specific for A. This same population would presumably be selected if one immunized with B. The net result would be that the diversity of highly (type 2) specific antisera an organism could generate would be even greater than the diversity of B-cell clones (or antibody structures). This principle can explain how polyclonal antisera can sometimes appear paradoxically more specific than a monoclonal antibody.

OTHER METHODS

We mention only a few of the other methods for measuring antigen-antibody interactions. Other useful techniques include quenching of the tryptophan fluorescence of the antibody by certain antigens on binding[81] (a sensitive method useful for such experiments as fast kinetic studies), antibody-dependent cellular cytotoxicity, immunofluorescence including flow cytometry, immunohistochemistry, and inhibition by antibody of plaque formation by antigenconjugated bacteriophage[82] (a method as sensitive as RIA as inhibition of even a few phage virions can be detected).

Quantitative Precipitin

Among the earliest known properties of antibodies were their ability to neutralize pathogenic bacteria and their ability to form precipitates with bacterial culture supernatants. Both activities of each antiserum were highly specific for the bacterial strain against which the antiserum was made. The precipitates contained antibody protein and bacterial products. The supernatants contained decreased amounts of antibody protein and, under the right conditions, had lost the ability to neutralize bacteria. However, quantitation of the antibody precipitated was difficult because the precipitate contained antigen protein as well as antibody protein.

Heidelberger and Kendall[83,84] solved this problem when they found that purified pneumococcal cell wall polysaccharide could precipitate with antipneumococcal antibodies. In this case, the amount of protein nitrogen measured in the precipitate was entirely due to antibody protein, and the amount of reducing sugar was mostly due to the antigen. Plotting the amount of antibody protein precipitated from a constant volume of antiserum by increasing amounts of carbohydrate antigen gives the curve shown in Figure 7.13.

As shown in Figure 7.13A, the amount of antibody precipitated rises initially, reaches a plateau, and then declines. The point of maximum precipitation was found to coincide with the point of complete depletion of neutralizing antibodies and is called the equivalence point. The amount of antibody protein in the precipitate at equivalence is considered to equal the total amount of specific antibody in that volume of antiserum. The rising part of the curve is called the antibody excess zone (antigen limiting), and the part of the curve beyond the equivalence point is called the antigen excess zone.

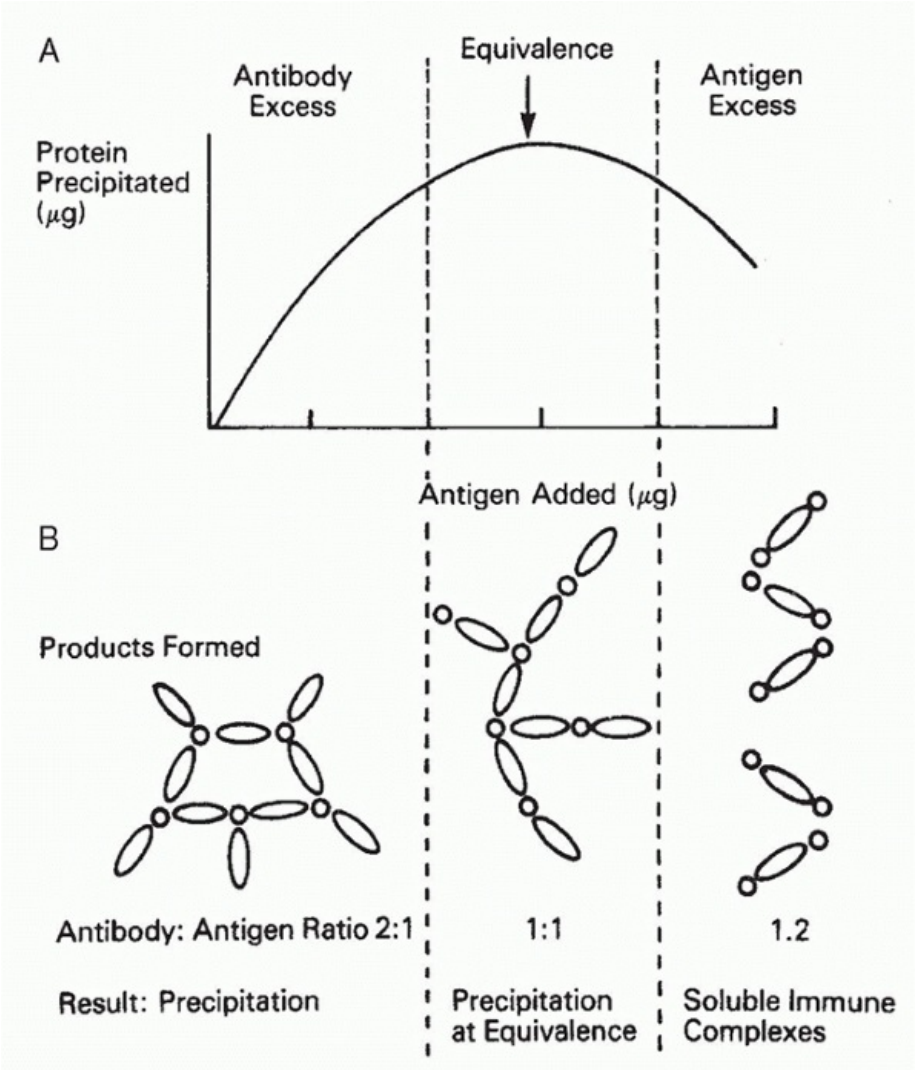

FIG. 7.13. Quantitative Immunoprecipitation. To a fixed amount of specific antibody are added increasing amounts of nonprotein antigen. The figure shows the amount of antibody protein **(A)** and the ratio of antibody to antigen **(B)** found in the precipitate. At antigen excess, soluble immune complexes are found in the supernatant, and the precipitate is decreased.

Supernatants and precipitates were carefully analyzed for each zone of antibody or antigen excess, as shown in Figure 7.13B. When antigen was limiting, the precipitate contained high ratios of antibody to antigen. The supernatant in this zone contained free antibody with no detectable antigen. As more antigen was added, the amount of antibody in the precipitate rose, but the ratio of antibody to antigen fell. At equivalence, no free antibody or antigen could be detected in the supernatant. As more antigen was added, the precipitate contained less antibody, but the ratio of antibody to antigen remained constant. The supernatant now contained antigen-antibody complexes because the complexes at antigen excess were small enough to remain in solution. No unbound antibody was detected.

The lattice theory[83,84] is a model of the precipitation reaction that explains these observations. It assumes that antibodies are multivalent and antigens are bivalent or

polyvalent. Thus, long chains can form consisting of alternating antibody linked to antigen linked to antibody, and so on. The larger the size of the aggregate, the less soluble the product. In the antibody excess zone, branch points can form whenever three antibodies bind to a single antigen, resulting in a three-dimensional lattice structure, which precipitates. In the equivalence zone, when equimolar amounts of antibody and antigen are mixed, the likelihood of more than two antibodies binding the same antigen molecule decreases. With fewer branch points, the product is more likely to consist of long chains of alternating antibody and antigen molecules in the molar ratio of 1:1. At even higher antigen ratios, each antigen molecule will have 0 or 1 antibody bound, so shorter chain lengths are found, until the product is small enough to remain in solution. Such soluble antigen-antibody “immune complexes” are detectable in the antigen excess zone, where no free antibody is found.

Besides explaining the observed precipitation phenomena on a statistical basis, the lattice theory made the important prediction that antibodies are bivalent or multivalent. The subsequent structural characterization of antibodies revealed their molecular weight and valency. Antibodies are indeed bivalent, except for IgM, which is functionally pentavalent and forms precipitates even more efficiently.

Antigens can be polyvalent either by having multiple copies of the same determinant or by having many different determinants, each of which reacts with different antibodies in a polyclonal antiserum. The predominant antigenic determinants of polysaccharides are often the nonreducing end of the chain. Branched chain polysaccharides have more than one end and are polyvalent. Nonbranched chains such as dextran (polymer of glucose) are monovalent for end specific antidextran antibodies and do not precipitate them.[85] However, a second group of antidextran antibodies is specific for internal glucose moieties. Because each dextran polymer consists of many internal units, it is polyvalent for

internal α(1 → 6)-linked glucose-specific antibodies. Thus, unbranched dextran polymer can be used to distinguish between end-specific and internal-specific antibodies, as it will precipitate with the latter antibodies but not the former.[85,86] Monomeric protein antigens, such as myoglobin or lysozyme, behave as if they were polyvalent for heterogeneous antisera but monovalent for monoclonal antibodies. This results from the fact that each antigen molecule has multiple antigenic determinants but only one copy of each determinant. Thus, a polyspecific antiserum can bind more than one antibody to different determinants on the same molecule and form a lattice. However, using antibodies directed against a single determinant (such as a monoclonal antibody), no precipitate will form. In this case, antigen-antibody reactions must be measured by some other binding assay, such as RIA or ELISA.

Immunodiffusion and the Ouchterlony Method

One of the most useful applications of immunoprecipitation is in combination with a diffusion system.[87] Diffusion could be observed by gently adding a drop of protein solution to a dish of water without disturbing the liquid. The rate of migration of protein into the liquid is proportional to the concentration gradient times the diffusion coefficient of the protein according to Fick's law,

$$\frac{dQ}{dt} = -DA\frac{dc}{dx} \qquad (43)$$

where Q = amount of substance that diffuses across an area A per unit time t; D = diffusion coefficient, which depends on the size of the molecule; and dc/dx = concentration gradient. Because antibody molecules are so large, their diffusion coefficients are quite low, and diffusion often takes 1 day or more to cover the 5 to 20 mm required in most systems. In order to stabilize the liquid phase for such long periods of time, a gel matrix is added to provide support without hindering protein migration. In practice, 0.3% to 1.5% agar or agarose will permit migration of proteins up to the size of antibodies while preventing mechanical and thermal currents. By carefully adjusting the concentration of antibody and antigen, these systems can provide a simple analysis of the number of antigenic components and the concentration of a given component. By adjusting the geometry of the reactants entering the gel, immunodiffusion can provide useful information concerning antigenic identity or difference, or partial cross-reaction, as well as the purity of antigens and the specificity of antibodies.

In single diffusion methods,[88,89,90,91] antibody is incorporated in the gel, and antigen is allowed to diffuse from one end of a tube gel in one dimension or from a hole in a gel in a petri dish in two dimensions. Over time, the antigen concentration reaches equivalence with the antibody in the gel, and a precipitin band forms. As more antigen diffuses, antigen excess is achieved at this position, so the precipitate dissolves and the boundary of equivalence moves farther. By integrating Fick's law, we find that the distance moved is proportional to the square root of time. If two species of antigen a and b are diffusing, and the antiserum contains antibodies to both, two independent bands will form. These will move at independent rates, depending on antigen concentration in the sample, diffusion coefficient (size), and antibody concentration in the agar. Similarly, in the two-dimensional method, at a given radius of diffusion, antigen concentration will be equivalent to the antibody in the gel, and a precipitin ring will form. The higher the initial antigen concentration, the farther the antigen will diffuse before precipitating and the wider the area of the ring will be. The area of the ring is directly proportional to the initial antigen concentration. This method provides a convenient quantitative assay that can be used to measure Ig classes by placing test serum in the well and antiserum to each class of human Ig in the agar. Sensitivity can be increased by lowering the concentration of antiserum in the gel, giving wider rings, as the antigen must reach a lower concentration to be at equivalence. However, the antiserum cannot be diluted too far, or no precipitate will form.

The double diffusion methods use the same principles, except that instead of having one reactant incorporated in the gel at a constant concentration, both antigen and antibody are loaded some distance apart in a gel of pure agarose alone and are allowed to diffuse toward each other. At some point in the gel, antigen diffusion and antibody diffusion will provide sufficient concentrations of both reactants for immunoprecipitation to occur. The line of precipitation becomes a barrier for the further diffusion of the reactants, so the precipitin band is stable. If the antigen preparation is heterogeneous, and the antiserum is a heterogeneous mixture of antibodies, different bands will form for each pair of antigen and antibody reacting at positions dependent on concentration and molecular weight of each. The number of lines indicates the number of antigen-antibody systems reacting in the gel. The ability of

immunodiffusion to separate different antigen-antibody systems gives a convenient estimate of antigen purity or antibody specificity.

In the most widely used Ouchterlony method of double diffusion in two dimensions,[87] three or more wells are cut in an agarose gel in a dish in the pattern shown in Figure 7.14. Antigen a or b is placed in the upper wells, whereas antiserum containing anti-a or anti-b is placed in the lower well. Each antigen-antibody reaction system will form its own precipitin line between the wells. As shown in Figure 7.14A, this should extend an equal distance to the left and right of the wells. When different antigens are present in different wells (see Fig. 7.14C), the precipitating systems do not interact immunochemically, so the precipitin lines cross. However, when the same antigen is present in both wells (see Fig. 7.14B), each line of precipitation becomes a barrier preventing the other antigen and antibody from diffusing past the precipitin line. This shortens the precipitin line on that side of the well. In addition, antigen diffusion from the neighboring wells shifts the zone of antigen excess, causing the equivalence line to deviate downward and meet between the two wells. Complete fusion of precipitin lines with no spurs is called a line of identity, indicating that the antigen in each well reacts with all the antibody capable of reacting with antigen in the other well.

The analytical power of this method is shown in Figure 7.14D. When a mixed antigen sample is placed in one well and pure antigen b is placed in the other well, antiserum to a plus b gives the pattern shown. Two precipitin lines form with the left well and one precipitin line with the right well. The line of complete fusion allows us to identify the second band as antigen b; the first band is antigen a. From their relative distance of migration, we can conclude that antigen a is in excess over antigen b, assuming their diffusion coefficients are comparable and both antibodies are present in equal amounts. Finally, because the precipitin line of antigen a-anti-a is not shortened at all, there is no contamination of the right sample with antigen a, and the two antigens do not cross-react.

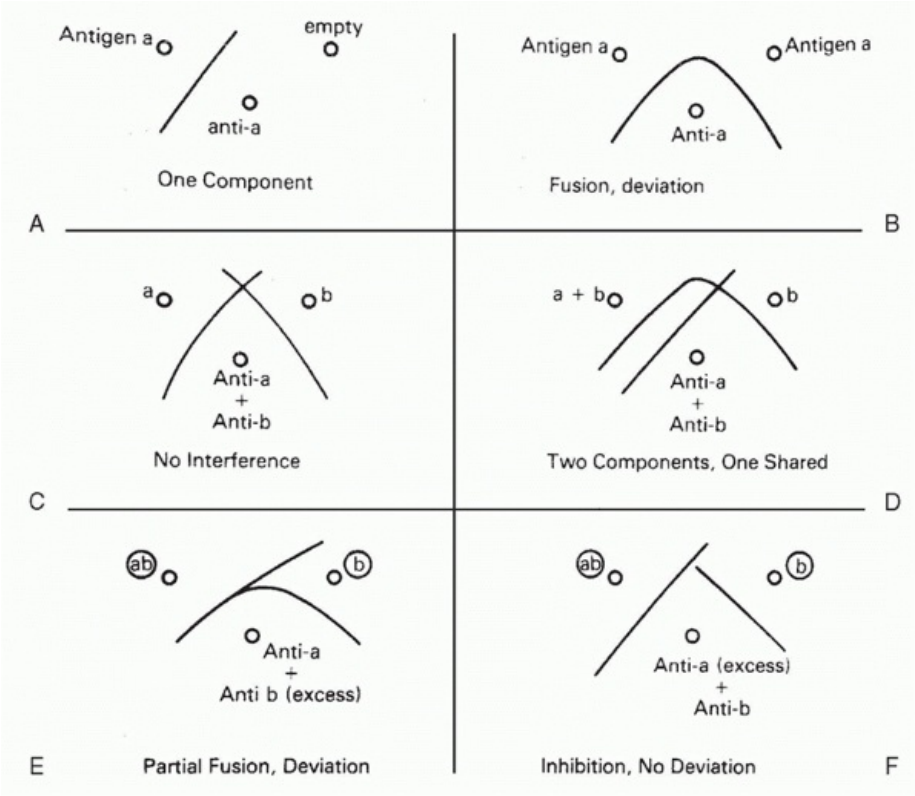

FIG. 7.14. Immunodiffusion of Two Components in Two Dimensions. Cross-reactions produce inhibition *(shortened bands)* or deviation *(curved bands)*. Lines of identity are shown in **(B)** and **(D)**.[87]

The type of cross-reactivity detected by this Ouchterlony double immunodiffusion in agar is what we have defined previously as type 2 cross-reactivity. The method is not suitable for measuring affinity differences required for quantitating type 1 cross-reactivity. Sensitivity can be increased by use of radioactive antigen and detection of the precipitate by autoradiography.

Immunoelectrophoresis

Some antigen-antibody systems are too complex for double immunodiffusion analysis, either because there are too many bands or they are too close together. Immunoelectrophoresis combines electrophoresis in one dimension (Fig. 7.15) with immunodiffusion in the perpendicular direction. In the first step, electrophoresis separates the test antigens according to charge and size, in effect, separating the origin of diffusion of different antigens. This is equivalent to having each antigen start in a different well, as shown in the right-hand panel. A horizontal trough is then cut into the agar and filled with antiserum to all the components. Immunodiffusion occurs between the separated antigens and the linear source of antibody. The results for a mixture of three antigens approximate those shown for three antigens in separate wells.87 Fusion, deviation, and inhibition between precipitin lines can be analyzed as described previously. The resolution of each band is somewhat decreased due to widening of the origin of diffusion during electrophoresis. However, the immunodiffusion of unseparated human serum proteins, for example, is greatly facilitated by prior electrophoresis. Starting from a single well, only the heavier bands would be visible.

However, prior electrophoresis makes it possible for each electrophoretic species to make its own precipitin line. Monospecific antiserum can be placed in a parallel horizontal trough so that each band of precipitation can be identified. Immunoelectrophoresis is commonly used to diagnose myeloma proteins in human serum. The unknown serum is electrophoresed, followed by immunodiffusion against antibodies to human Ig heavy or light chains. A widening arc of IgG suggests the presence of an abnormal Ig species. At this same electrophoretic mobility, a precipitin line with anti-κ, but not anti-λ, reactivity strongly suggests the diagnosis of myeloma or monoclonal gammopathy, as these proteins arise from a single clone that synthesizes only one light chain. All normal electrophoretic species of human Igs contain both light chain isotypes, although κ exceeds λ by the ratio of 2:1 in humans. As shown in Figure 7.15C, the abnormal arc with γ mobility reacts

with anti-IgG and anti-κ but not anti-λ antiserum. Thus, it is identified as an IgG-κ monoclonal protein.

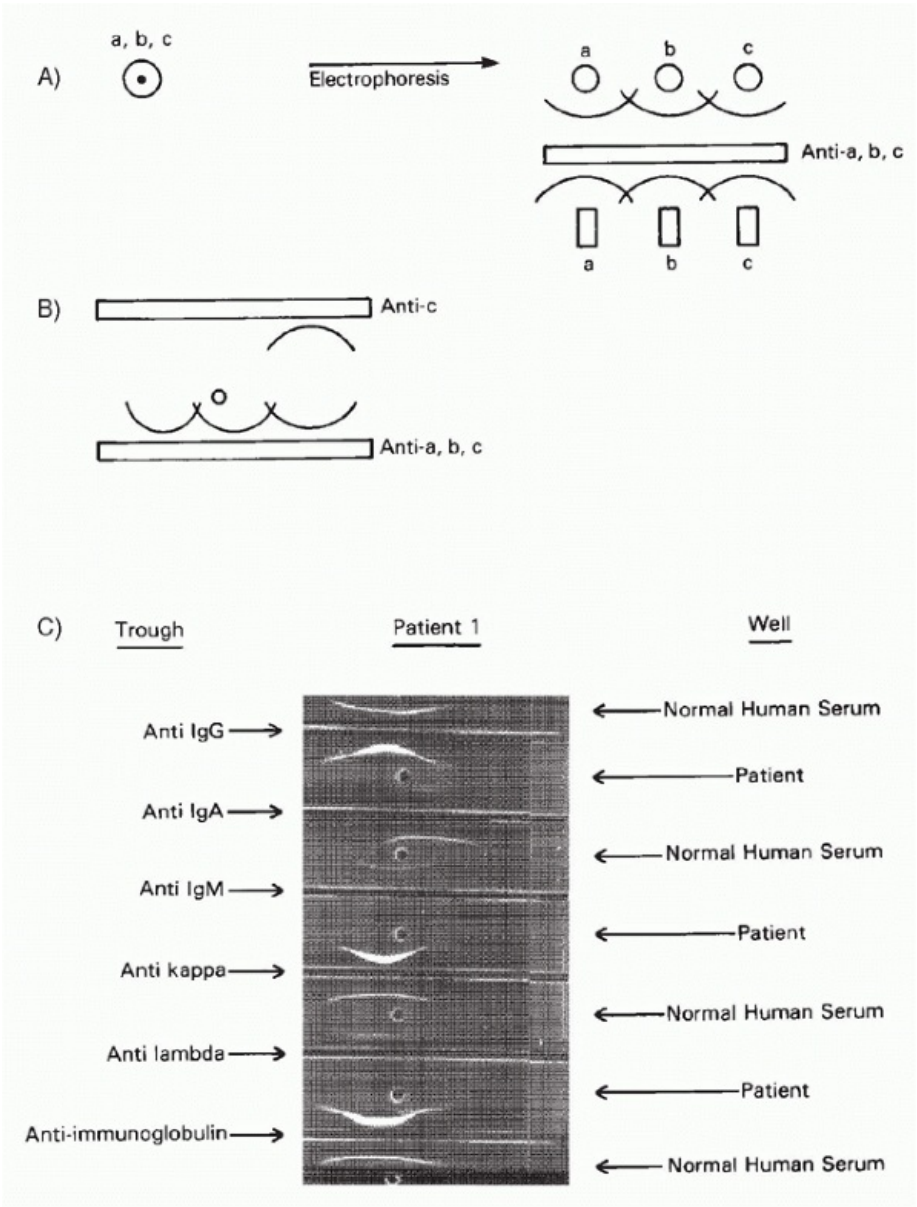

FIG. 7.15. Immunoelectrophoresis. A sample containing multiple components is

electrophoresed in an agarose gel, separating the antigens in the horizontal dimension. Then a horizontal trough is cut into the gel and antiserum is added. Immunodiffusion between the separated antigens and the trough is equivalent to having separate wells, each with a different antigen.[87] This technique is used to identify a myeloma protein in human serum. Sera from the patient or normal individual were placed in the circular wells and electrophoresed. Antisera were then placed in the rectangular troughs and immunodiffusion proceeded perpendicular to the direction of electrophoresis. The abnormally strong reaction with anti-immunoglobulin (Ig) G and anti-κ, but no reaction with anti-λ antibodies, indicate a monoclonal protein (IgG,κ), as polyclonal Ig should react with both antilight-chain antisera. Failure to form a band with anti-IgM and a reduced band with anti-IgA show typical reduction of normal Igs in this disease. (Photographs courtesy of Theresa Wilson, NIH Clinical Chemistry Section.)

Hemagglutination and Hemagglutination Inhibition

Hemagglutination

A highly sensitive technique yielding semiquantitative values for the interaction of antibody with antigen involves the agglutination by antibodies of red blood cells coated with the antigen.[92] For exogenous antigens that are adsorbed to the red blood cell surface, the reaction is called passive hemagglutination. Untreated red blood cells are negatively charged, and electrostatic forces keep them apart. Following treatment with tannic acid (0.02 mg/mL for 10 minutes at 37°C), however, they clump readily.

Untreated red blood cells are easily coated with polysaccharide antigens, which they adsorb readily. After tanning, the uptake of some protein antigens is good, giving a sensitive reagent, whereas for others it tends to be quite variable; coating red blood cells has been the limiting factor in the usefulness of this method for certain antigens. Apparently, slightly aggregated or partially denatured protein antigens are adsorbed preferentially.[92]

The test for specific antibodies is done by serially diluting the antiserum in the U-shaped wells of a microtiter plate and adding antigen-coated red cells. When cross-linked by specific antibodies, agglutinated cells settle into an even carpet spread over the round bottom of the well. Unagglutinated red cells slide down the sides and form a much smaller button at the very bottom of the well. The titer of a sample is the highest dilution at which definite agglutination occurs. With hyperimmune antisera, inhibition of agglutination is often observed at high doses of antibody, termed a *prozone effect*. Two interpretations have been offered: One is that, at great antibody excess, each cell is coated with antibody, so cross-linking by the same antibody molecule becomes improbable. The second interpretation is the existence of some species of inefficient or “blocking” antibodies that occupy

antigen sites without causing aggregation of cells.[9] To assure antigen specificity, the antiserum should be absorbed against uncoated red cells prior to the assay, and an uncoated red cell control should be included with each assay. IgM is up to 750 times more efficient than IgG at causing agglutination, which may affect interpretation of data based on titration. The titer may vary by a factor of 2 simply due to subjective estimates of the endpoint.

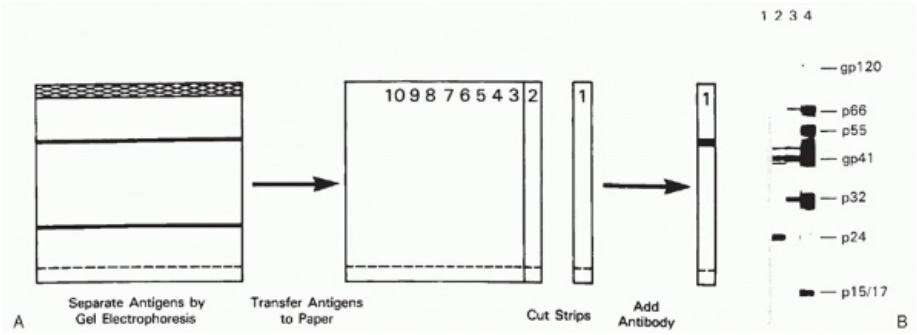

FIG. 7.16. A: Western blot technique. The antigen preparation is run through a polyacrylamide gel, which separates its components into different bands. These bands are then transferred to paper by electrophoresis in the horizontal dimension. The paper is cut into strips. Each strip is incubated with test antibodies, followed by further incubation with enzyme-labeled second antibodies. If the test antibodies bind to the component antigens, they will produce discrete dark bands at the corresponding positions on the strip. **B:** Clinical specimens from patients with acquired immunodeficiency syndrome tested on strips bearing human immunodeficiency virus-1 viral antigens, showing antibodies to viral gag (p15/17, p24, and p55 precursor), pol (p66 and possibly p32), and env (gp41 and gp120) proteins. Lane 1 is the negative control, and lanes 2 to 4 are sera from three different patients.

Once the hemagglutination titer of an antiserum is determined, its interaction with antigen-coated red blood cells can be used as a sensitive assay for antigen. To constant amounts of antibody (diluted to a concentration twofold higher than the limiting concentration producing agglutination) are added varying amounts of free antigen. Agglutination will be inhibited when half or more of the antibody sites are occupied by free antigen. In a similar fashion, the assay can be used for the detection and quantitation of anti-idiotype antibodies that react with the variable region of antibodies and sterically block antigen binding.

Immunoblot (Western Blot)

A most useful technique in the analysis of proteins is polyacrylamide gel electrophoresis, in which charged proteins migrate through a gel in response to an electric field. When ionic detergents such as sodium dodecyl sulfate are used, the distance traveled is inversely proportional to the logarithm of molecular weight. The protein components of complex structures, such as viruses, appear as distinct bands, each at its characteristic molecular weight. Because antibodies may be unable to diffuse into the gel, it is necessary to transfer the protein bands onto a nitrocellulose membrane support first, where they are exposed for antibody binding.[93]

The immunoblot is often used to detect viral proteins with specific antibodies that bind these proteins on the nitrocellulose blot. Then a second antibody, which is either enzyme conjugated or radiolabeled, is used to detect the antigen -antibody band. Crude viral antigen preparations can be used, as only those bands that correspond to viral antigens will be detected.

Typical results are shown in Figure 7.16. HIV-1 was cultured in susceptible H9 cells. The viral proteins were separated by polyacrylamide gel electrophoresis and detected by immunoblot, using the serum of infected patients. Each antigen band recognized by the antiserum has been identified as a viral component or precursor protein. The gp160 precursor is processed to mature gp120 and gp41 envelope proteins, whereas a p66 precursor is processed to the p51 mature form of reverse transcriptase, and a p55 precursor becomes the p24 and p17 gag and matrix proteins of the virus.[94] The practical uses of the HIV western blot include diagnosing infection, screening blood units to prevent HIV transmission, and testing new vaccines.

Surface Plasmon Resonance

Surface plasmon resonance (SPR) uses the electromagnetic properties of light to measure the binding affinity of a variety of biologic molecules, including antigen-antibody pairs. In this method, polarized light passes through a glass plate coated on the back surface with a thin metal film, usually gold. Biologic materials binding to the metal film behind the plate can alter its refractive index in ways that affect the angle and intensity of reflected light.

At angles close to perpendicular, light will pass through the glass, although it will bend at the interface due to

differences in the refractive index of glass and what is behind it. Above a certain angle, called the critical angle, bending will be so great that total internal reflection will occur. Small changes in refractive index behind the glass can be detected as significant changes in the critical angle, where light reflection occurs, and in the intensity of reflected light at this angle. By reading the reflected light intensity in a diode array detector, the critical angle and intensity can be determined simultaneously. Due to the wave nature of light, the effect of refractive index in the gold film extends about one wavelength beyond the glass or about 300 to 700 nm.[95] Within this layer, if an antigen is covalently attached to the gold, then antibody binding can be detected as a change in refractive index, resulting in a different critical angle and intensity of the reflected light.

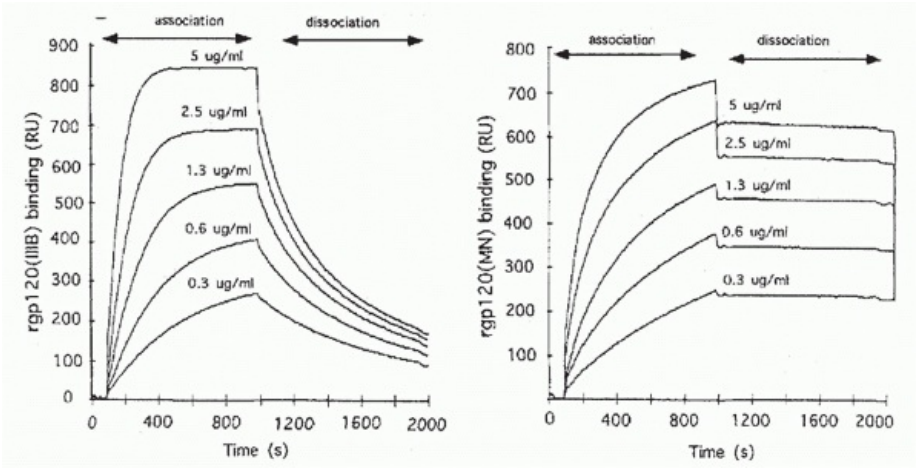

FIG. 7.17. Monoclonal Antibody to gp120 was Introduced into the Flow Cell at Time 0, and Antibody Binding was Followed Over Time as a Change in the

Critical Angle, Measured in Response Units. After 1000 seconds, free antibody was washed out, and the release of bound antibody was measured as a decrease in refractive index. Lower affinity binding to gp120 from the IIIB strain *(left)* was shown as a faster "off rate," as compared to the very slow rate of antibody release from the MN strain *(right)*. These results, obtained under nonequilibrium conditions, provide direct measurement of the forward and reverse rate constants for antibody binding, and the ratio of these two gives the affinity constant. Modified from VanCott et al.,[97] with permission.

SPR systems have three essential features[96]: an optical system that allows determination of the critical angle and light intensity at the same time, a coupling chemistry that links antigen or antibody to the gold surface, and a flow system that rapidly delivers the binding molecule in the mobile phase, so SPR can measure the rate of binding, rather than the rate of diffusion. Because binding causes a physical change in the gold film, there is no need for radioactive labels or enzyme conjugates. Molecular binding interactions can be followed in real time.

A typical SPR experiment is shown in Figure 7.17. HIV gp120 of type IIIB (*left panel*) or MN (*right panel*) were fixed to the gold layer, and various concentrations of monoclonal antibody to gp120 were added to the flow cell.[97] Over the first 1000 seconds, antibody binding was measured as a change in reflected light (in response units), allowing a calculation of the rate constant for the forward reaction of antibody binding. Once the signal reached a plateau, antibody was washed out of the flow cell, and the decrease in SPR signal over time indicated the rate at which antibody came off the antigen. The "on rate" for antibody binding to IIIB gp120 (*left*) was about twice as fast as for MN (*right*) at each antibody concentration. However, the "off rate" was about 50-fold less for MN than for IIIB. Combining these kinetic results indicates much greater binding affinity for gp120 of MN type, which may explain the observation that MN type virus was 10-fold more sensitive to neutralization by this antibody than was the IIIB strain.

MONOCLONAL ANTIBODIES

Homogeneous Igs have long played important roles in immunologic research. Starting in the 1950s, Slater et al.[98] studied sera from human patients with multiple myeloma and recognized the relationship between abnormal myeloma proteins and normal serum globulins. Potter[99] characterized numerous mouse myeloma tumors and identified the antigenic specificities of some of them. Human and mouse myeloma proteins were studied as representative Igs

and recognized for the advantages they had with proteins as diverse as antibodies for studies of Ig structure, function, and genetics. It was not yet possible, however, to induce monoclonal Igs of desired specificity.

This goal was achieved by the introduction of hybridoma technology by Köhler and Milstein[1,100] and by Margulies et al.[101] in the 1970s. Since that time, monoclonal antibodies have come to play an enormous role in biologic research and applications. They offer as

advantages the relative ease of the production and purification of large quantities of antibody, the uniformity of antibody batches, and the ready availability of Ig messenger ribonucleic acid and DNA from the hybrid cell lines.

Derivation of Hybridomas

Hybridomas producing monoclonal antibodies are generated by the somatic cell fusion of two cell types: antibodyproducing cells from an immunized animal, which by themselves die in tissue culture in a relatively short time, and myeloma cells, which contribute their immortality in tissue culture to the hybrid cell. The myeloma cells are variants carrying drug selection markers so that only those myeloma cells that have fused with spleen cells providing the missing enzyme will survive under selective conditions. Initial work used myeloma cells that secreted their own Ig products, but later such fusion partners were replaced by myeloma variants that fail to express Ig[102,103] so that the fused cell secretes exclusively antibody of the desired specificity. Successful hybridoma production is influenced by the characteristics of the cell populations (immune lymphocytes and myeloma fusion partner), the fusion conditions, and the subsequent selection and screening of the hybrids. A diagrammatic version of the overall process of hybridoma derivation is presented in Figure 7.18.

This section will not attempt to provide a detailed, stepby-step protocol for laboratory use. For that purpose, the reader is referred to monographs and reviews on the subject, including a detailed laboratory protocol with many hints and mention of problems to avoid.[104]

Hybridomas Derived from Species Other than Mice

Laboratory mice are the most common species immunized for hybridoma production, but for a variety of reasons, other animal species often have advantages. If an antigen of interest is nonpolymorphic in the mouse, the mouse component might be immunogenic in other species while mice would be tolerant to it. In the case of hybridomas for clinical use, mouse antibodies have the drawback of inducing antimouse Ig immune responses with possible deleterious effects.

Several approaches have been taken to the derivation of hybridomas in species other than mouse. First, interspecies hybridization can be performed using mouse myeloma fusion partners. The resulting hybrids are often unstable and throw off chromosomes, but clones can sometimes be selected that produce antibody in a stable fashion. Examples of this would be rat-mouse fusion to produce antibody to the mouse Fc receptor[105] and hamster-mouse fusion to produce antibody to the mouse CD3 equivalent.[106] Rabbit-mouse hybridomas have also been described.[107]

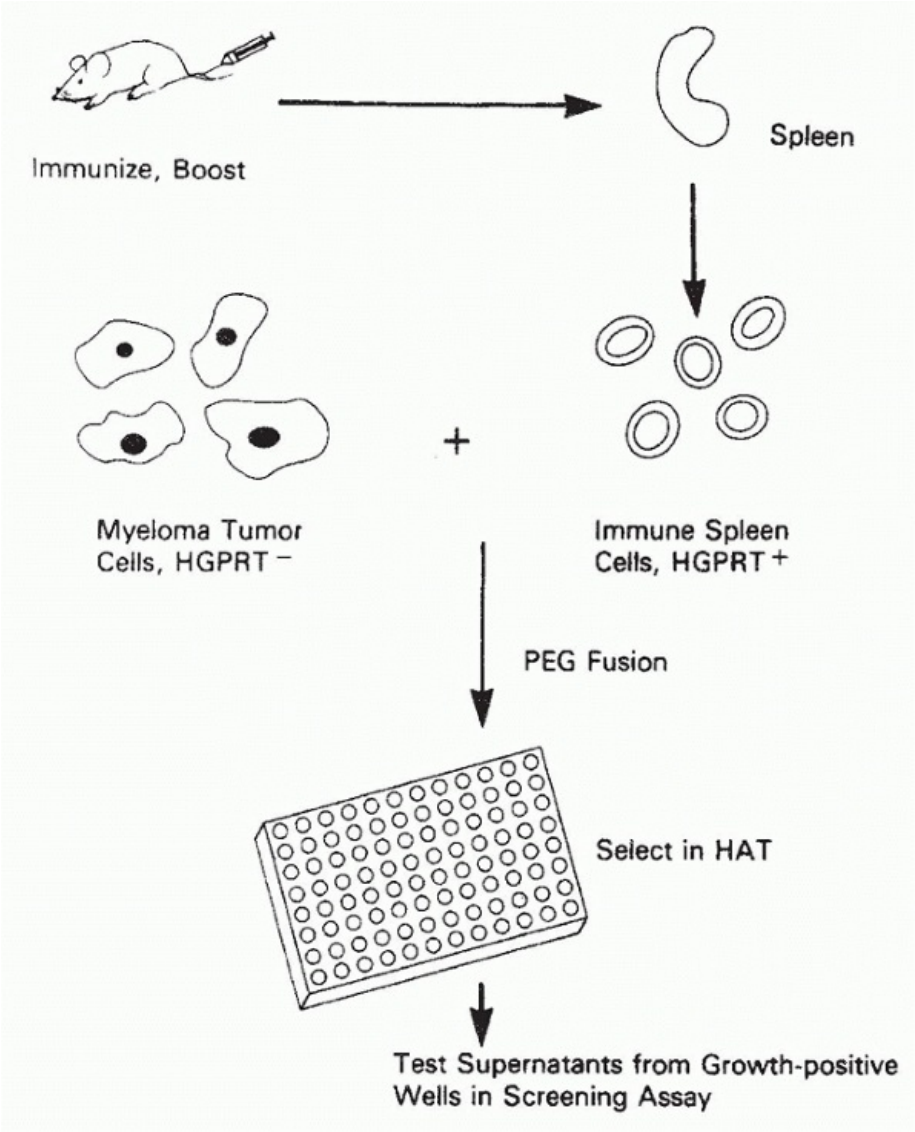

FIG. 7.18. Production of Hybridomas. Steps in the derivation of hybridomas can be outlined as shown. Spleen cells from immunized donors are fused with myeloma cells bearing a selection marker. The fused cells are then cultured in selective medium until visible colonies grow, and their supernatants are then screened for antibody production. HAT, hypoxanthine, aminopterin, thymidine; HGPRT, Hypoxanthine-guanine phosphoribosyltransferase; PEG, polyethylene glycol.

A second approach is the use of fusion partner cells from the desired species. Myeloma variants carrying drug selection markers are available in a number of species. A rat myeloma line adapted for this purpose, IR983F, was described by Bazin.[108] Production of human hybridomas is of special importance because their use in therapies would avoid the problem of human immune responses to Ig derived from other animal species, as discussed in detail in the later section on applications.

Use of Gene Libraries to Derive Monoclonal Antibodies

Monoclonal antibodies produced by hybridoma technology are derived from B cells of immunized animals. A recent alternative technology uses gene libraries and expression

systems instead. This approach has the advantages of avoiding laborintensive immunizations of animals and the screening of antibody-containing supernatants. Another advantage of the approach is circumventing tolerance. One can derive monoclonal antibodies to antigens expressed in the animal species

that donated the gene library, including highly conserved antigens for which there may be no available responder that does not express the antigen.

The first version of such an approach involved preparation of VH and Vκ libraries and expression of the libraries in bacteria. Further development of the system led to use of VH and VL libraries (see Chapters 5 & 6) made separately, and then preparation of a combinatorial library by cleaving, mixing, and religating the libraries at a restriction site.[109,110] A linker can be used so that VH and VL can both be expressed on one covalent polypeptide; the flexibility of the linker allows association of the VH and VL in a normal three-dimensional configuration and thus formation of an antigen-binding site.[110]

Another innovation involves expression of V_H and Vκ genes on the surface of bacteriophage as fusion proteins with a phage protein to permit rapid screening of large numbers of sequences.[110,111,112] Adsorption of antibody-bearing phage on antigen-coated surfaces allows positive selection of phage containing DNA encoding the desired variable region fragment (Fv) from combinatorial variable region gene libraries.[111,112]

Human antibody gene sequences can be recovered by polymerase chain reaction (PCR) from peripheral blood cells,[113] bone marrow,[114] or human cells reimmunized in severe combine immunodeficiency-hu mice.[115] The phage display technique can then be used to select antigen-binding clones and derive human reagents of desired specificity, such as antibody to hepatitis surface antigen[113] or HIV envelope.[114]

One limitation in the phage library technique initially was low affinity of the monoclonal antibodies derived because they were generated by a random process and not subject to further somatic mutation. Several approaches have now been used to improve affinities. Hypermutation and selection has now been achieved in vitro by a strategy using a bacterial mutator strain.[116] The process involves multiple rounds of mutation followed by growth in nonmutator bacteria and then selection for high-affinity binding led to an overall 100-fold increase in affinity.[116] Improved affinity has also been achieved by use of site-directed mutagenesis to alter residues in hypervariable regions affecting dissociation rates.[117]

Recombinant Monoclonal Antibodies Derived from Single B Cells After Cell Sorting

A new and very productive approach to making monoclonal antibodies is based on amplification of both the V_H and V_L chains of single B cells by reverse transcription-PCR.[118,119] In the first step, B cells are sorted by fluorescence-activated cell sorting, based on antigen specificity or other characteristics, and then distributed in 96 well plates at a dilution of one B cell per well. The cells are lysed, followed by reverse transcription of the messenger ribonucleic acid of a single cell and amplification of the V_H and V_L chains by nested PCR of each chain separately. The two chains are cloned into expression vectors in

frame with the appropriate constant regions. Both chains are coexpressed to reconstitute the antibody. The resulting monoclonal antibodies are then analyzed for sequence, antigen specificity, affinity, and biologic activity. The efficiency of antibody production has been as high as 30% to 60% per well in different experiments.

Advantages include the ability to focus on a particular B-cell compartment, such as memory B cells, during the sorting step, the large numbers of monoclonals produced in a single experiment (typically more than 100), and the absence of antigen boosting prior to cloning. Due to the high efficiency of cloning, these monoclonals are thought to represent the expressed B-cell repertoire at a given time, location, and stage of differentiation. For example, human monoclonals had the same ratio of kappa to lambda light chains (60% to 40%) as found in circulating B cells, and they showed allelic exclusion in 95% of wells. Key features of the method include the choice of fluorescent antigen for B-cell sorting, called the "bait," and the choice of primers for nested PCR. The bait should capture as many antigen specific B cells as possible; different bait will capture different monoclonals from similar populations of B cells (compare Pietzsch et al.[120] and Scheid et al.[121]). A complex bait with multiple epitopes, such as HIV gp140, will capture antibodies to different parts of the antigen.[119,122,123] In order to amplify highly variable antibodies, the forward (and reverse) PCR primers should be chosen upstream (or downstream) of the V_H region so they will capture sequence variation near both ends of the coding sequence.

In one study, 1.5 × 105 memory B cells from a chronically HIV-infected subject were sorted based on binding to a stabilized form of gp120.[121] Individual antigen-specific B cells were distributed in microtiter wells, and they produced 576 monoclonal antibodies that bound gp120 by ELISA. Sequencing the V_H and V_L chains showed that each monoclonal was often clonally related to several others, which differed only by somatic mutation. Overall, these monoclonals represented 200 distinct B-cell clones. The monoclonals could be divided into groups, based on binding four distinct epitopes on gp120. Within the same clonally related group, some monoclonals had potent HIV-neutralizing activity while other closely related monoclonals were inactive. The B-cell donor was a long-term nonprogressor. The analysis of a significant sampling of the antibody repertoire may provide insight into how these patients control their circulating virus, and these findings may lead to improved vaccine antigens.

Applications of Monoclonal Antibodies

Because monoclonal antibodies can be made easily and reproducibly in large quantities, they allow many experiments that were not possible or practical previously. Affinity chromatography based on monoclonal antibodies can be used as a step in purification of molecular species that are difficult to purify chemically. Homogeneous antibody can be crystallized and can also be crystallized together with antigen to permit the study of the structure of antibody and of antigen -antibody complexes by x-ray diffraction. Homogeneous antibodies are also valuable in the study of antibody diversity. Such analyses have revealed much about the roles of somatic mutation, changes in affinity, and changes in clonal dominance in antibody responses.

Catalytic Antibodies

One area of recent interest is the use of antibody molecules to catalyze chemical reactions.[124] In this role, antibodies serve as an alternative to enzymes, an alternative that can be customized and manipulated more easily in some cases.

The concept of antibodies as catalysts had been proposed a long time ago by Woolley.[124] Use of homogeneous antibodies permitted identification of some with significant catalytic effects; MOPC167 accelerates the hydrolysis of nitrophenyl phosphorylcholine by 770-fold.[125] Polyclonal antibodies have also been reported to possess detectable enzymatic activity.[126] With the advent of hybridoma technology, purposeful selection of antibodies with potent enzymatic function became possible. Antibodies have been characterized that catalyze numerous chemical reactions, with rates nearing 10^8-fold above the spontaneous rate.[124] One common strategy for elicitation of such antibodies is immunization with transition state analogs,[127] although there are other strategies.[128] Antibodies function as catalysts in a stereospecific manner,[129] a valuable property.

Molecular mechanisms of antibody-mediated catalysis vary, as do enzymatic reactions.[128,130] To accelerate a reaction, an antibody has to lower the activation energy barrier to the reaction, which means lowering the energy of the transition state by stabilizing it. For this reason, an antibody that recognizes the transition state is favorable, and immunizations with analogs of the transition state have advantages.

Antibodies can serve as what has been termed an *entropy trap*[124]; binding to the antibody "freezes out" the rotational and translational degrees of freedom of the substrate and thus makes a chemical reaction far more favorable energetically. Interactions with chemical groups on the antibody can neutralize charges or bury hydrophobic groups, thereby stabilizing a constrained transition state.

Discovery of such catalytic antibodies opens practical opportunities: Antibodies can be customized for an application by appropriate selection and can be produced relatively cheaply and purified easily. Catalytic antibodies can be developed to perform chemical reactions for which no enzyme is available. They can shield intermediates from solvent, for example, allowing reactions that do not occur in aqueous solution.[131] They can form peptide bonds,[132] suggesting a new approach to polypeptide synthesis. Thus, catalytic antibodies will likely have many practical applications.

Bispecific and Bifunctional Antibodies

Antibodies produced naturally by a single B cell have only one binding site specificity, and their effector functions are determined by the structure of the Fc domain. The availability of monoclonal antibodies made possible the generation in quantity of artificial antibodies as cross-linking reagents by linking binding sites of two specificities to form bispecific antibodies. A variety of techniques have been used to prepare such hybrid or bispecific antibodies, and they have been put to a variety of uses. In addition, antibody-binding sites can be linked to other functional domains such as toxins, enzymes, or cytokines to create "bifunctional antibodies."[133]

One of the most powerful uses of hybrid antibodies is in redirecting cytolytic cells to targets

of a defined specificity. In one early demonstration of this use,[134] a monoclonal antibody specific for the Fcγ receptor and one specific for the hapten dinitrophenyl were chemically cross-linked. In the presence of this hybrid antibody, FcγR-bearing cells were able to lyse haptenated target cells specifically. The FcγR played a critical role; antibody to MHC class I antigens on the cell could not be substituted. Antibody to the T-cell receptor complex has also been used extensively to redirect T-cell lysis to desired targets. For example, anti-CD3 was cross-linked to antitumor antibodies and mixed with effector cells. These “targeted T cells” were able to inhibit the growth of human tumor cells in vivo in nude mice.[135] Bispecific antibodies have also been used recently to alter the tropism of a viral gene therapy vector to target specific cells.[136]

Cumbersome cross-linking chemistry can now be replaced by genetic engineering for creation of designer antibodies.[133] Bifunctional and bispecific antibodies can be engineered as single chain variable fragment constructs or by specialized strategies using two chains. A wide variety of configurations are possible and can be used to make multivalent reagents as well as reagents with one site of each specificity. Tags can be built in by fusion of additional sequence such as streptavidin, or, as mentioned previously, antibody domains can be combined with other functional domains such as toxins, enzymes, or cytokines.

Clinical Applications

The possible clinical uses of monoclonal antibodies are many. In vitro, they are widely used in RIA and ELISA measurements of substances in biologic fluids, from hormones to toxins. They are also extremely valuable in flow cytometric assays of cell populations using antibodies specific for differentiation antigens expressed on cell surfaces. Monoclonal antibodies plus complement or toxin-conjugated monoclonal antibodies have also been used to remove T cells from bone marrow prior to transplantation.[137]

In vivo, although it took more than two decades for the original promise of hybridoma technology to be translated into widespread clinical applications, a number of monoclonal antibodies are now in use or in trials for a variety of purposes.[138,139,140] Monoclonal antibody OKT3 directed to a marker on human T lymphocytes is used as a treatment for rejection reactions in patients undergoing kidney transplant.[141] Other monoclonal antibodies, for example, ^{111}In-labeled CYT-103 referred to as Oncoscint (Cytogen Corp, Princeton, NJ),[142] are used as diagnostic tumor imaging reagents. Monoclonal antibodies have now been approved for various therapeutic uses.[140,143] Cancer therapies use either unconjugated monoclonal antibody[138,144,145,146,147,148] or toxin-coupled[149,150] or radiolabeled monoclonal antibody.[144,148,151] Molecules targeted in cancer therapies include CD25 (IL-2 receptor alpha chain) in adult T-cell leukemia,[138,140,148,152,153,154] CD20 in non-Hodgkin lymphoma using either unlabeled[147,155] or more recently radionuclide-labeled anti-CD20,[156,157] the HER-2/neu oncoprotein in breast and

ovarian cancer,[145,146,158,159] CD22 in hairy cell leukemia,[150] vascular endothelial growth factor to limit angiogenesis in diverse tumors (especially colorectal, renal, and non-smallcell

lung cancer),[160,161,162,163,164,165] antiepidermal growth factor receptor in colorectal carcinoma and others,[166] anti-CD52 in chronic lymphocytic leukemia,[167] and anti-CD33 in acute myelogenous leukemia.[168] Other therapies studied include antilipopolysaccharide for treatment of sepsis, anti-IL-6 receptor for treatment of multiple myeloma and for rheumatoid arthritis, anti-IgE for treatment of allergy,[139] anti-tumor necrosis factor for treatment of arthritis,[169,170] anti-respiratory syncytial virus for prevention of respiratory syncytial virus morbidity and mortality in infants,[171,172] and anti-IL-2 receptor (CD25) for prevention of graft rejection[148,173] as well as for treatment of autoimmune diseases such as uveitis[174] and multiple sclerosis.[175] Other monoclonal antibodies have been developed to modulate immune responses. On the one hand, antibodies to block checkpoint inhibitors in the immune response, especially against cancer, have been developed, such as the first licensed one, ipilimumab, against cytotoxic T-lymphocyte antigen-4 (CD152), an inhibitory receptor expressed on activated T cells,[176,177,178,179,180,181] and anti-PD-1, another inhibitory receptor on activated T cells that is currently in trials.[182,183,184,185,186] An antibody to transforming growth factor-beta, a soluble inhibitor of immune responses, is also in clinical trials in both cancer and fibrosis.[187,188,189,190] On the other hand, monoclonal antibodies are being developed to amplify immune responses and synergize with vaccines, such as agonist anti-CD40 antibodies.[191,192,193]

In the specialized case of B-cell lymphoma, monoclonal anti-idiotypes against the idiotype expressed by the patient's tumor have been tested as a “magic bullet” therapy.[194] Active immunization of the patient with idiotype[195,196,197,198,199] has the advantage that escape mutants[200] are less likely to emerge because multiple idiotopes are recognized. Another approach under study is immunization using not idiotype as protein but plasmid DNA-encoding patient idiotype.[201] This approach would have additional advantages, such as ease of preparing customized reagents for each patient.

Production of Human or Humanized Monoclonal Antibodies

Many of the side effects of monoclonal antibodies in clinical use are due to the foreign Ig constant regions. Recognition of foreign Ig epitopes can lead to sensitization and so preclude subsequent use in the same individual of different monoclonal antibodies. Thus, monoclonal antibodies with some or all structure derived from human Ig have advantages. Several approaches have been taken employing fusion of human cells with animal myelomas or with human tumor cells of various kinds[202,203] and use of Epstein-Barr virus to immortalize antibody-producing cells.[204] Production of populations of sensitized human cells to be fused presents another special problem, as the donors cannot be immunized at will. In one example, in vitro stimulation of lymphocytes with antigen followed by fusion with mouse myeloma cells has been used to generate a series of antibodies to varicella zoster.[205]

Another approach to production of monoclonal antibodies with human characteristics involves application of genetic engineering. The part of the antibody structure recognized as foreign by humans can be minimized by combining human constant regions with mouse variable regions[206,207] or even just mouse hypervariable segments[208] by molecular genetic

techniques. Antigen-binding specificity is retained in some cases, and the “humanized” chimeric molecules have many of the advantages of human hybridomas.

Production of fully human monoclonal antibodies in transgenic mice has now been achieved by multiple laboratories. The strategy has involved insertion into the mouse germ line of constructs containing clusters of human Ig V, D, J, and C genes (see Chapter 6) to generate one transgenic line and targeted disruption of the mouse heavy chain and κ chain loci to generate another transgenic line. From these two lines, mice are then bred that express only human antibodies.

To show feasibility of this approach, cosmids carrying parts of the human heavy chain locus were used to make transgenic mice.[209] The next step was to produce mice carrying human genes for both heavy and light chains to generate a functional human repertoire. Several groups using different technologies constructed heavy chain miniloci containing functional V segments representing several major V region families, D and J segments, constant and switch regions, and enhancers. The κ chain constructs were made that contained multiple functional Vκ segments, the J segments, Cκ, and enhancers.[210,211] Mice were bred that were homozygous both for the transgene loci and for disruption of the mouse heavy chain and κ light chain loci; note that the mouse λ locus was left intact. The human Ig genes could rearrange in the mouse genome, and expression of human Ig resulted. If these mice were immunized with a fragment of tetanus toxin, resulting antibodies included some that were fully human.[211] In one of the studies,[210] serum contained human μ, γ1, and κ as well as mouse λ and γ. Immunization of such mice with various antigens led to class switching, somatic mutation, and production of human antibodies of affinities of almost 10^8.

Ig expression in these mice demonstrates cross-species compatibility of the components involved in antibody gene rearrangement and diversification. The mice also provide a responder able to provide fully human antibodies to clinically important antigens, and they have the advantage that they are not tolerant to human antigens, such as the human IgE and human CD4 used by Lonberg et al.[210]

Nucleotide Aptamers: An Alternative to Monoclonal Antibodies

Antibodies are not the only biologic macromolecules that have evolved to permit an enormous range of specific structures. Oligonucleotides selected for ability to bind a ligand with high affinity and specificity are termed “aptamers” and can be used in many of the ways antibodies have been used. Selection, properties, and uses of aptamers have been reviewed.[212] Aptamers have the advantage that their

production does not require animals or cell culture. These well-defined reagents may be used increasingly in diagnostic testing and are also being tested in clinical trials for use as imaging agents or therapeutics.

Specificity and Cross-Reactivity

Specificity of Monoclonal Antibodies

Because all the molecules in a sample of monoclonal antibody have the same variable region structure, barring variants arising after cloning, they all have the same specificity. This

uniformity has the advantage that batches of monoclonal antibody do not vary in specificity as polyclonal sera often do. The most obvious fact about cross-reactions of monoclonal antibodies is that they are characteristic of all molecules and cannot be removed by absorption without removing all activity. An exception would be an apparent cross-reaction due to a subset of denatured antibody molecules, which could be removed on the basis of that binding. The homogeneity of monoclonal antibodies allows refinement of specificity analysis that was not possible with polyclonal sera. A few examples follow.

First, one can use monoclonal antibodies to distinguish closely related ligands in cases where most antibodies in a polyclonal serum would cross-react, and so absorption of a serum would not leave sufficient activity to define additional specificities. This ability is useful in designing clinical assays for related hormones, for example. Such fine discrimination also allows the definition of new specificities on complex antigens. When large numbers of monoclonal antibodies specific for class I and class II MHC antigens were analyzed, some defined specificities that could not be defined with existing polyclonal antisera.[213,214,215]

On the other hand, monoclonal antibodies are also a powerful tool for demonstrating similarities rather than distinctions between two antigens. In some cases, only a minor portion of an antibody response detects a cross-reaction, and so it is not detected by polyclonal reagents. For example, determinants shared by the I-A and I-E class II MHC antigens in the mouse were demonstrated using monoclonal antibodies215 while they had been suspected but were difficult to demonstrate using polyclonal sera.

Another type of fine specificity analysis possible only with monoclonal antibodies is the discrimination of spatial sites (epitope clusters) by competitive binding. In some cases, such epitope clusters correspond to specificities that are readily distinguished by other means. However, in other cases, the epitope clusters may not be distinguishable by any serologic or genetic means. An example is the splitting of the classical specificity Ia.7 into three epitope clusters by competitive binding with monoclonal antibodies.[215] The epitopes cannot be distinguished genetically, as all three are expressed on cells of all Ia.7-positive mouse strains. Thus, polyclonal sera cannot be absorbed to reveal the different specificities. Only with the use of monoclonal antibodies were the epitopes resolved from each other.

The importance of this type of analysis is shown by another example, the definition of epitope clusters on CD4, a surface molecule on a subset of human T cells that also functions as the receptor for HIV. Monoclonal antibodies to CD4 can be divided into several groups based on competitive inhibition.[216] The cluster containing the site recognized by OKT4A is closely related to virus infection, as antibodies to this site block syncytium formation. The cluster recognized by OKT4, however, is not related to infection because antibodies to it do not block syncytium formation,[216] and cells expressing variant forms of the CD4 molecule lacking the OKT4 epitope can still be infected by HIV.[217] This information about the sites on the molecule is important in understanding the molecular interactions of virus with its receptor and may be useful in designing vaccine candidates.

While most antibodies are not MHC-restricted in their recognition of antigens, distinguishing them from T-cell receptors, antibodies can be selected that recognize peptide -MHC complexes[218,219,220] (MHC-restricted antipeptide antibodies or peptide-dependent anti-MHC class I antibodies). Several monoclonal antibodies have been selected that require both

a certain MHC class I antigen and a particular peptide for reactivity. Such monoclonal antibodies are useful reagents capable of detecting cells presenting the appropriate peptide-MHC complexes on their surfaces.[218] Such monoclonal antibodies may also be useful in dissection of T-cell responses. In one study, the monoclonal antibodies could inhibit IL-2 secretion by a T-cell hybridoma of corresponding specificity and could also block induction of cytotoxic T lymphocyte recognizing that epitope when given in vivo during priming.[220] Such monoclonal antibodies have been used to address structural questions about antigen recognition by T and B cells.[219] Such antibodies also appeared to skew the repertoire of T cells for this particular HIV peptide MHC complex to specific T-cell receptor Vβ types and T-cell avidities.[221] However, only very rare monoclonal antibodies have this type of specificity and they were purposely selected in the fusions, so they do not provide a general comparison of T-cell receptor and Ab characteristics.

Cross-Reactions of Monoclonal Antibodies

Monoclonal antibodies display many type 1 cross-reactions, emphasizing that antibody cross-reactions represent real similarities among the antigens, not just an effect of heterogeneity of serum antibodies. Even antigens that differ for most of their structure can share one determinant, and a monoclonal antibody recognizing this site would then give a 100% cross-reaction. An example is the reactivity of autoantibodies in lupus with both DNA and cardiolipin.[222]

It should be emphasized that sharing a “determinant” does not mean that the antigens contain identical chemical structures, but rather that they bear a chemical resemblance that may not be well understood, for example, a distribution of surface charges. Antibodies to the whole range of antigens can react with Igs in idiotype anti-idiotype reactions, showing a cross-reactivity of the same antibodies with proteins (the anti-idiotypes) and with the carbohydrates, nucleic acids, lipids, or haptens against which they were raised.

Polyclonal versus Monoclonal Antibodies

When monoclonal antibodies first became available, some people expected that they would be exquisitely specific and would be superior to polyclonal sera for essentially all purposes. Further thought about the issues discussed previously, however, suggests that this is not always the case and depends on the intended use of the antibodies. Not only do monoclonal antibodies cross-react, but when they do, the cross-reaction is not minor and cannot be removed by absorption. A large panel of monoclonal antibodies may be needed before one is identified with the precise range of reactivity desired for a study.

In polyclonal sera, on the other hand, each different antibody has a distinct range of reactivity, and the only common feature would be detectable reactivity with the antigen used for immunization or testing. Thus, the serum as a whole may show only a low-titered cross-reaction with any particular other antigen, and that cross-reaction can be removed by absorption, leaving substantial activity against the immunizing antigen. For the purposes of an experiment, a polyclonal serum may be “more specific” than any one of its clonal parts and may be more useful. This concept is the basis of the theory of “multispecificity” (see previous discussion).

Polyclonal sera also have advantages in certain technical situations such as immunoprecipitation in which multivalency is important. Many antigens are univalent with respect to monoclonal antibody binding but display multiple distinct sites that can be recognized by different components of polyclonal sera. Thus, a greater degree of cross-linking can be achieved.

The ultimate serologic reagent in many cases may well be a mixture of monoclonal antibodies that have been chosen according to their cross-reactions. The mixture would be better defined and more reproducible than a polyclonal antiserum and would have the same advantage of overlapping specificities.

CONCLUSION

In conclusion, antibodies, whether monoclonal or polyclonal, provide a unique type of reagent that can be made with high specificity for almost any desired organic or biochemical structure, often with extremely high affinity. These can be naturally divalent, for example in the case of IgG or multivalent, for example in the case of IgM or can be made as monovalent molecules such as Fab or recombinant Fv fragments. They serve not only as a major arm of host defense playing a major role in the protective efficacy of most existing antiviral and all antibacterial vaccines but also as very versatile tools for research and clinical use. RIAs and ELISAs have revolutionized the detection of minute quantities of biologic molecules, such as hormones and cytokines, and thus have become indispensable for clinical diagnosis and monitoring of patients as well as for basic and applied research. Current solid-phase versions of these take advantage not only of the intrinsic affinity and specificity of the antibodies but also of the implicit multivalency and local high concentration on a solid surface. Cross-reactivity of antibodies often provides the first clue to relationships between molecules that might not otherwise have been compared. Conversely, methods that use antigens to detect the presence of antibodies in serum have become widespread in testing for exposure to a variety of pathogens, such as HIV. Antibodies also provide specific reagents invaluable in the rapid purification of many other molecules by affinity chromatography. They have also become indispensable reagents for other branches of biology, for example, in histocompatibility typing and phenotyping of cells using a myriad of cell-surface markers that were themselves discovered with monoclonal antibodies and for separating these cells by fluorescence-activated cell sorting, panning, or chromatographic techniques. Monoclonal antibodies have also finally emerged as clinically important therapeutics in cancer, arthritis, organ graft rejection, and infectious diseases. Thus, antibodies are among the most versatile and widely used types of reagents today, and their use is constantly growing. Understanding the fundamental concepts in antigen-antibody interactions thus has become essential not only to an understanding of immunology but also to the effective use of these valuable molecules in many other fields.

ACKNOWLEDGMENTS

We thank Drs. Charles DeLisi, Elvin A. Kabat, Henry Metzger, and Fred Karush for helpful suggestions and discussion, and Dr. Suzanne L. Epstein for her valuable contribution to the monoclonal antibody section.

Chapter 8

B-Lymphocyte Development and Biology

Richard R. Hardy

INTRODUCTION

B lymphocytes constitute one of the major arms of the immune system, being responsible for humoral immunity. B cells in humans and mice are produced throughout life, primarily in the fetal liver before birth and in the bone marrow after birth. Their development from hematopoietic stem cells (HSCs) has been extensively characterized in mice, and the generation of numerous gene-targeted and transgenic lines in many cases has provided crucial information on the role of transcription factors, cellular receptors, and interactions that are critical in their generation. Recently, the role of microribonucleic acids (miRNAs) in regulating hematopoietic development has also emerged. The complexity of this process is now apparent, and B-cell progenitor differentiation into multiple peripheral subsets with distinctive functions is also widely appreciated. This chapter will focus on B-cell development and function in the mouse, touching more briefly on aspects of human B cells that are similar or distinctive, with a focus on immunodeficiency and B-cell neoplasias. It will conclude with a brief description of novel aspects of B-lymphocyte development in other species, highlighting differences from development in mouse and human.

B-CELL DEVELOPMENT IN MICE

In mice, B cells are produced from HSCs through a complex process of differentiation that has been uncovered over the past 30 years or so. One of the goals of classical hematology has been the delineation of differentiation pathways for different lineages of blood cells. There has been considerable progress in utilizing the ordered expression of a diverse set of cell surface and internal proteins, some with known functions, others whose roles are only suspected, to construct a description of the intermediate stages that cells transit as they develop into B lymphocytes. A simplified example of such a description is presented in Figure 8.1. Thus, HSCs with the capacity to generate all the cell types in blood generate progeny with a more restricted capacity, recognizable in this example by expression of the receptor for interleukin (IL)-7. These in turn produce yet more restricted progenitor cells identified by expression of cluster of differentiation (CD)45R/B220 (and, importantly, by absence of CD19). This kind of pathway can be constructed by isolation and short-term culture of intermediate stages, allowing progression to occur, which helps to define the order. This framework for development serves as a starting point for analysis of the effects of transcription factors, microenvironmental interactions, cytokines, and natural or engineered mutations. It can also be extended by analysis of gene or protein expression at distinct intermediate stages. Critical processes, such as D-J rearrangement and immunoglobulin (Ig)

heavy chain expression, can also be mapped onto this framework. Progress in this work facilitates experiments that address additional issues, such as identification of key regulatory interactions, developmental checkpoints, and the mechanism of B-lineage commitment.

The following sections will cover the sites of B-lineage development at different stages of ontogeny, then focus on what is known about their development in the bone marrow of adult mice, highlighting the function of the pre-B-cell receptor and the crucial role of Ig heavy and light chains in guiding development. Later sections will consider their differentiation into various specialized peripheral populations and emphasize insights into B-cell selection gained from various transgenic models of tolerance.

Early Development

Sites of B Lymphopoiesis during Ontogeny

In the mouse, hematopoiesis occurs predominantly in the fetal liver prior to birth, in the spleen just prior to and shortly after birth, and in the bone marrow thereafter. Prior to liver hematopoiesis, the blood islands of the yolk sac (YS) contain the first identifiable hematopoietic cells, nucleated erythrocytes with embryonic forms of hemoglobin.[1] However, these early YS precursors appear incapable of generating other blood cell lineages, and generation of all blood cell types, including lymphocytes,[2,3] initiates at around 9 to 10 dpc in an embryonic region referred to as the splanchnopleura/AGM (or simply Sp/AGM). Cells from this site are capable of longterm repopulation of lethally irradiated adult recipients with all blood lineages.[4,5] These cells colonize the fetal liver at about 11 dpc, initiating hematopoiesis there. Thus, there are two sites of very early hematopoietic precursors, with one in the YS largely limited to erythropoiesis and the other in the Sp/AGM capable of complete (referred to as “definitive”) hematopoiesis. However, it may be that precursors in the YS have a broader lineage potential in the fetal microenvironment, as when they are injected directly into the newborn liver.[6] HSCs capable of developing into all the blood cell types are produced in the Sp/AGM and migrate to the fetal liver at about d10. Thereafter, B-lineage cells develop largely in a wave, with earlier stages present at earlier times and later stage predominating at later times, close to (and shortly after) birth.[7,8] This progression with gestation day is easily visualized by staining with antibodies that delineate B-cell

development, as shown in Figure 8.2. Early precursors can also be found in the fetal omentum.[9] In contrast with the bone marrow, cells at most differentiation stages in the fetal liver appear to be rapidly proliferating so that larger and larger numbers of B-lineage cells are detected at progressive days of gestation. Another distinction of fetal liver from bone marrow development in the adult is the absence of terminal deoxynucleotidyl transferase (TdT),[10,11] an enzyme that mediates nontemplated addition of nucleotides at the D-J and V-D junctions of Ig heavy chain. [12,13,14] Therefore, heavy chains produced during fetal development have little or no N-region addition, and CDR3 diversity is constrained even further by favoring of short stretches of homology at the V-D and D-J junctions.[15,16] Rearrangement of certain V or D elements may also differ between fetal and adult development, as for example, the reported high utilization of the DFL16.1 segment in fetal liver.[17] Differential expression of genes other than TdT also distinguish B-cell development during fetal life from that in the

adult including precursor lymphocyte regulated myosin light chain like PLRLC transcripts[11,18] and major histocompatibility complex (MHC) class II.[19,20] Interestingly, although absence of the cytokine IL-7 completely eliminates bone marrow B-lineage development,[21] it nevertheless spares some fetal development,[22] suggesting a difference in growth requirements. The B-cell progeny of this early fetal wave may largely consist of B cells quite distinct from adult-derived cells, populating the B-1 subset.[23]

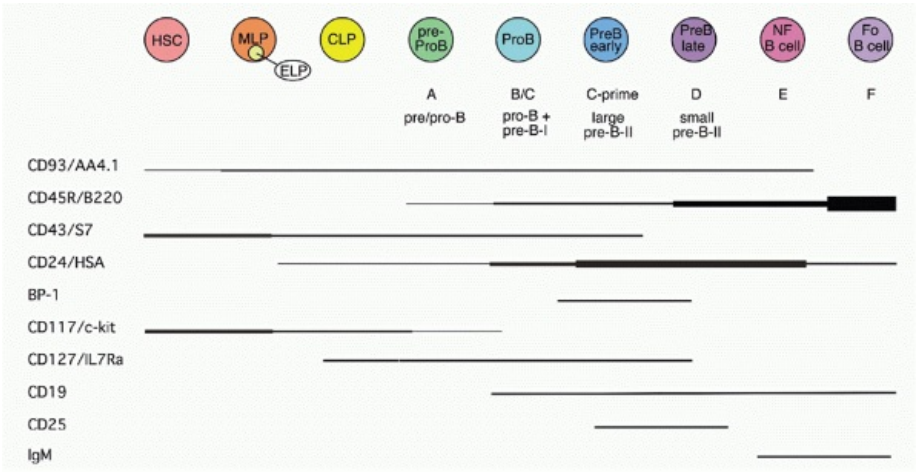

FIG. 8.1. Differentiation Diagram for Development of B Cells from Hematopoietic Stem Cells. Expression of the each surface protein is indicated by a line. Changes in level of expression is indicated by line thickness. CLP, common lymphoid progenitor; ELP, early lymphoid progenitor; Fo B, follicular B cell; HSC, hematopoietic stem cell; MLP, multilineage progenitor; NF B, newly formed B cell.

At birth, B-cell development can also be detected in spleen, but development at this site gradually decreases to very low levels by 2 to 4 weeks of age. Over this same period, B-cell development shifts to the bone marrow and thereafter it continues for the life of the animal. B lymphopoiesis decreases in aged mice. This may be due to diminished responsiveness of precursors to IL-7.[24,25]

Stem Cells, Commitment, and Early B-Cell Progenitors in Bone Marrow

B cells are continually generated from HSCs in the bone marrow of adult mice. Considerable effort has focused on evaluating the functional capacity of fractions of bone marrow cells to repopulate different lineages of blood cells; this work has progressed to the stage of defining a phenotype for such cells, with expression of c-KIT constituting an important marker in the so-called lineage negative subset.[26,27] This is the small fraction of bone marrow cells (< 5%) that lacks expression of a panel of “differentiation markers,” cell surface molecules that are expressed on later stages of various hematopoietic cell lineages. Careful analysis of this HSC fraction using additional markers has shown that it represent perhaps 1/30,000 of nucleated bone marrow cells with as few as 10 mediating multilineage repopulation in cell transfer assays.[28,29,30] An important capacity of “true” or “long-term repopulating” HSCs is their ability to give rise to cells in a recipient mouse that can also repopulate all the blood cell

lineages upon retransfer into a second host, indicating a capacity for extensive self-renewal without differentiation into more restricted progenitors.

A major focus in research on hematopoiesis has been defining and characterizing lineage-restricted progenitors, such as the common myeloid and common lymphoid

progenitors (CLPs).[31,32,33] The CLP cell fraction was identified by lack of a panel of "lineage markers," expression of the IL-7Rα chain, and distinctive, intermediate levels of c-KIT, compared to higher levels on HSCs. Initial characterization of these cells in various functional assays suggested that these cells could generate B, T, natural killer (NK), and a subset of dendritic cells but no other blood cell lineages. The reason for this restriction has been intensively studied, and downregulation of the receptor for granulocyte-myeloid colony stimulating factor has been suggested to be a key event in this process.[34] Cells with the phenotype of CLP constitute about 1/3000 of bone marrow cells. Prior to the CLP stage, multipotent progenitors exhibit low-level expression of genes characteristic of diverse cell lineages, leading to the idea that such promiscuous expression indicates chromatin accessibility that facilitates flexibility in cell fate decisions.[35]

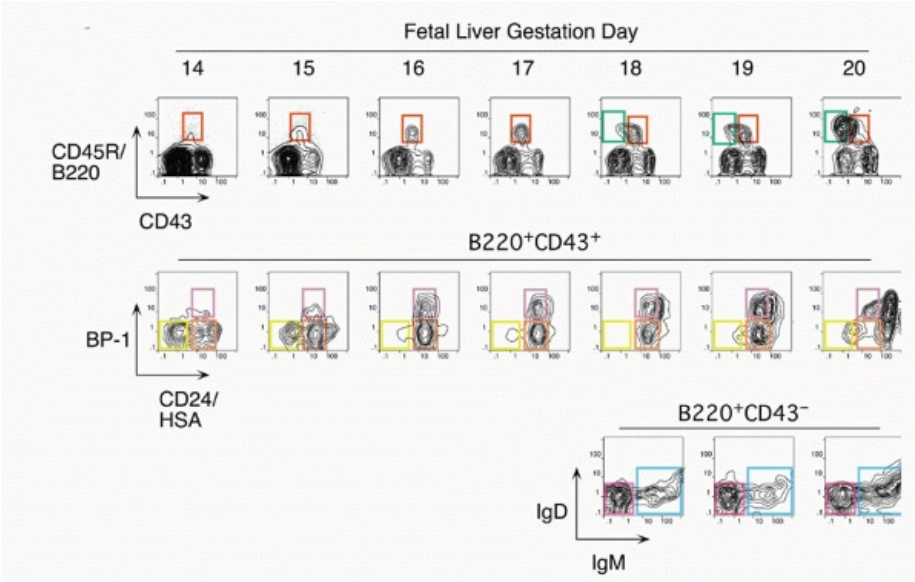

FIG. 8.2. Phenotypic Progression of Developing B-Lineage Cells in Mouse Fetal Liver Analyzed at Different Days of Gestation. Note that B220+cluster of differentiation (CD)43+ cells precede B220+CD43- cells and that within the B220+CD43+ fraction, heat stable antigen (HSA)- cells precede HSA+ cells, and BP-1- cells precede BP-1+ cells. Within the B220+CD43- fraction, the immunoglobulin M+ percentage increases until birth (at about day 20).

CLP cells can give rise in short-term cultures to cells of the B lineage, naturally raising the issue of when cells become restricted to the B lineage. Most cells growing in stromal cultures give rise only to B cells upon transfer into mice, and the phenotype of these cells has been well characterized. [36] Most have at least some heavy chain rearrangement and bear the B-

lineage marker CD19.[37,38] There is less certainty concerning the cells isolated directly from primary lymphoid tissues, as such cells are quite rare similar to CLPs and HSCs. Most of the CD45R/B220+ cells in bone marrow are also CD19+; such cells are committed to the production of B cells.[39] However, a subset of B220+ cells lacks detectable CD19 expression; cells within this fraction can generate CD19+ cells in short-term stromal culture with IL-7. Such cells are included in the CD43+CD24^{low} fraction (Fr. A, 1% of bone marrow) of B220+ cells in bone marrow, but this fraction also contains other cell types including NK-lineage precursors.[38,40] Thus, it is necessary to exclude cells lacking AA4.1 (about half[38]) and expressing Ly6c.[41] Many of these Ly6c+ cells also express CD4; recent work suggests that these are plasmacytoid dendritic cells.[42,43] A phenotypic approach for enriching and fractionating very early B-lineage subsets is shown in Figure 8.3A.

Careful analysis of the LIN− (including CD19) IL7Rα+cKIT+ CD45/B220− (CLP) and CD45/B220+ (Fr. A), as delineated in Figure 8.3, modified our understanding of the earliest stages of B-cell development in bone marrow.[44] First, while CLP stage cells fail to efficiently generate myeloid cells upon transfer into irradiated hosts, they nevertheless retain significant capacity to produce such cells in short-term cultures, likely due to continued (albeit reduced) expression of receptors for myeloid growth factors. In contrast, this myeloid capacity is greatly reduced as cells begin to express CD45R/B220 (ie, become “Fr. A”), concomitant with reduced expression of receptors for myeloid growth factor receptors. Yet these Fr. A cells, while poorly reconstituting T cells in cell transfer assays, nevertheless retain the capacity to generate T-lineage cells in culture, mediated by engagement of Notch by its ligand DL1.[45] Thus, the potential for alternate hematopoietic lineages appears to be lost somewhat later in progression down the B-lineage pathway in mouse bone marrow than previously thought. On the other hand, it appears that initiation of Ig rearrangement is initiated earlier than some studies have indicated. Determination of the extent of germline deoxyribonucleic acid (DNA) segments lost upon D-J rearrangement, and the formation of such D-J segments in individual cells isolated by electronic cell sorting showed that 30% to 50% of cells in CLPs and more than 80% of cells in Fr. A contained a D-J rearrangement on at least one chromosome.[44] This is consistent with high-level expression of genes important in Ig rearrangement, including TdT, Rag-1, and Rag-2, in CLP[46] and Fr. A stage cells.

An emerging view of CLPs (and possibly even the earlier multilineage progenitor [MLP]) stage cells considers them to be early B-lineage precursors rather than branch points in the production of other hematopoietic cell lineages. Thus, analysis of CD4/CD8/CD3 “triple-negative” cells in thymus failed to identify cells with a surface phenotype comparable to CLPs, and mutant mice lacking CLPs in bone marrow nevertheless have relatively intact thymic development, leading these authors to suggest a distinct “early T progenitor” different from CLPs.[47] Furthermore, cells with T/myeloid potential, but lacking B-lineage capacity, have been described.[48] It seems reasonable to hypothesize that MLP, CLP, and Fr. A stage cells occupy a distinctive microenvironmental niche in bone marrow where they receive signals that guide them along the early stages of B-lineage development culminating in CD19+ pro-B cells that are irreversibly committed to becoming B cells due to expression of PAX5[39] (see following section). Interestingly, cells considered to be progressing down a

lymphoid/B-lineage path can be redirected to become dendritic cells by signals through toll-like receptors (TLRs), suggesting that infection can profoundly alter early stages in hematopoietic development.[49]

Additional issues remain regarding the lineage restriction of cells at these early stages in B-cell development. For example, there is evidence that cells restricted to generating B and myeloid/macrophage (but not T) lineage may exist in the fetal liver[50] and even in bone marrow.[51] There is also apparently a different dependence of fetal liver B lymphopoiesis on expression of the transcription factor BSAP compared to bone marrow, as determined by analysis of PAX5 null mice.[52] Further comparison of B-cell development in fetal liver with that in bone marrow is needed to clarify this point. Finally, the precise delineation and characterization of B-cell precursors earlier than CLPs, prior to IL-7 expression, remains imprecise. It seems likely that at least some of the MLP stage cells mentioned previously are initiating a B-lineage program based on their expression of E2A, Rag-1, Rag-2, and TdT.[44] However, potential heterogeneity in this fraction needs to be assessed. Determination of Rag-1 transcriptional activity at the single cell level by a green fluorescent protein reporter, used for identification of the early lymphoid progenitor fraction,[53] may provide a key approach for such studies.

Transcription Factors Regulating B-Lineage Development

The GATA-2 and Runx1/AML1 transcription factors are required for the development of HSCs that are the precursors of all the blood cell lineages, including B cells[54,55,56,57,58] (Fig. 8.4). Experiments with the core-binding factor-associated leukemia fusion protein CBFbeta-SMMHC, whose expression

inhibits RUNX function, have revealed that its expression negatively impacts pre-pro-B-cell through pre-B-cell populations in bone marrow.[59] Although the frequency of CLP stage cells was unaffected, the expression of B-lineage associated genes (such as CD79a and λ5) was decreased, demonstrating the key importance of early RUNX activity.

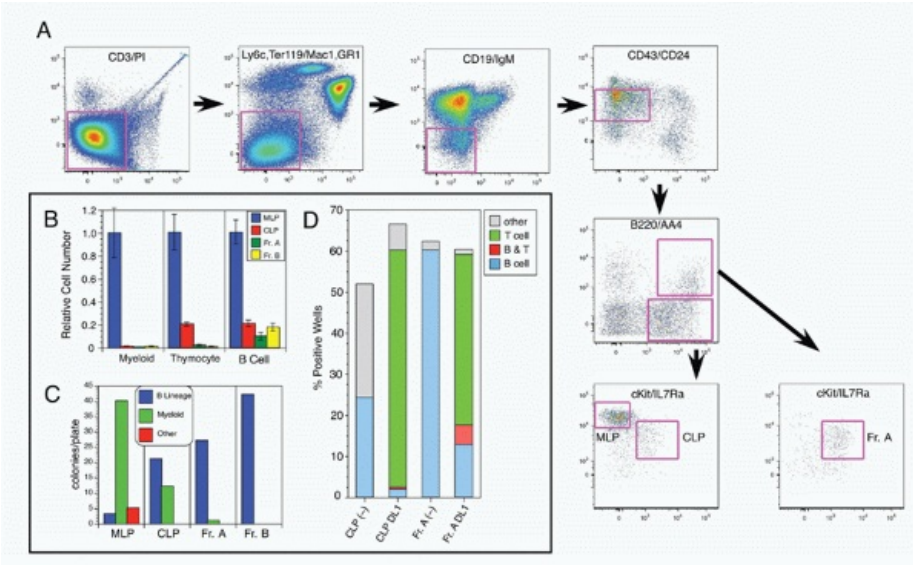

FIG. 8.3. A: An approach for purifying the earliest stage of B-lineage cells in mouse bone marrow. Bone marrow cells expressing cell surface proteins characteristic of differentiated stages of T, myeloid, erythroid, and B lineages are depleted sequentially by electronic gating in the first three panels. Cells with low-level expression of cluster of differentiation (CD)24/heat stable antigen (HSA) and intermediate levels of CD43(S7) are selected in the fourth and the distribution of CD45R/B220 versus CD93/AA4 is shown in the fifth. AA4+B220− cells contain multilineage progenitors (MLPs) and common lymphoid progenitors (CLPs), resolved by analysis for c-Kit versus interleukin (IL)-7Rα in panel six. AA4+B220+ cells, shown in the final panel, are enriched for c-Kit+IL-7Rα+ cells, termed Fr. A. CLP stage cells resemble Fr. A, but lack detectable expression of CD45R/B220. In contrast with CLP and Fr. A, MLP stage cells have higher levels of c-Kit and lack IL-7Rα expression. **B:** Functional analysis of early B-lineage cells by in vivo competition assay, showing absence of myeloid or T-lineage generation, but production of B-lineage cells from Fr.A. In contrast, CLP stage cells generate B and T cells, whereas MLPs repopulate B, T, and myeloid lineage cells. MLP, CLP, and Fr. A as identified in **A**. Fr. B stage cells are DJ/DJ rearranged pro-B cells, identified as CD19+CD43+CD24(HSA)+. **C:** Functional analysis of early B-lineage cells by in vitro S17 stromal cell assay, showing predominant B-lineage colony formation from Fr. A, but some myeloid generation from CLP stage cells. **D:** Functional analysis of early B-lineage cells by in vitro DL1-OP9 stromal cell culture, revealing significant T-lineage potential in Fr. A stage cells.

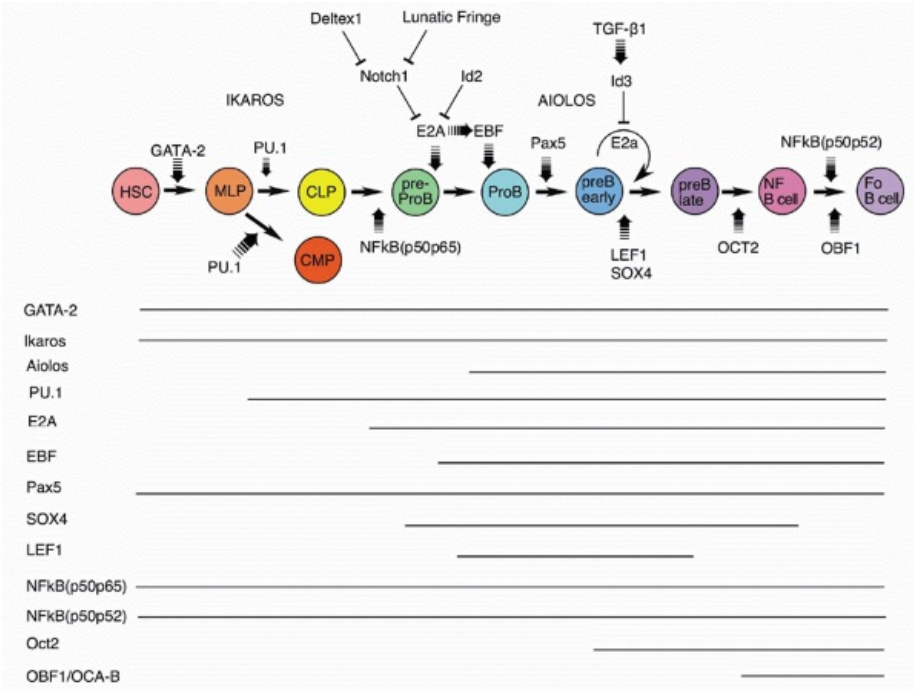

FIG. 8.4. Transcription Factors Important at Different Stages in B-Cell Development in Mouse Bone Marrow. Some regulatory networks are also shown. Positive/activating activity is indicated by *arrows*, whereas negative or blocking activity is indicated by *bars*. The rapidly cycling stage, early pre-B cell, is also indicated.

Predominant stages of expression are indicated below the diagram.

Somewhat later acting, but still very early in development, is the Ikaros transcription factor.[60,61,62] Ikaros and the related transcription factor Aiolos[63] play important roles in lymphocyte development. Ikaros is expressed early in hematopoietic precursors. Ikaros null mice lack B-lineage cells[62]; a different Ikaros mutant that acts as a dominant negative completely blocks lymphoid development.[60] Ikaros activates numerous early B-lineage genes, including TdT, Rag-1, λ5, and VpreB. Expression of EBF1 in Ikaros−/− hematopoietic progenitor cells restored generation of CD19+ cells, but these cells were not committed to the B-cell fate and failed to rearrange IgH genes.[64] Thus, Ikaros acts in a transcription factor pathway, inducing EBF1 expression, and acting in concert with PAX5 to maintain B-lineage commitment, but also altering chromatin compaction around the IgH locus, which together with Rag expression results in heavy chain rearrangement. Aiolos is detected somewhat later in development at about the stage of B-lineage commitment, and its expression increases further at later stages. It is induced by pre-B-cell receptor (BCR) signaling (see section on the role of Ig heavy chain and the pre-BCR), and it acts to down-regulate transcription of λ5 (initially induced by action of Ikaros), a part of the pre-BCR complex. In this way, Ikaros family members play key roles both initiating and terminating pre-BCR signaling, a critical checkpoint in B-cell development.

The PU.1, an Ets family transcription factor, is critical for progression to the earliest stage of lymphoid development, as demonstrated by the inability of PU.1 null precursors to generate lymphocytes.[65,66] An important target of PU.1 for B-lineage development is the gene for Igβ, known as MB-1. The level of PU.1 appears to be critical for development

along the B lineage, as, while low-level expression induced in PU.1 null mice allowed B-lineage development, high-level expression blocked this and fostered myeloid lineage development,[67] likely due to differential induction of the IL-7Rα and macrophage colony-stimulating factor receptor chains.[68] In fact, retroviral mediated expression of the IL-7Rα chain complements defective B lymphopoiesis in PU.1 null bone marrow HPCs.[69] Surprisingly, recent work from several groups indicates that some B-cell development can occur in the absence of PU.1 expression.[70] Furthermore, analysis of conditional PU.1 knockout mice showed that expression of this transcription factor was not required after the pre-B-cell stage.[71]

E2A codes for two proteins, E12 and E47, members of the basic helix-loop-helix family of transcription factors; its induction is crucial from the earliest stages of B-lineage development, as all stages after CD19 expression are absent from E2A null mice.[72,73] These mice lack detectable D-J rearrangements, and, interestingly, such rearrangements can be induced in nonlymphoid cells by introduction of the Rag genes and ectopic expression of E2A,[74] implicating this transcription factor in the process of chromatin remodeling of the Ig heavy chain locus that permits accessibility by the recombinase machinery.[75] The regulation of E2A is crucial for B-lineage development, as negative regulators such as Notch1 and ID2 have been show to block this lineage and induce alternate cell fates, the T and NK

lineages.[76,77,78,79] Consistent with this picture, ectopic expression of genes that negatively regulate Notch1, lunatic fringe, and Deltex-1 induce the B-cell fate.[80,81,82]

Expression of the early B-cell factor, EBF1, a member of the O/E protein transcription factor family, is requisite for progression of early B-lineage progenitors to the D-J rearranged pro-B stage (Fr. B), as shown in EBF1 null mice.[83] The expression of EBF1 is induced by action of the epigenetic histone H2A deubiquitinse MYSM1, as revealed by targeting this gene.[84] EBF1 and E2A act at a similar stage in early in B-lineage development; these two transcription factors can act together to upregulate a family of early B-lineage-specific genes, including Ig-α/β, VpreB/λ5, and Rag-1/2.[85,86] There is evidence that E2A upregulates expression of EBF1, found by transfection of E2A in a macrophage cell line,[87] suggesting an ordering of these two in development. Furthermore, recent studies showed that there are two distinct promoters for EBF1 that are regulated differently.[88] A distal promoter is activated by IL-7 signaling, E2A and EBF1, whereas a proximal promoter is regulated by PAX5, Ets1, and PU.1. Such complex regulation indicates that B-cell development occurs through the action of several feedback loops in a regulatory network that is becoming understood.[89,90]

BSAP, the product of the PAX5 gene, is expressed throughout B-cell development until the plasma cell stage.[91] PAX5/BSAP transcriptional targets include CD19 and BLNK; expression of this transcription factor acts to upregulate V to D-J heavy chain rearrangement.[52] Analysis of chromatin structure around the Ig heavy chain locus revealed that PAX5 induces V to D-J locus contraction, thereby promoting rearrangement.[92] PAX5 null mutant mice show an arrest in bone marrow development at the pro-B stage, likely due to the lack of complete heavy chain rearrangements and also due to the absence of the critical B-cell adaptor protein BLNK that serves to link the pre-BCR to the intracellular signaling pathway via the tyrosine kinase Syk.[93] BSAP/PAX5 also acts to repress alternate cell fates, as pro-B phenotype cells isolated from PAX5 null bone marrow can generate diverse hematopoietic cell lineages, in contrast with such cells from wild-type mice that are B-lineage restricted.[39,94] This occurs by repression of the myeloid growth factor receptor gene c-fms[95] and by repression of the Notch1 signaling pathway[96] critical for T-cell fate specification.[45,97] Conditional targeting of PAX5 in more mature B-cell stages shows that its continued expression is necessary for maintenance and function of mature B cells.[98] Finally, as mentioned previously, in contrast with bone marrow, the absence of BSAP/PAX5 arrests B-cell development prior to the B220+ stage in fetal liver, suggesting a crucial difference in the early dependence on this transcription factor.[52]

The Forkhead family transcription factor FoxO1 plays important roles at several stages of B-cell development.[99] Early in development, it acts to induce expression of the receptor for IL-7 at the CLP stage. It also functions to regulate Rag-1 and Rag-2 expression during heavy and light chain rearranging stages of development.[100] Finally, in mature B cells, it is needed for normal expression of L-selectin, a homing receptor important for normal recirculation of peripheral B cells through the lymphatics. GA binding protein, a ubiquitously expressed Ets family transcription factor, is another player regulating expression of the IL-7R.[101]

Importantly, through interaction with PAX5, it acts in concert to induce expression of critical PAX5 target genes such as CD79a. There is recent evidence that FoxO1 regulates Ikaros activity by altering splicing of its messenger ribonucleic acid (mRNA), rather than altering Ikaros transcription.[102] FoxO1 activation of Ikaros was sufficient for induction of rearrangement of proximal VH genes, but expression of PAX5 was required for rearrangement of distal VH genes. Thus, FoxO1, Ikaros, and PAX5 appear to function in a network to coordinate the ordered rearrangement of Ig genes during B-cell development.

Lymphoid enhancer binding factor (LEF-1) shows a pattern of expression restricted to the pro-B and pre-B stages of B-cell development.[103] Targeted inactivation of the LEF-1 gene allows B-cell development but with reduced numbers.[104] This is because LEF-1 regulates transcription of the Wnt/β-catenin signaling pathway whose activation increases proliferation and decreases apoptosis of early B-lineage cells. In fact, exposure of normal pro-B cells to Wnt protein induces their proliferation.[104] Interestingly, there is a counterproliferative signal that can act at the pre-B proliferative stage, mediated by transforming growth factor-β1.[105] It appears that this occurs due to induction of the ID3 inhibitor that negatively regulates the activity of E2A.[106] Another transcription factor whose expression is similar to LEF-1 is SOX-4; its inactivation also results in the inability of normal early B-lineage cell expansion and a block at the pro-B stage.[107]

Several forms of NF-κb subunits are expressed throughout B-cell development; this transcription factor can regulate kappa light chain expression and also growth factor signaling.[108] Mice lacking the p65 subunit die before birth, so development must be analyzed by transfer of fetal liver precursors into wild-type recipients. Such experiments showed diminished B-lineage cell numbers, but the major defect was in mature B-cell mitogenic responses.[109] Mice lacking the p50 subunit showed relatively normal B-cell development but again poor response to mitogen by mature B cells.[109] However, mice lacking both the p50 and p65 subunits failed to generate any B220+ B-lineage cells. Curiously, when mixed with wild-type fetal liver cells, normal numbers of mature B cells could be generated from the double-defective precursors, suggesting that the defect could be overcome by secreted or membrane-bound signals provided by the wild-type precursors. Another double mutant, p50p52, showed a late stage defect in B-cell development, with a failure to generate mature B cells in spleen.[110]

Inactivation of the Oct-2 transcription factor results in neonatal lethality, but transfers of fetal precursors can reconstitute lymphoid cells in wild-type recipients, allowing assessment of effects on the B lineage. Such studies have shown that fewer mature follicular B cells are generated in these mice and B-1 (CD5+) B cells are completely eliminated.[111,112,113] Similarly, the Oct binding factor, OBF-1, also known as OCA-B and BOB-1, appears to function in the maturation of newly formed B cells in the bone marrow to become follicular B cells in the periphery, as inactivation of this gene resulted in a significant deficit in mature B cells.[114,115,116] Both of these transcription factors have been shown to regulate the follicular B-cell chemokine receptor CXCR5, which may explain at least part of the defect.[117] Curiously, unlike Oct-2 null mice, there was reportedly no deficit in B-1 B cells in OBF-1 null

mice. Interestingly, when the OBF-1 mutant mouse is crossed with btk-deficient mice, there is a complete lack of peripheral B-cell generation,[118] suggesting that this transcription factor may function in the BCR-mediated selection of mature B cells.

Impact of Microribonucleic Acids on B-Cell Development

The miRNAs are small noncoding ribonucleic acids that facilitate the degradation of mRNAs and thereby act at a posttranscriptional level to regulate gene expression. The generation of mature functional miRNAs requires action of Dicer, a protein that cleaves pre-miRNAs, so the targeting of Dicer allows assessment of the global effect of miRNA on B-cell development. Ablation of Dicer in early B-lineage progenitors results in a block at the pro- to pre-B cell stage, likely due to upregulation of the proapoptotic molecule Bim.[119] Counteraction of Bim function by a Bcl-2 transgene reveal further dysregulation of normal development, including nontemplated nucleotide addition (N-regions) at the Ig light chain V-J junction, due to aberrant expression of the terminal deoxynucleotidyl transferase gene that is normally extinguished at the pre-B-cell stage.

Another approach for assessing the importance of specific miRNAs is direct overexpression or knockdown of expression; such a study with miR-150 reveal its role in regulating c-Myb, a transcription factor that regulates pro-B to pre-B progression and also the survival of mature B cells.[120] Transgenic overexpression of miR-17-92, a miRNA often found to be amplified in lymphoma, resulted in a lympho-proliferative syndrome and autoimmune disease, resulting in premature death.[121] One target of miR-17-92 is Bim; its decrease in the transgenic animals may have resulted in excessive cell survival and a loss of normal tolerance to self-antigens. The potential relevance to normal growth regulation is quite interesting, considering the amplification of this miRNA in some lymphomas. Another miRNA with a cancer association, miR-21, has been studied as a transgene in mice, where it results in tumors with a pre-B malignant lymphoid-like phenotype.[122] The miRNAs that are amplified in cancers and likely contribute to the neoplastic process are now termed “oncomirs.”

miRNAs can also influence lineage choice or act at key checkpoints during hematopoietic development. Retroviral provision of miR-34a in bone marrow hematopoietic progenitors blocked B-cell development at the pro-B to pre-B checkpoint, resulting in reduced numbers of mature B cells in mice repopulated with such precursors. A possible explanation for the developmental block is action of miR-34a on Foxp1, a transcription factor that appears to be important at this stage, as cotransfection of FoxO1 lacking its normal 3' UTR target of miR-34a restored B-cell development. A novel regulator of lineage choice appears to be Let-7, a family of miRNAs regulated by the highly conserved ribonucleic acid-binding protein Lin28.[123] While Lin28 has been studied for its role in pluripotency, developmental timing, and oncogenesis, a recent study indicates that it may regulate a developmental switch in both B and T cells, such that its expression in adult hematopoietic progenitors results in reprograming development toward a more “innate-like” pattern, normally only seen during fetal/neonatal timing.[124]

Bone Marrow Developmental Stages

Functional Definition

Distinct stages of developing B-lineage cells can be delineated based on their capacity for growth under different culture conditions. That is, the earliest precursors require cell contact with the stromal microenvironment in addition to specific cytokines, notably IL-7.[105,125] This stromal cell/precursor adhesive interaction is mediated, at least in part, by binding of VLA-4 to intercellular adhesion molecule-1.[126,127] Later stage cells do not require cell contact but maintain a need for cytokines.[128,129] Both cell types can undergo considerable cell proliferation in culture. Interestingly, the difference between cell contact requirement and independence is linked to the expression of heavy chain protein.[128,130] A population of cytoplasmic heavy chain-expressing B-lineage cells later than either of these, the so-called late or small pre-B cells, does not proliferate in culture. These cells likely require different culture conditions for survival, as they usually do not persist for extended periods, but rather die with a half-life of less than 24 hours unless protected from apoptosis by a Bcl-2 transgene.[131]

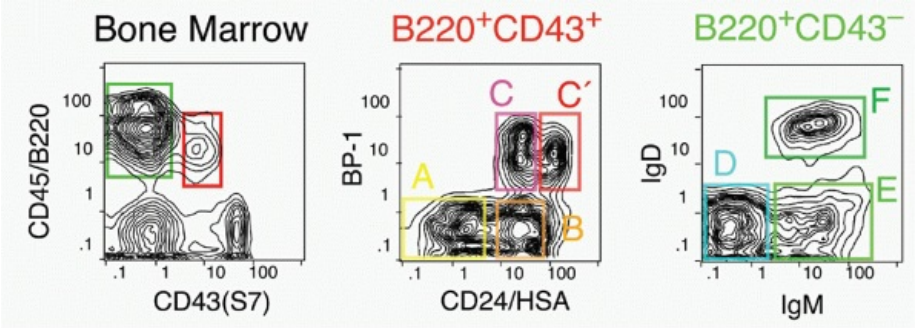

FIG. 8.5. Flow Cytometry Approach for Analyzing Different Stages of Cluster of Differentiation (CD)19+ B-Cell Development in Mouse Bone Marrow. Note that the antibody used for CD24/heat stable antigen (HSA) staining, 30F1, is important, as other monoclonal antibodies that recognize HSA do not resolve high from low-level expression as well. The cells expressing low levels of CD24/HSA, labeled “A”, are CD19- and is enriched for very early B-lineage precursors but also is contaminated by other cell types that can be detected by staining for AA4, NK1.1, DX5, and Ly6c; early B-lineage precursors are AA4+NK1.1-DX5-Ly6c-.

Phenotypic Definition

Further clarification of the heterogeneity in bone marrow can be achieved by analysis using fluorescent staining reagents and either microscopic or flow cytometric analysis. For example, the earliest determination that there were both heavy chain surface-positive B cell and cytoplasmic-positive pre-B cells was through microscopic examination using anti-Ig staining.[132,133] Later studies in mouse showed that there were specific surface proteins or “markers” that could be useful in identifying these populations, notably a restricted isoform (CD45Ra) of the common leukocyte antigen, CD45.[134] This largely B-lineage-restricted 200

kDa molecular mass isoform is often referred to as “B220.” Some highly B-lineage-restricted monoclonal antibodies, such as RA3-6B2, recognize a specific glycosylation of the CD45Ra isoform.[135] However, as described previously, even highly specific antibodies such as 6B2 may also recognize other cell types, such as particular differentiation stages or subsets of NK or dendritic cells.

The application of multiparameter/multicolor flow cytometry and additional monoclonal antibodies specific for other cell surface proteins differentially expressed during B-lineage development has facilitated delineation of multiple additional intermediate stages in this pathway.[129] For example, the B220+ population in bone marrow can be further fractionated into an earlier subset expressing CD43 (about 3% to 5% of marrow cells) and a later fraction with much lower CD43 expression (20% to 30% of marrow). The precursor/progeny relationship of cells in these two fractions can be readily demonstrated by short-term culture, with CD43+ cells giving rise to CD43− cells. These two populations can be further subfractionated based on additional developmentally regulated surface proteins, such as CD24/heat stable antigen (HSA), BP-1 (a zinc-dependent cell surface metallopeptidase also known as aminopeptidase A[136]), and the surface Ig molecules IgM and IgD.[129] This is shown in Figure 8.5. Again, these cell populations can be isolated and short-term culture used to determine their order in the pathway. Alternative approaches based on other developmental markers can be correlated with this framework of cell stages, notably the system developed by Melchers' group[137] using expression of CD45R/B220, CD19, c-KIT, and the IL-2Rα chain. A diagram summarizing this type of phenotypic subdivision and relating different nomenclatures is shown in Figure 8.6.

Culture Systems and Critical Microenvironmental Interactions

The combination of phenotypic characterization coupled with analysis of growth and differentiation in culture has provided a powerful approach for the further understanding of B-cell development, as employed by many different investigators. Bone marrow cultures developed by Whitlock and Witte,[138,139,140] and fetal liver cultures developed by Melchers' group[141,142] have allowed determination of the critical cytokines and some of the cell adhesion molecules important in the in vivo development of these cells. Many of these are summarized in Table 8.1. A typical B-lineage colony proliferating on S17 stromal cells in the presence of IL-7 is shown in Figure 8.7.

Survival and growth of the earliest stages of developing B-lineage cells require cell contact with nonlymphoid adherent cells that can be isolated from bone marrow, cells referred to generically as “stromal cells.” A number of lines have been derived from primary cultures of bone marrow adherent cells and characterized in terms of their capacity to support B lymphopoiesis in vitro.[143] This work has led to the discovery of adhesion molecules that play important roles in mediating the organization of clusters of developing B-lineage cells on stromal layers, including CD44 interacting with hyaluronate and VLA-4 interacting with vascular cell adhesion molecule 1.[126,127,144,145] Both of these interactions could be disrupted by addition of blocking antibodies

to CD44 and VLA-4 on B-cell precursors, resulting in a disruption of normal pre-B proliferation

in vitro.[146] Such adhesion interactions may serve to transmit signals directly to the stromal cells or B precursors, or both. There is some evidence that stromal cells are induced to elaborate specific growth mediators after interaction with B-cell precursors or soluble regulators.[147]

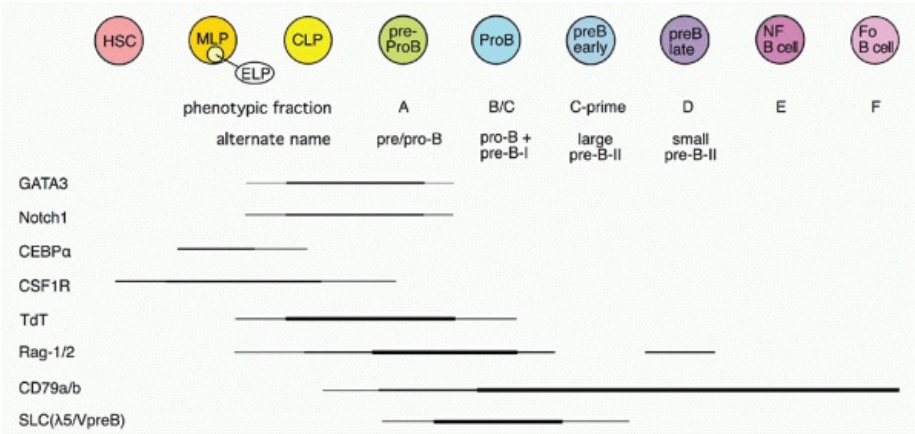

FIG. 8.6. Diagram of Distinct Phenotypic Stages and Characterization of Terminal Deoxynucleotidyl Transferase, Biphasic Rag Expression, Immunoglobulin-α/β, and Surrogate Light Chain Expression. Genes characteristic of myeloid and T-cell lineage are also shown. The cell type descriptions are cross-referenced to the alphabetic phenotypic fraction nomenclature and also to the Basel nomenclature. The early lymphoid progenitor population is identified by activation of the Rag-1 locus in a green fluorescent protein reporter mouse.

Another function of the stromal cells is to produce growth factors critical to B-lineage survival, proliferation, and differentiation; the most important of these for mouse B-cell development is IL-7.[105,125,148,149] IL-7 promotes the survival and proliferation of pro-B and pre-B stage cells, both in vivo and in vitro.[150,151] Neutralizing antibody to IL-7 can block B-cell development in vitro,[129] and IL-7 expressed as a transgene can deregulate normal B-cell development, leading to B-cell lymphadenopathy.[152] The IL-7 receptor consists of a unique IL-7Rα chain[153] paired with the common gamma chain (λc) that is also found in the receptors for

IL-2, IL-4, IL-9, IL-15, and IL-21.[154] IL-7Rα null mice have a severe deficit of both B and T cells in the periphery and lack most B-lineage cells in bone marrow.[155] Mice with targeted inactivation of the γc or IL-7 do have some B-lineage development, suggesting an alternate cytokine; this appears to be thymic stromal lymphopoietin (TSLP). This protein was first identified as a pre-B-cell growth factor produced by a thymic stromal line[156] and shows some of the same effects in culture as IL-7, although possibly inducing less proliferation and more differentiation.[157] Its receptor has been cloned; it consists of two chains, the TSLP receptor and IL-7Rα.[158] The TSLP receptor shares both sequence homology and genomic exon

organization with the common gamma chain.[159] Signaling through the IL-7 receptor requires JAK3 and activates the transcription factor STAT5, whereas signaling through TSLP is JAK3 independent but also activates STAT5.[157,160] Unexpectedly, the growth response to TSLP requires synergy with the pre-BCR in bone marrow but not in fetal liver,[161] leading some to propose that this might be a marker for distinctive B1 B-cell development in bone marrow.[162] When TSLP is overexpressed from an inducible transgene, B1 B cells expand, apparently at the expense of marginal zone (MZ) B cells.[163]

TABLE 8.1 Regulators of Growth of Early B-Lineage Cells

Mediator	Effect	Reference
L-7	Stimulates CLP and B-precursor proliferation	105,148,149,590
TSLP	Alternate IL-7-like cytokine	156,157
IGF-1	Stimulates accumulation of Cμ+cells in culture	185
FLT-3/FLK2-L	Critical for earliest stages of B-lineage development	168,172,591,592
c-KIT-L	Synergizes in IL-7-induced proliferation	26,166
IL-3	Substitute for IL-7 in proliferation of pre-B clones	176
CXCL12/CXCR4	Crucial chemokine interaction for early B-lineage precursors	194,196,198,199
Hemokinin	Novel regulator of B lymphopoiesis	187
VLA-4/VCAM-1	Adhesive interaction; antibodies to either block B lymphopoiesis	126,127,593
CD44/hyaluronate	Adhesive interaction; mediates association of B-lineage/stromal cells	144,146
TGF-β	Inhibits proliferation stimulated by IL-7	105
Sex steroids	Decrease B-lineage precursors in bone	594,595

	marrow	
Growth hormones	Required for normal B lymphopoiesis	188,189,596
TLRs	Innate immune system regulation	190

CD, cluster of differentiation; CLP, common lymphoid progenitor; IL, interleukin; TGF, transforming growth factor; TLR, toll-like receptor; TSLP, thymic stromal lymphopoietin; VCAM, vascular cell adhesion molecule.

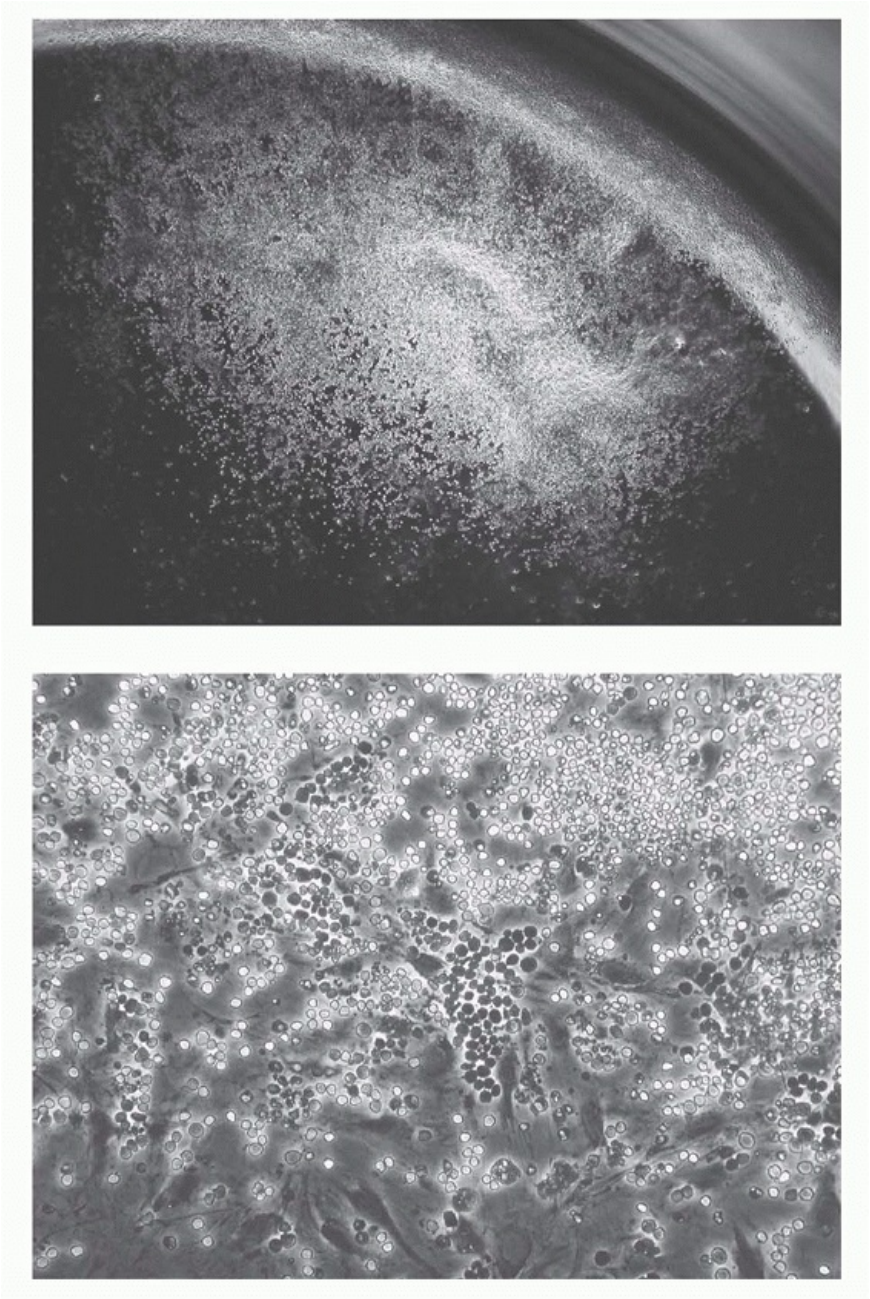

FIG. 8.7. Photomicrographs of B-Lineage Colony Proliferating on S17 Stromal Layer (in the Well of a 96-Well Microplate) in the Presence of Interleukin-7. Day

10 colony derived from a single Fr. A phenotype (see Fig. 8.5) cell. Low power and high power views. All of these cells now express CD19 and many have progressed to BP-1+.

The earliest precursors in the B-lineage pathway, probably including cells that are not B-lineage committed but that can efficiently give rise to B cells in a short time in vitro, have receptors for SCF/c-KIT-ligand[26,27,164,165,166,167] and FLK2/FLT3-ligand.[168,169,170,171,172] Thus, the most permissive cultures for expanding precursors of B-lineage cells will include these cytokines, in addition to IL-7 and a stromal adherent cell layer, such as S17.[173,174,175] IL-3 has also occasionally been suggested as playing a support role for pre-B cells in vitro,[176] although its role in vivo may be at a much earlier stage. While culture conditions have been reported that can support B-lineage development in the absence of stromal cells,[177,178] the clear-cut alteration of contact-dependence prior and post heavy chain expression[128,129,130,179,180] argues that the most physiologic model for early B-lineage growth will include stromal cells. Besides providing important cell-cell contacts that may signal survival, proliferation, and differentiation, it is also likely that stromal cells bind at least some cytokines to their surface, providing higher local concentrations to the clusters of B-lineage precursors that adhere.[181,182] B-lineage development may be modified by exposure to hormones; considerable interest has focused on sex steroids released during pregnancy that serve to depress B lymphopoiesis, particularly the pre-B-cell pool.[183] This may be important to avoid autoimmune responses by the mother but could have negative consequences due to possible transient immunodeficiency. Interestingly, fetal B lymphopoiesis is not similarly depressed due to the absence of hormone receptors on fetal B-lineage cells.[184] Insulin-like growth factor has been reported to potentiate progression in vitro to the Cμ+stage,[185,186] and, more recently, there is a report of a bioactive peptide, a type of tachykinin, that synergizes with IL-7 to enhance the growth of IL-7-dependent cultures.[187] Besides insulin-like growth factor, other pituitary hormones, thyroxine, and growth hormone have effects on B lymphopoiesis.[188] For example, thyroxine treatment can restore normal B-cell development in dwarf Pit-1 mutant mice with deficient pituitary function.[189] Recent work has highlighted the effect that activation of TLRs during infection may have on altering development.[190] Thus, it is likely that more detail remains to be filled in to complete our picture of the growth requirements and modulating influences of B-lineage cells in mouse bone marrow. Another function of cell-cell interaction is cell fate determination during the lineage commitment stage, very early in development of B-lineage cells. The Notch signaling pathway is implicated in cell fate determination in invertebrates and more recently has been shown to function in lymphoid lineage specification.[45,76,191] Notch family transmembrane receptors regulate transcription by being cleaved upon ligand binding to release an intracellular cytoplasmic domain that translocates to the nucleus where it interacts with the transcriptional repressor CSL.[192] Recent studies have shown that Notch1 can play a pivotal role in commitment of common lymphoid progenitors to the T-cell

lineage.[76] That is, expression of Notch1 by retroviral transduction has been shown to redirect B-lineage differentiation in bone marrow along the T lineage. Furthermore, a reciprocal result was found in conditional Notch1 null mice, blocking T-cell development in the thymus to be replaced by B-cell development.[97] Finally, altering the Notch1 modifier lunatic fringe by overexpressing this molecule under regulation of an lck promoter resulted in B-cell development in the thymus.[80] Differentiation of lymphoid precursors to NK or dendritic cell lineages was unaffected in Notch1 null CLP cells, so Notch apparently affects only the B/T-lineage decision.

Role of Chemokines in Migration of B-Cell Precursors

One of the most distinctive features of B-cell development in bone marrow is the migration of developing precursors from early stages nearest the bone endosteum layer to latter stages progressively closer to the central arteriole, where they will eventually exit.[193] This migration is likely due to differential expression of specific adhesion molecules and also to expression of chemokine receptors. Analysis of B-cell migration has identified a critical chemokine that is important in this process, SDF-1, now known as CXCL12,[194,195] and its receptor CXCR4.[196] CXCL12 is expressed by fetal liver and bone marrow stromal cells, whereas CXCR4 is found on hematopoietic precursors and B-cell progenitors.[197] Deletion of either the receptor or ligand results in severely impaired B lymphopoiesis.[198,199,200] Interestingly, the critical defect appears to be failure to retain precursors in the primary lymphoid organ, as progenitors and precursors can be found in the blood of mutant mice.[201]

Gene Expression and Immunoglobulin Rearrangement

In addition to delineation of developmental stages based on changes in protein surface expression, B-lineage cells can also be characterized for expression of internal proteins related to critical processes in their progression along this pathway, specifically those related to rearrangement and expression of the B-cell antigen receptor (Fig. 8.8). Thus, expression of μ heavy chain constant region, prior to Ig rearrangement, from a cryptic promoter generates a “sterile transcript” that reflects an open chromatin structure important for the onset of rearrangement,[202,203,204] and so analysis of sterile μ expression can be used to investigate very early stages of B-cell development. Classical northern analysis can be done with transformed lines, but much work analyzing RNA levels in B-lineage cell fractions, whether directly isolated or cultured, has depended on polymerase chain reaction amplification of complementary DNA.[38] For example, using this approach, sterile μ can be detected in a very early fraction of B220+CD43+CD19- (Fr. A) cells. Expression of the recombinase activating genes Rag-1 and Rag-2, which together make the double-strand breaks in DNA required for Ig rearrangement,[205,206,207] also occurs in Fr. A stage cells, which also have high levels of TdT, the enzyme responsible for adding nontemplated nucleotides at the D-J and V-D junctions of the heavy chain.[12,13] Rag-1 binds in a highly specific fashion to discrete sites within the IgH locus, recombination signal sequences, defining “recombination centers.”[208] The extent of heavy chain or light chain rearrangement can be quantitated either in bulk isolated populations[129] or in individual cells.[137,209,210] At the heavy chain locus, D-J rearrangement occurs prior to V-DJ rearrangement, and cells with

extensive D-J but little V-DJ rearrangement can be detected at the B220+CD43+CD19- (Fr. A) stage, where Rag-1/2 and TdT are strongly expressed.[44] V-DJ rearrangements are readily detected in the abundant B220+CD43− (Fr. D) stage small pre-B cells, although productive rearrangement has already completed by the large pre-B (Fr. C-prime) stage (see following discussion). Single-cell sequence analysis of rearrangements in Fr. C stage cells shows a large proportion with nonproductive rearrangements on both chromosomes, suggesting that this may represent a dead-end fraction.[209] Some light chain rearrangement is detectable in early stage B220+CD43− (Fr. B) cells, and this is consistent with the observation that low-level kappa light chain rearrangement is detectable in bone marrow of mice where μ heavy chain has been crippled by deletion of the membrane exon.[211] However, much higher levels of kappa rearrangement can be detected in B220+CD43− (Fr. D) stage cells consistent with the finding of sterile kappa mRNA increase just prior to this stage likely induced by pre-BCR signaling (see following discussion).

Role of Immunoglobulin Heavy Chain and the Pre-B-Cell Receptor

Many years ago, the analysis of severe combined immunodeficiency (SCID) mouse[212] bone marrow revealed the presence of a population of B220+ cells, all with a very early CD43+ phenotype, suggesting a block in B-cell development at this stage.[213] SCID mice have a defect in the catalytic subunit of the DNA-dependent protein kinase DNA-PKcs,[214,215] and, as a result, B-lineage cells in these mice are very ineffective at completing productive Ig heavy chain rearrangements. This block could be overcome by introduction of an Ig heavy chain transgene, indicating a critical role for μ protein in progressing past an early developmental checkpoint.[216] Furthermore, a gene targeting experiment that eliminated the membrane exon of μ heavy chain (μ-mt) also generated a block at this stage.[217,218]

The μ heavy chain is associated with a set of B-cell-specific peptides at the early pre-B-cell stage,[219] and this complex is referred to as the pre-BCR. It seems clear that pre-BCR mediates a type of signaling function analogous to the BCR in mature B cells. Prior to light chain expression, two peptides known as λ5 and VpreB, originally isolated as B-lineage-specific complementary DNAs,[220,221] associate with heavy chain. The λ5 shows homology to a lambda constant region and VpreB is so-called because it has homology to a variable region domain. Together, these peptides constitute a pseudo- or surrogate light chain (SLC). The critical role of λ5 was demonstrated unambiguously in genetargeted mice, where B-cell development was blocked at the B220+CD43+ stage.[222] The production of some mature cells that accumulate in this mutant is likely due to early kappa rearrangement, with light chain substituting for SLC, as demonstrated in light chain transgenic experiments.[223]

The μ heavy chain has a very short cytoplasmic region consisting of only three amino acids; signal transduction

through the BCR is mediated by accessory peptides, similar to the CD3 components of the T-cell receptor, known as Ig-α and Ig-β.[224,225,226,227] Inactivation of Ig-β[228] results in a block at the B220+CD43+ stage in mouse bone marrow, similar to that seen in μ-mt and λ5

null mice. Finally, the Syc tyrosine kinase plays a critical role in transducing BCR cross-linking signals in mature B cells and inactivation of this gene results in a “leaky” block at this same stage.[229,230] Thus, any mutation that affects this pre-BCR complex (see following section; see Fig. 8.10A) precludes efficient progression past the earliest stages of B-cell development.

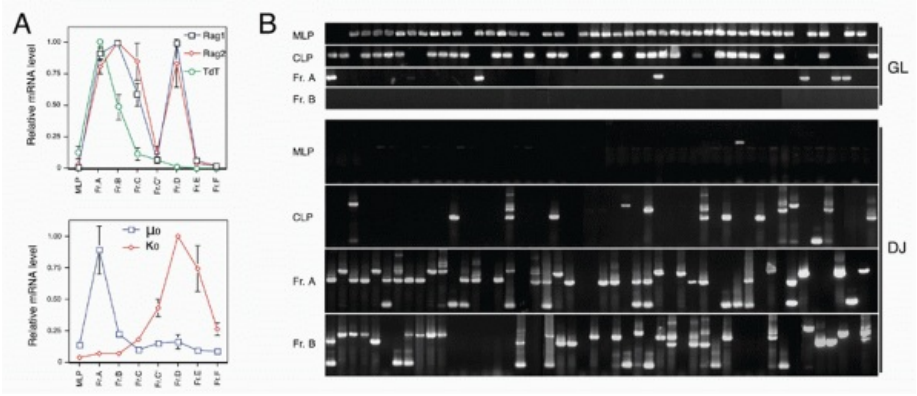

FIG. 8.8. A: Profiles of immunoglobulin (Ig) rearrangement-related gene expression. Cells isolated using fractionation scheme in Figure 8.3 for multilineage progenitors and Fr. A; in Figure 8.5 for Fr. B through Fr. F. Relative messenger ribonucleic acid levels assessed by performing semiquantitative reverse transcription-polymerase chain reaction using limited numbers of cycles, blotting, then probing, and quantitating the probe signal. Note the biphasic expression of Rag genes and the early expression of sterile μ (labeled *μ0*) during the first wave, where heavy chain rearranges, and the upregulation of sterile kappa transcripts *(κ0)* during the second Rag wave, when most light chain rearrangement takes place. **B:** Single-cell polymerase chain reaction analysis of Ig heavy chain rearrangement in four early stages of developing B-lineage cells. Deoxyribonucleic acid prepared from individual cells isolated following the scheme shown in Figure 8.3 was divided into two aliquots and analyzed for retention of a deoxyribonucleic acid segment lost upon any D-J rearrangement (labeled *GL*, germline) and also for D-J rearrangement. Note that D-J rearrangement initiates at the common lymphoid progenitor stage, where 30% to 50% of cells show a rearrangement.

Careful examination of B-cell development in normal mice shows that heavy chain is first expressed at a late fraction of the B220+CD43+ stage, termed Fr. C-prime (Fig. 8.9A). This fraction is also interesting because it shows a much higher proportion of cells in cycle (revealed by a high frequency of cells with greater than 2N DNA content; Fig. 8.9B), compared with any other B220+ stage in bone marrow.[129] Mice unable to assemble a pre-BCR, due to inability to rearrange heavy chain (Rag-1 null), show a block in development at the CD43+ stage that can be complemented by introduction of a functionally rearranged μ heavy chain as a transgene[180] (Fig. 8.9C). Analysis of several types of pre-BCR defective mutant mice shows a complete absence of Fr. C-prime stage cells, suggesting that pre-BCR signaling results in the upregulation of CD24/HSA and also entry into rapid cell proliferation. Thus, a model of pre-BCR function is that it signals the clonal expansion phase of pre-B-cell development, amplifying cells with in-frame VDJ rearrangements capable of making heavy

chain protein. The precise nature of pre-BCR signaling remains to be completely understood. An early model suggested that cross-linking of heavy chain was mediated through interaction of SLC with a bone marrow expressed ligand. However, subsequent experiments showed that normal light chain could substitute for SLC, and that even a V_H truncated μ heavy chain could mediate progression past this stage. Furthermore, intensive searches for the putative ligand over a 10-year period have been fruitless, leading to the model

that pre-BCR signaling is more akin to "tonic" signaling in mature B cells.[231,232,233] That is, simple assembly of the complex (or possibly some degree of multimerization fostered by the self-aggregating nature of SLC[234]) probably is sufficient for the cell to pass this developmental checkpoint (Fig. 8.10B). One clear-cut finding is that pre-BCR signaling in a transformed pro-B-cell model system can occur in the absence of any additional cell type, suggesting that if a ligand exists, it must be expressed on B-lineage cells rather than stromal cells.[235] Possibly, pre-BCR homodimerization is mediated through glycosylation at a conserved asparagine residue in the first μ constant region domain.[236] Studies of the T-cell analog of the pre-BCR, pre-Tα, provide strong evidence that it signals through spontaneous dimerization, without requirement for an external ligand.[237,238,239]

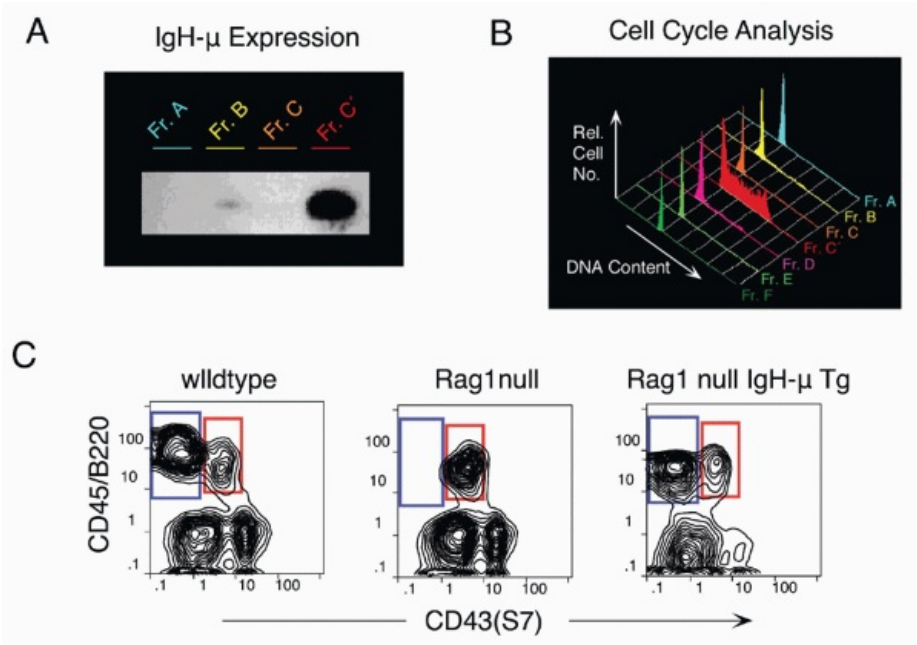

FIG 8.9. A: Western blot of immunoglobulin μ heavy chain expression showing high-level expression in Fr. C-prime. **B:** Cell cycle analysis of individual fractions shows most cells in Fr. C-prime are cycling. Propidium iodide staining of permeabilized sorted cells allows determination of deoxyribonucleic acid content per cell using flow cytometry. **C:** Block in B-cell development in Rag-1-deficient mice can be overcome by introduction of an immunoglobulin μ heavy chain transgene.

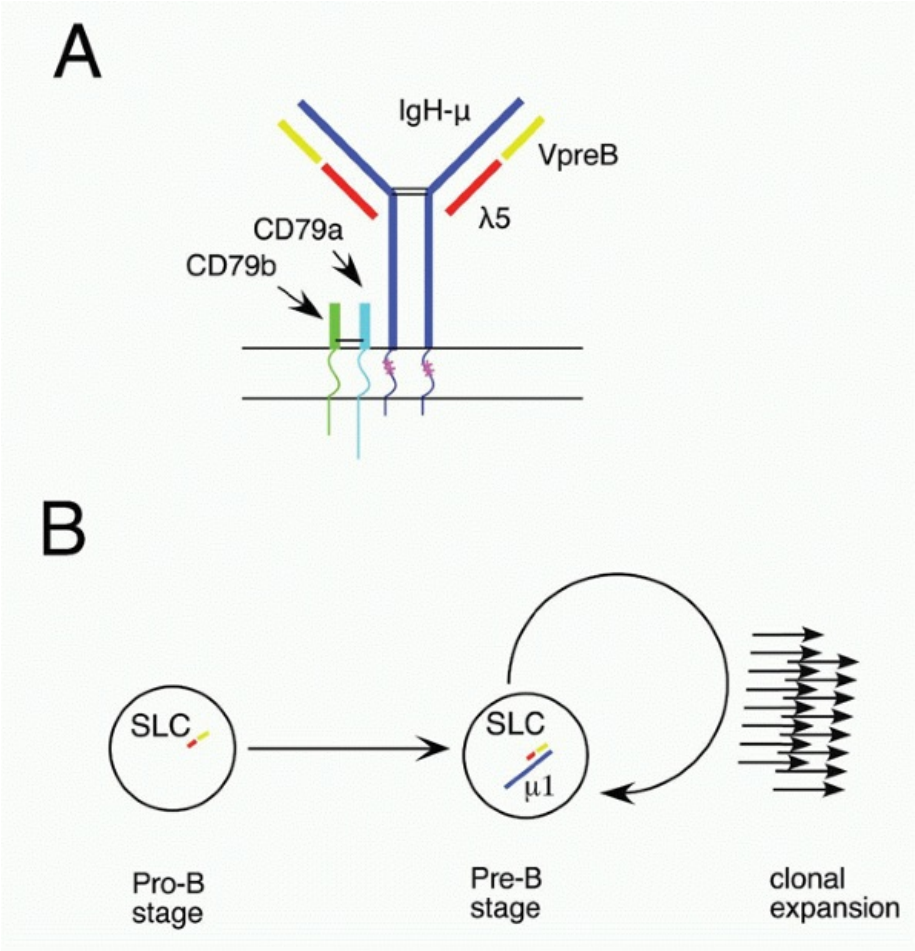

FIG 8.10. A: Diagram of the pre-B-cell receptor (BCR) μ heavy chain with surrogate light chain (λ5 and VpreB) in place of conventional light chain. As in the BCR, immunoglobulin (Ig)-α and Ig-β serve to couple signals between the receptor and cytoplasmic components, such as BLNK and Syk. Starred m transmembrane residues are important in mediating interaction with Ig-α/Ig-β, as mutation of these diminishes BCR function. **B:** Clonal expansion mediated by pre-BCR assembly. Association of newly generated μ heavy chain with pre-existing surrogate light chain leads to a burst of proliferation at the pre-B stage.

Mutations in other molecules in the pre-BCR signaling pathway have been shown to affect B-cell development and pre-B-cell clonal expansion. Although the Btk mutation is less severe in mouse than in human, there nevertheless is an alteration in pre-B-cell expansion in Btk-deficient mice.[240] Also, X-linked immunodeficiency (xid) B cells (deficient in Btk) have been reported to proliferate more in stromal cell cultures, possibly due to decreased differentiation to later nonproliferative stages.[241,242] The role of Btk is thought to modulate BCR signaling strength,[243] and this is probably also the case for pre-BCR signaling, allowing only strongly signaling pre-BCRs to progress in the mutant mice. BLNK/SLP65 serves to link the pre-BCR to the Syk kinase critical in BCR signaling.[244,245] Mutant mice lacking BLNK show a partial block in B-cell development at the pro-B to pre-B transition.[246] Curiously, whereas pre-BCR signaling is thought to mediate allelic exclusion (expression of a single heavy chain allele),

this remains intact in BLNK-deficient mice.[247] Animals deficient in both BLNK and Btk develop an extensive pre-B expansion that progresses to lymphoma, leading to study of such mice as a model for human pre-B acute lymphoblastic leukemia (ALL).[248,249]

Syk-deficient mice show a more severe block at the pro-B to pre-B transition and a lack of allelic exclusion.[229,230,247] There is also evidence that pre-BCR signals through Erk to induce proliferation.[250]

Outcomes of pre-BCR signaling, in addition to pre-B proliferation, are downregulation of the Rag genes,[251] down-regulation of TdT,[235] and transcriptional activation of the kappa locus, detected as upregulation of sterile kappa transcripts.[252] A control element for regulating Rag expression has been identified.[253,254] Extinction of recombinase activity is probably important for chromosomal stability during the clonal burst period of B-cell development[255,256,257] and is also at least a part of the mechanism that assures allelic exclusion, the expression of a single heavy chain by any given B cell.[258] There is evidence that pre-BCR selection requires low levels of IL-7[259] and probably occurs naturally as the developing precursors migrate through different stromal cell microenvironments in bone marrow.

The function of the pre-BCR may be more complex than simply to sense whether an in-frame VDJ rearrangement has occurred. This possibility is suggested by the observation that heavy chains with different VDJ segments vary in their capacity to assembly with SLC components.[260,261,262,263] V regions are classified into families based on sequence homology, and many members of two of these families, the 7183 and Q52, appear to frequently generate heavy chains that assemble poorly with SLC.[262] A consequence of this will likely be poor pre-BCR signaling and little clonal expansion; such cells will become underrepresented at later stages of B-cell development relative to cells containing heavy chains that signal effectively. One explanation for this SLC assembly-mediated clonal expansion is that it serves a quality control function to test heavy chain V regions for their potential to fold with real Ig light chain, a critical requirement if the cell is to express a complete BCR. An alternative (not necessarily mutually exclusive) explanation is that making pre-B-cell proliferation dependent on pre-BCR expression provides a simple mechanism for regulating the extent of clonal expansion, as an immediate consequence of pre-BCR signaling is to terminate SLC expression. Thereafter, SLC protein levels decay and are diluted by cell division so that after several rounds of proliferation, pre-BCR levels will decrease to below the threshold required to provide the signal to maintain the cell in cycle. Figure 8.11 illustrates a model for bone marrow B-cell development, showing the pre-BCR checkpoint.

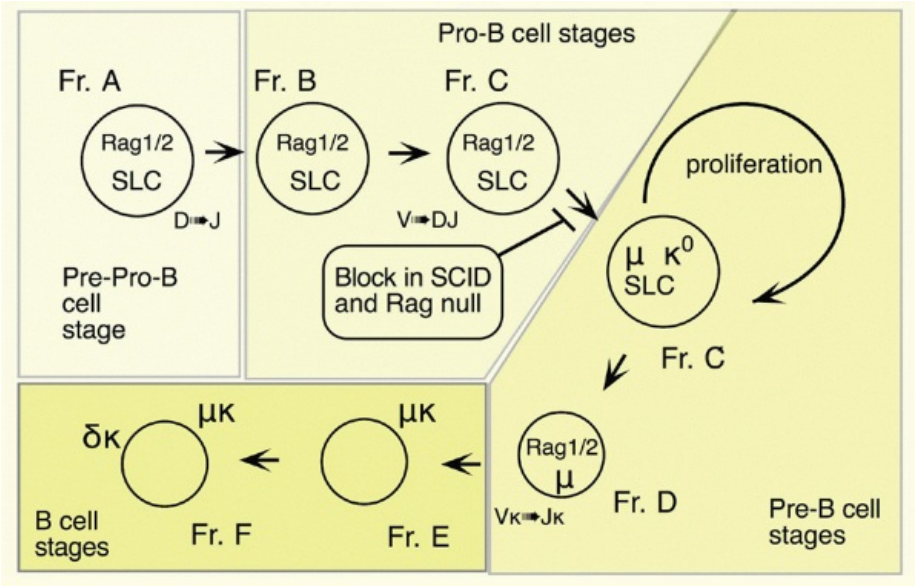

FIG. 8.11. Model of Mouse Bone Marrow B-Cell Development Showing Relationship of Immunoglobulin Rearrangement with Progression and Proliferation.

One of the most striking examples of pre-BCR selection is seen with the D-proximal V_H gene, V_H81X, where early precursors show biased overutilization due to preferential rearrangement of this V_H gene.[11,264,265] In fact, regulatory sequences interspersed throughout the distal VH region, termed PAX5-activated intergenic repeat elements, appear to enhance utilization of distal J558 family VH genes.[266] Furthermore, a recombination regulatory region, the intergenic control region 1, which lies between the VH and D clusters, has been shown to inhibit proximal and promote distal VH gene utilization.[267]

Curiously, although it is abundant in early B-cell precursors, V_H81X is rarely seen in the mature B-cell compartment. The demonstration of the decrease in representation of cells with V_H81X rearrangements at the pre-B clonal expansion phase in bone marrow,[268,269] together with the finding that heavy chains utilizing VH81X frequently fail to assemble functional pre-BCRs,[260,261,270] explained this paradox. Models of pre-BCR three-dimensional structures based on x-ray crystallography may help to explain variation in the ability of different heavy chains to assemble with SLC.[271]

However, it is still puzzling that the most frequently rearranged V_H gene is so strongly selected *against* at the clonal expansion stage. A possible explanation may lie in comparisons of V_H utilization during fetal development. That is, in contrast with bone marrow precursor cultures, the ratio of productive/nonproductive V_H81X does not decrease during cultures of fetal precursors.[272,273] Furthermore, the proliferative burst that pre-BCR assembly provides to bone marrow pre-B cells may instead result in exit from cell cycle in fetal precursors,[263] leading to selection of very different BCR repertoires during fetal and adult B lymphopoiesis. The possible significance of this is discussed subsequently in the section on B1 B cells.

Leaving aside such developmental difference, the role of the pre-BCR in B-cell selection remains subject to debate, with evidence suggesting it functions to eliminate[274] or enrich[275] self-reactivity.

Light Chain Rearrangement and Generation of Immature B Cells

Besides termination of TdT and SLC gene expression, pre-BCR signaling also results in the downregulation of Rag-1 and Rag-2 expression, mediated by activity of Gfi1b on Erag, the B cell-specific Rag regulatory element,[254] and the repression of FoxO1.[276] It appears that induction of Bcl-6 by pre-BCR signaling functions in this progression by repressing Myc and Ccnd2, thereby promoting exit from cell cycle.[277,278] As mentioned previously, there is evidence that the pre-BCR signals through ERK and this Ras-MEK-ERK signaling acts to silence transcription of Ccd3, encoding the cell cycle protein cyclin D3, thus promoting cell quiescence.[279] Opposing cell cycle exit, IL-7R signaling activates STAT5, maintaining Ccd3 expression. Eventually, the pre-B cell escapes from

IL-7 signaling, exits the cell cycle, and the Rag genes are reexpressed at high levels. Sterile kappa transcripts become detectable during the cycling stage, likely reflecting chromatin remodeling to make the kappa light chain locus accessible,[252] so induction of the recombinase machinery can initiate kappa light chain V to J rearrangement.

An interesting feature of the Vκ locus is that the approximately 100 genes are in both transcriptional orientations, and so these genes can rearrange either by deletion (generating an extrachromosomal excision circle) or by inversion.[280] The absence of intervening D segments also means that it is possible for upstream V kappa genes to rearrange to downstream J kappa segments, “leapfrogging” the initial rearrangement, assuming it was to any Jκ other than Jκ5. The successive association of different kappa chains with the same heavy chain in a B cell is referred to as BCR “editing” and was originally observed in the context of autoreactivity, which maintains Rag expression even at the B-cell stage[281,282] (see following section on B-cell tolerance). Because assembly and expression of a complete BCR (that is not self-reactive) terminates Rag expression, an additional reason for light chain editing in the bone marrow may be to replace an initial light chain that fails to assemble effectively with the particular heavy chain present in that pre-B cell. This is probably the explanation for multiple light chain rearrangements detected in single early B-lineage cells.[283] Complete failure of kappa rearrangement, possibly after receptor editing to avoid self-reactivity, leads the pre-B cell to a second phase of light chain rearrangement, dependent on IKK-mediated NF-κB signaling, where the λ light chain locus rearranges.[284]

Newly formed B cells can be distinguished from mature B cells on the basis of their inability to proliferate in response to BCR cross-linking (ie, they are functionally immature). This is also the stage where negative selection is reported in transgenic models of autoreactivity.[285,286] Cells at this stage have a short half-life of only a few days, compared to mature follicular B cells with a half-life measured in months. They can be distinguished by surface phenotype from other B cells based on expression of certain combinations of markers, such as IgM+IgD−, absence of CD23, and high-level expression of CD24/HSA.[287] Recently, there have been reports of single markers that are useful in distinguishing newly formed cells from

any mature subset, such as the molecules recognized by monoclonal antibodies 493[288] and AA4.1.[289] The AA4.1 target molecule has been cloned and identified as the mouse ortholog of a component of the human C1q receptor.[290]

Cells similar to newly formed B cells can be generated to varying extent during stromal cell culture of B-cell precursors, although the more primitive cycling pre-B or pro-B cells are usually more abundant and tend to increase in frequency with prolonged culture. It is possible to induce differentiation of B cells in these cultures by withdrawing IL-7, which induces a wave of small pre-B and then newly formed B-cell generation. Such cells do not persist for more than a day, unless the cultures are established from Bcl-2 transgenic mice,[131] suggesting that the short half-life of newly formed cells in these cultures, and possibly also in vivo, is due to their low level of antiapoptotic mediators. Both Bcl-2 and Bcl-X_L mRNA are present at only very low levels in these cells, in contrast with other B-lineage stages where either one or the other predominates. Overexpression of Bcl-X_L from a transgene results in accumulation of a population of pro-B phenotype cells with nonfunctional rearrangements,[291] implicating this protein in the process of pre-BCR selection of cells with functional rearrangements.

Peripheral Maturation Stages and Functional Subsets

Transitional B Cells

Newly formed immature B cells migrate to the spleen where they either die or undergo further maturation to a mature B cell. These maturing B cells can be subdivided based on differential expression of several surface proteins, including CD21, CD23, CD24/HSA, and AA4.1. These subdivisions have been referred to as "transitional B cells."[292] One recent subdivision based on CD21, CD23, AA4.1, and IgM levels has shown progression from an AA4.1+CD21−CD23− T1 stage to an AA4.1+CD21-CD23+ T2 stage, followed by down-regulation of IgM as a T3 stage, and finally loss of AA4.1 with upregulation of CD21 to yield the mature follicular phenotype.[289] As shown in Figure 8.12, this approach also resolves two AA4.1- subsets that lack CD23, the B-1 subset with low CD21 and the MZ subset with very high CD21 (see following). The transitional stage cells are all short-lived as shown by bromodeoxyuridine incorporation.[289,293] They are also not functionally competent, as shown by inability to proliferate after BCR cross-linking.[287,294] Another well-characterized functional distinction is that B-cell tolerance, rather than an immune response, is induced by BCR cross-linking of immature B cells.[295,296,297] More recent studies with transgenic models of self-reactivity have shown that these B cells can be deleted, undergo receptor editing, or rendered functionally unresponsive (anergic) by BCR signaling at the immature stage.[281,285,298,299,300,301,302] One group has suggested that the "T3" stage is not an intermediate in production of follicular B cells, but rather a population of autoreactive anergic cells,[303] so additional work needs to be done to establish the identities of all the B-cell subpopulations present in spleen. For example, careful comparison of T1 and T2 B-cell populations shows that a fraction of T2 cells do respond to certain microenvironmental stimuli and include a portion of cycling cells that appear to constitute a branchpoint in generation of MZ B cells.[304]

It is not simply the inability to receive T-cell help due to differences in microenvironment or receptor expression that makes immature B cells incapable of responding as mature B cells. Different from the result with mature B cells, cross-linking the BCR on immature B cells has been shown to induce apoptosis, suggesting distinctions in the signaling pathways between these two stages.[305,306] Studies with transgenic mice suggest that this apoptosis is not mediated through the Fas/Fas-ligand pathway, as central deletion is intact in Fas-mutant mice.[307,308] Prior to induction of apoptosis, immature B cells have been shown to complete

some of the early events associated with entry into cell cycle while failing to complete this program.[309] Distinct stages in maturation appear more or less capable of responding to BCR cross-linking by reinduction (or maintenance) of Rags to facilitate receptor editing.[286] Furthermore, it appears that immature B cells are more sensitive to smaller changes in intracellular free calcium, compared to mature B cells.[310] It is possible that the capacity to upregulate antiapoptotic molecules, such as A1, may play a critical role in the inability of immature B cells to survive and complete a normal response.[311,312] The characterization of signaling pathways in different immature stages of developing B cells is ongoing and should eventually provide insights into the detailed mechanism for immature B-cell tolerance.

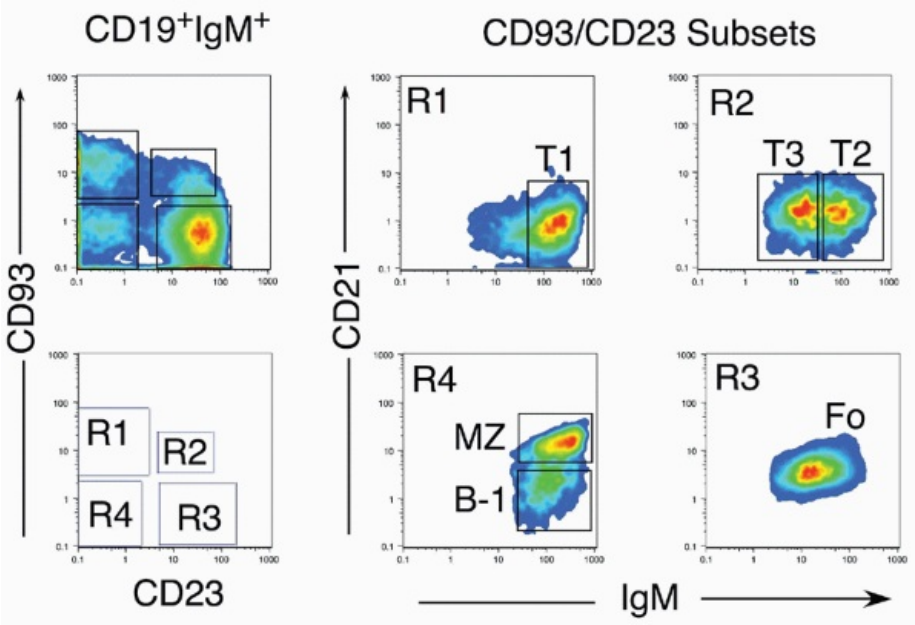

FIG 8.12. Flow Cytometry Approach for Resolution of Transitional (T1-T3) and Mature (Follicular, B1, Marginal Zone) Populations of B Cells in Mouse Spleen. Left panels show the distribution of AA4.1 and cluster of differentiation (CD)23 on B cells (defined as CD19+immunoglobulin [Ig] M+). Cells in the boxed regions are then analyzed for correlated expression of CD21 and IgM, facilitating resolution of three AA4.1+ fractions (T1-T3), the follicular subset (AA4.1−CD23+CD21+), the marginal zone subset (AA4.1−CD23−CD21++), and the B-1 subset (AA4.1−CD23−$CD21^{low}$).

Analyses of various normally occurring or engineered mutant mice have provided approaches

for investigation of the process of progressing from a newly formed B cell to a mature follicular B cell. B-cell populations and B-cell function has been studied for many years in CBA/N mice bearing the xid mutation. This mouse has a mutation in the Btk gene that produces a milder phenotype than the complete absence of peripheral B cells seen in humans. The Btk gene likely plays a role at several stages of B-cell development and activation, which complicates the analysis, but it appears clear that one major consequence is altered BCR signaling that has a profound effect on progression through the various transitional stages in spleen. A likely consequence of diminished strength of BCR signaling is a compensatory requirement for higher surface BCR expression that eventually produces at decreased frequency a type of "mature" B cell that is still functionally handicapped.[313,314] Several groups have produced xid mice on a nu/nu T-cell less background that results in a more profound absence of mature B cells, suggesting a requirement for T cells or T cell-produced factors in the maturation of xid B cells.[315,316] A more recent variation of this type of investigation is the production of xid/CD40-deficient mice that show a similar deficit in mature B cells, suggesting a role for the CD40/CD40L interaction in the generation of mature B cells from transitional B cells, particularly when the BCR is handicapped by defective Btk.[317]

Lyn is a Src family protein kinase that is associated with the BCR and functions in signaling in mature B cells.[318] Lyn-deficient mice exhibit defects in maturation of immature cells,

suggesting a positive role for BCR/Lyn signaling at this stage, but these mice also develop a severe autoimmune condition, suggesting an additional negative regulatory role for Lyn in maintaining tolerance in mature B cells.[319,320] Cross-linking of the BCR on T2 and mature B cells results in c-Rel activation that upregulates antiapoptotic genes and the prosurvival BAFF receptor.[321] Furthermore, migration of early bone marrow emigrants to areas where T1 and T2 cell mature has been shown to depend on chemokine signaling that is disrupted in Rac1/Rac2 double-deficient mice.[322] Finally, progression of transitional cells to the mature B-cell stage is dependent on "tonic" BCR signaling, as mice engineered to express low-surface BCR levels, and, thereby lower tonic BCR signaling showed decreased generation of mature B cells.[323] Analysis of these mice suggested that maturation was dependent on activation of ERK via a signaling pathway requiring Ras. CD72 is a predominantly B-lineage restricted C-type lectin, and ligating this molecule was recognized for many years (when it was known as Lyb2) as having functional consequences.[324] Recent analyses of a CD72 null mouse has clarified its function in B-cell development and activation.[325] CD72 has been shown to recruit SHP-1 to the BCR, supporting a negative regulatory role in BCR activation.[326] Consistent with this model for CD72 function, null gene-targeted mice have been shown to produce B cells that are hyperresponsive.[325] Interestingly, late stages of B-cell development are affected, with fewer mature B cells and relatively normal numbers of immature B cells in spleen.[325] Thus, too intense signaling may also delay maturation of immature B cells.

A number of studies have demonstrated the important role that the phosphoinositide 3-kinase (PI3K) signaling pathway plays in the maturation of transitional cells and generation of mature B cells. Under conditions of normal tonic signaling, PI3K signaling inhibitors block the

normal downregulation of Rags in immature B cells and also decrease progression past this stage.[327] This BCR signal is dependent on CD19 and BCAP, a BCR complex adapter molecule,[328] and acts through AKT to activate PI3K. The survival of B cells at the mature stage has been shown to depend on an intact BCR. More recent work revealed that the survival of BCR-deficient B cells can be rescued by activation of the PI3K signaling pathway alone.[329]

Follicular B Cells

The major population of mature recirculating B cells in the spleen is located in the B-cell follicle region, hence the term follicular B cells. Entry into this anatomic site appears to constitute a final stage in maturation for developing bone marrow B cells, as competition for this site is compromised in several transgenic models of B-cell tolerance.[330,331,332,333] Cells in this compartment do not proliferate but persist in the resting state for several months. A conditional knockout study, eliminating expression of the BCR (by deleting the V region), revealed that expression of the BCR is required for cell survival.[232,233] It is not yet established whether this is due to "tonic signaling" (simple assembly of the BCR signaling complex) or instead reflects signaling by low-affinity binding to cross-reactive self-determinants, a kind of "positive selection." It is interesting to note that ablation of heavy chain from immature B cell, thereby eliminating any possibility of pre-BCR or BCR tonic signaling, results in a "reversion" of cell phenotype to an earlier developmental stage.[334] Finally, the maintenance of follicular B cells has been found to depend on the function of the c-Myb transcription factor due to its role in BAFF signaling[335] (see following section). The repertoire of the follicular B-cell pool appears to differ from the earlier immature splenic B-cell population, as assessed by sequence analysis of the light chain repertoire in heavy chain transgenic mice.[336] The approach of fixing the heavy chain and then examining the light chain repertoire simplifies the analysis, and the results of this study were interpreted to indicate that BCR-mediated antigen selection is indeed operating. However, the resolution of the analysis probably could not have rigorously excluded populations known to show V gene biases, such as B-1 or MZ B cells (see following sections), so further work will be required to provide convincing evidence of antigenic selection in the follicular B-cell pool.

B-Cell Migration and Maintenance

Newly formed B cells migrate from the bone marrow to the spleen, undergo further maturation in the red pulp, and eventually enter the follicle where they constitute the mature B-cell pool that recirculates. Their migration is dependent on chemokines/receptor interactions, notably the SLC(CCL21)/CCR7 interaction, as demonstrated by the inability of mature B cells to be retained normally in spleens of CCR7 null mice.[337] The role of the CXCR5 receptor on B cells in homing to the lymphoid follicle due a gradient of the B-lymphocyte chemoattractant CXCL13 is also well known, and CXCL13 can directly induce Ltα1β2 on the recruited cells.[338] Finally, it is also possible that the SDF1 (CXCL12)/CXCR4 interaction, critical for normal B lymphopoiesis, may also be important at this later stage, although investigation of this issue is complicated by the early defect. This is an ongoing area of investigation and may eventually be clarified by developmentally regulated gene targeting studies.

Recently, considerable interest has focused on the role of a tumor necrosis factor family member cytokine known variously as BAFF, BLyS, TALL-1, zTNF4, or THANK in the process of peripheral B-cell maturation.[339] BAFF is a tumor necrosis factor family member found to enhance survival of B cells or even produce autoimmunity in transgenic mice constitutively expressing it.[340,341] Initially, two receptors defined for BAFF, BCMA and TACI, provided a complex picture, as targeted inactivation of BCMA yielded no B-cell defect and deletion of TACI had increased B cell numbers (suggesting that TACI might be a negative regulator). This puzzle was resolved by identification of a third receptor, BAFF-R/BR3,[342,343] which was mutated in a strain of mice known to lack most mature B cells, A/WySnJ.[344] A second ligand, APRIL, can bind to BCMA and TACI, but not to BAFF/BR3, and this binding is proliferative rather than survival promoting.[345] Thus, the critical interaction for maintenance of follicular B cells is BAFF/BLyS with its receptor. B-1 cells are not deficient in A/WySnJ,[344] suggesting that their maintenance does not depend on this pathway

but instead is more BCR dependent. Interestingly, excessive levels of BAFF promote survival of highly autoreactive BCR transgenic mouse B cells, consistent with the finding of elevated levels in patients with autoimmune diseases such as systemic lupus erythematosus and Sjögren syndrome.[346]

Mechanism of B-Cell Receptor Signaling

Considering that the structure of the Ig molecule was elucidated more than 40 years ago, it is surprising that the details of initiation of B-cell activation following antigen binding are still not firmly established. Recent work using single-molecule imaging demonstrated that antigen binding altered the mobility of BCRs within microclusters on the B cell, resulting in rigid oligomeric structures that generated a signal.[347] Interestingly, this oligomerization required the membrane proximal domain of IgH-μ (Cμ), and such domains in isolation spontaneously formed aggregates in the membrane, leading to the hypothesis that antigen ligation induces a conformational change in Cμ4 that then promotes assembly of signaling clusters. Other work visualizing simple Ig molecules has demonstrated the importance of the membrane cytoskeleton in limiting diffusion of the BCR and revealed the importance of Igb/CD79b in mediating such restriction, showing that alterations in BCR distribution rapidly result in strong intracellular signaling.[348] Finally, an alternative model has been proposed, based on analysis using quantitative bifluorescence complementation, suggesting that preexisting BCR aggregates are less active in signaling, and that the disruption of such complexes upon antigen binding is responsible for generating a signal.[349] Additional work using such advanced imaging techniques will undoubtedly resolve this apparent contradiction and lead to a more complete understanding of BCR signaling.

B-Cell Turnover

It is estimated that 10 to 20 million B cells are produced in bone marrow of the mouse each day,[350] yet it appears that only about 10% of this number reach the periphery.[293] Thus, there is considerable loss at this bone marrow emigration stage/spleen entry stage, possibly due to elimination of autoreactive cells (B-cell tolerance) or to homeostatic regulation. The latter possibility is supported by the observation that depletion of the mature B-cell population

results in a relatively rapid recovery of this pool, suggesting that most of the immature B-cell population can enter the mature follicular subset in this situation.[351]

Once functionally mature B cells are generated, it has been difficult to unambiguously determine their half-life, although accumulating data from several laboratories using bromodeoxyuridine labeling has led to the idea that follicular B cells have a relatively long half-life on the order of months.[293,352] A recent elegant study provided definitive confirmation of this by conditional elimination of Rag-2 expression, allowing termination of B-cell development in adult mice.[353] This study showed that follicular B cells have a half-life of about 4.5 months. This same analysis showed that two other subsets of B cells, B-1 and MZ B cells, did not diminish over time, consistent with their well-known capacity for self-renewal and lifelong persistence.

Germinal Center B Cells

T cell-dependent immune responses usually give rise to anatomically distinctive structures in spleen and lymph nodes that are referred to as germinal centers (GCs) and contain large numbers of rapidly cycling B cells.[354,355] These cells can be recognized in stained sections of spleen by binding of high levels of peanut agglutinin and by the absence of IgD.[356,357] Many of the B cells with this phenotype have downregulated-Bcl-2/upregulated-Fas expression and, in the absence of strong BCR signaling, will likely die by apoptosis.[358,359,360,361] The termination of IgD expression means that surface BCR expression decreases at least 10-fold, and so limiting amounts of antigen will favor the cells with increased affinity for antigen, generated by a process termed *somatic hypermutation*. Recently, a miRNA, miR-155, has been found to be critical for the generation of GCs by regulating cytokine production.[362]

A major advance in understating the GC response has been the discovery that activation-induced cytidine deaminase (AID), an RNA-editing enzyme that can induce class switch recombination in fibroblasts,[363,364,365] is also a key player in the process of hypermutation.[366,367] In fact, a third means for Ig gene diversification used in nonmammalian species, V gene conversion, is also dependent on AID.[368,369] AID is now thought to be responsible for genetic mutations outside the Ig loci in lymphomas that arise from GC B cells.[370]

The precise mechanism of selection for higher affinity B cells generated by hypermutation of the BCR V regions remains to be fully understood, but the regulation of pro-apoptotic and antiapoptotic genes likely plays a major role. B cells able to bind antigen with high affinity can present antigen to specialized CD4+ T cells (follicular helper T cells) that then signal the B cell through a CD40/CD40L interaction, resulting in the upregulation of Bcl-X_L.[358,359,360] Most GC B cells have sharply downregulated levels of Bcl-2 and up-regulated levels of Fas,[360,361] and so in the absence of rescue by expression of the alternative antiapoptotic mediator Bcl-X_L, cell death by apoptosis will be the fate of most B cells in the GC. Careful regulation of selection is critical to affinity maturation, and elimination of self-reactive cells that potentially could be generated during this process must also occur efficiently to avoid the potential of autoimmune disease. Recently, the role of the immunoinhibitory receptor PD-1,

present at high levels on follicular helper T cells, in GC B-cell selection has been described.[371] Furthermore, high-resolution imaging of fluorescent reporters is revealing details of cell dynamics within the GC, indicating that competition for T-cell help is a key limiting factor in the selection of higher affinity B cells.[372]

Memory B Cells

Memory B cells were initially defined functionally as cells that could respond rapidly by production of high-affinity antibody when challenged in a host reconstituted with B cells and T cells from a primed animal.[373,374,375,376,377,378] Subsequently, such cells have been purified based on their antigen-binding properties[379] and shown to consist primarily of isotype-switched (IgG+) B cells that continue to express CD45R/B220 and have distinctively

lower levels of cell surface BCR.[380] They arise during the T cell-dependent immune response, probably only from follicular B cells, in the GC. They are very long-lived or self-regenerating, as cell transfer assays have shown that memory responses can be detected for long periods after the primary immunization.[380,381] More recent work has focused on examining the heterogeneity of secondary B-cell subsets, examining cell surface proteins that may aid in distinguishing them.[382] In terms of genes that distinguish memory B cells, it appears that phospholipase C gamma 2 is important both for the generation and maintenance of memory B cells.[383]

It is not clear whether all B cells are capable of giving rise to memory B cells. Memory or "secondary" B cells were originally described as expressing distinctively low levels of CD24/HSA, recognized by the monoclonal antibody J11d.[384] Some years later, fractionation of naïve spleen B-cell precursors into J11d^{low} and J11d^{high} subsets in a spleen focus assay system showed that while rapid antibody secretion derived from J11d^{high} cells, memory came largely from the J11d^{low} subset.[385] Subsequent experiments demonstrated that GCs (the site where most memory B cells are generated) were only produced in cell transfers of J11d^{low} B cells and not with J11d^{high} or CD5+ B cells.[386] Considering the rapid Ig secretory response of B1 B cells and MZ B cells, both contained in the CD24/HSA^{high} fraction, and the fact that most other CD24/HSA^{high} cells are immature (transitional) B cells, likely to be highly susceptible to apoptosis, it seems quite reasonable that memory B cells would not be a major product of this fraction. Rather, the most likely candidate for the memory B-cell precursor is the follicular B-cell subset (Fo), which has variable but lower expression of CD24/HSA. Whether there is heterogeneity for GC formation or memory B-cell generation within the Fo population remains to be determined.

Whether the maintenance of memory requires periodic restimulation by antigen has been a longstanding controversial issue. On the one hand, transfer of B cells and T cells into irradiated recipients usually required simultaneous challenge with antigen in order to elicit the full response and maintain B-cell memory in recipients.[387] Antigenic fragments can persist for very extended periods on follicular dendritic cells, which are very potent antigen-presenting cells, and, so in this model, the memory B cells are periodically triggered to self-

renew by interaction with antigen on follicular dendritic cells. However, on the other hand, memory B cells can be maintained in the apparent absence of T cells or follicular dendritic cells.[388,389] Furthermore, analysis by bromodeoxyuridine labeling of memory B-cell populations showed that they were nondividing.[381] This issue has been addressed in elegant experiments using inducible Cre recombinase to switch the BCR on memory cells away from the immunizing antigen.[390] Such antigen-negative memory cells still persisted for extended periods, clearly demonstrating that this was a physiologic property of the cell type, independent of the presence of antigen.

B1 B Cells

B1 B cells, initially described as Ly-1/CD5+ B cells, are distinguished from follicular B cells by phenotype, anatomic distribution, and function.[23,391] The B1 B-cell phenotype encompasses both CD5+ and CD5− B cells that are IgM^{high}, $IgD^{low/-}$, CD23−, and CD43+. They constitute a large proportion of the B cells found in the peritoneal and pleural cavities (30% to 50% of B cells, around 10^6 cells), but are also found in spleen where they are present at numerically similar levels, but constitute a much lower proportion of the total B-cell pool (2% of B cells, around 10^6 cells). The B1 B cells in the peritoneal cavity are also CD11b/Mac-1+ unlike those in spleen. They appear early in ontogeny, representing 30% or more of the B cells in spleen of 1-week-old animals. They also have a distinctively higher frequency of λ light chain usage compared to follicular B cells (20% vs 5%). Also unlike follicular B cells, they maintain their population in adult animals largely by self-renewal (possibly dependent on periodic stimulation by self-antigen; see following discussion), rather than by input from precursor cells, as shown in cell transfer studies.[392] There is also a recently described population of IgM-secreting cells in bone marrow with a B1 cell surface phenotype.[393] Perhaps the most distinctive feature of CD5+/B1 B cells is their enrichment of certain self-reactive specificities, notably for branched carbohydrates, glycolipids, and glycoproteins, including phosphorylcholine, phosphatidylcholine (PtC), the Thy-1 glycoprotein, and bacterial cell wall constituents.[394,395,396,397] These antibodies, although autoantibodies, are not pathogenic, but rather referred to as “natural autoantibodies” whose existence has been recognized in serum for several decades.[398,399,400] Their function is still under active investigation, but at least some natural autoantibodies are thought to function in clearance of senescent cells or proteins and to provide an initial immunity to common bacterial or viral pathogens, serving as a kind of “hardwired” memory B-cell population.[401,402,403,404]

Under physiologic conditions in normal mice, most of the CD5+ B cells in the B1 population (so called “B1a B cells”) arise from precursors in fetal liver, as cell transfer studies showed many years ago that B cells with this phenotype were inefficiently generated from bone marrow precursors in adult mice, compared to fetal or neonatal precursors.[405] This is shown by repopulation of SCID mice by pro-B stage cells isolated from fetal liver and adult bone marrow (Fig. 8.13). Part of the reason for this difference may be that novel BCRs are enriched by distinctive mechanisms of fetal B lymphopoiesis, including recombination in the absence of TdT (thereby favoring rearrangement of certain D-J and V-D junctions possessing short regions of homology[16]) and distinctive pre-BCR selection.[263,273,406]

Forced expression of transgenic BCRs cloned from CD5+ B cells can give rise to CD5+ B cells from bone marrow of adult animals, but the physiologic relevance of this remains to be carefully assessed. B1 B cells that lack CD5, termed B1b B cells, can be generated from bone marrow and a distinctive phenotype for a precursor capable of producing such cells has been described,[162] although the developmental relationships between conventional ("B2") B-cell precursors and these cells are complex.[407] Embryonic day 9 YS hematopoietic progenitors have been sown to give rise to B1 and MZ B cells but not conventional follicular B cells. The development of B1/CD5+ B cells is thought to be more dependent on antigenic selection compared to follicular B cells. This idea was first suggested by the finding of particular specificities enriched in this population and

strengthened by the observation of repeated occurrences of particular V_H/V_L pairs.[408] Thus, for example, the anti-PtC specificity is predominantly encoded by V_H11V_K9 and $V_H12V\kappa4$ utilizing two V_H genes rarely found in conventional T-dependent immune responses.[395,409] These cells appear to participate in T-independent responses, but in normal physiology may in fact provide an initial low-affinity "first wave" response to many pathogens that eventually will also elicit a T-dependent response.[404,410]

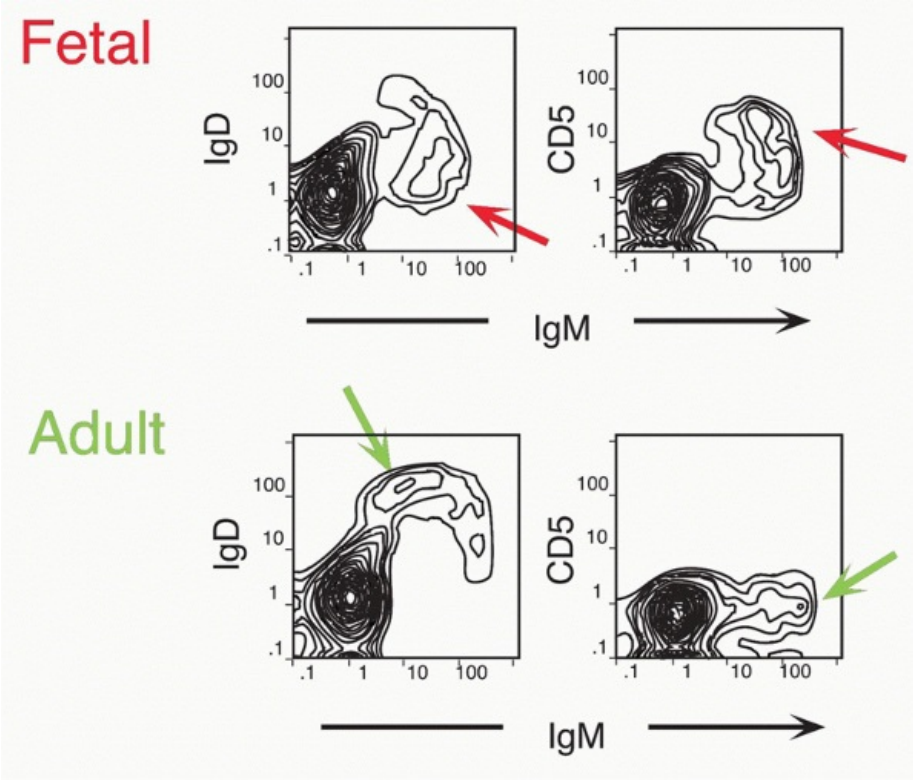

FIG 8.13. Generation of B Cells in Severe Combined Immunodeficiency (SCID) Mice Shows the Distinctive Phenotypes Produced from Fetal and Adult Pro-B Cells. Similar numbers of pro-B cells, isolated as in Figure 8.5, Fr. B/C, were injected intravenously into sublethally irradiated adult SCID mice. Recipients were analyzed 3 weeks later for spleen cell lymphocytes by staining as shown in the figure.

The observation of their self-reactive bias, their capacity for self-renewal, and their restricted repertoire of distinctive BCRs all are consistent with an important role for BCR-antigen interaction in generation and maintenance of this population. This has been formally confirmed recently by studying mice bearing a BCR transgene specific for a glycosylation present only on the Thy-1 membrane protein.[411] In these mice, transgene-encoded serum anti-Thy-1 autoantibody[396] was readily detected, and there was a corresponding accumulation of a population of CD5+ transgene BCR+ B cells in the peritoneal cavity. Importantly, in Thy-1 null mice generated by gene targeting, neither serum autoantibody nor the B-cell population was found, demonstrating the critical role for antigen in selection of this B-cell population.[412]

Consistent with the importance of antigen selection in the generation and/or maintenance of these cells, this population is often severely affected in mice bearing mutations that alter BCR signaling intensity. The loss of negative mediators such as PTP1C/SHP-1 in “moth-eaten” mice,[413] of CD72 that recruits this phosphatase,[413] and of the CD22 coreceptor[414,415] all result in an increased frequency of B1/CD5+ B cells relative to follicular B cells. On the other hand, the loss of critical BCR signaling components or positive mediators in this pathway such as an Ig-α tail mutant,[416] Btk deficiency (in xid or Btk null mice),[417,418] CD19 null mice,[419,420] CD21 null mice,[421] CD45 null mice,[410] and vav null mice[422] all negatively impact this B-cell population. A further indication of a signal-dependent selection model is the accumulation of B1-type B cells with high-level expression of a BCR surrogate, LMP2A, but only B2 B cells and MZ B cells with low-level expression.[423]

The functional role of B1 B cells is still incompletely understood. Whereas it is clear that they produce natural autoantibody, there also is evidence for their participation in immune responses. B1 B cells have also been shown to accumulate in draining lymph nodes of the respiratory tract during influenza infection of mice.[393] Treatment of mice with *Francisella tularensis*-derived lipopolysaccharide protects them from subsequent exposure to the live bacteria (the etiologic agent of tularemia) by activating a small fractions of B1 B cells with this antigen specificity.[424]

IL-10 is a cytokine with anti-inflammatory properties that also enhances B-cell survival and antibody production. Thus, it can function to damping down cellular immune responses and promote humoral immunity. Many years ago, B1 B cells were identified as the B-cell source of this cytokine that is also secreted by monocytes, mast cells, and regulatory T cells.[425] Recently, based on observations of alterations in the level of inflammation in mice lacking or overexpressing CD19, a CD1d(high) subset of B-1 cells expressing IL-10 has been identified.[426] Considering the anti-inflammatory regulatory effects of IL-10, this subset has been referred to as “B Regs” or “B10” B cells. Investigation of this subset in the experimental autoimmune encephalomyelitis mouse

model of multiple sclerosis showed that initiation and progression of disease was influenced reciprocally by depletion of B cells. Because experimental autoimmune encephalomyelitis is considered a T cell-mediated disease, this provides strong evidence for the capacity of B1 cells in modulating T cells during the initiation of disease. Curiously, depleting B cells after

experimental autoimmune encephalomyelitis was already established actually diminished symptoms, indicting that B cells were required for persistence of autoreactive T cells. This suggests that simple depletion of all B cells in certain autoreactive pathologies may have different consequences, depending on the progression of the disease. Finally, examination of B10 function in the autoimmune lupus-prone NZB/W mouse F1 indicated that these cells were responsible for inducing regulatory T cells that could ameliorate the course of disease in these animals.[427]

Marginal Zone B Cells

Another B-cell subset distinct from follicular B cells is the MZ B-cell population. MZ B cells are localized in a distinct anatomic region of the spleen that represents the major antigen filtering and scavenging area (by specialized macrophages resident there). It appears that they are preselected to express a BCR repertoire similar to B1 B cells biased toward bacterial cell wall constituents[428] and senescent self-components (such as oxidized low-density lipoprotein [LDL]).[429,430] Similar to B1 B cells, they respond very rapidly to antigenic challenge, likely independently of T cells, but participating in the early phase of T-dependent responses.[431,432,433] Uniquely, among all populations of B cells, MZ B cells are dependent on Notch2 signaling for their development.[434,435]

There are similarities and differences in the cell surface phenotype of MZ and B-1 B cells. Thus, they both are IgM+++IgD-/+, CD23-, and CD9+.[436] However while B1/CD5+ B cells express CD5 and CD43, MZ B cells do not, and MZ B cells express distinctively high levels of CD21, while B1 cells have distinctively low levels (see Fig. 8.12). Also, MZ B cells have high levels of CD1d, while most B1 B cells do not,[437] the exception being the “B10” subset mentioned previously. Certain mutant mice show similar effects on MZ and B1 B cells, distinct from follicular B cells. For example, most of the mutations described for B1 B cells that alter BCR signaling have similar consequences for MZ B cells,[438] although cells that resemble MZ B cells are present in xid/Btk-deficient mice, leading to some controversy in their origins.[439] Both are decreased by a mutation in the Ig-α tail that weakens overall BCR signaling.[440] They are also both decreased in the Aiolos transcription factor null mouse.[63] Interestingly, deletion of the Pyk-2 tyrosine kinase results in elimination of MZ B cells while B1 cells are still found.[441] MZ B-cell development can be studied in a heavy chain transgenic mouse model system where large numbers of such cells are produced.[428,442] In this V_H81X heavy chain mouse, B cells with a specific light chain accumulate with an MZ phenotype. This MZ population is eliminated by deletion of CD19, Btk, or CD45, all genetic changes that weaken BCR signaling.[438] MZ B cells are generated in mice even when B-cell development is blocked shortly after birth by conditional deletion of Rag-2,[353] showing that like B1 B cells, a significant portion of MZ B cells are produced during fetal development. Consistent with this fetal origin, many MZ B cells have Ig heavy chains with little or no TdT-mediated N-regions at their V-D and D-J junctions.[443] Interestingly, irradiated mice repopulated with bone marrow precursors still accumulate significant numbers of MZ B cells with low levels on N-addition, indicating that the strong BCR-mediated selection guiding entry into this subset can select such cells from adult bone marrow-generated B cells. In recent

years, there has been considerable progress in understating some of the non-BCR-related pathways that regulate the generation of MZ B cells. For example, the can-nabinoid receptor 2 appears important in localization of MZ B-cell precursors to the anatomic region where Notch signals are available.[444] Notch ligand expression for generation of MZ B cells is regulated by the E3 ubiquitin ligase Mind bomb 1, which also is critical for T-cell development.[445] Furthermore, Notch2 activation in MZ B cells is potentiated by expression of the fringe glycosyltransferases lunatic fringe and manic fringe.[446] Notch activation requires its proteolysis, and this is now known to occur through activity of a disintegrin and metalloproteinase 10 (ADAM10).[447]

B-Cell Tolerance and Receptor Editing

A number of transgenic mouse models have been developed for the study of B-cell tolerance (Table 8.2). In two of these systems, high-affinity BCRs are expressed as IgM-IgD transgenes, one specific for the antigen hen egg white lysozyme (HEL), the other for a specific polymorphic determinant on MHC class I.[281,298,299,300,448,449,450] The advantage of these systems is that they utilize antigens that can be regulated: Transgenic B cells can develop in either the presence or absence of antigen, and cell transfer experiments can be employed to alter the B cell's antigenic milieu. These have been used initially to confirm ideas on B-cell tolerance that originated in work with nontransgenic B cells, namely that exposure to antigen is generally deleterious to developing B cells, resulting in their elimination or failure to mature (instead entering an “anergic” state). However, the resolution of these systems, coupled with advances in gene targeting and other molecular technologies, have uncovered important new details regarding the way that self-reactive B cells develop (or fail to develop). For example, studies in the anti-H-2 model uncovered an alternative to deletion in response to immature B-cell encounter with antigen, BCR editing to escape autoreactivity.[281]

In the HEL system, differences have been discovered in immature B-cell responses to soluble versus membrane-bound antigen, suggesting that the extent of BCR cross-linking can influence cell fate.[299] Furthermore, studies with this system on different mutant backgrounds that shift BCR signaling thresholds up or down has shown that such alterations can result in striking alterations in selection outcomes.[451,452] Work in this system has shown that one consequence of B-cell tolerance may be arrest of B-cell migration so that follicular entry is inefficient.[330,331] Presumably, failure to reach such follicular niches contributes to handicapping the autoreactive B cells, resulting in their relatively speedy elimination.

TABLE 8.2 Transgenic Models of B-Cell Tolerance

Ig Transgene	Antigen	Background	Effect	Reference
3-83 μk	MHC class I	H-2Kk	Deletion, receptor	281,300,450

			editing	
	H2-Kk,b	H2-Kd	Normal development	
3-83 μk	MHC class I	H-2Kk lpr autoimmune-prone	Deletion unaffected	308
	H-2Kk,b			
anti-HEL μδ	HEL	sHEL-Tg	Anergy	298,448,449
		Wild-type	Normal development	
anti-HEL μδ	HEL	mHEL-TG	Deletion	299
anti-HEL μδ	HEL	HEL-Tg lpr autoimmune prone	Deletion unaffected	307
anti-HEL μδ	HEL	sHEL-Tg	Self-antigen promoted	452
		CD45 null	development	
anti-HEL μδ	HEL	sHEL-Tg motheaten	Deletion by lower valency autoantigen	451
3H9 μ-only	ssDNA with many light chains	BALB/c	No anti-DNA autoantibodies	301
3H9 μ-only	ssDNA with many light chains	lpr Autoimmune-prone	Anti-DNA autoantibodies	597
3H9 μκ	dsDNA	BALB/c	Deletion, editing	302
3H9 μκ	dsDNA	J_H^-/J_K^-	Deletion	285

3H9 μλ	dsDNA	Wild-type and lpr Autoimmune prone	Anergy	332,333
3H9-R/Vκ4-R	dsDNA	BALB/c	Deletion, editing	598
3H9-R/Vκ8-R	ssDNA		anergy	
3H9-R/Vκ4-R	dsDNA, ssDNA	Rag-2$^-$	Deletion, activation	599
3H9-R/Vκ8-R				
3H9/56R	dsDNA, ssDNA	BALB/c	Deletion, editing	600
3H9/56R76R				
Antierythrocyte	Red blood cell	Wild-type	Tg$^+$ cells only in peritoneal cavity	457,458,459
$V_H11^μ$, $V_H12μ$	PtC, BrMRBC	Wild-type	Increased number of B1 B cells	601,602
6C10μ	ATA determinant (glycosylation of Thy-1)	Wild-type Thy-1 null	ATA B cells ATA serum Normal development; no ATA	412
ATA μκ (6C10μVκ21c)	ATA determinant	Wild-type	Receptor editing or development block in bone marrow; ATA in serum	464,465
		Thy-1 null	Normal development	

ATA, antithymocyte autoantibody; DNA, deoxyribonucleic acid; HEL, hen egg white lysozyme; Ig, immunoglobulin; MHC, major histocompatibility complex.

Another major line of investigation has focused on a more “physiologic” example of pathogenic autoreactivity, the anti-DNA antibodies produced in lpr (Fas-deficient) mice that are generally considered to model the human disease of systemic lupus erythematosus. Analysis of transgenic mice bearing a heavy chain transgene known to be capable of generating anti-dsDNA reactivity with numerous light chains showed that only light chains with ssDNA activity were tolerated in the periphery, and even these did not contribute to the serum antibody pool.[301] Follow-up work uncovered receptor editing in this model[302,453,454,455] and also showed that when such editing was blocked, the B cells were eliminated in the bone marrow at an immature stage.[285]

Receptor editing, due to failure of Rag downregulation, in replacement of the original light chain by a different one, resulted in decrease or elimination of autoreactivity. Although discovered in several BCR transgenic models, it also occurs at some level in the newly formed B-cell stage in bone marrow, as random pairing of heavy and light chains will result in autoreactivity by some of these cells. Studies with a NF-κB-dependent IκB alpha gene reporter mouse revealed that autoreactive BCRs resulted in activation of the reporter and that reporter+ cells have elevated levels of IRF4, indicating that BCR cross-linking by self-antigen signals through a NF-κB pathway and acts through IRF4 to regulate receptor editing.[456]

Later work analyzing transgenic B cells expressing λ light chain (or in kappa null mice) where B cells have dsDNA binding has shown the failure of follicular entry previously described in the HEL system.[332,333] Interestingly, similar analyses on an “autoreactive” (Fas-deficient) background have shown that this follicular exclusion is lost and production of pathogenic autoantibodies ensues, providing a powerful model for the further characterization of the development of autoimmunity due to breakdown of B-cell tolerance.

A different model of a pathogenic antierythrocyte autoantibody has shown another possible mechanism whereby

self-reactive B cells may avoid deletion or receptor editing by sequestration from self-antigen.[457,458] In this system, the transgenic

B cells are largely absent from spleen but instead survive in the peritoneal cavity where exposure to the distinctive microenvironment may also contribute to the persistence of these cells. Eventual activation of the B cells by mitogen or antigen can lead to an autoimmune condition in these mice.[459] B cells may express BCR coreceptors or modulators of signaling pathways that change the response to self-antigen cross-linking. For example, it appears that enzymatic acetylation and deacetylation of a cell surface carbohydrate by sialate: O-acetylesterase alters B-cell responsiveness, by regulating the function of CD22, a sialic acid binding Ig-like lectin (siglec) that inhibits BCR signaling.[460] As mentioned previously, the level of CD19 also modulates BCR signaling and selection, such that altering CD19 expression can alter the frequency of B1 B cells. Recent work has revealed that mutation of

the Wiskott-Aldrich syndrome protein selectively in B cells results in severe autoimmunity due to BCR and TLR hyperresponsiveness.[461]

A common thread in all of the studies described here is the negative impact that the B cell experiences upon interaction with self-antigen, an expected result for systems that model the regulation of pathogenic autoantibodies. However, a class of autoantibodies is produced in healthy individuals, and these "natural autoantibodies" may play a role in early responses to certain classes of pathogens.[401,402,404,462] Such a natural autoantibody has been used to construct a transgenic model system where the self-antigen can be regulated. Most natural self-antigens are common glycosylations or cell constituents such as PtC that cannot be eliminated, but a class of natural autoantibodies binds to thymocytes (antithymocyte autoantibody [ATA]) and many of these recognize a glycosylation that is only present on the abundant thymocyte cell surface glycoprotein CD90/Thy-1.[412] Thy-1-null mice have already been generated,[463] so production of ATA-BCR μ-only transgenic mice enabled the study of the role of antigen in the generation of this natural autoantibody. Interestingly, both production of serum ATA and accumulation of B cells with the appropriate light chain (by rearrangement of endogenous Ig light chain locus) for the ATA-BCR required the presence of Thy-1 self-antigen.[412] Thus, at least some B cells are selected for binding to self-antigen, although these may belong exclusively to specialized B-cell compartments, such as the B1 B-cell subset.

This ATA-BCR/Thy-1 tolerance model has been extended by the production of ATA μκ transgenic mice, where most developing B cells express the natural autoreactive specificity.[464] In such mice, most of B cells developing from bone marrow become arrested in spleen and either cease maturation or else "edit" their BCR by replacing the transgene-encoded light chain by a different light chain as a consequence of rearranging the endogenous light chain locus. This resembles typical "negative selection," as seen with other transgenic models.[281,298,299,300,448,450] Nevertheless, some B1 B cells are detected, and high levels of serum autoantibody are produced, suggesting that some B cells with this BCR are capable of maturing, perhaps in specialized microenvironments or at distinctive (fetal/neonatal) times.

The role of BCR signaling intensity in directing B cells to various specialized subpopulations has been studied using the ATA μκ BCR transgenic model, by altering the levels of Thy-1 self-antigen and then examining B-cell development.[465] This analysis observed follicular B-cell development in the absence of antigen, but MZ B-cell production in the presence of very low levels of autoantigen. As shown previously, normal physiologic levels of the Thy-1 autoantigen results in a block in bone marrow development, but allowed B1 production, with concomitant generation of ATA detected in serum. This work led the authors to propose a model of B-cell development where strong BCR signaling produces B1 B cells (particularly during fetal development), intermediate BCR signaling yields MZ B cells, and weak (or negligible) BCR signaling results in follicular B-cell generation.

Role of Complement, Serum Antibody, and Cluster of Differentiation 5 in B-Cell Tolerance and Response

The importance of complement in the immune system has long been recognized based on

classic experiments showing that cobra toxin decreased responses.[466,467,468] Over the past 10 years, the importance of complement in immune responses, explaining the function of adjuvants, has become clearer.[469] In the context of B-cell development, components of the complement system also play a role in modulating BCR responses and negative selection of B cells. At least in the HEL-Ig/sHEL system, altering the strength of the BCR signal, by CD45R or PTP1C/SHP1 inactivation, could either reduce or enhance B-cell deletion.[452] Similar results could be obtained by altering the BCR-associated chain CD19.[470] Considering the role of complement as a coreceptor for modulating BCR signaling thresholds, the finding that HEL double transgenic mice that also are Cr2 (CD21/CD35) null develop peripheral B cells that are apparently not fully anergized, as they could still respond to antigen challenge.[471] This could be due to an inefficient retention of antigen (sHEL) on stromal/dendritic cells and, therefore, weaker signaling by a monomeric soluble antigen to developing/transitional B cells in the bone marrow or spleen. Potentially, a major role for complement would be to localize self-antigens on bone marrow stromal and dendritic cells facilitating tolerance at the newly formed B-cell stage. An implication of these findings is that complement deficiency could result in accumulation of functional autoreactive cells, possibly leading to autoimmunity. Natural autoantibody, a major component of the serum, may have a role (together with complement) in maintaining tolerance to highly conserved self-antigens.[469] Some such IgM antibodies, highly conserved phylogenetically, have been shown to recognize conserved carbohydrates beta-glucan and chitin structures present on fungi and so serve to enhance host defense.[472] It also appears that it plays a role in amplifying immune responses, as suggested by studies with a mutant mouse lacking the μ heavy chain secretory exon.[473] The deficit due to a lack of serum IgM was particularly severe in an acute peritonitis model, where some restoration of responsiveness could be obtained by injection of a monoclonal IgM antibody derived from CD5+ B cells.[473] Finally, in infection with influenza virus, it appears that early presence

of natural autoantibody was equally as important as antibody induced during the course of infection in mediating viral clearance and survival.[404] This work has led to the proposal of a two-phase description of immune responses, with an early T cell-independent phase dominated by natural autoantibody, likely critically dependent on innate immune recognition and activation of complement, leading to a later T cell-dependent phase culminating in the GC reaction, producing high-affinity antibody and memory B cells.[474]

The presence of CD5 on many of the B1 B cells has led to the question of whether it plays a direct role in maintaining such self-reactive B cells, particularly in light of its role in altering T-cell selection thresholds as demonstrated in the CD5-null mouse.[475] Analysis of B-cell responses to BCR cross-linking in CD5-null mice suggested that the presence of CD5 makes the normal population less likely to respond by secreting IgM,[476] effectively “raising the threshold” for their response, possibly by promoting interaction of the BCR with SHP-1.[477] Analysis of the effect of CD5 expression on tolerance in the HEL-Ig/sHEL system also suggested a modulating role, with absence of CD5 leading to a loss of B-cell tolerance and production of serum anti-HEL autoantibody.[478]

B-CELL DEVELOPMENT IN HUMANS: SIMILARITIES AND DIFFERENCES FROM MOUSE

Fetal Development

As described for mouse, human B-cell development can be broadly divided into that taking place prior to birth and that operating after birth and throughout life. The liver and spleen are major sits of fetal B lymphopoiesis in humans and, as in mouse, the bone marrow is the predominant site in adults, with production continuing over most of an individual's lifespan, with some decrease in the aged. The fetal omentum has also been described as a site for B-cell development similar to mouse.[9,479] There is some indication that VH gene usage is more restrictive in fetal development.[480] TdT, absent from mouse fetal development, is similarly missing very early in human fetal development but is expressed by the eighth or ninth week of gestation based on detection of N-region addition.[480] In general, there is more N-addition (and consequently longer CDR3 regions) in human antibodies compared to mouse at all stages of development, including the adult, although the significance of this is not known. Analysis of human T-cell development indicates that fetal and adult T cells arise from distinct developmental pathways, with fetal cells allowing more self-reactivity to persist[481] similar to mouse.[482] Finally, as recently described in mouse, B cells with the capacity to rapidly secrete IL-10 have also been identified in humans, and such cells appear to be increased in patients with autoimmune disease, such as rheumatoid arthritis.[483]

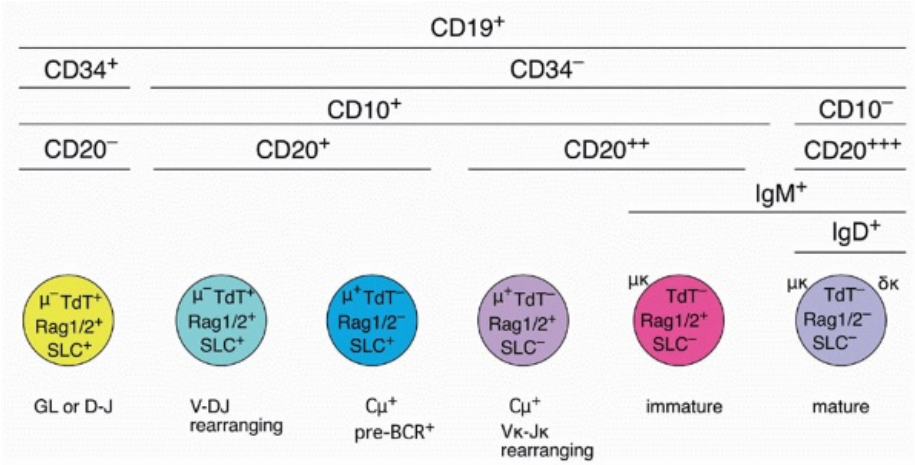

FIG. 8.14. Stages of Developing B-Lineage Cells in Human Bone Marrow can be Delineated, Based on Expression of Combinations of Cell Surface Proteins, Similar to Mouse.

Bone Marrow Development

B-cell development can be detected in human bone marrow from 20 weeks of gestation and continues throughout life.[484,485] Phenotypic subdivisions similar to those in the mouse have been described for developing bone marrow cells[486] (Fig. 8.14). Thus, CD19 identifies B-lineage cells at all stages, with the earliest stages also expressing CD34, a molecule found

on MLPs.[487] These CD19+CD34+ cells have been shown to express TdT, Rag-1 and Rag-2, the SLC orthologs,

and Ig-α/Ig-β.[486] They contain D-J, but not productive VDJ rearrangements. The next stage can be defined by loss of CD34, with a fraction that is still IgM− (pre-B cells) and another subset that is IgM+. The pre-B cells express heavy chain in their cytoplasm and have downregulated expression of TdT.[486] All of the IgM+ cells express a marker lost upon final maturation, CD10, so they are immature B cells. A recent study examined the B-lineage potential of cells expressing different levels of CD10 and found that increasing levels of this molecule were found on more differentiated B-lineage cells, suggesting its potential for identifying distinctive stages in B-cell development in humans.[488] Human early B-lineage cells have proven much more difficult to grow in culture than mouse cells, although conditions have now been defined that allow their expansion in vitro. One of the most surprising differences between mouse and human B precursor growth has been much less dependence on IL-7, suggesting that a different cytokine may substitute in humans.[489,490,491] The finding that lack of the cytokine common gamma chain (λc) in mouse blocks B-cell development but spares T-cell development, whereas the reverse is the case in humans,[154,492] demonstrates clear differences in cytokine dependence between mouse and human lymphopoiesis.

Human B precursors also express orthologs of λ5 and VpreB, although their organization and number differ from the mouse.[493,494,495] Their expression occurs at a corresponding stage and analysis of the human EBF gene has shown that its targets are similar to those of mouse EBF, including Ig-α, Ig-β, and 14.1 (the human ortholog of λ5).[496] Importantly, mutations in components of the pre-BCR lead to immunodeficiency diseases in humans, pointing out the similar and crucial role that pre-BCR signaling plays in human B-cell development.[497,498,499]

Germinal Center Differentiation

As in mouse, GCs are anatomic structures in secondary lymphoid organs where T-dependent immune responses occur, selecting high-affinity clones during the process of somatic hypermutation and eventually generating memory B cells. The GC consists of B cells at a variety of differentiation states, from early activated B cells through the plasmablast stage. Therefore, study of this process has benefited significantly from resolution of intermediate stages using multiparameter flow cytometry and carefully chosen cell surface markers. In one study, this allowed definition of two IgD+ stages, two GC stages, and a memory stage in tonsillar B cells.[500] This work focused on the levels of somatic mutations accumulating as cells passed through this pathway, finding that it was first detected in the initial GC stage (centroblast). Subsequent work has shown that IgD+ somatically mutated cells can be detected in peripheral blood, based on expression of CD27, suggesting that they are IgM+IgD+ memory B cells.[500]

Recent work has found an interesting link between somatic hypermutation and certain Bcls. Bcl-6 is a transcriptional repressor that is linked to both GC B cells and to B lymphomas that likely derive from GC B cells.[501,502] Bcl-6 expression is high in GC B cells and is required

for formation of the GC.[503] Strikingly, its 5′ regulatory region is mutated as a consequence of hypermutation in GC B cells, the first example of hypermutation targeted outside the Ig regions,[501,502,504] and links this process to deregulated cell growth and lymphomagenesis. These findings have focused interest on Bcl-6, and recent work has shown that it binds to the promoter of the antiapoptotic proto-oncogene Bcl-2 by interacting with the transcriptional activator Miz1, also suppressing Miz1 activation of Bcl-2.[505] In lymphomas, Bcl-6-mediated suppression of Bcl-2 is lost, either by chromosomal translocations to Bcl-2, mutation of Bcl-2, or Miz1 deregulation.

Abnormalities of Development

A key discovery in the past decade has been the finding that a well-known immunodeficiency, xid, characterized by inability to respond to bacterial infections and a severe deficit in peripheral B cells,[506] is due to mutations in Btk.[507] Shortly after this finding, the mouse ortholog of Btk was shown to be the cause of murine xid, an extensively studied mutation originally identified in CBA/N mice.[508] Btk deficiency in humans is more severe than xid, with little B-cell development past the early B-cell stage, in contrast with an absence of normal peripheral B-cell development in mouse and inability to respond to certain types of T-independent antigens.[509] This difference is not simply due to specific difference in the mutations, as a complete null mutation in mouse is indistinguishable from xid.[418] Thus, human B-cell development, likely at the pre-BCR signaling stage, is much more dependent on Btk.

While xid is by far the most common B-cell deficiency, amounting to more than 80% of those identified, non-X-linked mutations have also been observed. These correspond to mutations in the pre-BCR signaling complex, and, in most cases, similar effects had been observed in the mouse. For example, deletions or mutations in the μ constant regions accounted for another 5%.[499] Examples have been found of mutations in the 14.1 gene, the human ortholog of the mouse surrogate light chain λ5 protein,[497] and also in Ig-α.[498] In both of these cases, early B-lineage cells, identified as CD19+CD34+ were present in normal numbers in bone marrow, but CD19+CD34- Cμ+ cells (pre-B cells) and all later stages were absent. Finally, a patient with a mutation in BLNK, an adaptor protein that links pre-BCR signaling from syk to the rest of the signaling cascade, showed a similar phenotype.[510]

Very few peripheral B cells are detected in any of these disorders, which suggests that pre-BCR signaling is more critical in human than in the mouse, where mutations in λ5 and BLNK allow the generation of variable numbers of peripheral B cells. The reason for this difference is not yet understood. Interestingly, common variable immunodeficiency has been shown to result from mutations in the common gamma chain[154] or in the JAK3 gene[511] consistent with IL-7 playing a much less critical role in human pre-B-cell growth than in mouse, as had already been determined from culture studies.[489,490] B-cell development is relatively

intact, whereas T cells are ablated. The reverse is true for mouse.[512,513]

Analysis of B cells with mutations in genes required for normal TLR signaling has revealed the importance of such signaling for maintenance of B-cell tolerance.[514] This study

examined the binding specificity of BCRs isolated from B cells of patients with defects in IL-1 receptor-associated kinase 4, myeloid differentiation factor 88, and UNC-93B. As all TLRs but TLR3 depend on IL-1 receptor-associated kinase 4 and because TLR3 depends on UNC-93B, this work assessed the contribution of all TLR signaling. Autoreactive BCRs were found at high frequency in the newly formed and mature B-cell pools in all patients, establishing a critical role for TLR signaling in establishing and maintaining B-cell tolerance. Interestingly, none of these patients had serum autoantibody or autoimmune disease, suggesting that some further signal, possibly TLR mediated, is needed for disease progression.

Insights into B-Cell Malignancies

One of the principle reasons for studying the regulation of B-cell development is that defects in this process may result in lymphoma. Human B-lineage neoplasias can be viewed as transformed counterparts of normal B-cell developmental stages, such as pro-B, pre-B, immature B, mature B, or plasma cell, based on rearrangement status and surface phenotype.[493] In some cases, transformed cells may even retain growth characteristics of the normal counterpart. This type of classification scheme, correlating features of lymphomas and leukemias with their normal counterparts, has been useful in diagnosis and prognosis of B-lineage neoplasias. For example, B-precursor ALL, the most common type of ALL in children (ALL accounts for 25% of childhood cancer), is a clonal expansion of a cell defined by surface phenotype and Ig rearrangement status as representing the pro-B stage.[515,516,517] Recent analyses of B-precursor ALL suggests that they can be subdivided into a pro-B type, predominant in pediatric patients, and a pre-B type, more frequent in adults.[518] A subtype of adult pre-B ALL is Philadelphia chromosome-positive, being defined by the oncogenic BCR-ABL1 kinase and showing deletion of the Ikaros gene in most cases. Pre-BCR signaling mediated cell cycle arrest has been shown to depend on normal Ikaros function,[519] providing an explanation for the high incidence of Ikaros deletion in this disease.

Whereas traditional chemotherapeutic agents typically target proliferating cells without specificity for malignant cells, the identification of molecular abnormalities that result in the abnormal survival and proliferation of leukemic cells may lead to the design of novel therapies that specifically target these cells. For example, the successful treatment of mice carrying human B-precursor leukemias with antisense strategies and tyrosine kinase inhibitors holds promise for efficacy in humans.[520,521] The identification of novel translocations in B-precursor ALL also may identify mechanism(s) responsible for this disease at the molecular level.[522,523,524,525]

Another example is diffuse large B-cell lymphoma (DLBCL) that appears to arise from GC B cells[526] that are undergoing somatic hypermutation of their IgV genes mediated through activity of AID.[366,367] As mentioned previously, aberrant somatic hypermutation in DLBCL has been shown to induce mutations in the Bcl-6 gene.[501,502,504] As mentioned previously, Bcl-6 is often found to be overex-pressed in DLBCL by either hypermutation of its promoter or chromosomal translocation, but investigation of DLBCLs lacking these genetic alterations has revealed that Bcl-6 is targeted for ubiquitylation and proteasomal degradation by a SKP1-CUL1-F-box protein ubiquitin ligase complex that contains the orphan F-box protein

FBXO11.[527] FBXO11 was found to be mutated or deleted in DLBCL cell lines and also in primary leukemias, thus revealing another mechanism for Bcl-6 dysregulation, leading to lymphoma.

AID in DLBCL likely is responsible for widespread genome instability,[528] and using a mouse model system, AID was clearly identified as responsible for c-myc to Ig V-J(H) translocations.[529] Examination of known non-Ig targets of AID also identified a high rate of mutation of PAX5 in both classic and nodular lymphocyte-predominant Hodgkin lymphoma.[530] Microarray gene profiling showed that the NF-κB signaling pathway is constitutively activated in DLBCL and as normal NF-κB activation by BCR cross-linking requires CARD11, a cytoplasmic scaffolding protein, this gene was examined for mutations. Ten percent of DLBCL tested had missense mutations, providing a rationale for development of new therapeutic agents targeting this pathway.[531] Other work has identified a negative regulator of NF-κB signaling, A20, as a frequent target in B-cell lymphomas, by using genome-wide analysis of genetic lesions.[532] Thus, early “whole genome” analyses of leukemias and lymphomas by microarray gene profiling has been followed up by high-resolution determination of gene copy and targeted sequence analysis. Now, the availability of whole exome or even whole genome high-throughput sequence determination will undoubtedly identify as yet unsuspected key driver mutations in these diseases, potentially leading to new and more personalized therapies.

Another therapeutic approach makes use of knowledge of the surface phenotype of the transformed cell, as in the recent development of anti-CD20 therapy for several types of B lymphomas.[533] CD20 is a 33 kDa phosphoprotein expressed highly on the surface of mature B cells.[534,535,536] Antibodies to CD20, originally called B1, were initially characterized by their stimulatory and inhibitory effects on human B cells, indicating the importance of CD20 in regulating B-cell proliferation and differentiation.[537,538,539] Therapeutic anti-CD20, called rituximab, is a chimeric antibody derived by fusing the V regions of a mouse antibody to the human IgG1 constant segment.[540] The precise mechanism of depletion is not yet fully understood but likely include contributions from antibody-dependent cell-mediated cytotoxicity, complement-mediated cytotoxicity, and direct antibody binding effects, including sensitization to apoptosis.[533] As most of the cells in many indolent B-cell neoplasms, such as non-Hodgkin lymphoma or chronic lymphocytic leukemia (CLL), are not predominantly in cycle, the problem may be more a failure to die appropriately, rather than a failure to regulate proliferation. A greater understanding of the

growth and sensitivity to apoptosis of different types of lymphomas and leukemias may allow more specific targeting using this approach.[541] For example, while CLL cells express relatively low levels of CD20, likely requiring higher doses of anti-CD20 for a response, a combination with another antibody recognizing a molecule that is highly expressed on CLL, CD52 has shown promise.[542] Alternatively, treatment with anti-CD20 may render the cells generally more sensitive to apoptosis so that use in combination with more conventional chemotherapeutic agents will be efficacious. These combination therapies are already in clinical trials. Finally, new insights into distinctive growth properties of transformed B cells,

such as the role of Wnt signaling in CLL.[543] may suggest new approaches to treat such disorders.

ALTERNATIVE STRATEGIES FOR B-CELL DEVELOPMENT

The broad outlines and even many of the details of B-cell development are quite similar in mouse and man, but there are striking differences in other species. There is a notable common alternative approach that involves generation of Ig+ cells during fetal/neonatal development with a relatively restricted repertoire that is then diversified by novel approaches (gene conversion or somatic hypermutation) in specialized lymphoid organs that are associated with the gut. In these species, most development from Ig- precursors appears to cease by birth, and the B-cell population is maintained by self-renewal of mature B cells. Here, we consider the development and diversification of B cells in chicken and rabbit.

Chicken

B-cell development in the avian occurs in the bursa of Fabricius.[544,545] In fact, the term "B" cell refers to "bursa derived," reflecting the historic origins of research in lymphocyte development. That is, removal of the bursa just after hatching eliminated the ability to mount an antibody response, demonstrating the importance of this organ in generating cells capable of antibody formation.[544] In contrast with the bone marrow, the bursa, being associated with the gut,[546] facilitates exposure of developing cells to external antigens and bacterial flora. B-cell development in chicken is usually divided into three stages: prebursal, bursal, and postbursal.[547]

During prebursal development, at day E5, early precursors can be identified in the para-aortic foci,[548] likely corresponding with similar precursor stages localized in this anatomic site in mammals.[2] B-lineage commitment, as indicated by D-J rearrangements, is detected in the YS at day E5/6, and V gene rearrangement is found 3 days later.[549] Unlike mammalian ordered development, light chain rearrangement is detected at about the same time as heavy chain, and light chain can precede heavy chain.[550] This means that there is no pre-B stage, per se, and also probably no requirement for SLC. Rearranging B-lineage precursors migrate into the bursal mesenchyme at about day E12, and, thereafter, these cells begin to proliferate in bursal epithelial buds. This proliferation selectively expands cells that have BCRs. These receptors have limited diversity, as the heavy chain is formed by rearrangement of a single VH, several Ds, and a single JH pairing with a light chain generated by rearrangement of a single VL with a single JL.[551,552] As in mouse fetal development, there is no TdT-mediated N-region addition at the junctions.[552]

This "prebursal" receptor is diversified by gene conversion by a set of V pseudogenes during this proliferative phase. At about hatching, these cells become exposed to the contents of the bursal lumen that is connected to the gut lumen via the bursal duct similar to the appendix. Thus, these proliferating B cells are exposed to the contents of the digestive tract, and there is also reverse peristalsis at the end of the gut that transports external antigens into the bursal duct.[546] At about this time, the level of apoptosis increases dramatically, and it is possible that only 5% of the cells generated in the bursa eventually emerge.[553] This death

may be due to generation of nonfunctional receptors during the course of gene conversion or it may reflect antigenic selection. At hatching, emigration of B cells from the bursa increases, but most of these cells constitute a population with a relatively short half-life measured in days.[554] The long-lived pool colonizes the peripheral lymphoid organs over several weeks as the bursa atrophies. By 3 weeks after hatching, bursectomy no longer results in agammaglobulinemia, indicating that the postbursal phase has become established.

Rabbit

B-cell development in rabbit is similar to chicken, in that B cells initially are produced with a limited BCR diversity[555,556,557] during fetal life, with little new production after birth.[558,559] This repertoire is then expanded through gene conversion[555,560] and somatic hypermutation[560,561] in a specialized gut-associated organ, the appendix.[562] However, unlike chicken, this diversification process is dependent on antigen availability.[563,564,565]

Pre-B cells can be found in rabbit before birth in the liver, bone marrow, and omentum,[558,566,567,568] but B lymphopoiesis decreases at birth and is negligible in adult animals.[559] Ig rearrangement during fetal and neonatal times is dominated by usage of the most D-proximal V_H gene paired with multiple V_L genes in the light chain.[556,557,569,570,571,572] In contrast with chicken and mouse, there is significant N-addition.[557,571] From 4 to 8 weeks after birth, there is a striking increase in the diversity of this primary repertoire that occurs during proliferation of B cells in the gut-associated lymphoid tissues (GALTs).[559,560] V genes are diversified by both gene conversion[555] and also by somatic hypermutation.[560,561] Importantly, surgical removal of GALT organs, appendix, sacculus rotundus, and the Peyer patch, from neonatal rabbits led to unresponsiveness to many antigens, suggesting that this diversification was crucial for normal immune function.[573] This finding has been confirmed by sequence analysis, demonstrating that removal of the GALT blocks diversification.[562]

Considering the relatively late diversification in rabbit compared to the chicken, these gut areas will provide a milieu

of microbial antigens, and this appears to be a critical aspect of the diversification process.[574] For example, surgery to prevent access of intestinal flora to the appendix blocked diversification in this organ[575,576] that could be restored by reversing the ligation.[575] Furthermore, analysis of rabbits reared in germfree conditions revealed abnormal cellular development in the GALT[564] and a lack of responsiveness to certain antigens.[563] The dependence of V gene diversification on antigen has been directly demonstrated in animals where the sacculus rotundus and Peyer patches were removed at birth and the appendix ligated. Testing the peripheral blood B cell V gene repertoire showed an absence of diversification in contrast to controls.[565] Although the mechanism for this stimulation remains to be established, possibilities include B-cell activation by a BCR superantigen[577,578,579] or through a B-cell TLR.[580]

Two B-Cell Developmental Pathways

The similarities of chicken and rabbit B-cell development with that in other species such as sheep, swine, and cow suggests that the initial production of a limited BCR repertoire during fetal/neonatal life, diversification at a later time, and maintenance of the B-cell pool in adult life by self-renewal (rather than de novo generation from unrearranged precursors) is a major pattern in the design of the immune system (Fig. 8.15). This pattern contrasts with that described for mouse and man, where ordered heavy and light chain rearrangement, pre-BCR selection, and replacement of senescent B cells by newly generated B cells are major aspects of development. This raises the interesting question of whether there is an analogous B-cell development pathway in humans or mouse, perhaps as a vestige.

The idea of two pathways in bone marrow development was suggested previously based on the observation that heavy and light chain ordering is not absolute: Light chain rearrangements are detected in mice incapable of making heavy chain rearrangements and can be detected in cells early in B-cell development.[581] In one pathway, heavy chains rearrange first and the pre-BCR is assembled and signals downregulation of Rag-1/2 expression (ending heavy chain rearrangement), clonal expansion, and accessibility of the kappa locus. Cessation of proliferation is coincident

with reinduction of Rag-1/2 and light chain rearrangement. Expression of a complete BCR signals a final termination of Rag expression. In this model, pre-BCR and BCR mediates allelic exclusion by a feedback mechanism regulating Rag expression. Thus, most B cells have D-J or even VDJ rearrangements on both alleles. In the alternative pathway, heavy and light chains rearrange stochastically, and allelic exclusion is mediated by relative inaccessibility of the loci (and thereby low frequency of rearrangement). If this is the major pathway in chicken and rabbit, it is consistent with the observation that most chicken B cells have only one allele rearranged.[552,582,583] Furthermore, the careful ordering of TdT expression, being downregulated at the light chain rearranging stage, is apparently not the case for rabbit, where a large percentage of light chains have N-regions.[572]

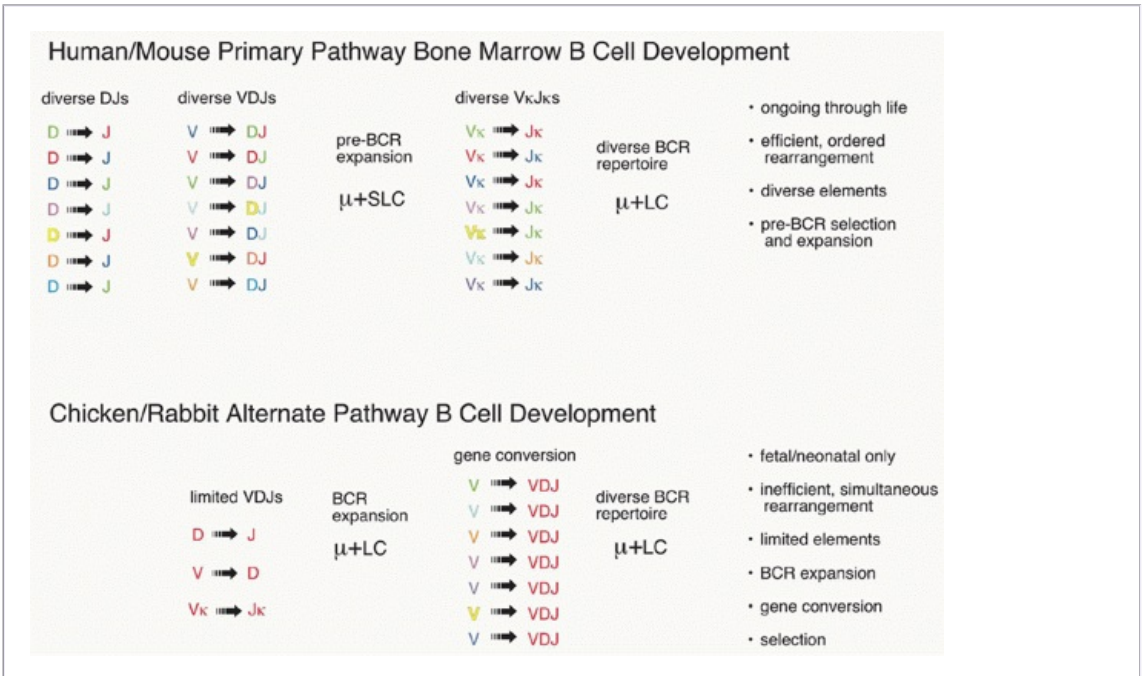

FIG. 8.15. Alternative Strategies of Repertoire Diversification and B-Cell Development. In both mouse and human bone marrow B-cell development, ordered rearrangement predominates, with a pre-B-cell receptor (BCR_ selection phase dividing heavy and light chain rearrangement. The eventual outcome is a population of newly formed B cells with a diverse set of BCRs produced throughout life. In chicken and rabbit, immunoglobulin rearrangement appears less efficient (usually the other allele is germline) and much less diverse, with a single BCR for chicken. However, these cells proliferate and undergo gene conversion during fetal/neonatal life, followed by selection, eventually generating a set of B cells with a more diverse repertoire that persist for the life of the animal.

Most rabbit B cells express CD5.[584] In mouse, much of the CD5+ B-cell population is generated during fetal/neonatal development and persists in the adult through self-renewal.[392] Furthermore, these cells express a relatively restricted BCR repertoire that is dependent on antigen selection.[23] Finally, the pre-BCR selection phase of several heavy chains abundant in CD5 B cells appears to follow different rules than classical pre-BCR-mediated expansion.[263] In fact, the process of development in mouse fetal liver may predominantly follow this alternative pathway.[406] Thus, in mouse, fetal development, culminating in production of B1 B cells, may represent a type of alternative or "primitive" B-cell development, as has been proposed previously.[585] It is less clear whether a similar distinction exists in human B-cell development, as data are lacking. Nevertheless, one can envision a primordial pathway, randomly combining heavy and light chains and simply selecting cells that express BCRs with weak reactivity to self or environmental antigens as an alternative to ordered rearrangement, pre-BCR selection, and BCR selection—an elaborate process fine tuned to generate more variation.

CONCLUSION

There has been considerable progress over the past decade in understanding the mechanisms that regulate B-cell development, with important insights coming from application of the novel genetic approaches of transgenesis and gene targeting. In a sense, this has allowed progression from research with simple model systems using cell lines to analysis of "normal B cells" in whole animals. The use of such mutant mouse "reagents," together with much higher resolution of normal development made possible by multiparameter flow cytometry, has proven a powerful combination for unraveling much of the complexity of this process. It is daunting to attempt to predict where new advances in the field will come, but undoubtedly, the completion of the genome sequence for both mouse and human will provide impetus to large-scale gene profiles of B-cell development, as have already begun.[586,587] A complementary approach to gene targeting based on such profiling will involve characterizing new mutant mice generated by chemical mutagenesis.[588,589] Considering the recent unanticipated discoveries of AID in isotype switching and BAFF in peripheral B-cell development, it seems likely that the coming decade will provide many surprises. A goal will be to eventually understand how the interplay of the innate and adaptive immune systems generates protective responses while avoiding autoimmune

pathologies at the organism level.

Susan K. Pierce

INTRODUCTION

The primary function of mature B lymphocytes in response to foreign antigens is to proliferate and differentiate into antibody-producing plasma cells that secrete large quantities of antibodies. Effective antibody responses are highly specific and of high affinity for the inducing antigen and of the appropriate isotype to allow the antibodies to carry out the effector functions, as described in Chapter 5, that best serve to eliminate an antigen-containing pathogen. For B cells to produce the most effective antibodies, they must have mechanisms that allow them to discern their specificity and affinity for antigens and to produce plasma cells that secrete antibodies of the appropriate isotype. In this chapter, we explore what we know and are learning about these mechanisms. Understanding how B cells recognize and respond to antigens will aid in our efforts to develop effective vaccines and to target therapies to block hyper-B-cell responses as in systemic autoimmune diseases and in some B-cell tumors.

B cells are activated by antigen by a process of clonal selection, a fundamental feature of the adaptive immune response. Each B cell expresses a membrane form of a single heavy (H) chain (V_HC_H) and a single light (L) chain (V_LC_L) that are assembled together with a noncovalently bound immunoglobulin (Ig)α-Igβ heterodimer into an antigen receptor, the B-cell receptor (BCR), which is expressed on the B-cell surface (Fig. 9.1). It is conservatively estimated that during a lifetime, an adult human expresses more than 10^{13} unique clonally distributed BCRs. This estimate is based, in part, on the diversity of H and L chain variable (V) regions that can be generated given the germ line encoded V gene segments and the molecular combinational and mutational mechanisms that create the V genes described in Chapter 6. When an antigen enters the immune system, it selects from among this extraordinarily large array those B cells whose receptors fit it best and signal these to proliferate and differentiate into antibody-secreting plasma cells. Even very simple antigens are predicted to find hundreds of B cells that express BCRs with sufficient specificity and affinity to be activated. This process of antigen selecting best fits from among the enormous array of preexisting B cells to proliferate and differentiate into antibody-secreting cells is a complicated process that takes place in highly specialized microenvironments in the secondary lymphoid organs and involves the functions of both T cells and innate immune system cells, as will be described in Chapter 10. Here, we focus on the events that follow antigen binding to the BCR that initiate signaling, an essential, critical first step in B-cell activation.

Antigen binding to the BCR triggers several signaling cascades that lead to the transcriptional activation of a variety of genes associated with B-cell activation (see Fig. 9.1). The BCR is also an internalizing receptor; under the influence of the signaling cascades, the BCR and bound antigen are actively endocytosed into the cell and trafficked to specialized intracellular compartments in which the antigen is processed and presented on major histocompatibility complex (MHC) class II molecules, as described in Chapter 22. The MHC-peptide complexes then move to the B-cell surface where they activate antigen-specific helper T cells to provide T-cell help, a complex process involving both direct interactions between B cells and T cells as well as the release of soluble cytokines by the T cells.

A considerable amount of what we know about the biochemical nature of the signaling

pathways triggered by antigen binding to the BCR comes from studies in which multivalent antigens are provided to the B cell in solution (see Fig. 9.1). Although B cells can respond to antigens in solution, a variety of recent studies suggest that antigens are presented to B cells on the surface of antigen-presenting cells (APCs) including macrophages and dendritic cells present in the local microenvironments of the lymph nodes and spleen in which B cells are activated in vivo (see Fig. 9.1). Antigens may be presented on macrophages and dendritic cells as part of complement-fixed complexes bound to the complement receptors or immune complexes bound to FcRs expressed by these cells. We do not yet know if the molecular mechanisms by which antigens in solution and antigens on cell surfaces initiate signaling are identical, even though it appears in both cases that the engagement of antigen by the BCR results in the triggering of similar signaling cascades.

In this chapter, we describe what we are learning about the events that occur following the binding of the BCR to antigen that trigger signaling cascades that lead to B-cell activation. The question that will be addressed is how is the BCR's specificity and affinity for an antigen read by the BCR and transduced across the B cell's membrane to trigger intracellular signaling cascades that induce the B cell's response. The signaling cascades that are set off upon antigen binding have been described in considerable biochemical detail and will be reviewed in this chapter. However, biochemical analyses do not capture the spatial and temporal dynamics of the events that are triggered by antigen binding to the BCR. The recent applications of live cell imaging technologies are providing the first views of B cells as they encounter antigen with the resolution to follow individual BCRs. These images are showing us

that the activation of B cells by antigen is far more dynamic than originally thought. It has been possible to infer from the behavior of the B cells and BCRs in these images the mechanisms underlying antigen-driven events that lead to B-cell activation. Such images are changing our view of BCR-mediated B-cell activation and are providing the tools to gain an understanding of the mechanisms underlying diseases that result from inappropriate B-cell activation including systemic autoimmune diseases and certain B-cell tumors.

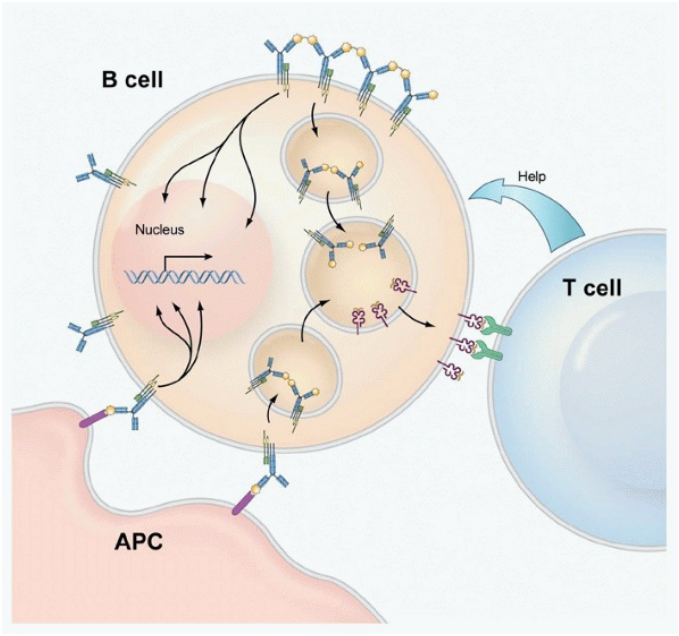

FIG. 9.1. Overview of the Activation of B Cells by Antigen. B-cell activation is initiated by the binding of antigen to the B-cell receptor (BCR). B cells encounter antigen either in solution or on the surface of an antigen-presenting cell (APC), likely as complement coupled antigens or as immune complexes bound to APC complement receptors or FcRs. Antigen binding triggers signaling cascades that lead to the activation of a variety of genes associated with B-cell activation. The BCR is also a trafficking receptor; under the influence of BCR signals, it transports antigens into intracellular compartments where the antigens are processed and presented on major histocompatibility complex class II molecules for recognition by helper T cells.

As we consider the mechanisms by which antigens trigger B cells through BCRs, we need to be aware that B cells encounter antigen in both developmental and environmental contexts, and that these contexts greatly influence the outcome of antigen engagement. Consider, for example, that B cells express BCRs throughout their development from immature B cells to memory B cells. However, engagement of the BCR by antigen at different developmental stages has different outcomes. The binding of self-antigens to the BCRs expressed on immature B cells signals these cells, but the signals do not result in activation. This means that the developmental state of the B cell dictates the outcome of the BCR's engagement of antigen, either driving proliferation and differentiation in mature B cells or triggering mechanisms that lead to elimination or silencing of self-reactive immature B cells, as described in Chapter 8. The basic structure of the BCR does not change from the immature to the mature B-cell stage, but the BCR signals differently in different developmental cellular contexts. The outcome of BCR signaling is also influenced by the environmental context in which the antigen is encountered. Antigens enter the immune system in various contexts as relatively simple vaccines to complex microorganisms including viruses, bacteria, and parasites. Both vaccines and pathogens bring with them materials that can activate B cells through coreceptors other than the BCR as well as activate T cells and cells of the innate immune system to secrete products that bind to B cell coreceptors that influence how the BCR signals in response to the antigen. The molecular form of the antigen itself can influence the outcome of BCR antigen binding, as described in Chapters 10 and 23. Bacteria and some viruses display rigid arrays of antigens on their surface that induce antibody responses in the absence of helper T cells (coined T-independent antigens), as do polysaccharides on bacteria in which the carbohydrate moieties are arrayed as multimers. Thus, in predicting the outcome of BCR-antigen binding, we need to consider not only the antigen's interaction with the BCR but also the developmental state of the B cells, the environment in which the B cell is activated, and the nature of the antigen itself. In other words, BCR signaling always occurs in a context; to predict the outcome of antigen binding to the BCR, we need to be aware of that context.

The BCR also signals during development to provide survival signals to the B cell, often referred to as tonic signaling, and to keep B cells in nonresponsive or tolerant states, termed *anergic signaling*; however, we do not yet know how these signals relate to those that activate mature B cells.

Concerning the impact of the environmental context in which B cells are activated, this chapter will focus on the effect of B-cell coreceptors that directly affect BCR signaling. We will provide a comprehensive list of the coreceptors and what they respond to and describe how two of the best studied coreceptors, the enhancing cluster of differentiation (CD)19/CD21 complex and the inhibitory FcγRIIB receptor, function to influence B-cell responses. We will also comment on the interactions between the innate immune system's toll-like receptors (TLRs) and the BCR that appear to serve to regulate each other's signaling.

We hope that this chapter leaves the reader with a clear view of the early events that follow the engagement of antigen by the BCR and the signaling cascades that are triggered that ultimately activate B cells to proliferate and differentiate into antibody-secreting cells. We also hope that the reader gains an appreciation that B-cell activation occurs in both a developmental and environmental context that dictates the outcome of antigen binding to the BCR. Lastly, we consider the repercussions of uncontrolled BCR signaling that may result in B-cell tumors and in systemic autoimmune diseases.

THE STRUCTURE OF THE B-CELL RECEPTOR

The BCR belongs to the multichain immune recognition receptor (MIRR) family that includes the T-cell receptor for antigen and the high-affinity receptor for IgE. MIRR family members contain ligand-binding chains, which for the BCR is a membrane form of Ig (mIg) (Fig. 9.2). B cells express BCRs composed of Igs of all isotypes that are expressed in a developmentally controlled fashion beginning with IgM-BCRs in immature B cells, IgM- and IgD-BCRs in mature B cells, and then isotype switched BCRs, containing IgGs, IgAs, and IgEs in memory B cells. The mIgs have short cytoplasmic tails of 3 to 28 amino acids that, with the exception of IgG- and IgE-BCRs, do not connect directly with the cell's signaling apparatus.[1,2,3] Rather, the MIRRs ligand binding chains noncovalently associate with membrane proteins that contain immunoreceptor tyrosine-based activation motifs (ITAMs) in their cytoplasmic tails. For the BCR, the mIg associates with a disulfide linked heterodimer, Igα and Igβ, each chain of which has a single ITAM in its cytoplasmic tail (see Fig. 9.2).[4] The stoichiometry of

the BCR complex is 1mIg:1Igα-Igβ determined by biochemical analysis as well as by live cell imaging (see Fig. 9.2).[5,6]

In considering how the BCR's engagement of antigen triggers signaling, it is helpful to consider what we know about the structure of the BCR. From x-ray crystallographic studies, we know that the antibody Fab does not undergo large conformational changes between the free and antigen-bound states that could transduce the information that the BCR has bound antigen to the BCR's cytoplasmic domains to initiate signaling.[7] However, the BCR is a complicated multichain complex and to date, there is no structure of a complete BCR containing mIg, Igα, and Igβ. Thus, a full understanding of the molecular basis of the antigen-induced initiation of BCR signaling will await the determination of the structure of the BCR. Recently, as an effort toward this goal, the structure of the disulphide-linked homodimer of Igβ was solved, which allowed the modeling of an Igα-Igβ heterodimer with the existing structure of the Cα4 domain.[8] These results predicted an unexpectedly extensive contact surface between the ectodomains of mIg and both Igα and Igβ through multiple charged residues that could potentially be sensitive to antigen-induced changes in the BCR's mIg.

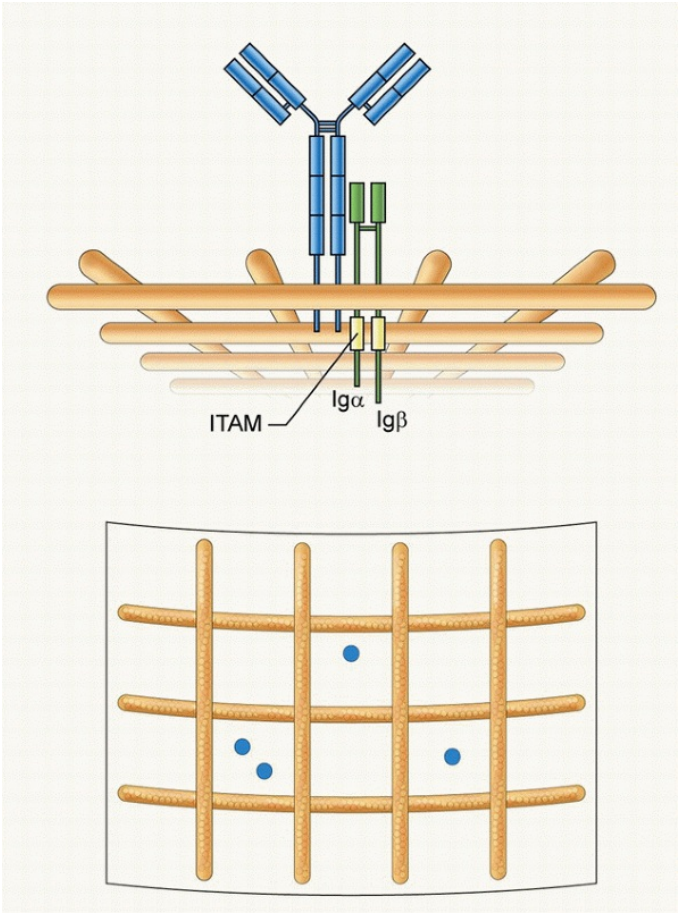

FIG. 9.2. The Structure and Organization of the B-Cell Receptor (BCR). The immunoglobulin (Ig)M BCR is composed of a membrane form of IgM associated with a covalently linked heterodimer of Igα and Igβ that contain in their cytoplasmic domains immunoreceptor tyrosine-based activation motifs. The BCR is depicted compartmentalized on the plasma membrane by actin cytoskeleton "fence"[9] as proposed by Batista et al.[21] Two different views are provided: a side view showing the BCR short cytoplasmic tail and the Igα-Igβ tails in the cytosol and a view from above showing the BCRs compartmentalized by actin "fences."

In considering how the BCR's engagement of antigen triggers signaling, it is also useful to consider the organization of the plasma membrane in which the BCR resides (see Fig. 9.2). Our current understanding of the plasma membrane is that it is not simply a fluid mosaic structure of freely diffusing proteins in a phospholipid bilayer, but rather, the plasma

membrane appears to be partitioned into highly dynamic compartments formed by actin cytoskeleton “fences” and actin-anchored protein “pickets.”[9,10] These compartments serve to organize the plasma membrane to control the diffusion of membrane proteins and concentrate proteins in one compartment or conversely segregate proteins into separate compartments. The fences and pickets are also

dynamic structures that can disassemble and reassemble during B-cell activation.

THE ANTIGEN-INDUCED CLUSTERING OF THE B-CELL RECEPTOR

Like other MIRRs, the BCR has no intrinsic receptor kinase activity, but upon antigen binding, the ITAM tyrosines in the Igα and Igβ chains are phosphorylated by the membrane-tethered kinase Lyn.[11,12] The phosphorylation of the BCR ITAMs leads to the recruitment of the Src homology 2 (SH2) domain-containing kinase Syk and the initiation of a variety of downstream signaling pathways described later in this chapter. The focus of this section is on the early events following antigen binding that lead to the phosphorylation of the BCR.

Until recently, most of what we learned about the responses of B cells to antigens came from biochemical studies of B cells responding to antigens in solution. Such studies showed that BCR signaling can only be initiated by the binding of multivalent antigens. As an example, only the bivalent $F(ab')_2$ fragments, but not the monovalent Fab fragments, of anti-IgM antibodies trigger BCR signaling.[12] By immunofluorescence imaging, following multivalent antigen binding, BCRs were observed to form microscopic clusters or patches on the cell surface that then move to one pole of the B cell to form a cap. Based on these biochemical studies, a widely accepted concept emerged that the physical aggregation of the BCR by multivalent antigens promoted the patching and capping of BCR that initiated signaling.

However, there is growing evidence both from studies in vitro as well as from intravital imaging in live animals that B cells are activated by membrane-bound antigens and not by antigens in solution. B cells were shown to be efficiently activated by antigens expressed on the surfaces of APCs in vitro resulting in the formation of a polarized bull's eye-like structure in which the BCRs are concentrated in the center, surrounded by the adhesion molecule lymphocyte function-associated antigen, which engages intercellular adhesion molecule on the APC surface.[13] Recent intravital imaging studies showed that B cells interacted with antigens on the surfaces of APCs in lymph nodes in vivo.[14,15,16,17,18] Antigens in lymphatic fluid enter lymph nodes through efferent vessels and gain access to B cells through various mechanisms.[19] Small soluble antigens move through follicular conduit networks and are presented to B cells within the follicles. Particle-like antigens, including viruses and immune complexes, are captured by macrophages lining the subcapsular sinuses and are then transported into the cortex of the lymph node where they are presented to B cells. In addition, B cells are also able to engage antigens on dendritic cell surfaces in the lymph nodes.[20] These findings provided a new view of the initiation of antigen-driven BCR signaling in which BCR signaling is initiated at the contact interface between B cells and APCs. Live cell imaging technologies are providing the tools to observe B cells as they first engage antigen on membrane surfaces. To facilitate these studies and gain high-resolution images, B cells are often activated by antigens incorporated into fluid planar lipid bilayers as surrogate APCs. These studies are revealing the B cells' engagement of membrane-bound antigens to be a remarkably dynamic event[21,22] that contrasts with the view of the patching and capping of BCRs that resulted from the simple physical cross-linking of BCRs by multivalent antigens in solution.

B cells first touch the antigen-containing bilayer through finger-like protrusions of their plasma membrane from which the BCRs engage antigen and form microclusters (Fig. 9.3).

These BCR microclusters are enriched in tyrosine phosphorylated proteins and are the site of Lyn and Syk recruitment and thus appear to be the elemental signaling units. B cells subsequently spread over the bilayer allowing the engagement of additional antigens (see Fig. 9.3). Following maximal spreading, the BCR-antigen microclusters are actively moved toward the center of the contact area, and the B cell contracts to form an immunologic synapse. This dynamic process of touching, spreading, and contraction occurs within minutes of the BCR's first contact with the bilayer.[23] These observations bring us back to the fundamental questions: How are BCR microclusters formed, and how do BCR microclusters trigger BCR signaling? Our understanding of these processes is still incomplete. However,

based on current data, several models have been proposed that address these questions.

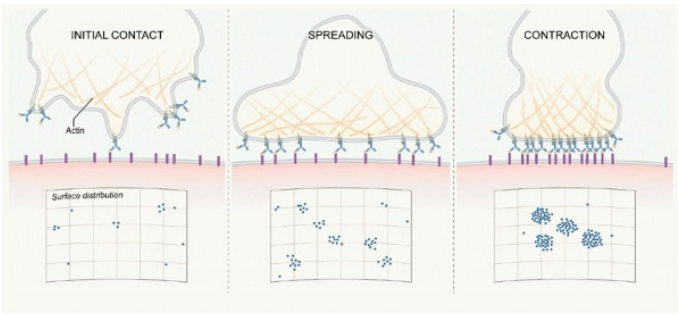

FIG. 9.3. The Activation of B Cells on Antigen-Presenting Cell (APC) Surfaces. The initial contact of the B cell with an antigen-containing APC surface is through finger-like protrusions of the membrane. Antigen binding induces B-cell receptor (BCR) clustering and signaling that triggers the B cell to spread over the APC surface, forming additional BCR clusters as antigens are encountered. After maximal spreading, the B cell contracts, actively moving BCR clusters to the center of the contact area ultimately forming an immune synapse.

One model, the conformation-induced oligomerization model, is based on evidence from live cell imaging at the level of individual BCRs. Single BCR tracking provided evidence that BCRs are dispersed and freely diffusing in the plasma membrane of resting B cells. Upon binding antigens presented on lipid bilayers, BCRs formed immobile oligomers that grew into microclusters by trapping additional antigen-bound BCRs.[24] Remarkably, contrary to soluble antigens, monovalent antigens presented on fluid lipid bilayers, which could not physically cross-link BCRs, activated B cells equivalently to multivalent antigens. This observation led to the conclusion that the physical cross-linking of BCRs by multivalent antigens was not a requirement for BCR oligomerization or clustering. Early oligomerization and microcluster formation that occurred within 60 seconds of antigen binding were shown to be BCR-intrinsic events that did not require the signaling apparatus of the BCR.[25] Mutagenesis studies showed that the membrane-proximal Cμ4 portion of the ectodomain of mIgM (or the Cγ3 membrane-proximal domain of mIgG) was both necessary and sufficient for BCR oligomerization and signaling.[25] Thus, the membrane proximal domain of the mIg appeared to contain an oligomerization domain that was not exposed in the absence of antigen binding. It was hypothesized that the B cell's binding antigen presented on an APC surface exerted a force on the BCR that revealed the oligomerization domain, allowing oligomerization of antigen-bound BCRs as they randomly bumped on the membrane. This model provides a mechanism by which the universe of foreign, structurally distinct antigens can bring BCRs into a precise signaling-active oligomer by the monovalent binding of BCRs to epitopes on APC-presented antigens. This model also suggests how BCRs are able to so exquisitely discriminate their affinity for antigen by monovalent binding, avoiding the affinity obscuring effects of the avidity contributed by multivalent antigen binding to bivalent BCRs.

Another model for the initiation of BCR signaling based on live cell single molecule imaging focuses on the role of the actin cytoskeleton in signaling.[26,27,28,29] In this model, the membrane cytoskeleton fences and pickets restrict BCR mobility and interactions with signaling molecules and coreceptors. BCR signaling results in the disruption of the cytoskeleton barriers and increases the likelihood that the antigen-engaged BCR will encounter activated kinases and coreceptors.[29] The actin cytoskeleton may also segregate BCRs from kinases and phosphatases at steady state. Current evidence suggests that the cytoskeleton fences and pickets confine the BCR and inhibitory phosphatases to the same areas, and that BCR signaling serves to disrupt the cytoskeleton and allow the BCRs and phosphatases to diffuse away, promoting B-cell activation.

A third model, the dissociation activation model, is based on biochemical studies.[6,30] In this model, in resting B cells in the absence of antigen most BCRs exist on the B-cell surface as signaling-inactive, autoinhibited oligomers in equilibrium with a small number of signaling-active BCR monomers.[30] The binding of multivalent antigen disrupts the oligomers shifting the equilibrium toward BCR active monomers, which are then clustered by the multivalent

antigen in a manner that prevents the formation of inactive oligomers within the cluster. This model also accounts for the ability of structurally diverse antigens to activate B cells by proposing that antigens keep BCRs apart rather than bringing them together into well-ordered oligomers.

THE ROLE OF B-CELL RECEPTOR AFFINITY AND ISOTYPE IN SIGNALING

Affinity maturation and class switching are two hallmark features of humoral immune responses.[31] In a typical T-cell-dependent antibody response, antigen-specific antibodies become increasingly higher in affinity and predominantly of the IgG isotype through the linked molecular processes of somatic hypermutation and class switching. Because the B-cell immune response functions through clonal selection, it is presumed that affinity maturation and class switching reflect an advantage of B cells expressing high-affinity, classswitched BCRs in the selection process. Indeed, adoptive transfer studies provided clear evidence that high-affinity B-cell outcompete low-affinity B-cell clones for survival in vivo.[32,33,34,35,36,37,38] Similarly, when comparing IgM and class-switched BCRs, several seminal studies showed that class-switched B cells outcompete IgM B cells for survival in vivo, and that this survival advantage can be attributed to the 28 amino acid cytoplasmic tail of mIgG,[1,2] missing in mIgM and mIgD. The question is at what point in the antigen-selection process does a high-affinity, class-switched BCR gain an advantage?

Biochemical experiments suggested that the signals that are triggered through high-affinity BCRs are qualitatively different from signals through low-affinity BCRs.[39] At an earlier point in B-cell activation, the affinity of the BCR for antigen was shown to determine the degree to which B cells spread over antigen-containing fluid lipid bilayers, allowing increased accumulation of antigen into the immune synapse and subsequent enhanced responses.[23] The IgG-BCR cytoplasmic tail is responsible for the enhanced B-cell proliferative responses to antigen in vitro and signaling cascades that have been shown to be qualitatively different from those triggered by IgM-BCRs.[3,40,41,42] Enhanced signaling through IgG-BCRs is dependent on the phosphorylation of a tyrosine in the IgG tail that serves to recruit growth factor-receptor-bound protein 2 (Grb2), resulting in sustained kinase activation and enhanced B-cell proliferation.[3]

Recent studies using high-resolution imaging to follow single BCRs showed that the earliest events that occur following antigen binding to the BCR are also highly sensitive to both the affinity of the BCR for antigen and the isotype of the BCR. Comparing BCRs that differed 50-fold in their affinity for antigen, it was observed that high-affinity BCRs more readily formed BCR microclusters that grow more rapidly, thereby resulting in larger microclusters that recruit more Syk and signal for more robust calcium responses.[24] These imaging experiments also demonstrate that IgG-BCRs are dramatically enhanced in their ability to oligomerize and to grow microclusters, ultimately leading to increased recruitment of Syk and more robust calcium responses as compared to IgM-BCRs of the same affinity.[43] The enhanced function of IgG-BCRs was mapped to a novel membrane proximal 15 amino acid region of the cytoplasmic tail. These studies place the effects of both affinity maturation and class switching at the earliest steps in the initiation of BCR signaling.

HOW B-CELL RECEPTOR CLUSTERING TRIGGERS SIGNALING

Another fundamental yet still open question related to the initiation of BCR signaling is how BCR clustering in response to antigen recruits Lyn to phosphorylate the antigen-bound BCRs and triggers signaling. One simple explanation is that Lyn is constitutively associated with the cytoplasmic domains of some monomeric BCRs, but only phosphorylates BCRs in trans when the BCRs are clustered. However, recent studies suggest that the mechanism for recruitment of Lyn may be more complicated. Lyn is lipidated and tethered to the inner leaflet of the plasma membrane. BCR clustering has been shown to perturb the local lipid environment leading to the transient coalescence of lipid rafts around the BCR oligomers followed by a more stable association of the BCR microcluster with lipid tethered Lyn.[44] Thus, the BCR's perturbation of the membrane may serve to recruit Lyn to the BCR cluster. BCR clustering has also been shown to alter the way the Igα and Igβ chains' cytoplasmic domains associate. In the absence of antigen, the domains are in close proximity in a “closed” conformation and upon antigen binding, the domains “open”; the opening is simultaneous with Lyn's phosphorylation of the ITAMs.[5] Thus, BCR clustering may serve to reveal the ITAMs for

phosphorylation by Lyn.

B-CELL RECEPTOR-TRIGGERED SIGNALING CASCADES

BCR signaling is a multistep process that involves the initiation of signaling by the activation of protein tyrosine kinases (PTKs), serine-threonine kinases, and lipid kinases; amplification of signaling by recruiting adaptors; generation of second messengers; and finally activation of the transcription of genes involved in B-cell responses.

Initiation of B-Cell Receptor Signaling—Protein Tyrosine Kinase Activation

Following BCR clustering, three different families of PTKs, Src, Syk, and Tec, are activated sequentially. This sequential activation of the members of the three different PTK families is essential to trigger and regulate downstream signaling. The importance of these PTKs in the B-cell signaling is underscored by the fact that deficiencies in any one of the three families result in aberrant B cell development and function (Table 9.1). The first kinases that are activated following BCR cross-linking are the Src family PTKs, primarily Lyn, but also Blk and Fyn followed by the activation of Syk and the Tec family kinase, Btk[45] (Fig. 9.4). ITAM phosphorylation of Igα-Igβ by Lyn generates phosphotyrosine motifs that allow the binding of the SH2 domains (Box 9.1) of the second kinase, Syk, resulting in rapid Syk activation. Upon binding to phosphorylated ITAMs, Syk undergoes autophosphorylation at multiple tyrosines within its linker regions that not only prolongs Syk's activation but also creates SH2 binding sites on Syk for the recruitment of downstream signaling molecules, including PLC-γ2,[46] leading to a positive feedback of BCR signaling and the concomitant influx of calcium.[12] Btk is the third PTK that is activated upon BCR cross-linking.[47] The importance of Btk in BCR signaling for the development, activation, and differentiation of B cells is underscored by the fact that the loss-of-function mutations of the gene encoding Btk lack circulating B lymphocytes, are unable to generate Igs, and cannot mount humoral immune responses.[48] This primary immunodeficiency is named X-linked agammaglobulinemia.[49,50] Similarly, a spontaneous mutation in the mouse Btk gene leads to X-linked immunodeficiency.[51] Btk consists of multiple protein domains including PH, SH2, SH3, and kinase domains (see Box 9.1), which define its subcellular location and regulate its activity. For Btk activation, plasma membrane localization is important, which is governed by the interactions between the PH domain of Btk with phosphatidylinositol (PI)(3,4,5)P_3, the product of PI3K activity and between the SH2 domain of Btk with phosphorylated BLNK, an adaptor protein. Mutation in the PH domain of Btk (R28C) leads to classical X-linked agammaglobulinemia,[52] substantiating the importance of plasma membrane localization for Btk activation. Following BCR cross-linking, Btk translocates from the cytosol to the plasma membrane where it is activated by phosphorylation at Y551 in its catalytic domain by Lyn[53,54,55] followed by an autophosphorylation of its SH3 domain.[54,56] Once activated, Btk triggers a cascade of signaling events that culminate in calcium mobilization through phosphorylation of PLC-γ2, cytoskeletal rearrangements, Vav activation, and transcriptional activation involving NF-κB.

Amplification of B-Cell Receptor Signaling— Recruitment of Adaptors

BCR-mediated signaling is a complex process in which each phosphorylation event is linked with another in a regulated manner, thereby generating a large number of protein-protein interaction networks ultimately resulting in the formation of a large, well-ordered structure often referred to as a signalosome. Interactions between signaling networks are regulated by a number of scaffolding or adaptor proteins, which regulate BCR-mediated signaling cascades not only by recruiting multiple signaling intermediates to the proper location but also by controlling interactions between signaling components. Recent studies have identified the roles of

adaptors in B-cell activation, leading to important insights into how they integrate BCR signaling. Although adaptors generally lack any enzymatic activity, they consist of multiple protein-protein or protein-lipid interaction domains, including SH2, SH3, PH and PX homology domains (see Box 9.1). Each of these domains has the potential to interact with a number of proteins that are critical to amplify BCR signaling by facilitating the coupling of multiple downstream signaling pathways. Essentially, the adaptors define where and when macromolecular complexes are assembled, allowing both spatial and temporal regulation of signaling cascades. To illustrate the importance of adaptors, we describe the functions of three: B-cell linker protein (BLNK); B-cell adaptor for PI3K (BCAP), and B-cell adaptor

molecule of 32 kDa (Bam32).

TABLE 9.1 The Phenotype of Mice Deficient in Key B-Cell Signaling Components

Target Protein	Major Phenotype	Reference
Igα cytoplasmic domain	Normal pre-B-cell development; completely impaired mature B-cell development	184
Igβ	Complete block at the pro-B-cell stage	185
Igμ	Deletion of mature B cells; increased Fas expression	186
Lyn	Normal B-cell development in the bone marrow; reduced number of peripheral B cells; increased proportion of immature B cells; enhanced BCR induced ERK activation and hyperproliferative responses	187
Syk	Block in transition of the pro-B-to the pre-B-cell stage; intact Igα-Igβ ITAM phosphorylation in remaining B cells; abolished BCR-induced calcium influx; failure to transmit downstream signals	188,189
Btk	Reduced number of peripheral B cells; increased immature B cells; complete loss of B1 B cells; fail to respond to TI-II antigens	190,191,192,193
BLNK	Block in transition of the pro-B-to the pre-B-cell stage; incomplete block in B-cell development; fail to respond to both TD and TI antigens	194,195,196
PLC-γ2	Decreased mature B cells; block in pro-B-cell differentiation; B1 B-cell deficiency; block in BCR-induced calcium influx and proliferation	197,198
BCAP	Reduced number of B cells; B1 B-cell deficiency; reduced serum IgM and IgG3 levels; abolished TI antibody response; reduced BCR induced calcium influx and proliferation	82
PI3K, p110 subunit	Reduced numbers of B1 and marginal zone B cells; reduced serum Ig levels; defective primary and secondary response to TD antigens; diminished response to TI-II antigens; reduced BCR, CD40, and LPS induced proliferation	199,200
PI3K p85 subunit	Reduced number of peripheral B cells and B1 cell; reduced serum Ig levels; reduced BCR- and CD40-induced proliferative response; abolished TI antibody response	201,202
PKC-β	Failure to activate IKK and degrade IκB; failure to upregulate NF-κ-dependent survival signals; impaired humoral immune responses and reduced cellular responses	203,204

Bam32	Normal B-cell development; impaired TI-II antibody responses; reduced responses to BCR cross-linking	89
Vav1/2	Reduced number of B cells; defects in formation of germinal centers and class switching; defective immune responses against TD and TI antigens; impaired BCR-induced calcium influx and proliferation	205,206
Rac	Reduced number of mature and marginal zone B cells and B1-a cells and IgM secreting plasma cells; increased number of peripheral B cells in blood; reduced serum IgM and IgA concentration	207
CD19	Defective response to TD antigens; failure to form germinal centers and undergo affinity maturation; lack of B-1, marginal zone B cells; reduced BCR- and CD40-induced proliferative responses	191,208,209
CD22	Decreased surface IgM levels; augmented BCR-induced calcium; compromised marginal zone B-cell compartment	210,211
PIRB	Increased number of peritoneal B1 cells; constitutive activation of follicular B cells; increased BCR-induced proliferation	212
Calcineurin	Reduced number of B1 cells; reduced plasma cell differentiation; decreased TD antibody response; BCR-induced proliferation defects	102
IKKα	Reduced mature B-cell population; impaired basal and Ag-specific Ig production; disrupted splenic architecture including germinal center formation; decreased expression of NF-κB target genes	213,214
IKKβ	Disappearance of mature B cells 215 NEMO Disappearance of mature B cells	215

BCR, B-cell receptor; CD, cluster of differentiation; Ig, immunoglobulin; ITAM, immunoreceptor tyrosine-based activation motif; LPS, lipopolysaccharide; TD, T-dependent; TI, T-independent.

BLNK—Integrating Protein Tyrosine Kinases and PLC-γ2

BCR clustering activates Lyn and Syk that regulate a variety of effectors including PLC-γ2, an essential phospholipase for

calcium responses. Although Syk can directly phosphorylate PLC-γ2 in vitro,[57] expression of a functional BCR, Lyn, and Syk in nonlymphoid cells did not induce PLC-γ2 phosphorylation or calcium mobilization,[58] leading to the discovery of the B-cell-specific adaptor protein, BLNK. BLNK (also known as SLP-65 or BASH) is a cytoplasmic protein consisting of an N-terminal region containing a short leucine zipper motif, a proline-rich region within the middle third of the molecule, and a C-terminal SH2 domain. BLNK contains 13 tyrosine residues, of which 6 are in putative SH2 binding motifs and are phosphorylated upon BCR clustering.

BLNK is recruited to the clustered BCR by binding through its SH2 domain to the phosphorylated non-ITAM tyrosine 204 in Igα. Mice with a Igα Y204 mutation exhibit reduced BLNK phosphorylation and calcium fluxes.[59] Once translocated to the plasma membrane, BLNK is phosphorylated by Syk, which creates docking sites for SH2 domains of multiple effector molecules facilitating interactions among them and allowing them to phosphorylate and activate their respective signaling pathways. One of the best studied examples of how BLNK bridges multiple signaling components is provided by the activation of PLC-γ2. PLC-γ2 activation is completely abolished in Syk-deficient B cells.[60] In addition, BCR-induced PLC-γ2 activation is diminished in Btk-deficient B cells, suggesting that both Syk and Btk are required for PLC-γ2 activation.[61] However, the mechanisms underlying how these two families of PTKs regulate PLC-γ2 activation became clear only after the discovery of BLNK. After phosphorylation by Syk, BLNK creates binding sites for the SH2 domains of both Btk and PLC-γ2, bringing them into close proximity with each other, and hence facilitating PLC-γ2 phosphorylation at Tyr753 and Tyr759 by Btk, which is required for PLC-γ2 activation.[62,63,64,65,66,67,68] Cells expressing a mutant BLNK lacking either Btk or PLC-γ2 binding sites

show significant reduction in calcium activation, further suggesting that BLNK acts as a scaffold for bridging Btk to PLC-γ2.[69] A single BLNK molecule can bind three PLC-γ2 molecules, thus BLNK also functions as an amplifier of BCR signaling.[62] Following BCR clustering, both BLNK and Btk are also translocated to the plasma membrane bringing along PLC-γ2 and allowing it to gain access to its substrate $PI(4,5)P_2$ in the inner leaflet of the plasma membrane.[66,67,68] In addition to phosphorylating PLC-γ2 and recruiting it to the plasma membrane, Btk also recruits PIP5 kinase to the plasma membrane, which catalyzes $PI(4,5)P_2$ synthesis from PIP(4)P to ensure that activated PLC-γ2 does not run out of its substrate.[70] Once activated, PLC-γ2 hydrolyzes PI(4,5) P2 to generate two important second messengers: inositol trisphosphate (IP3) and diacyl glycerol (DAG). BLNK not only couples Btk and PLC-γ2, but it also binds to the SH2 domains of Vav and Nck, resulting in activating the mitogen-activated protein (MAP) kinase pathway, cytoskeletal rearrangements, and BCR internalization.[71]

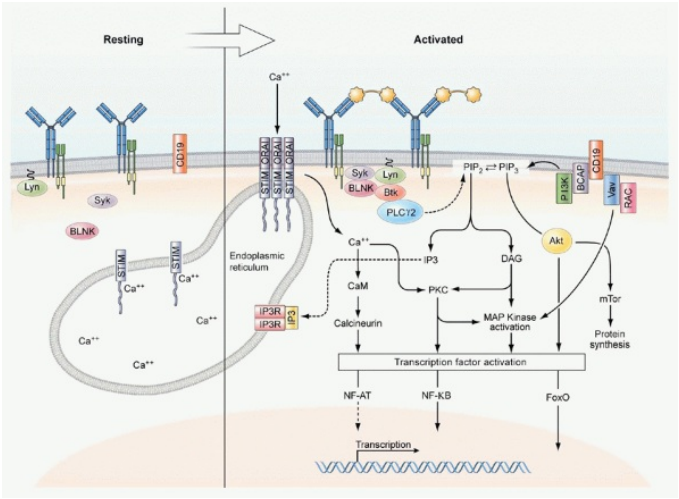

FIG. 9.4. Schematic Depiction of B-Cell Receptor (BCR) Signaling. Presented is a highly simplified version of the signaling pathways triggered by antigen-induced BCR clustering. Antigen binding to the BCR leads to the formation of signalosome consisting of BCR, protein tyrosine kinases, adaptors, and effector molecules. BCR clustering results in PI3K activation, leading to the production of PIP3 from PIP2 and PLC-γ2 activation resulting in the production of IP3 and diacyl glycerol (DAG) from PIP2. Binding of IP3 to the IP3 receptor on the endoplasmic reticulum (ER) opens channels in the ER membrane leading to calcium release and depletion of ER calcium. Calcium depletion is sensed by STIM, a calcium-binding protein, which results in its oligomerization and movement to regions of the ER membrane in close proximity to the plasma membrane where it interacts with Orai opening the calcium release-activated channel, resulting in calcium influx. Calcium, DAG, and PIP3 trigger signaling cascades leading to mitogen-

activated protein kinase and transcription factor activation and activation of the Akt pathways promoting cell survival and growth.

BOX 9.1. PROTEIN MODULES INVOLVED IN SIGNAL TRANSDUCTION

Src homology 2 (SH2) domain. The SH2 domain is a structurally conserved protein domain present in the Src oncoprotein from which its name is derived and in many signaling molecules including those involved in B-cell signaling. SH2 domains bind with high affinity to peptide sequences within target proteins that contain phosphorylated tyrosine residues but have no affinity for the unphosphorylated sequence. This allows tyrosine phosphorylation to act as a molecular switch, recruiting SH2 domain-containing proteins to activated receptors and initiating signaling cascades. Important SH2 domain-containing proteins involved in B-cell signaling include Lyn, Syk, Btk, PLC-γ2, BLNK, and Grb2.

Src homology 3 (SH3) domain. SH3 domains are protein modules that recognize proline-rich sequences, in particular those containing a PxxP motif, which do not require phosphorylation. However, recent studies have suggested that the SH3 domains also bind to nonproline-rich sequences accounting for diverse functions they mediate. Some examples in B cells are Lyn, Btk, and Grb2.

Pleckstrin homology (PH) domain. The PH domain is a lipid binding module that recognizes phosphoinositides phosphorylated at the 3 position of the inositol ring, the most important of which is PI(3,4,5)P_3, the product of PI3K's phosphorylation of PI(4,5)P_2. This property allows PH domain-containing proteins to bind to the inner leaflet of the plasma membrane following PI3K activation where they function. PH domain-containing proteins in B cells include Btk, Vav, Akt, Gab, and Bam32.

Phox homology (PX) domain. The PX domain is another phosphoinositide-binding domain that was originally identified in two cytosolic components of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, p40phox and p47phox. In a majority of cases, PX domains contain a proline-rich motif, PxxP, in the middle that serves as SH3 binding motif, suggesting that PX domains might directly interact with SH3 domains as well. PX domains have been shown to play diverse cellular functions including vesicle docking and fusion, cell signaling, and protein sorting. An example in B cells is phospholipase D.

BCAP—Integrating Protein Tyrosine Kinases and PI3K

PI3K is a heterodimeric enzyme consisting of a catalytic subunit (p110) and a regulatory subunit (p85) that phosphorylates phosphatidylinositol lipids generating lipid derivatives at the inner leaflet of the plasma membrane that serve as second messengers for downstream signaling.[72,73] Of particular interest is the generation of PI(3,4,5)P_3 from PI(4,5)P_2, which serves as a ligand for the proteins containing PH domains and tethers these to the membrane. Although multiple isoforms of PI3K are known, p110δ and p85α are the predominant isoforms in B cells. Gene targeting experiments have established the role of these subunits in the development and activation of B cells (Table 9.2). Deletion or inactivation of either of the two subunits of PI3K demolish BCR-induced phosphorylation of Akt, FoxO, and protein kinase D and results in reduced calcium flux, impaired cell cycle progression, and reduced glucose metabolism.[74,75,76,77,78,79,80] Despite the critical role of PI3K in BCR signaling, the mechanisms by which the BCR-associated PTKs regulate the PI3K pathway is unclear. It has been proposed that tyrosines in the cytoplasmic tail of CD19, which are phosphorylated upon BCR clustering, provide binding sites for the SH2 domains of the p85 subunit of PI3K, recruiting it to the plasma membrane and increasing the specific activity of the enzyme. However, the observation that defects in p85α KO mice are more severe than those in CD19 KO mice suggested that additional adaptor molecules may participate in bridging BCR-associated PTKs and PI3K, leading to the discovery of another B-cell-specific adaptor molecule, BCAP.[81] BCAP contains multiple tyrosines, which are phosphorylated after BCR stimulation through the concerted actions of Syk and Btk, thereby creating binding sites for SH2 domains of the p85 subunit of PI3K. BCAP was shown to regulate PI3K signaling in CD19-deficient B cells, but in BCAP KO mice, PI3K signaling was largely unaffected in B cells,[81,82] suggesting that in the absence of BCAP, CD19 functions as a major adaptor. Indeed, CD19/BCAP double knockout mice show an almost complete block of BCR-mediated Akt activation and severe defects in the generation of immature and mature B cells.[83] Recently a GTPase, TC21, was also identified as an adaptor for PI3K activation by binding directly to Igα-Igβ.[84]

Bam32—Linking B-Cell Receptors to Mitogen-Activated Protein Kinase Activation and Cytoskeletal Rearrangements

Bam32 bridges clustered BCRs to two important pathways, namely, Rac and cdc42, which trigger cytoskeletal rearrangement leading to cell adhesion, polarization, and motility and to activation of the MAP kinase c-Jun N-terminal kinase (Jnk) and extracellular signal-regulated kinases (ERK)

that play central roles in the activation of transcription factors that regulate the expression of genes involved in B-cell proliferation, differentiation, and survival.[85,86,87,88] Following BCR clustering, Bam32 translocates to the plasma membrane in a PI3K-dependent mechanism through its PH domain[88] where it binds to Rac and cdc42 leading to their activation, triggering downstream signaling to Jnk and ERK. Mice deficient in Bam32 show diminished Jnk and ERK phosphorylation.[89] Rac activation is diminished in Bam32-deficient B cells, whereas overexpression of Bam32 results in enhanced Rac activation.[90]

TABLE 9.2 B-Cell Coreceptors that Influence B-Cell Receptor Signaling

Coreceptor	Activating (+) or Inhibitory (−)	Phosphorylated Motif(s)	Ligand(s)	Signaling Molecules Recruited upon Motif Phosphorylation	Expressed in Humans (H) or Mice (M)	References
CD19	+	Tyr residues	C3-coated antigen	PI3K + Vav + Lyn + PLC-γ2	H + M	126,127,216
FcμR (FAIM3/TOSO)	+	Ser + Tyr residues	IgM	PI3K + PLCγ-1	H + M	131,217
FcRL1 (FcRH1)	+	ITAM	Unknown	Unknown Tyr kinase?	H + M	132,218,219

CD, cluster of differentiation; HLA, human leukocyte antigen; Ig, immunoglobulin; IC, immune-complex; IgSF, immunoglobulin superfamily; ITAM, immunoreceptor tyrosine-based activation motif; ITIM, immunoreceptor tyrosine-based inhibitory motif; MHC, major histocompatibility complex; PTP, protein tyrosine phosphatase; SFK, Src-family kinase; SHIP, SH2-containing inositol 5′-phosphatase; SHP, SH2-domain-containing protein tyrosine phosphatase.

[a] FcRL6 motif, ligand, and signaling molecule information was obtained from studies of human T and natural killer cells.

Generation of Second Messengers

As described previously, binding of the PTKs and various signaling intermediates such as PLC-γ2 and PI3K on various adaptors results in the activation of these enzymes resulting in the generation of second messengers including calcium, DAG, and phosphoinositides. These second messengers play a crucial role in regulating BCR signaling by virtue of their ability to affect downstream signaling initiated by the BCR.

Calcium as a Second Messenger

Calcium mobilization is a multistep process that is initiated with the activation of PLC-γ2 that hydrolyzes $PI(4,5)P_2$ present in the inner leaflet of the plasma membrane to generate IP3 and DAG. A receptor for IP3 (IP3R) is present as a tet-ramer on the ER membrane that forms a calcium channel.[91] The binding of IP3 to the IP3R activates the receptor and opens the channel resulting in the release of calcium from the ER into the cytosol. Depletion of intracellular ER calcium stores results in the oligomerization of the ER calcium sensor, STIM1, an ER membrane protein that contains in its cytoplasmic domain an EF-hand calcium-binding domain.[92,93] STIM1 oligomers rapidly redistribute into clusters and move to junctions of the ER and plasma membrane where STIM1 interacts with Orai, a calcium release-activated channel, and activates Orai to open, triggering the entry of extracellular calcium into the cytosol.[94,95,96] A single missense mutation (R91W) in human Orai or a truncation mutation in STIM1 causes severe combined immune deficiency supporting the functional roles of STIM1 and Orai in calcium signaling in the immune system.[97,98] The increase in cytosolic calcium is sensed by various calcium-binding proteins, ultimately leading to activation of several downstream pathways including activation of protein kinase C (PKC) and transcription factors nuclear factor of activated T cells (NFAT) and NF-κB. One of the major cytosolic calcium-binding proteins, calmodulin, functions as a calcium sensor by binding to calcium with its two EF hands. Calcium-bound calmodulin activates several molecules including calcineurin, which is a phosphatase that dephosphorylates NFAT resulting in NFAT's translocation into the nucleus where it activates the transcription of target

genes. One of the targets of NFAT in B cells is interferon

regulatory factor 4, a critical transcription factor for the differentiation of plasma cells.[99,100,101] Indeed, calcineurin-deficient B cells show reduced plasma cell differentiation and decreased antigen-specific antibody responses to antigens.[102]

Diacylglycerol as Second Messenger

The second product of $PI(4,5)P_2$ hydrolysis by PLC-γ2 is DAG that together with calcium activates PKC-β that regulates the NF-κB pathway. NF-κB in resting B cells is retained in the cytoplasm by binding to its inhibitor, IκB. BCR clustering induces IκB phosphorylation, through a PKC-β-initiated pathway, ubiquitination, and subsequent degradation, allowing translocation of NF-κB into the nucleus.[103,104,105] Aberrant activation of NF-κB has been linked to defective B-cell activation leading to multiple immune disorders. Ablation of PKC-β, which leads to the defective activation of the NF-κB pathway, results in defective B-cell activation and maturation.[106] In humans, mutations in components of the NF-κB pathway are associated with the formation of lymphomas.[107,108,109,110,111,112,113] In addition to activating PKC-β, DAG also recruits the DAG binding Ras guanine nucleotide releasing protein 3 (RasGRP3) to the plasma membrane, thus initiating the Ras to Raf to MEK to ERK pathway.[114] Deletion of the DAG-binding domain from RasGRP blocks the movement of RasGRP3 to the plasma membrane and the activation of Ras. The Ras-Raf-MEK-ERK signaling pathway plays a critical role in antigen-induced proliferation of mature B cells.[115] Ras is also involved in developing B cells, as transgenic expression of dominant negative forms of Ras blocks developmental progression to the pre-B cell and immature B-cell stages.[116,117] Major targets of ERK in B cells are Ets-family transcription factors, resulting in the expression of early response genes including Egr1 that has been shown to promote expression of adhesion molecules.[118]

Phosphoinositides as Signaling Mediators—A Diverse Group of Molecules Regulating Diverse Pathways

PI is unique among membrane lipids as it can undergo reversible phosphorylation at multiple sites on its inositol head group by lipid kinases and phosphatases to generate a variety of phosphorylated PI lipids called phosphoinositides. Phosphoinositides play crucial roles in cell signaling and membrane trafficking. As described previously, BCR clustering leads to the accumulation of the phosphoinositide, $PI(4,5)P_2$, the substrate for PLC-γ2, which generates two crucial second messengers, IP3 and DAG. Another important phosphoinositide is the PI3K-generated $PI(3,4,5)P_3$ that provides a ligand for recruiting important PH domain-containing proteins to the plasma membrane, including Btk, PLC-γ2, and Akt. Akt is activated at the membrane by phosphorylation and in turn phosphorylates several proteins and transcription factors that regulate protein synthesis, cell survival, and proliferation. Some of the targets of Akt in B cells are mammalian target of rapamycin, glycogen synthase kinase 3, forkhead family transcription factors, Caspase-9, and proapoptotic protein, BAD.[119,120,121] Given the crucial role of $PI(3,4,5)P_3$ in B-cell activation, its levels are tightly regulated by two different lipid phosphatases that oppose the activity of PI3K, phosphatase and tensin homolog, which removes a phosphate from the D3 position generating $PI(4,5)P_2$, and SH2-domain-containing inositol 5′ phosphatase (SHIP), which generates $PI(3,4)P_2$ by removing a phosphate from the five position and essentially shuts down signaling. One of the pathways that activates SHIP in B cells is the ligation of the inhibitory FcR FcγRIIB,[122] as described in the next section of this chapter.

The Spatial and Temporal Dynamics of B-Cell Receptor Signaling Cascades

Advanced fluorescence-based imaging techniques are just now providing the first view of the spatial and temporal dynamics of the recruitment of individual signaling molecules to BCR microclusters following BCR oligomerization in response to membrane-bound antigens. Each newly formed BCR cluster recruits the earliest PTKs, Lyn and Syk[24,123,124]; as the BCR moves to form an immune synapse, Syk is lost and PI3K is recruited. It has also recently been possible to use imaging to follow signaling as the BCR is internalized into the B cell. Such studies showed that BCR signaling is initiated at the plasma membrane with the recruitment and phosphorylation of Lyn and Syk and continues after the BCR is endocytosed and trafficked through early endosomes then to late endosomes and multivesicular antigen

processing compartments with the recruitment and phosphorylation of downstream kinases, initially cRaf and subsequently the MAP kinases, ERK, p38, and Jnk.[125] Internalization of the BCR is necessary for proper signaling as when internalization is blocked, phosphorylation of kinases become dysregulated as does gene transcription. The continued application of imaging technologies to describe B-cell activation should lead to an increasingly detailed spatial and temporal view of BCR signaling.

CORECEPTOR REGULATION OF B-CELL RECEPTOR SIGNALING

The outcome of signaling through the BCR is carefully regulated not only by the developmental stage of the B cells but also by a variety of B-cell coreceptors that both promote and attenuate BCR signaling in response to antigen. Ideally, co-receptors ensure that sufficient amounts of antigen-specific antibodies are produced to control an infection, and that once controlled, antibody production is turned off. We have provided a list of B-cell coreceptors and have indicated whether they function to enhance or inhibit BCR signaling and, when it is known, what they recognize and the molecular basis of their effect on BCR signaling (see Table 9.2). Presumably, all B-cell coreceptors respond to clues from the environment as to the course of the immune response and relate this information to the B cells by enhancing or inhibiting BCR signaling. The best understood examples of the role of coreceptors in B-cell responses are the activating CD19/CD21 complex and the inhibitory FcγRIIB. Both coreceptors become physically cross-linked to the BCR through the recognition of antigen-containing complexes. The CD19/CD21 complex binds complement fixed antigens (C3d-modified antigen, as described in Chapter 36) through CD21, a complement receptor that binds to C3d. Complement modification of antigens can be viewed as a sign that the antigen is dangerous, having the ability to

activate the complement pathway, and thus, the CD19/CD21 complex serves to enhance BCR signaling. The FcγRIIB binds to antigen-antibody immune complexes (described in Chapter 24) through the Fc portion of the IgG antibody complexed with the antigen. Immune complexes form when antigen-specific antibodies reach sufficient levels relative to the antigen, an indication that further B-cell activation should be curbed, and thus, the FcγRIIB inhibits BCR signaling.

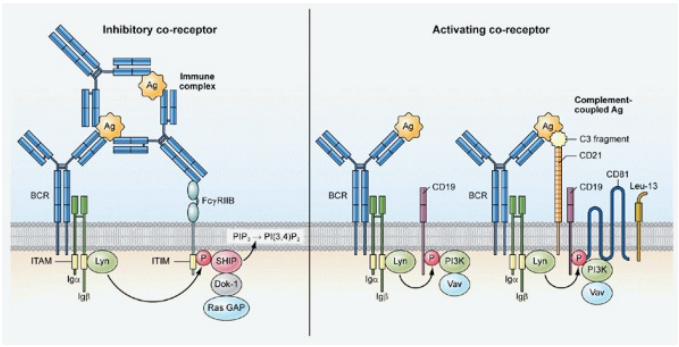

FIG. 9.5. Inhibitory and Activating B-Cell Receptor (BCR) Coreceptors. Antigen-containing immune complexes engage both the BCR and the inhibitory coreceptor FcγRIIB (**Left**). Lyn associated with clustered BCRs phosphorylates the immunoreceptor tyrosine-based inhibitory motif of FcγRIIB, recruiting SH2-domain-containing inositol 5′ phosphatase that dephosphorylates PI(3,4,5)P_3, the product of PI3K activation, to PI(3,4)P_2, blocking downstream signaling. Antigen binding to BCRs induces their clustering and signaling that results in the phosphorylation of CD19 by BCR-associated Lyn, recruiting PI3K and Vav (**Right**) and enhancing BCR signaling. Enhancement of BCR signaling is stronger when complement conjugated antigens engage both the BCR and the complement receptor, CD21, recruiting CD19 to the signaling complex where it is phosphorylated by Lyn recruiting PI3K and Vav (**Right**).

CD19/CD21, a transmembrane glycoprotein complex expressed on the surface of all B cells, is the best understood activating coreceptor for BCR signaling. On mature B cells, the CD19 component can exist alone or as part of a tetra-meric complex with CD21 (complement receptor type 2), the tetraspanin family protein, CD81, and the small interferon-induced transmembrane protein 1, Leu-13[126] (Fig. 9.5). CD21 links this complex to the BCR in

response to complement-coupled antigens and boosts BCR signaling and ultimately antibody production. Upon binding of complement-coupled antigen, the BCR and CD19/CD21 complex are coligated, and several tyrosine residues in the cytoplasmic tail of CD19 are phosphorylated by Lyn, providing binding sites for the SH2 domains of the p85 subunit of PI3K, Vav and Lyn, thus enhancing the signaling triggered by BCR antigen binding.[127] It is hypothesized that the association of Lyn with CD19 may counteract the autoinhibition of Lyn, which is maintained by interaction between its SH2 domain and its carboxy-terminal phosphotyrosine, thus stimulating the enzymatic activity and phosphorylation of Lyn during BCR signaling.[128] CD81 may aid in the stable association of the BCR with saturated lipids that coalesce around the antigen-bound BCRs to sustain antigen-induced signaling when the CD19-CD21 complex is coengaged with the BCR.[129] CD81 and Leu-13 may also be involved in mediating cell-cell interactions during the B-cell response to antigen.[130]

In addition to the CD19-CD21 complex, B cells express other activating coreceptors whose ligands and mechanisms by which they affect BCR signaling are less well characterized (see Table 9.2). These activating coreceptors include the recently identified Fc receptor for IgM (FcμR), which contains several conserved tyrosine and serine residues in its cytoplasmic tail that are targets for phosphorylation after receptor ligation with IgM-containing immune complexes.[131] Although the physiologic role of FcμR in B-cell responses is not known, it has been hypothesized that FcμR may become coligated to the BCR and CD19/CD21 complex through the recognition of complement-coupled IgM-antigen immune complexes and drive the B cell response toward isotype-switched antibodies. Other activating coreceptors are Fc receptor-like 1 (FcRL1)[132] and paired Ig-like receptor A (PIRA)[133,134] that respectively contain or associate with cytoplasmic ITAMs. The tyrosine residues within these ITAMs are phosphorylated by one of the Src-family tyrosine kinases of B cells (Lyn, Fyn, or Blk) upon receptor engagement by their ligands, mediating costimulatory signals by creating docking sites

for other proteins involved in the B-cell signaling pathway. Instead of ITAMs, the cytoplasmic domains of the activating coreceptors CD45R and CD148 contain an active protein tyrosine phosphatase domain that dephosphorylates a key regulatory tyrosine at the C-terminal end of Src kinases during BCR signaling.[135,136,137,138]

While various coreceptors promote BCR signaling, there are also numerous coreceptors that are poised to counter B-cell activation. FcγRIIB, the best characterized inhibitory coreceptor for BCR signaling, is expressed on the surface of all B cells and is composed of two extracellular Ig-like domains: a transmembrane domain and a cytoplasmic domain that contains a single immunoreceptor tyrosine-based inhibitory motif (ITIM)[139] (see Fig. 9.5). When a B cell binds IgG-antigen immune complexes, FcγRIIB and the BCR are coengaged. Serum contains a relatively high concentration of soluble IgG, but the affinity of the FcγRIIB for soluble IgG is low and such that it is only able to stably engage multi-meric IgG-antigen immune complexes. The presence of IgG immune complexes indicates that sufficient antigen-specific antibody has been made to counter any foreign threat, and that antibody production can be attenuated or stopped, depending on the amount of IgG-immune complex present. Coengagement of FcγRIIB and the BCR promotes phosphorylation of the ITIM of FcγRIIB by BCR-associated Lyn, recruiting the lipid phosphatase SH2-containing inositol 5′-phosphatase (SHIP).[140] SHIP dephosphorylates PI(3,4,5) P_3 to PI(3,4)P_2, preventing the recruitment of PH domain-containing kinases (eg, BTK and PLC-γ2) to the cell membrane, thereby downregulating downstream signaling and proliferation.[141] SHIP also recruits RasGAP via the adaptor Dok-1, which inactivates Ras and thus further downregulates proliferation.[142,143]

Besides affecting downstream BCR signaling, it has also been shown that coengagement of FcγRIIB with the BCR greatly destabilizes newly formed BCR oligomers that are essential for the initiation of signaling.[144] This early point of inhibition is not influenced by interactions between the cytoplasmic tails of the two receptors but instead by the perturbation of the local lipid environment by FcγRIIB, which destabilizes BCR association with saturated lipids and Lyn.[144,145] It is of interest that a loss-of-function mutation in the transmembrane domain of FcγRIIB that is associated with the autoimmune disease systemic lupus erythematosus (SLE) prevents the association of ligated FcγRIIB with saturated lipids[146,147] and thus inhibits the ability of FcγRIIB to block BCR oligomerization and signaling. FcγRIIB may also function when

engaged by immune complexes independently of the BCR. Cross-linking FcγRIIB by immune complexes that do not contain the antigen for which the BCR is specific leads to apoptosis through a c-Abl-dependent pathway.[148,149] Recent evidence indicates that this pathway may be important in eliminating preexisting FcγRIIB-expressing plasma cells in the bone marrow after infection or immunization, creating space in the limited niches in the bone marrow for newly formed plasma cells.[150]

In addition to FcγRIIB, B cells express a variety of other coreceptors that inhibit BCR signaling via a similar ITIM-mediated mechanism, such as those shown in Table 9.2. In general, the Lyn-phosphorylated ITIMs recruit lipid phosphatases (eg, SHIP) or protein phosphatases (eg, SH2-domain-containing protein tyrosine phosphatase-1 [SHP-1]) that effectively block BCR signaling.[151] SHP-1 likely downmodulates BCR signaling by dephosphory-lating early signaling components that include BLNK.[152] Coreceptors such as FcRL2, 3, and 5 have both ITAM-like and ITIM sequences in their cytoplasmic tails, but the inhibitory effects of their ITIMs appear to dominate their regulatory function.[153,154,155] Negative modulators of BCR signaling other than FcγRIIB do not require coligation to the BCR by immune complexes to attenuate signaling but are instead regulated functionally by binding various ligands on the B-cell surface.

A recurrent theme throughout the discussion of the mechanism by which the CD19/CD21 complex and FcγRIIB function is the requirement for coligation to the BCR by complement-coupled antigens or immune complexes. The requirement for joint binding of the BCR and coreceptors to antigen-containing complexes ensures that only the antigen-specific B-cell response is regulated. However, some coreceptors that function to regulate BCR signaling do not appear to require physical cross-linking with the BCR to affect BCR signaling. In fact, for several such coreceptors their ligands, if they exist, are not known. These coreceptors raise a number of yet unanswered questions concerning how they sense that a BCR is activated and the mechanism by which they regulate BCR signaling. For example, CD19 regulates BCR signaling independently of CD21. In response to antigen presented on fluid lipid bilayers as surrogate APCs, CD19 was shown by live cell imaging to transiently associate with signaling-active BCR microclusters, mediating the recruitment and activation of associated signaling molecules and, therefore, amplifying signaling within the individual microclusters.[28,124] CD19-deficient B cells are unable to form BCR microclusters and undergo a spreading response or flux calcium in response to membrane-bound antigens, suggesting that the BCR-CD19 complex may be a basic signaling unit, essential for BCR activation. Notably, B-cell spreading is not abrogated in the absence of CD21, suggesting that CD19 can function independently of the CD19/CD21 complex. As evidence toward an independently functioning CD19, mice lacking CD19 exhibited a more severe phenotype than those lacking CD21.[156] It is interesting that a CD19 deficiency in mouse B cells does not impair the BCR response to soluble antigens,[127] suggesting that the process by which BCRs cluster in response to membrane-associated antigens provides a mechanism for recruiting CD19 to the BCR, resulting in enhanced signaling. In addition to affecting early BCR signaling, a CD19 deficiency is also implicated in impaired pre-BCR-dependent development and responses to antigen in vivo.[157,158] Another potential example of ligand-independent coreceptor regulation of BCR signaling is FcRL4, a member of the FcR-like family of proteins, which has no known ligand.[132] FcRL4 is expressed on a subpopulation of atypical memory B cells that are expanded in individuals with chronic infections, including

acquired immunodeficiency syndrome and malaria, and are hyporesponsive to BCR triggering. Antigen binding leads to association of FcRL4 with the BCR and a block in BCR signaling at the point of Syk phosphorylation[159] and eliminating FcRL4 expression in atypical memory B cells from individuals infected with human immunodeficiency virus restores BCR signaling.[160] An important unanswered question is in the absence of coligation, by what mechanism do these coreceptors associate with the BCRs? Possible suggested mechanisms are through intracellular adaptor molecules or through membrane perturbations that facilitate BCR-coreceptor interactions. In the absence of a mechanism that triggers the association of these coreceptors with the BCR, it is also not easy to guess what environmental clues these receptors are responding to.

Another family of innate immune system receptors that receive information from the B cell's environment and can affect signaling through the BCR is the TLR family. TLRs are distinctive in that they recognize highly conserved motifs present in microorganisms, including bacteria,

viruses, fungi, and protozoans, referred to as pathogen-associated molecular patterns, as described in Chapter 15.[161] As for the BCR, TLR-initiated signaling results in the activation of MAP kinases and NF-κB[162]; thus, TLR and BCR signaling have the potential to synergize. Of particular interest to BCR signaling are TLR7 and TLR9, which reside in intracellular compartments of B cells and respectively recognize pathogen-associated molecular patterns in single-stranded ribonucleic acid (ssRNA) derived from RNA viruses and un-methylated CpG-containing deoxyribonucleic acid (DNA) of bacterial and viral origin. The ssRNA-induced TLR7 signaling and CpG-containing DNA-induced TLR9 signaling have been shown to synergize with antigen-induced BCR signaling in NF-κB activation.[162] It was recently shown that synergistic signaling in response to CpG-containing DNA-containing antigens is mediated by a novel mechanism in which, following antigen binding, the BCR signals from the plasma membrane to recruit TLR9 from small endocytic intracellular vesicles to autophagosomal compartments into which the BCR traffics the CpG-containing antigen and from which synergistic signaling occurs.[163] By this mechanism, TLR9 can alert the BCR to the presence of pathogenic DNA in the environment and heighten BCR signaling. Similar mechanisms may be at play for BCR and TLR7 signaling in response to ssRNA-containing antigens.

ABNORMAL B-CELL RECEPTOR SIGNALING IN HUMAN DISEASE

In this chapter, we have provided an overview of our current understanding of the molecular mechanisms underlying the early BCR-intrinsic events that lead to normal BCR oligomerization and subsequent signaling and have emphasized that early events in the initiation of BCR signaling are tightly regulated. It might be predicted that alterations in any step of the initiation of signaling could drive the BCR to hyperactivation. For example, the outcome of antigen engagement could be affected by mutations in the BCR itself, changes in the composition of the membrane lipids that stabilize BCR oligomers, or mutations affecting the activity of coreceptors or the kinases in the BCR signaling pathway. Hyperactivation of the BCR is associated with both B-cell tumors and autoimmune disease. In the future, it may be possible to develop new therapeutic strategies that target spontaneous BCR oligomerization clustering and chronic active signaling to treat B-cell tumors and systemic autoimmune disease.

The BCR is required for the survival of the activated B cell-like (ABC) subtype of diffuse large B-cell lymphomas (DLBCLs).[164] Using live cell imaging, the BCRs on these activated DLBCLs were found to form immobile oligomers within microclusters similar to those observed on normal antigen-stimulated B cells. In contrast, the BCRs on Burkitt's lymphoma, mantle cell lymphoma, and germinal center B cell-like DLBCL tumors, which are not dependent on the BCR for survival, show no clustering. Somatic mutations affecting the cytoplasmic domains of Igα and Igβ are detected frequently in ABC DLBCL biopsy samples but rarely for other DLBCLs and never for Burkitt lymphoma or mucosa-associated lymphoid tissue (MALT) lymphoma, although the contributions of these mutations to chronic BCR clustering is not known.

Interestingly, the spontaneous BCR clustering on ABC DLBCLs is similar to that observed for human H chain disease in which ligand-independent BCR self-aggregation and constitutive activation are a consequence of BCR H chain gene mutations that cause misfolding and disrupt antigen binding.[165] Impaired glycosylation and folding of the μ-H chain are implicated in chronic lymphocytic leukemia, which has symptoms similar to those of μ-H chain disease; however, it has not yet been determined whether this misfolding leads to enhanced BCR ligand-independent, or chronic active, signaling.

In addition to the BCR itself, other BCR signaling molecules that are key regulators of the NF-κB pathway are also known targets of mutations found in B-cell lymphomas. Specifically, MALT1 and Bcl10 are independently associated with chromosomal translocations in MALT lymphoma, whereas CARD11 has activating point mutations in a percentage of ABC DLBCLs that result in constitutive NF-κB activation.[113,165,166,167] The ABC DLBCLs are also dependent for their survival on MyD88, the adaptor that mediates TLR signaling.[168] Remarkably, nearly 30% of ABC DLBCLs have a single gain-of-function mutation in MyD88 that promotes cell survival by activating the NF-κB pathway. The dual dependence on both the BCR and TLR pathways suggest that these work in concert to drive B-cell tumorigenesis.

B cells from patients with systemic autoimmune disease exhibit B-cell hyperactivation that may be due to alterations in the BCR signaling pathway or alterations in coreceptor

function.[169] In SLE, stimulating peripheral blood B cells with BCR ligand leads to increased intracellular calcium flux and increased phosphorylation of various cytosolic proteins as compared to healthy individuals and patients with other rheumatic diseases.[170] In most of patients with SLE analyzed, expression of Lyn is also significantly decreased in resting, and BCR stimulated peripheral blood B cells[171]; the ability of Lyn to associate with saturated membrane lipids is reduced in SLE B cells as compared with healthy donors.[172]

Decreased Lyn expression negatively impacts its ability to inhibit BCR signaling via phosphorylation of FcγRIIB and other inhibitory coreceptors that contain ITIMs. In addition, a loss-of-function mutation in the transmembrane domain of FcγRIIB that is associated with SLE susceptibility prevents BCR-ligated FcγRIIB from associating with saturated membrane lipids[146] and consequently inhibits the ability of FcγRIIB to block BCR oligomerization, clustering, and subsequent signaling. The synergistic engagement of the BCR and TLR7 and TLR9 in response to antigens containing ssRNA or CpG-containing DNA has also been implicated in the activation of autoimmune B cells. Many of the antigens targeted in SLE contain DNA and RNA that are thought to be released from apoptotic cells. Indeed, genetic variations in TLR9 are linked to SLE susceptibility[173]; in a mouse model of SLE, multiple copies of a normal TLR7 gene are sufficient to drive SLE.[174] Overall, it seems that enhanced B-cell signaling as a result of a multiple genetic abnormalities is the defining pathogenic event of SLE and provides a therapeutic target for treating autoimmune disease.

BCR signaling can also be altered in infectious diseases by viruses that commandeer B cells for their own replication. Epstein-Barr virus (EBV) is the causative agent of infectious mononucleosis and is implicated in Burkitt's lymphoma, Hodgkin disease, nasopharyngeal carcinoma, and various lymphoproliferative disorders that arise in immunocompromised individuals.[175] EBV infects B cells of the oral epithelium and establishes a lifelong latent infection in a subset of those cells.[176] Latent membrane protein 2A (LMP2A) messenger RNA is readily detected in the peripheral blood B cells of healthy individuals, and LMP2A is often found in tumors from EBV-associated malignancies.[177] To subvert immune responses and consequently maintain viral latency in B cells, EBV blocks signaling and antigen-trafficking functions of the BCR through the activity of the cytoplasmic tail of LMP2A[178,179,180] that, when phosphorylated, binds to Lyn (Y112) and Syk (Y74, Y85),[181,182] thus blocking BCR signaling. LMP2A also activates the PI3K/Akt pathway, which normally provides a survival signal in response to BCR signaling.[183] Overall, LMP2A maintains viral latency by preventing normal BCR activation, which initiates viral replication, while sustaining survival pathways in latently infected B cells.

CONCLUSION

B-cell activation is initiated by the binding of antigen to the BCR resulting in the triggering of a number of signaling pathways that ultimately drive B-cell proliferation and differentiation to antibody-secreting cells. At present, we understand the biochemical nature of the signaling pathway in some detail. What remains less well understood is the nature of the events following antigen binding to the BCR that trigger these signaling cascades. New tools of live cell imaging both in vitro and in vivo are anticipated to provide an increasingly detailed spatial and temporal picture of events that initiate signaling in both time and space. Our increased understanding of B-cell activation is likely to lead to new approaches for developing therapies for diseases caused by hyper-B-cell activation.

Chapter 10

B-Lymphocyte Responses

Michael McHeyzer-Williams

INTRODUCTION

B-lymphocyte responses provide the effective and longlasting immune protection induced by most vaccines in use today. We measure antibody molecules as the circulating agent of immune protection but now understand much more about the underlying B-lymphocyte response that progressively matures in response to foreign antigen exposure. This chapter will focus on the highly-regulated cellular and molecular development of antigen-specific B-lymphocyte responses.

The three cardinal features of effective B-cell immunity are antigen specificity, antibody class, and antigen binding affinity. To be effective, antibodies must bind vulnerable antigens on the targeted pathogen. During infection, this is a struggle between the evasion mechanisms of the pathogen and preexisting diversity within the adaptive immune system. Different classes of antibodies engage distinct mechanisms of antigen clearance. These various classes of antibody provide either more or less protection depending on the pathogen's portal of entry at infection. Finally, the right antigen-specific antibody still requires induction of sufficiently high binding affinity to provide adequate sensitivity for long-term immune protection. Many promising antigens fail to achieve adequate immunogenicity in contemporary vaccine strategies due to poor affinity maturation. Here, we focus on the sequential mechanisms that program these central attributes of effective antigen-specific B-cell memory.

In the past few years, experimental access to immune response biology has dramatically shifted with the advent of multiphoton laser-based intravital imaging techniques. These studies provide direct access to the mechanics and cell dynamics of antigen-specific cognate regulation in vivo. This information serves to integrate existing knowledge in the field using a real-time scaffold for developmental progression in vivo. Importantly, follicular helper T (T_{FH}) cells have recently emerged as a new class of antigen-specific immune regulator that controls multiple stages of high-affinity B-cell immunity. Understanding antigen-specific T_{FH}-cell development and function remains an active research challenge with great potential for the rational design of future vaccines. Current information regarding the role of antigenspecific T_{FH} cells will be integrated into this chapter to provide a regulatory dimension to B-lymphocyte responses.

Following initial exposure to antigen, T_{FH} -cell-regulated B-cell immunity progresses in three separable stages of antigen-specific development. Each stage is characterized by a B-cell antigen-recognition event followed by contact with cognate T_{FH} cells that determines

subsequent B-cell fate. Naïve B cells recognize foreign antigen and then present antigenic peptides to specific T_{FH} cells to progress in development across two major pathways (pre-germinal center [GC] development). Extrafollicular development permits antibody class switch and plasma cell differentiation while entry into the GC reaction is the major pathway to highaffinity B-cell memory (GC cycle). GC B cells in this pathway can switch antibody class and affinity mature their expressed B-cell receptor (BCR) following access to antigen and presentation to GC T_{FH} cells. Upon antigen reexposure, memory B cells recognize, uptake, and then present antigen to memory T_{FH} cells to promote rapid memory B-cell responses and boost circulating high-affinity antibody (memory B-cell response). Antigen recall is the least studied facet of B-lymphocyte responses but provides an important developmental juncture for vaccine-based prophylactic or therapeutic intervention.

This chapter mainly focuses on what is known of antigen-specific B-lymphocyte responses in mouse models with reference to work conducted in humans. Further, there is an emphasis on the response to model antigens that provides a greater understanding of how to manipulate adaptive immunity for preventative vaccination rather than a focus on the immune response to infection.

PRE-GERMINAL CENTER DEVELOPMENT

The initial antibody response to many infectious agents is largely based on the rapid T-cell independent (TI) expansion of B cells and their subsequent differentiation into plasma cells. B1 and marginal zone B cells are largely responsible for these rapid TI humoral responses suggesting that some level of “natural memory” function resides in these B-cell subsets and may be predetermined in an evolutionarily conserved manner. TI antigens can be separated into two broad categories based on their ability to polyclonally activate B cells (TI-1) or require BCR recognition of multivalent epitopes to induce B-cell differentiation in the absence of T-cell help (TI-2). TI-2 antigens can activate BCR signaling but require accessory signals to promote the development of antigen-specific plasma cells. In contrast, monovalent protein antigens require antigen-specific helper T-cell regulation to promote high titer antibody responses and the development of B-cell memory. These T_{FH}-cell-dependent antibody responses take longer to emerge and display a spectrum of BCR affinities and antibody isotypes as multiple strategies for antigen-specific clearance in vivo. Immune responses to

model protein antigens provide experimental access to this complex cascade of cellular and molecular events that underpin long-term protective immunity.

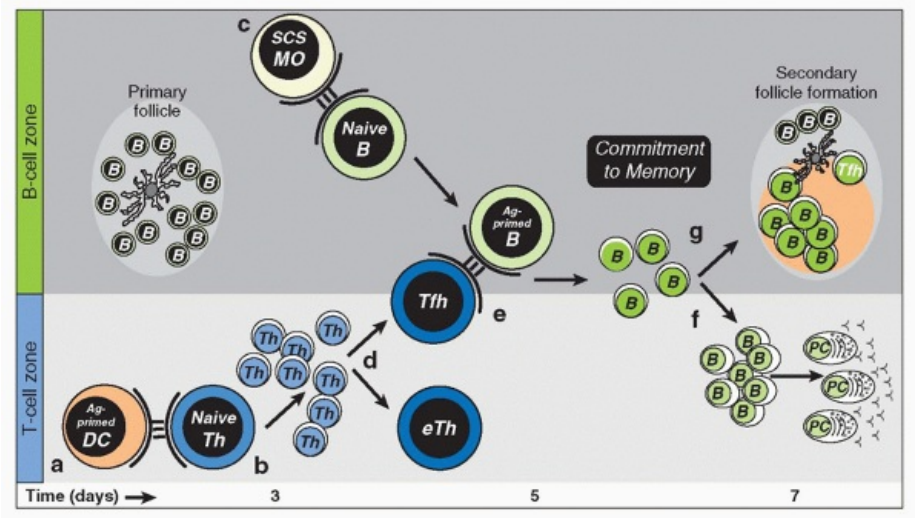

FIG. 10.1. Pre—Germinal Center (GC) Development. A: Local protein vaccination induces dendritic cells (DC) maturation and migration to the T-cell zones of draining lymph nodes (LNs). **B:** Peptide major histocompatibility class II expressing DCs will engage naive antigen-specific helper T (T_H) cells to induce proliferation and effector T_H-cell differentiation. **C:** Whole antigen will be trapped by subcapsular sinus macrophage and presented to naive follicular B cells. Antigen-specific B cells will become activated and uptake, process, and present antigenic peptides and migrate toward the T-B borders of the draining LN. **D:** Effector T_H cells emerge in multiple forms with emigrant T_H cells exiting the LN to function at distal tissue sites and T_{FH} cells relocating to T-B borders and interfollicular regions. **E:** Cognate contact between pre-GC T_{FH} cells and antigen-primed B cells is required for multiple programming events in the pathway to B-cell immunity. **F:** Clonal expansion, antibody class switch, and non-GC plasma cell development proceeds within extrafollicular regions of LNs. **G:** Secondary follicle formation and antibody class switch precede formation of the GC reaction as the dominant pathway to memory B-cell formation.

B-cell immunity is initiated on two fronts. Initially, naïve B cells are activated through cell-associated antigen to uptake antigen, process and present peptide major histocompatibility complex [MHC] class II (pMHCII) complexes to enable cognate contact with pMHCII-specific T_{FH} cells. These antigen-primed B cells relocate to T-B-cell borders in lymphoid tissues to increase the likelihood of contact with antigenprimed T_{FH} cells. On the second front, populations of dendritic cells (DCs) also take up antigen, process and present pMHCII, and migrate to draining lymphoid tissues to initiate T_{FH}-cell responses. One outcome of contact with pMHCII-expressing DCs is differentiation of the T_{FH}-cell lineage and the productive contact between pMHCII-specific T_{FH} cells and antigen-primed B cells. This pre-GC cell contact and bidirectional exchange of molecular programming is central to the development of effective B-cell immunity. Antibody class switch, extrafollicular plasma cell differentiation, and initiation of the GC reaction are major B-cell fates associated with this initial phase in B-cell immunity (Fig. 10.1).

Antigen Presentation to B Cells

B cells can acquire soluble antigen by free diffusion into lymphoid follicles[1] or through the lymphoid system of conduits.[2] However, populations of lymph node (LN) subcapsular sinus (SCS) macrophages appear most effective at presenting cell-associated antigen to follicular B cells.[3] B cells take up noncognate antigen presented by SCS macrophages through complement receptors and transfer it into follicular regions and onto follicular DCs (FDCs), which can serve as a source of antigen to prime naïve B cells.[4] In contrast, priming with the cognate antigen at first contact with SCS macrophages results in movement of antigen-specific B cells to the T-B-cell borders and antigen-specific B-cell responses to captured antigens.[4,5,6] Hence, the SCS macrophages filtering the lymphatic fluid not only protect from systemic infection,[7] but also effectively initiate T helper cell-regulated antigen-specific B-cell immunity.

DCs can also effectively prime B-cell immunity. Injection of DCs pulsed with protein antigen can induce isotype switch and promote efficient B-cell responses. B cells can form synapse-like interactions with antigen-pulsed DCs.[8,9] More recently, two-photon imaging revealed that naïve B cells entering local LNs surveyed protein antigen-pulsed DCs before entering the follicular areas.[10] In this model, engagement of BCR led to calcium flux, migration arrest, and the local accumulation of the antigen-specific B cells. Furthermore, there is a reticular network of collagen fibers that physically connects the subcapsular and paracortical sinuses of LNs to blood vessels and separates these regions from T- and B-cell areas.[11] This organization facilitates the efficient delivery of

soluble antigen toward the lumen of high endothelial venules without entering the LN parenchyma. While resident DCs can access this conduit transport system, follicular B cells may have difficulty accessing soluble antigen.

Nevertheless, in the context of protein antigens, B cells must recognize their cognate antigen and internalize, process, and present peptides from this antigen in the context of MHCII in order to receive pMHCII-specific T-cell help. If the antigen is cell associated, in the presence of adequate costimulation, some aspects of the B-cell response can proceed in a TI manner. B-cell proliferation and plasma cell development can occur in the absence of cluster of differentiation (CD)40-CD40L interactions with some residual isotype switch induced by the action of TACI and BAFF-R.[12] Thus, B cells can respond in a TI manner to protein antigens but do not express the characteristic range of outcomes and the full extent of protective immunity that is found with cognate regulation and T-cell help.

Antigen-Specific B-Cell Activation

Initial activation of naïve B cells through the BCR triggers multiple gene expression programs that enable effective contact with cognate T helper cells. Dynamic contacts with membrane-associated antigens determines the amount of antigen naïve B cells accumulate following antigen exposure.[13] Effective cell contacts require expression of the signaling adaptor dedicator of cytokinesis 8 (DOCK8).[14] Mutations in DOCK8 disrupted integrin ligand accumulation in the immune synapse without altering BCR signaling events. B-cell-specific

conditional ablation of the calcineurin regulatory subunit 1 (CNB1),[15] myocyte enhancer factor 2c,[16,17] and stromal interaction molecule 1 and stromal interaction molecule 2[18] have shown that calcium responsiveness is necessary for cell cycle progression in these early pre-GC stages of B-cell responses. Hydrogen voltage-gated proton channels 1, which are internalized with the BCR, have been recently implicated in early B-cell programming events.[19] Single-pulsed BCR signaling[20] that only partially activated NF-κB increased CC chemokine receptor 7 and MHC class II expression, and responsiveness to CD40, indicating some of the early facets of B-cell activation. Severe defects in early B-cell proliferation have also implicated integrin-binding CD98hc[21] and extracellular signal-regulated kinase activation[22] in preparing the antigen-primed B cells to receive cognate T-cell help in vivo. Hence, initial antigen recognition, uptake, processing, and presentation critically impact the early B-cell developmental fate. High-resolution dynamic imaging has provided substantial insight into the earliest events associated with initial BCR engagement on naïve B cells. The membrane cytoskeleton controls BCR diffusion; disruption of this organization initiates signaling.[23,24] Discrete microclusters form upon antigen binding[25] and recruit multiple components of the intracellular BCR signaling network to initiate signal transduction.[26] One rapid response involves B-cell spreading to increase surface contact with antigen on the presenting cells.[13] Central clustered antigen at the cellular interface is then internalized into antigen-processing lysosomes for presentation with MHCII[8] as the cognate point of T_{FH} contact. Curiously, antigen presentation appears asymmetrically segregated with one daughter retaining larger antigen stores thereby more able to contact pMHCII-specific T_{FH} cells.[27] Whether these developmental outcomes are directed by initial context of antigen presentation or stochastically assorted[28] remains an interesting fundamental issue with an early impact on antigen-specific B-cell development.

Dendritic Cell Maturation

DCs are essential antigen-presenting cells (APCs) for initiating adaptive immunity. Multiple DC subsets exist prior to antigen challenge. Different phenotypic schemes can be used to characterize DC subsets with the origins and developmental relatedness of different DC subsets still subject to debate.[29,30] In the murine system, three main bone marrow-derived DC subsets enter all secondary lymphoid organs via the blood and reside at different levels. These bloodderived DCs all express CD11c and are distinguishable as $CD11b^{hi}$ $CD8a^{neg}$ DCs, $CD8a^{hi}$ DCs, and $6B2^{hi}$ plasmacytoid DCs. In LNs draining the skin, there are at least two further CD11c+ DC subsets, Langerhans cells (LCs) and dermal DCs, that emigrate from the skin, even at homeostasis.[31] Thus, before antigen challenge, multiple subsets of DCs are available to differentially process and present antigen to the adaptive immune compartment.

Protein antigen administration in the absence of inflammation induces immune tolerance. In contrast, coadministration of an immune adjuvant activates facets of innate immunity, induces inflammation, and primes antigenspecific adaptive immunity. Sensing pathogens involves pattern recognition receptors such as the evolutionarily conserved toll-like receptors[32,33] and the more recently described nucleotide oligomerization domain-like receptors.[34] Most

forms of antigen and innate stimulators require DC priming at some level for B-cell immunity, whereas particulate antigen in virus-like particles are more reliant on B-cell innate receptor activation.[35] Nevertheless, both families of innate receptors recognize different types of microbial components initiating programs of DC maturation that promote immediate local inflammation and innate effector clearance mechanisms.

Temporal and spatial constraints on DC maturation provides another layer of regulation for the innate system that can impact adaptive immunity. In the steady state, DCs form dense networks at the T-B borders of LNs. Interestingly, motile lipopolysaccharide-activated DC immigrants will rapidly coalesce with this preexisting network in vivo.[36] In separate studies using genetically tagged LCs, the emigrants of LCs and dermal DCs were shown to emerge separately in time and colonize separate regions of the T-B border.[37] A similar temporal regulation was seen using antibodies to specific pMHCII complexes with resident DCs presenting an early wave of pMHCII and dermal DCs emerging later in a second wave.[38] In each of these studies, the immune stimulus was varied and the coordinated response of the innate system also qualitatively and quantitatively different.

Clonal Selection in Helper T Cells

The initial outcome for pMHCII+ DC interactions with naive T_H cells is T-cell receptor (TCR)-driven clonal selection. T_H- cell responses that focus the specific T_H-cell response to a set of dominant TCRs provide access to the mechanisms that underpin T_H clonal selection.[39,40,41] Earlier studies indicate the importance of TCR-pMHCII affinity in determining T_H cell fate.[39,42,43,44] In this model, selective expansion of clonotypes expressing higher-affinity TCRs would rely on competition for pMHCII complexes on APCs. Alternatively, in vitro studies using altered peptide ligands suggested that the duration of TCR-pMHCII contact was critical to cell fate and therefore defined “best fit” in vivo.[45,46,47,48] In support of this model, T_H cells expressing TCR with fast off rates were lost over time in vivo.[49] Further, there is evidence for different peptides stabilizing the pMHCII to create a hierarchy of dominant peptides.[50] Each and all of these variables would impact what is considered “best fit” and influence the outcome of clonal selection. More recently, we provide evidence for a model of T_H clonal selection that is based on a TCR affinity threshold.[51] Multiple affinity-based thresholds underpin cell fate and T_H clonal expansion[52] with evidence that the highest affinity TCR assort into the T_{FH} compartment.[53] Hence, selection thresholds generate antigen-specific clonal diversity in ways that impact the development of effector T_H cell function in vivo.

Follicular Helper T Cells

There were early reports of effector T_H cells specialized to regulate B-cell responsiveness. CXCR5 expression was first reported on CD4+CD45RO+ cells in the peripheral blood and secondary lymphoid tissue in humans.[54] Gene ablation studies emphasized the role of CXCR5 and CC chemokine receptor 7 in the correct positioning of T and B cells in secondary

lymphoid tissue that was also needed to support effective T_H cell-dependent B-cell immunity.[55,56] Blocking CD28 and OX40 interactions in vivo blocked the development of CXCR5+ T_H cells and the GC reaction.[57] Further, CXCR5 expression was induced in an antigen-specific manner on T_H cells in vivo, and these cells relocated to follicular areas and the GC of responding lymphoid tissue.[58] CXCR5+ T_H cells were sorted from human tonsil and shown to support antibody production in vitro.[59,60] The tonsillar CXCR5+ T_H cells expressed high levels of CD40L and ICOS and were found in both the follicular mantle and GC. Adoptive transfers distinguished CXCR5+ B cell helper activity (T_{FH}) from P-selectin ligand^{hi} tissue homing inflammatory mediation (DTH-promoting T_H) that emerged together from the same set of precursors in vivo.[61] The term T_{FH} cells was coined to categorize this functionally and phenotypically distinct effector T_H cell compartment.[59,60]

As the name implies, the cardinal characteristic of all T_{FH} cells is their repositioning into the follicular regions of secondary lymphoid tissues. Early assessments of cytokine production by in vitro restimulated CXCR5+ T_{FH} cells indicated interleukin (IL)-2, interferon (IFN)-γ, and IL-10 from human peripheral blood[60] with evidence for IL-4 and IFN-γ from TCR transgenic mouse T_{FH} cells.[61] Early microarray analyses suggested separable gene expression programs for T_{FH} cells and other known T_H-cell subsets. CXCL13 was highlighted early[62] with evidence for ICOS, IL-21,[63,64] IL-21R,[65] and the differential expression of Bcl-6[63] being used as the most reliable attributes of T_{FH} function in vivo. Thus, acquisition of special pre-GC T_{FH}-cell functions was associated with the programming of a separate T_H-cell lineage.

Molecules important in the development of normal B-cell immunity were implicated in early studies of T_{FH} development. CD28 deficiency or treatment with blocking CD28 antibodies led to profound defects in B-cell immunity.[66] CD28 was required early to initiate naive T_H-cell responsiveness to pMHCII+ CD80- and CD86-expressing DCs. In contrast, CD40-CD40L interactions were central to the delivery of T-cell help to B cells.[67,68,69] The CD28 family member ICOS[70] was implicated in T_{FH}-cell function in pre-GC interactions with pMHCII-expressing B cells.[71,72,73] ICOS-deficient humans and mice[74,75,76] and ICOS-L-deficient mice had marked deficits in all aspects of B-cell immunity. ICOS deficiency was associated with decreased T_{FH}-cell development and considered an important molecule in the delivery of effector T_{FH} function.[77,78] Conversely, overexpression of ICOS in mice with a regulatory defect in ICOS expression[79] resulted in an overproduction of CXCR5+ T_{FH} cells and breakthrough autoimmune disease.[64] Recent studies indicated that ICOS can substitute for CD28 and rescue the T_{FH} defects and B-cell defects in CD28-deficient mice.[80] Furthermore, the abundant CXCR5+ T_{FH} cells in this model act in a T-cell autonomous manner to promote autoantibody production.[81] PD-1, another CD28 family member that has been implicated in the negative regulation of chronically activated T cells, was also found on GC T_{FH} cells in

human tonsil and mouse.[82] Positive and negative influences of antigen-specific T_{FH}-cell costimulation are balanced in ways that remain poorly understood in vivo and are an active avenue of current research in this field. BCL6 is required for development of the T_{FH} program[83,84,85] and is reinforced within T_{FH} cells upon pre-GC B-cell contact.[86,87] IL-21 also plays a major role in T_{FH} function with substantial loss of B-cell immunity in its absence.[88,89] Recent studies have identified BCL6 in antigen-specific T_{FH} cells and BLIMP1, which has an opposing function, in non-T_{FH} cells.[53] BCL6 and BLIMP1 expression was mutually exclusive across these two T_H-cell subtypes, already evident by the second cell division in vivo.[29] More recently, transcription factors c-Maf and BATF were shown to act with BCL6 to program T_{FH} development.[90,91] Hence, distinct transcriptional programming of unique cellular functions directs the early T_{FH}-cell development that is central to subsequent B-cell immunity (Fig. 10.2).

Pre-Germinal Center Follicular Helper T-B-Cell Contact

First contact between antigen-specific T_{FH} and antigenprimed B cells has also been captured through dynamic imaging.[92] Stable "monogamous" interactions between one antigen-specific T_{FH} cell and one B cell can last for a duration of 10 to 60 minutes in the follicular regions of the LNs. These interactions were accompanied by highly dynamic movements, with the B cells migrating extensively and leading

the T_{FH} cells.[92] A recent study demonstrated that expression of the adaptor molecule signaling lymphocytic activation molecule-associated protein (SAP) was needed to form long duration contacts with antigen-primed B cells.[93] In these studies, there was no role for SAP in early T_{FH}-DC contacts, and the SAP-deficient T_{FH} cells reached the follicular regions and expressed all the hallmarks of pre-GC T_{FH} cells ($CXCR5^{hi}$, CD40L+, $ICOS^{hi}$, and $OX40^{hi}$).[93] Furthermore, in the absence of SAP, T_{FH} cells were still capable of cytokine production[94] but unable to promote GC formation.[95,96] More recently, dynamic imaging places ongoing critical pre-GC contacts in the interfollicular zones of LNs[97] with a requirement for persistent BCL6 expression in B cells to maintain effective cognate contact.[98] Therefore, early T_{FH}-cell developmental programs establish the capacity for cognate contact needed to promote ongoing antigen-specific B-cell immunity.

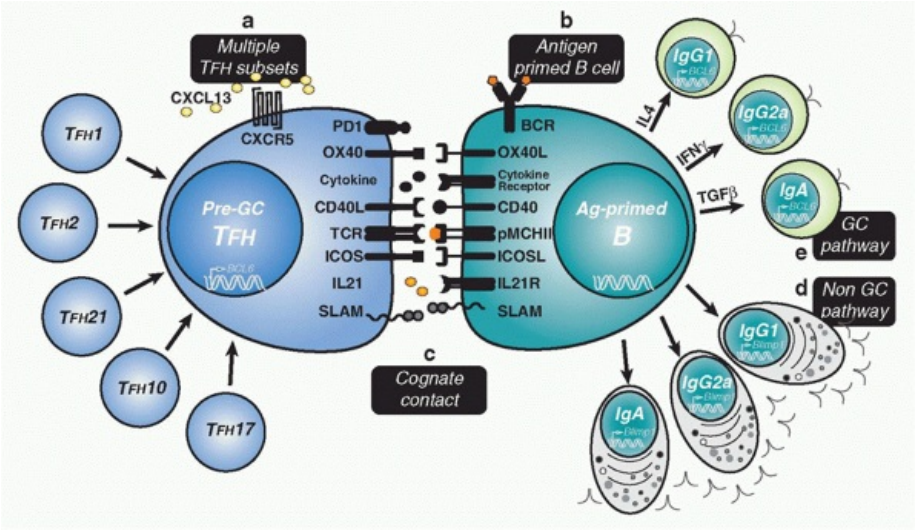

FIG. 10.2. Pre-Germinal Center (GC) Follicular Helper T (TFH)-B-Cell Contact. A: Multiple subsets of antigen-specific pre-GC T_{FH} are produced to regulate B-cell immunity. The organization of function within T_{FH} subsets remains speculative. There is evidence for different cytokine-secreting T_{FH} cells that regulate commitment to separate antibody class as well as different types of T_{FH} cells that regulate non-GC plasma cell differentiation. Bcl-6 and CXCR5 expression is thought to be a common feature of all T_{FH} cell subsets. **B:** Antigen-primed B cells must process and present peptide major histocompatibility class II to receive cognate help from pre-GC T_{FH} cells. Upregulation of molecules involved in helper T cell contact is a poorly resolved component of early antigen-driven B-cell maturation. **C:** Cognate contact between antigen-specific T-cell receptor and peptide major histocompatibility class II complexes focus pre-GC T_{FH}-B cell intercellular exchange of molecular information. Modifying interactions at first contact are known to involve costimulatory molecules (eg, cluster of differentiation [CD]40L-CD40, ICOS-ICOSL), accessory interactions (eg, signaling lymphocytic activation molecule family interactions, OX40-OX40L), cytokine and cytokine receptors (eg, IL4-IL4R, interferon [IFN]γ-IFNγ receptor, IL21-IL21R). Distribution of these functional attributes within pre-GC TFH compartments is not yet well resolved in vivo. **D:** The non-GC pathway to plasma cell development permits antibody class switch recombination (CSR) without somatic hypermutation (SHM) depending largely on the cytokine stimulus provide by pre-GC T_{FH} cells. Blimp-1 expression is required for plasma cell commitment across all antibody classes. **E:** The GC pathway to memory B-cell development begins with extensive B-cell proliferation within secondary follicles that will polarize into dark and light zone to initiate the GC reaction. The GC pathway is associated with Bcl-6 upregulation and activationinduced cytidine deaminase expression to supports both antibody CSR and SHM. These GC features emerge across all antibody classes and require productive and long duration pre-GC TFH contact.

It has been unclear how differential BCR affinity can impact the early fate of antigen-primed B cells. Very-low-affinity B cells are capable of forming GCs[99] but fail to do so in the presence of high-affinity competition.[100] In contrast, there is evidence for the highest-affinity B cells

preferentially entering the non-GC plasma cell pathway, leaving lower-affinity B cells to mature within the GC cycle.[101] This issue has been addressed more recently using intravital imaging to examine the early pre-GC selection events.[102] In this model, access to antigen was not impacted by BCR affinity, but the differential capacity to present antigen to pre-GC T_{FH} cells assorted with BCR affinity. Increased T-cell help promoted greater access to both the plasma cell pathway and the GC reaction. Thus, BCR affinity thresholds regulate B-cell fate at the earliest pre-GC junctures of antigen-specific T_{FH}-B interactions. Overall, the precise function of different costimulatory molecules and their combinatorial impact on antigen-specific B cell fate remains an exciting area of current interest. Quantitative differences in cell surface molecules in combination with mixtures of cytokines will likely synergize in

predetermined ways to skew pMHCII-expressing B cells into separate pathways of B-cell immunity. Unraveling these molecular combinations will help to define the rules of molecular control for antigen-specific B-cell immunity.

Controlling Antibody Class

Pre-GC cognate T_{FH}-cell contact controls multiple antigenspecific B-cell differentiation options. Beyond this early pre-GC developmental juncture, antibody class switch appears in both in the extrafollicular pathway to plasma cell differentiation and the GC pathway to memory development.[103] Class switch also requires multiple rounds of cell division in the target cell before expression of non-immunoglobulin (Ig)M antibody.[104] Hence, it is likely that initial commitment to antibody class occurs at the first pre-GC point of cognate contact and is propagated in a lineal manner across each developmental option (see Fig. 10.2).

Class switch recombination (CSR) is an intrachromosonal deletional process between the switch (S) regions that reside 5′ of each constant region gene in B cells (except Cδ).[105] Signaling through CD40 and cytokine receptors induces germline transcription through the targeted S regions providing activation-induced cytidine deaminase (AID; also known as Aicda) access to deaminate cytosines in the single stranded template. AID is required and sufficient for the initiation of the CSR reaction in the activated locus.[106] AID-deficient animals[107] and humans[108] display no CSR or somatic hypermutation (SHM) of the Ig genes. Recent evidence indicates that following antigen stimulation, AID expression is regulated in B cells by paired box gene/protein 5, E-box proteins,[109] homeobox C4,[110] and forkhead box O1.[111] Removal of the resulting uracils and deoxyribonucleic acid (DNA) cleavage generates double strand breaks that trigger the recruitment of DNA damage machinery, mismatch repair, and nonhomologous end joining to complete the CSR event.[112] The adapter protein 14.3.3 is recruited with AID to switch regions[113] and polymerase ζ has been implicated in the repair process associated with CSR.[114] Peripheral B cells undergoing CSR in the absence of the x-ray-repair crosscomplementing protein 4 component of the double strand break repair machinery are also highly susceptible to translocation events and oncogenic transformation.[115] Antibody class switch is a destabilizing and potentially dangerous cellular event that can proceed without SHM in the extrafollicular pathway.

Induced CD40L on pre-GC T_{FH} cells and the receipt of this signal through CD40 on B cells is required for antibody class switch.[67,116] Animals and humans lacking CD40 display a hyper-IgM syndrome with profound defects in class switch, GC formation, and the development of affinity matured B-cell memory.[116] ICOS expression on activated T_{FH} cells is thought to act upstream of CD40L in this temporally orchestrated set of events.[117] ICOS-deficient animals also have clear defects in antibody class switch, GC formation, and the development of B-cell memory.[74,75,76] Some residual class switch in the absence of CD40/CD40L interactions may be explained by the action of TACI and BAFF-R.[12] OX40/OX40L interactions also quantitatively impact class switch while CD27-CD70 interactions promote plasma cell (PC) production.[118] Thus, the range of molecules expressed at the pre-GC T_{FH} cell surface influences the developmental impact of TCR-pMHCII contact on antigen-primed B cells. Considering the range of antibodies that can be produced, there must be multiple subtypes of pre-GC T_{FH} cells that control antibody class. Different classes of pre-GC T_{FH} would vary in production of T_{FH} cell-derived cytokines to control antibody isotype. IL-4 and IFN-γ are reciprocal regulators of IgG1 and IgG2a production.[119] Animals lacking IL-4 or Stat 6 have decreased IgG1 levels and no IgE.[120,121] IL-4 also acts together with IL-21 to control IgG subtypes and IgE levels.[88] In contrast, transforming growth factor (TGF)β is implicated in the induction IgA, while IL-2 and IL-5 augment IgA production.[122] Similarly, IL-6 may selectively support IgG2a and IgG2b expressing B cells in vivo.[123] Each of these factors can exert their effects in vitro or in a bystander manner in vivo. However, it is thought that the directed delivery of these soluble molecules toward points of TCR-pMHCII contact allows soluble signals to focus locally in an antigen-specific cognate manner.

Within antigen-responsive B cells, the molecular machinery that regulates CSR is deployed in an antibody class-specific manner. The global CSR machinery is targeted by transcription factors downstream of the cytokine receptors that control specific antibody classes. For example, IFNγ activates signal transducer and activator of transcription downstream of the IFNγ receptor to induce T-bet and promote IgG2a class switching.[124,125] Similarly, TGFβ signals through TGFβ-receptor to activate SMAD and RUNX transcription factors to promote IgA class switch.[126] Furthermore, the transcriptional regulator BATF required for T_{FH} development is also required in B cells to generate germline switch transcripts and promote AID expression.[91] Finally, Ikaros regulates antibody class decisions by differentially controlling transcriptional accessibility of constant region genes.[127] How the initial commitment to antibody class is maintained and propagated during clonal expansion, BCR diversification, and affinity-based selection within the GC reaction remains an important but unresolved issue. Therefore, it remains plausible that functional reprogramming accompanies CSR creating separable lineages of class-specific memory B cells in vivo.

Extrafollicular Plasma Cell Development

Under the cognate regulation of pre-GC T_{FH} cells, a cohort of antigen-primed B cells clonally expand within the T-cell zones of secondary lymphoid organs and rapidly give rise to PCs. Within the first few days after antigen exposure, small foci of B-cell blasts can be seen within

the T-cell zones.[103] This plasmablast stage appears transitional and defines pre-PCs that may secrete antibody but also retain the capacity to proliferate. In contrast, PCs are typically considered terminally differentiated and in a postmitotic state.[128,129] PCs display a marked increase in IgH and IgL messenger ribonucleic acid and prominent amounts of rough endoplasmic reticulum to accommodate translation and secretion of abundant Ig. They have reduced or lost numerous cell surface molecules

including B220, CD19, CD21, and CD22 with an increase in the proteoglycan syndecan-1 (CD138),[130,131] often used as a distinguishing marker for PCs. We recently demonstrated that class-switched plasma cells retained robust antigenpresentation capacity as a negative feedback loop for regulation of T_{FH} cells.[132] These studies further highlight the bidirectional programming between antigen-primed B cells and pMHCII-specific T_{FH} cells during developing immune responses.

In mice deficient for SAP, the extrafollicular pathway to PC development, remains largely intact but the GC pathway is blocked.[95] Recent studies indicate that SAP-deficient T_{FH} cells exhibit heightened CD40L expression but decreased ICOS induction that alone can account for this defect.[94] More recent studies indicate that SAP-deficient T_{FH} cells can only form short duration cognate contact with antigen-primed B cells, which are insufficient for GC entry but adequate for PC formation. It will be important to dissect the separable signals and cellular subsets of pre-GC T_{FH} cells that regulate the rapid but short-lived effector B-cell response in vivo. Extrafollicular PCs have half-lives of 3 to 5 days[133] and express germline-encoded antigen-specific antibodies.[131,134] Newly formed PCs migrate via the marginal zone bridging channels into the red pulp of the spleen and into the medullary cords of LNs. Migration patterns in vivo appear controlled by increased responsiveness to the CXCR4 ligand CXCL12 and decreased expression of CXCR5 and CC chemokine receptor 7.[135] There is evidence for BCR affinity-based selection even at this early stage in the response.[131] In some studies, B cells expressing low affinity BCR remain non-GC and high-affinity B cells preferentially enter the GC pathway. 100 The converse can also be seen with high-affinity B cells preferentially entering the non-GC short-lived PC pathway.[101] While seemingly contradictory, these different outcomes in vivo may reflect the plasticity of intercellular control at the T_{FH}-B point of contact.

The transcriptional control of PC development also exists in multiple layers controlling a cascade of developmental change. The transcriptional repressor prdm-1 (encoding Blimp-1) plays a central role in the regulation of PC development.[136] B cells lacking Blimp-1 do not differentiate into extrafollicular PC or post-GC PC, with TI and TD antibody responses profoundly diminished in vivo.[137] These Blimp-1-deficient animals also display defective levels of serum antibody, suggesting that spontaneous production of antibody by B-1-B cells also requires Blimp-1 expression. Structurefunction analysis indicates the modular action of Blimp-1 integrating a variety of environmental cues that lead to PC development.[138,139] Blimp-1 represses proliferation through c-myc as one direct target among many others involved in cell cycle control. Blimp-1 also induces antibody secretion by repressing the

transcription factor Pax-5, thereby derepressing Xbp-1. The transcription factor Xbp-1 controls the unfolded protein response, and many facets of the cellular secretory mechanism that are critical to PC function and survival.[140,141,142]

The transcriptional coactivator OBF-1 also appears important for B cells to complete the PC program.[143] In the absence of OBF-1, Bcl-6, Pax-5, and AID are not repressed, blocking the induction of Blimp-1 and PC development. In contrast, ablation of the transcription factor MitF leads to the spontaneous development of PC that appears independent of antigen stimuli.[144] Interestingly, reexpression of bcl-6 and its cofactor MTA3 re-activates the B-cell program and increased CD19 and MHC II, and decreased CD138 in plasma cell lines.[145] This remarkable study suggests that PC fate is not as terminal and passive as it has been thought to be, and that the PC fate remains subject to dynamic gene expression programs. Regulation of the unfolded-protein response by X-box-binding protein 1 is not needed for plasma cell development but is necessary for antibody secretion.[146,147] Epstein-Barr virus-induced molecule 2 also appears essential for B-cell movement to extrafollicular sites and the non-GC plasma cell response.[148,149] In addition, Epstein-Barr virus-induced molecule 2 guides recently activated B cells to interfollicular LN regions and then to outer follicular areas as a prelude to GC formation. Furthermore, there appears to be an early pre-GC proliferative phase at the perimeter of follicles that also precedes GC formation and BCR diversification.[150] Interestingly, recent dynamic imaging studies indicate migration of T_{FH} cells to the follicle interior, even before accumulation of GC B cells.[97]

THE GERMINAL CENTER CYCLE

Movement of antigen-primed B cells into the follicular regions of lymphoid organs after effector T_{FH}-cell contact initiates the GC pathway to memory B-cell development. These pre-GC B cells expand rapidly within the follicular region to form areas of B220+IgD^{low} antigen-specific B cells referred to as secondary follicles. Secondary follicles polarize into T-cell proximal dark zones of cycling centroblasts and opposing light zones of largely noncycling centrocytes among the dense processes of FDC and sparse presence of GC T_{FH} cells.[151,152] This broad anatomical distribution of the GC reaction orients the activities of clonal expansion, BCR diversification, and clonal variant selection that underpin the evolution of high-affinity memory B cells and post-GC plasma cells in this pathway (Fig. 10.3). Under normal physiologic conditions, the GC reaction emerges as the most efficient means to control affinity maturation and memory B-cell development. However, in the disorganized or absent preimmune lymphoid subcompartments of mice lacking LTa, LTb, tumor necrosis factor receptor I, and LTbR, the activities of the GC reaction remain disorganized but largely intact.[153,154,155,156] Vestiges of the GC or small cell aggregates manage the expansion, diversification, and selection steps required for affinity maturation and memory B-cell development.

Germinal Center Cellular Dynamics

Dynamic imaging of the GC reaction in situ has provided outstanding clarity to the kinetics of GC B cell[157,158] and GC T_{FH}-cell movements and interactions.[159] There was evidence for

interzonal movement of GC B cells indicating bidirectional migration between light and dark zones,[157,158,159,160] with one study emphasizing the majority of movement to be

intrazonal.[157,160] Surprisingly, cell division appeared in both zones of the GC in contrast to classical models.[157,158,159] There was also evidence for the ability of naive B cells to traverse the GC environment with evidence that high-affinity B cells could also enter and dominate existing GCs.[158] All studies identified highly motile GC B-cell movements with evidence for continuous uninterrupted movement over FDC processes. This movement contrasted with the capacity of GC B cells to form frequent short-term contacts but infrequent stable contacts with GC T_{FH} cells.[159] The latter group suggested that these infrequent cognate contacts play a dominant role in the selection of high-affinity BCR expressing GC B cells.[161] Hence, a unique model for affinity-based selection emerges with uninterrupted access of GC B cells to antigen-coated FDCs followed by the ability of "reprimed" B cells to express pMHCII complexes to amounts that gain competitive access to pMHCII-specific GC T_{FH} cells.

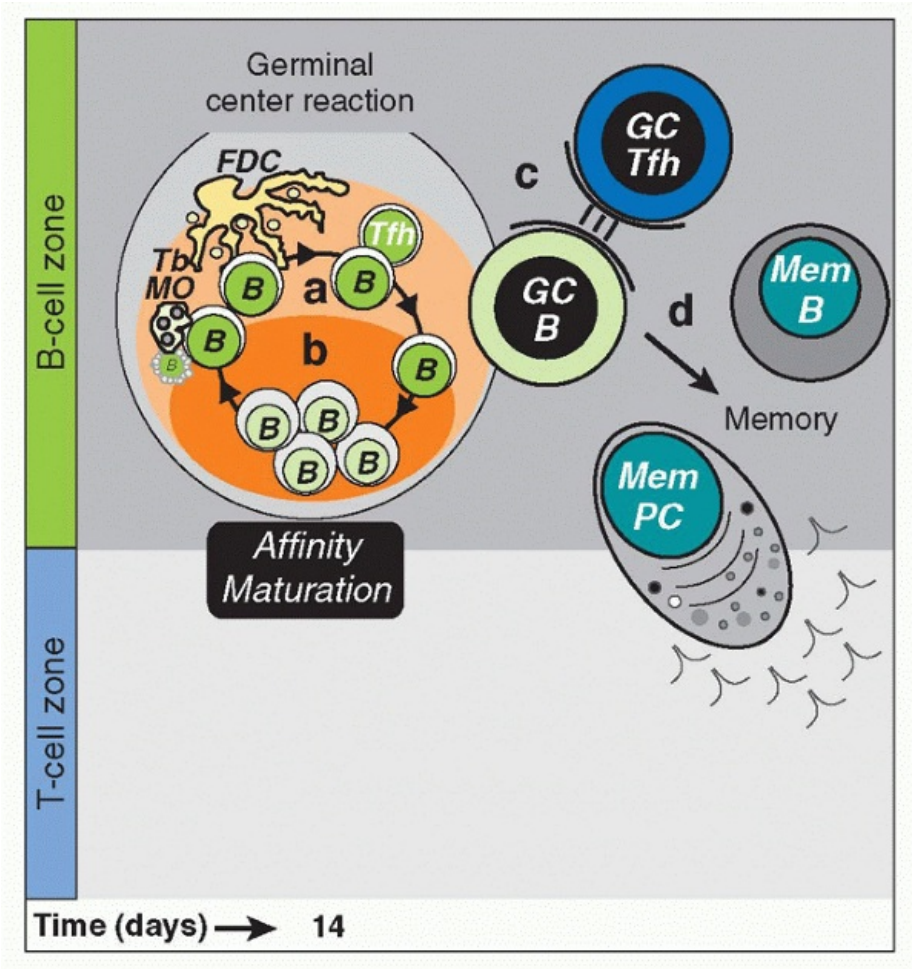

FIG. 10.3. The Germinal Center (GC) Reaction. A: Polarization of the secondary follicle anatomically signifies initiation of the GC cycle with the dark zone supporting GC centroblast expansion, class switch recombination and B-cell receptor (BCR)

diversification through somatic hypermutation. **B:** Noncycling GC centrocytes move to the light zone and continually scan follicular dendritic cell networks. Centrocytes that lose antigen binding will undergo apoptosis while those that express variant BCR with higher affinity can compete for binding to antigen-specific GC TFH cells. **C:** Cognate contact with GC TFH cells requires peptide major histocompatibility class II expression by GC centrocytes that can promote reentry into the dark zones and the GC cycle or exit from the GC. **D:** Entry into the affinity-matured memory B cell compartments of nonsecreting memory B cells and post-GC plasma cells.
