Besides the mechanisms suggested previously, Gammon et al.[239] and Sercarz et al.[246] have proposed the possibility of competition between different MHC-binding structures (“agretopes”) within the same processed fragment. If a partially unfolded fragment first binds to MHC by one such site already exposed, further processing may stop, and other potential binding sites for MHC may never become accessible for binding. Such competition could also occur between different MHC molecules on the same presenting cell.[239] For instance, BALB/c mice, expressing both A^d and E^d, produce a response to hen lysozyme specific for 108 to 120, not for 13 to 35,[239] and this response is restricted to E^d. However, B10.GD mice that express only A^d respond well to 13 to 35 when immunized with lysozyme. The BALB/c mice clearly express an A^d molecule, so the failure to present this 13 to 35 epitope may be due to competition from E^d, which may preempt by binding the 108 to 120 site with higher affinity and preventing the 13 to 35 site from binding to A^d. Competition between different peptides binding to the same MHC molecule could also occur.

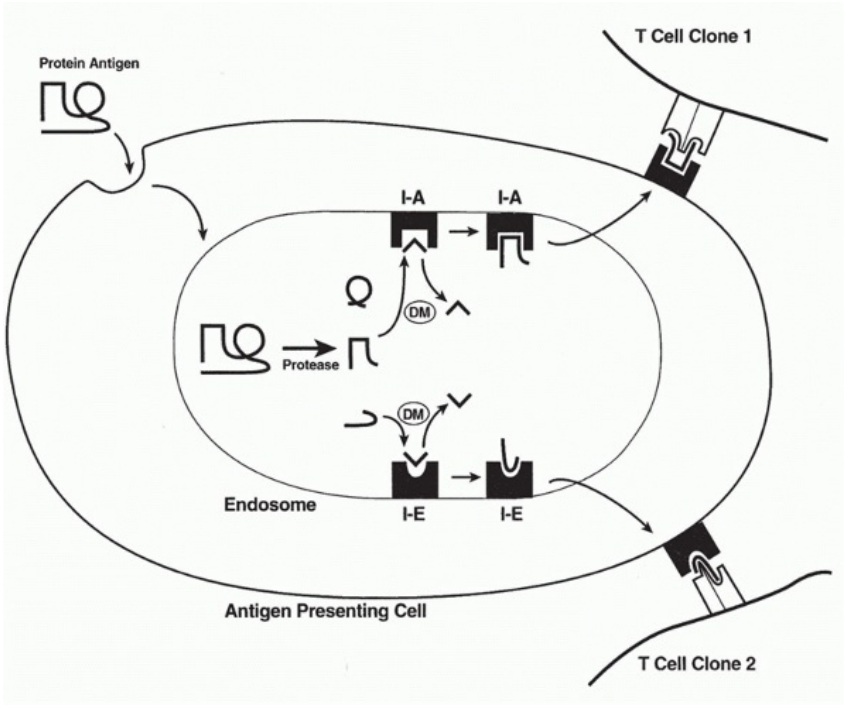

FIG. 23.6. Steps in Antigen Presentation by Class II Major Histocompatibility Complex (MHC) Molecules. Soluble antigen enters the presenting cell by phagocytosis, pinocytosis, or receptor-mediated endocytosis. It is partially degraded to peptide fragments by acid-dependent proteases in endosomes. Antigenic peptides associate with MHC class II molecules (I-A or I-E in the mouse) to form an antigenic complex that is transported to the cell surface. Before an MHC class II molecule can bind the peptide, it must release the class II-associated invariant chain peptide fragment of invariant chain from the binding groove, which is catalyzed by human leukocyte antigen (HLA)-DM. Binding of T-cell receptors to the peptide-MHC complex triggers T-cell proliferation, resulting in clonal expansion of antigen-specific T cells.

All these results, taken together, indicate that antigen processing not only facilitates interaction of the antigenic site with the MHC molecule and/or the TCR but also influences the specificity of these interactions and, in turn, the specificity of the elicited T-cell repertoire. The molecular mechanisms behind such effects are just now being elucidated, as described in the following sections.

Processing of Antigen for T Cells Restricted to Class II Major Histocompatibility Complex Molecules. It has long been known that T-cell responses such as delayed hypersensitivity in vivo or T-cell proliferation in vitro to exogenous proteins can be stimulated not only by the native protein but also by denatured protein[176] and fragments of native protein.[219] Indeed, this feature, along with the requirement for recognition in association with class II MHC molecules, distinguishes T- from B-cell responses. In a number of cases, the site recognized by cloned T cells has been located to a discrete synthetic peptide corresponding to a segment of the primary sequence of the protein. Examples include insulin,[187,219] cytochrome c,[188] lysozyme,[182,213] and myoglobin.[178,185,189] In each case, the stimulatory peptide must contain all the information required for antigen presentation and T-cell stimulation. The lack of conformational specificity does not indicate a lack of TCR specificity. Rather, it results from antigen processing into peptide fragments that

destroys conformational differences prior to binding the TCR. One way to accomplish this is via antigen processing, which involves the partial degradation of a protein antigen into peptide fragments (Fig. 23.6).

Evidence of processing came from the fact that a single protein antigen could stimulate T cells to different epitopes, each specific for a different MHC antigen. For example, when a series of myoglobin-specific T-cell clones were tested for both antigen specificity and MHC restriction, six clones were specific for a site centering on amino acid Glu 109, and all six recognized the antigen in association with I-A^d. Nine additional T-cell clones were specific for a second epitope centered on Lys 140 and were restricted to a different MHC antigen, I-E^d. Thus, the antigen behaved as if it was split up into distinct epitopes, each with its own ability to bind MHC.[215]

That T cells recognize processed antigen was demonstrated by the fact that inhibitors of processing can block antigen presentation. Early experiments by Ziegler and Unanue[247] showed that processing depends on intracellular degradative endosomes, as drugs such as chloroquine and ammonium chloride (NH4 Cl), which raise endosomal pH and inhibit acid-dependent proteases, could block the process. However, prior degradation of proteins into peptide fragments allows them to trigger T cells even in the presence of these inhibitors of processing.[248] For example, T-cell clone 14.5 recognizes the Lys 140 site of myoglobin equally well on the antigenic peptide (residues 132 to 153) as on the native protein (Fig. 23.7). The difference between these two forms of antigen is brought out by the presence of processing inhibitors. Leupeptin, for example, inhibits lysosomal proteases and blocks the T-cell responses to native myoglobin but not to peptide 132 to 153. Thus, native myoglobin cannot stimulate T cells without further processing, whereas the peptide requires little or no additional processing.[249]

Why is antigen processing necessary? For class II MHC molecules, experiments suggest that antigen processing may uncover functional sites that are buried in the native protein structure. For example, a form of intact myoglobin that has been partially unfolded through chemical modification can behave like a myoglobin peptide and can be presented by APC even in the presence of enough protease inhibitor or chloroquine to completely block the presentation of native myoglobin.[249] Denatured lysozyme could also be presented without processing to one T-cell clone.[184] This result suggests that the requirement for processing may simply be a steric requirement, that is, to uncover the two sites needed to form the trimolecular complex between antigen and MHC and between antigen and TCR. Thus, unfolding may be sufficient without proteolysis, and proteolysis may simply accomplish an unfolding analogous to Alexander's approach to the Gordian knot.

The importance of antigen unfolding for T-cell recognition and the ability of unfolding to bypass the need for antigen processing apply to a range of polypeptide sizes from small peptides to extremely large proteins. At one extreme, Lee et al.[250] found that even fibrinogen, of Mr 340,000, does not need to be processed if the epitope recognized is on the carboxy-terminal portion of the α chain, which is naturally unfolded in the native molecule. At the other extreme, even a small peptide of only 18 amino acid residues, apamin, requires processing unless the two disulfide bonds that hold it in the native conformation are cleaved artificially to allow unfolding.[251] Therefore, large size does not mandate processing, and small size does not necessarily obviate the need for processing, at least for class II presentation. The common feature throughout the size range seems to be the need for unfolding. This evidence, taken together with the earlier data on unfolding of myoglobin and

lysozyme, strongly supports the conclusion that unfolding, rather than size reduction, is the primary goal of antigen processing, and that either antigen presentation by MHC molecules or TCR recognition frequently requires exposure of residues not normally exposed on the surface of the native protein. This conclusion is supported by recent studies of peptides eluted from class II MHC molecules, and the crystal structures of class II MHC-peptide complexes, which show that longer peptides can bind with both ends extending beyond the two ends of the MHC groove[252,253,254] (see “Antigen Interaction with MHC Molecules” section).

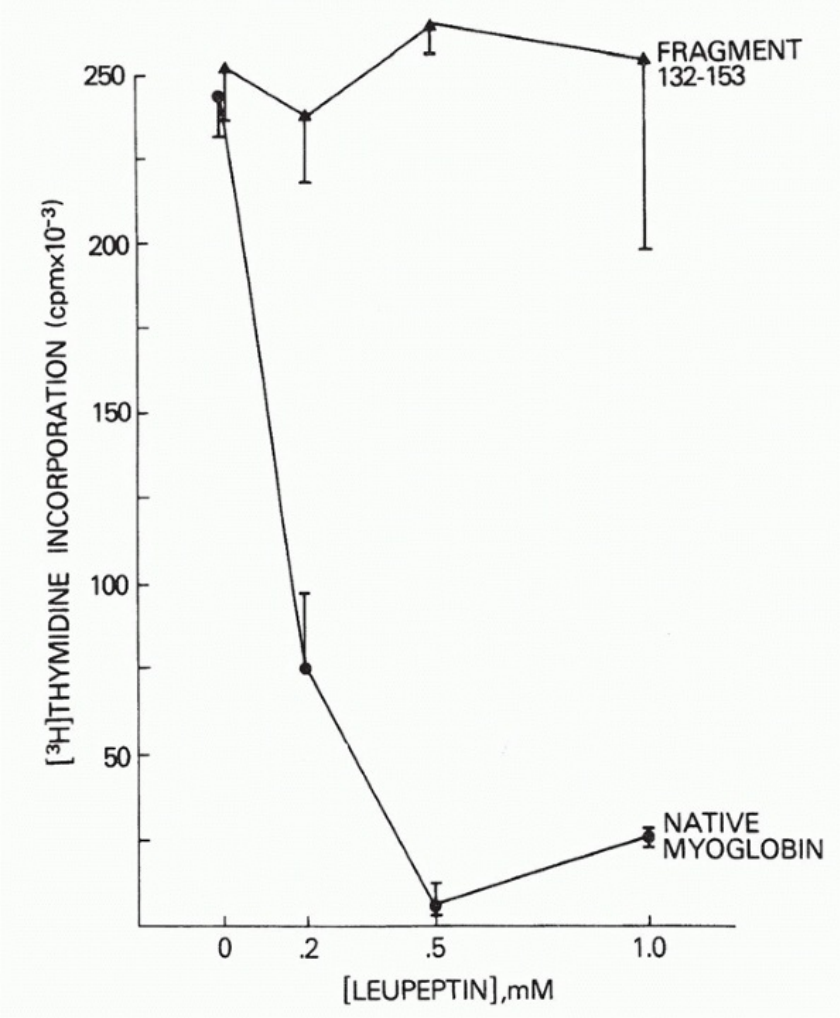

FIG. 23.7. Inhibition of Antigen Presentation by the Protease Inhibitor Leupeptin: Differential Effect on Presentation of the Same Epitope of Native Myoglobin or Peptide 132 to 153 to the Same Monoclonal T-Cell Population. Splenic cells from nonimmunized B10.D2 mice, as a source of antigen-presenting cells, were incubated with leupeptin at the concentration indicated for 15 minutes prior to and during exposure to 2 μM native myoglobin or 1 μM peptide fragment, washed, irradiated, and cultured at 400,000 cells per well with 10,000 T cells of clone 14.5; thymidine incorporation was measured after 4 days of culture.[249]

Besides proteolysis, unfolding may require the reduction of disulfide bonds between or within protein antigens. A gamma interferon-inducible lysosomal thiol reductase (GILT) is expressed in APCs and localizes to the late endosomal and lysosomal compartments where MHC class

occurs.[255] Unlike thioredoxin, this enzyme works at the acid pH of endosomes and uses Cys but not glutathione as a reducing agent. APCs from GILT knockout mice were tested for the ability to present hen egg lysozyme to hen egg lysozyme-specific T-cell lines.[256] For two epitopes, the T-cell response was insensitive to the GILT defect, even though they involved a disulfide bond in the native protein. But for one epitope, located between disulfide bonds, the T-cell response was completely inhibited when the APCs lacked GILT reductase. In this case, reduction of disulfide bonds was an essential step for antigen presentation, presumably needed to generate free peptides for MHC class II binding.

Processing of Antigen for T Cells Restricted to Class I Major Histocompatibility Complex Molecules. Early studies on class I-restricted T cells, such as cytolytic T cells (CTLs) specific for virus-infected cells, assumed that they responded mainly to unprocessed viral glycoproteins expressed on the surface of infected cells. However, since the mid-1980s, it has been clear that CTLs, like other T cells, recognize processed antigens. For example, influenza NP was a major target antigen for influenza specific CTLs, even though NP remains in the nucleus of infected cells and none is detectable on the cell surface.[257] Further support came from the finding that target cells that take up synthetic NP peptide 366 to 379 were lysed by NP-specific CTLs.[228] This constitutes evidence that antigen presented in association with class I molecules requires processing into antigenic fragments. Also, the demonstration that synthetic peptides could sensitize targets for CTLs introduced a powerful tool for mapping and studying CTL epitopes.

Even for influenza hemagglutinin, which is expressed on the surface of infected cells, surface expression was not required for antigenicity, implying that it is the processed antigen that stimulates a T-cell response. Target cells expressing leader-negative hemagglutinin, which is not transported to the cell surface but remains in the cytosol, were lysed equally well as those with surface hemagglutinin.[229] Similar conclusions were drawn from anchor-negative mutants.[258] Indeed, studies of HIV-1 gp160 genes with or without a leader sequence suggest that removal of the leader sequence can increase the amount of protein that is retained in the cytosol and is available for processing and presentation through the class I MHC processing pathway.[259] The explanation may be that the signal peptide results in cotranslational translocation of the growing peptide chain into the endoplasmic reticulum (ER), whereas proteins without a signal peptide remain in the cytosol, where they are accessible to the processing machinery of the class I pathway (see subsequent discussion). This cytosolic protein processing machinery consists primarily of the 26S proteasomes.[260,261] The specificity of such proteasomes to cleave at certain positions in a protein sequence thus provides the first hurdle that a potential epitope must surmount to be presented by class I MHC molecules to be cut out correctly but not destroyed by the proteasome.

In the standard proteasome, 14 distinct subunits assemble to form a high-molecular weight complex of about 580 kD with three distinct protease activities located on different subunits. The proteasome is a barrel-shaped structure, with the protease activities arrayed on the inner surface, and unfolded proteins are believed to enter the barrel at one end, leaving as peptides at the other end. The different proteases cut preferentially after aromatic or branched chain amino acids (chymotryptic-like activity of the β5 subunit), basic amino acids (trypsin-like activity of the β2 subunit), or acidic residues (glutamate preferring of the β1 subunit).[262,263] Protease activity is increased against misfolded proteins, such as

senescent proteins, which are tagged with ubiquitin and directed to the proteasome. In addition, viral proteins produced during infection and proteins synthesized with artificial amino acids are particularly susceptible to degradation by proteasomes. The products of protease digestion are peptides ranging from to 3 to 14 amino acids in length, including 9-mers, of just the right size for MHC binding. The chymotrypsin- and trypsin-like activities may be particularly important for antigenic peptides, as many peptides that naturally bind MHC end in hydrophobic or basic residues.[264]

The proteasome is the major processing machinery of the nonendosomal processing pathway. This is shown by the effect of proteasome inhibitors on MHC class I assembly and antigen presentation and by the effect of Large Multifunctional Peptidase (LMP-2) and LMP-7 mutations on antigen processing. A family of proteasome inhibitors have been described[262,263,265] that consist of short peptides, three to four amino acids in length, ending in an aldehyde, such as Ac-Leu Leu norLeu-al, carbobenzoxy-Leu Leu nor-Val-al,[263] or nonpeptides such as lactacystin.[266] Although the peptides appear to be directed primarily at the chymotrypsin-like protease activity, as false substrates, in fact, they inhibit all three types of protease activity.

By inhibiting antigen processing, these inhibitors induce a phenotype of reduced expression of MHC class I and inability to present antigen to class I-restricted CTL.[263] The MHC class I heavy chains remain in the ER, as shown by failure to become resistant to endoglycosidase H,[267] which occurs in the Golgi. They are also unable to form stable complexes with β2-microglobulin due to a lack of peptides. These effects are specific for the protease function because the inhibitors do not block presentation of synthetic peptides, which also rescue MHC class I expression, and because inhibition is reversible when inhibitor is removed. These results suggest that proteasomes are the primary supplier of antigenic peptides for class I, as other pathways are unable to compensate. However, it is also possible that the inhibitors could block other potential processing enzymes as well. An alternative processing pathway that bypasses the proteasome is provided by signal peptidase. As signal peptides are cleaved from proteins entering the ER, these hydrophobic peptides can bind MHC class I.[268] Particularly for MHC molecules such human leukocyte antigen (HLA)-A2, which prefer hydrophobic sequences, this peptidase can be an alternative source of antigenic peptides that are independent of proteasomes and transporter associated with antigen presentation (TAP)-1/2 transport (see section on “Transport”)because they are formed inside the ER.

The proteins destined for proteasomal processing include some normally short-lived proteins with a half-life of about 10 minutes, which constitute about 25% of the proteins in the cell. The rest arise from long-lived proteins, with a half-life

of about 1 day, which may be synthesized incorrectly. These defective ribosomal products are ubiquitinated and marked for rapid degradation in proteasomes.[269,270] In a normal cell, these can arise from errors in ribonucleic acid transcription, protein translation, assembly, folding, or targeting. But in a virally infected cell, misfolded viral proteins provide a ready supply of antigenic peptides for antigen presentation and T-cell recognition almost as soon as the virus starts to produce new viral proteins. Similarly, incorporation of amino acid analogues, such as canavavanine in place of arginine, creates misfolded proteins that are rapidly processed and more efficiently presented via the proteasomal pathway.[271]

Interestingly, the MHC itself encodes, near the class II region, three proteins, known as LMP-2 and LMP-7 for “lowmolecular-weight protein,” and MECL-1, for “multicatalytic endopeptidase complex-like 1,” which contribute to the proteasome structure. The LMP-2,

MECL-1, and LMP-7 subunits are upregulated by interferon-γ, and substitute for the subunits β1, β2, and β5, respectively, forming what has been dubbed an "immunoproteasome," present in professional APCs. All complexes with LMPs contain proteasome proteins, but only 5% to 10% of proteasomes contain LMP-2 and LMP-7. The ones without LMPs are called constitutive proteasomes.

These MHC-encoded subunits of the immunoproteasome shift the preference of proteasomes for cleaving after certain sequences, resulting in the production of different peptide fragments.[272,273,274] Proteasomes lacking LMP-2 through mutation or gene knockout have the same affinity, but decreased cleavage rate, for sequences ending in hydrophobic or basic amino acids. The effect is specific for these proteolytic sites, as the activity against sequences containing acidic amino acids actually increased.[273] Despite the shift in specific peptides released, the overall level of MHC class I expression was reduced only slightly in LMP-7 knockouts[274] and not at all in the LMP-2 knockouts. However, presentation of specific epitopes of the male H-Y antigen or of influenza NP was reduced by three-fold to five-fold in these knockouts. Toes et al.[275] quantitatively compared the cleavage fragments produced by standard proteasomes and immunoproteasomes and defined the prevalence of different amino acids on each side of the cleavage site. Consistent with earlier studies, there is a strong preference for both to cleave after leucine and also to a lesser extent after other hydrophobic residues, both aliphatic and aromatic. However, the immunoproteasomes have a stronger tendency to cleave after such hydrophobic residues and a much reduced cleavage frequency after acidic residues, Asp and Glu, than standard or constitutive proteasomes. This shift in specificity is concordant with the observation that class I MHC molecules tend to bind peptides with C-terminal hydrophobic or basic residues, not acidic ones. Thus, the immunoproteasomes in professional APCs may be more effective at generating antigenic peptides that can be presented by MHC molecules.[272,275] Protein degradation by proteasomes is processive, so the peptides released after 5% digestion are the same as the fragments released after 90% digestion. This suggests that intact proteins may enter the barrel, but they are not released at the other end until processing is complete.

Immunoproteasomes were shown to be essential for production of a hepatitis B virus core antigenic epitope[276] and to increase production of epitopes from adenovirus[277] and lymphocytic choriomeningitis virus.[278] Similarly, certain epitopes of latent membrane protein 2 of Epstein-Barr virus depended on immunoproteasomes.[279] In that case, the requirement for immunoproteasomes depended on the context of the peptide within the native protein. Incomplete protein synthesis due to puromycin or expression of the epitope surrounded by protein fragments with fewer membrane spanning domains allowed epitope generation by constitutive proteasomes.

On the other hand, some epitopes are generated more effectively by the constitutive proteasome than the immunoproteasome.[275,280] When the repertoire of seven defined class I MHC-restricted epitopes was compared in an elegant quantitative study in LMP-2-deficient or wild-type C57BL/6 mice, it was found that responses to the two epitopes that are immunodominant in wild-type mice were greatly reduced in the LMP-2-deficient mice, which lack immunoproteasomes, and two normally subdominant epitopes became dominant.[281] However, from adoptive transfer experiments in both directions, it was found that the reduced response to one normally dominant epitope was due to decreased production without immunoproteasomes, but that to the other was due to an altered T-cell repertoire in the LMP-2-deficient mice, presumably due to alterations in the peptides presented in the thymus. Further, the increased response to one of the subdominant determinants was related to

increased production of this peptide by the constitutive proteasomes compared to the immunoproteasomes. Thus, the immunoproteasome specificity plays a significant role in determining the repertoire of epitopes presented, and in selecting those that are immunodominant, as well as regulating the $CD8^+$ T-cell repertoire generated in the thymus.

Another protein associated with proteasomes is the proteasome activator PA28, which assembles into 11s structures.[282] Like LMP-2 and LMP-7,[272] PA28 is inducible by interferon-γ, and its induction causes a shift in proteasome function that may lead to the production of greater amounts of and different repertoires of antigenic peptides. For example, synthetic substrates were designed to test the ability of proteasomes to generate authentic MHC-binding peptides. These substrates contained the MHC-binding ligand flanked by the natural sequence as found in the original protein.

To generate the MHC-binding ligand, the proteasome would have to cleave the substrate twice.[283] By itself, the 20s proteasome was able to produce singly cleaved fragments, but with added PA28, doubly cut peptides were generated preferentially. Thus, PA28 favored the production of antigenic peptides, possibly by keeping the peptide in the proteasome until processing was complete. Alternatively, PA28 may coordinate the proteolytic activity of two adjacent sites to generate doubly cut peptides of just the right length (8- to 9-mers) to fit in the MHC groove. The distance between these nearby sites would determine the size of the peptides produced. The PA28 has been shown to increase generation of a dominant lymphocytic choriomeningitis virus epitope independently of the presence of the other interferon-γ-inducible components LMP-2, LMP-7, and MECL-1.[284]

The specificity of this proteasomal processing system determines the first step in winnowing the number of

protein segments that can become CTL epitopes, by selectively producing some peptide fragments in abundance and destroying others. Thus, it is probably not just coincidental that the C-terminal residues produced by proteasomal cleavage often serve as anchor residues for binding class I MHC molecules, or that the lengths of peptides produced are optimal for class I MHC binding.[272,285] Better understanding of the specificity of proteasomes will contribute to the new methods to predict dominant CD8+ T-cell epitopes.[232]

An analysis of proteasomal target sites was based on the proteasomal degradation pattern of three proteins: beta-casein, enolase, and prions.[286] The resulting peptides were analyzed by mass spectrometry, and the cleavage sites identified, including four amino acids on the amino end of each cleavage site and two amino acids on the carboxy end. The results are summarized in Figure 23.8. The three proteolytic activities of the proteasome were represented by favorable amino acids: Arg (trypsin-like), Tyr and Phe (chymotrypsin-like), and peptidylglutamylpeptide (Asp and Glu) at position P1. At this site, Pro was unfavored, as were Asn, Lys, and Ser. Additional negative effects were observed for Asp, Pro, and Ile at position P2. On the carboxy side of the cleavage site, at position P'1, the positive effect of Tyr was noted as well as negative effects of Ile, Phe, and Val.

Additional downstream processing steps, after the proteasome, are known to be important for generation of antigenic peptides. One of these occurs in the cytoplasm, prior to TAP transport, and others occur after transport into the ER. The proteasome creates a first draft of the peptides, which are then selected and trimmed to produce the final pool of antigenic peptides of optimal size and sequence for MHC binding while protecting the nascent peptides from degradation before they can bind MHC.

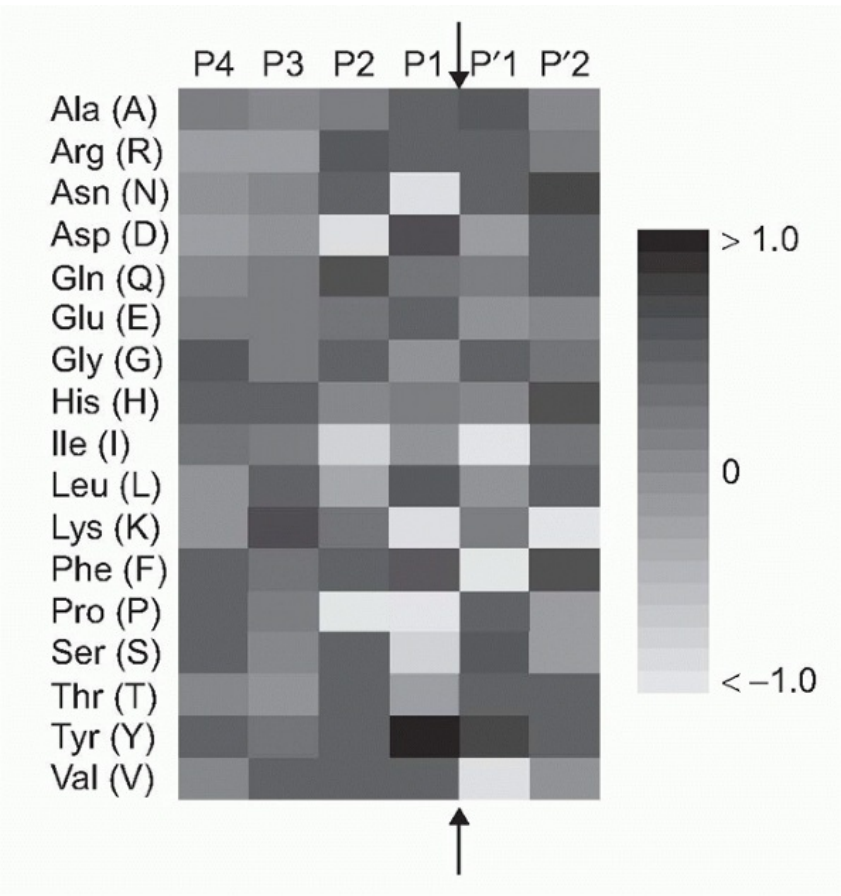

FIG. 23.8. The Effect of Specific Amino Acids on Proteasomal Cleavage between Positions P1 and P'1. Amino acids that favor cleavage are shown in *black*, whereas those that inhibit cleavage are shown in *white*. Reproduced from Donnes and Kohlbacher[286] with permission.

Recent studies have revealed that most peptides are released from the proteasome when they still need further processing to become antigenic peptides.[287,288] In the cytoplasm, the major proteolytic activity comes from an enzyme called tripeptidyl amino peptidase II (TPPII), which is located on a large particle. It has amino peptidase activity, which can remove 1 to 3 amino acids at a time and is useful for peptides of 15 amino acids or less. It also has endopeptidase activity that can cut in the middle of peptides larger than 15 amino acids, with the release of fragments of at least 9 amino acids. These are a significant source of 9-mers with new carboxyl ends, and this may be the only way to generate carboxyl ends other than the proteasome itself.

The importance of TPPII activity for antigen processing is shown by the fact that a specific inhibitor, butabindide, can prevent peptide loading of MHC, resulting in reduced surface expression. The most likely path for most protein antigens is to enter the proteasome and emerge as peptides of 15 amino acids or larger. These are then trimmed by TPPII, resulting in peptides ready for TAP transport. Longer peptides are trimmed internally by TPPII endoprotease, which may generate carboxyl ends needed for TAP binding. The resulting peptides are then transported by TAP into the ER, where they may be trimmed further to prepare them for MHC binding. An additional role of TPPII is shown by the generation of unique epitopes that are not produced by proteasomes. For example, an important T-cell epitope of the Nef protein of HIV requires TPPII processing. Proteasomal inhibitors have no

effect on it, but butabindide prevents its processing and presentation to HLA-A3- or A11-restricted T cells.[289] This pathway seems particularly important for generating epitopes ending in lysine groups, which bind these two MHC types but are rarely generated by proteasomes alone. TPPII can act in parallel with proteasomes or in tandem with them to release this epitope from intact protein or its partially degraded fragments.

Transport into a Cellular Compartment Where Major Histocompatibility Complex Binding Can Occur

The second hurdle a potential epitope must surmount is to be transported into the cellular compartment for loading onto MHC molecules. These compartments are different for class I and II molecules, as noted previously.

Transport Pathways Leading to Major Histocompatibility Complex Class I Presentation. The second hurdle for peptide presentation by class I MHC molecules is to get from the cytosol, where the peptides are produced, to the ER, where the newly synthesized class I MHC molecules are assembled and loaded with peptide. The discovery of a specific active transporter suggested that specificity of transport could further restrict the repertoire of peptides available to load onto class I MHC molecules. Genetic analysis of mutant cell lines that failed to load endogenous peptides onto class I MHC molecules revealed homozygous deletions of part of the MHC class II region near the DR locus. Molecular cloning of DNA from this region revealed at least 12 new genes, of which 2, called TAP-1 and TAP-2 showed a typical sequence for ABC transporter proteins.[290,291,292] Their function is

to transport processed peptides from the cytosol to the ER. Once in this compartment, peptides are handed off by TAP to newly formed MHC class I molecules and stabilize a trimolecular complex with β2-microglobulin. This complex is then transported to the cell surface, where antigen presentation occurs. Without the peptide transporters, empty dimers of MHC class I with β2-microglobulin form, but these are unstable. Excess free peptide would rescue MHC class I by stabilizing the few short-lived empty complexes that reach the surface, as shown by Townsend et al.[293] and Schumacher et al.[294] Thus, MHC-linked genes coding for proteolysis, peptide transport, and presentation at the cell surface have been identified. In effect, the MHC now appears to encode a complex system of multiple elements devoted to the rapid display of foreign protein determinants on the surface of an infected cell. By continuously sampling the output of the protein synthesizing machinery, this system permits rapid identification and destruction of infected cells by CTL before infectious virus can be released.

In an infected cell, as soon as viral proteins are made, peptide fragments generated by the proteasome become available to the TAP-1 and TAP-2 transporter proteins (Fig. 23.9). These transport the peptide fragments into the ER for association with newly formed MHC class I molecules, which would carry them to the cell surface for antigen presentation, all within 30 minutes. Indeed, the finding of a physical association between TAP and the nascent class I heavy chain/β2-microglobulin complex suggests that the peptide may be directly handed off from TAP to the new MHC molecule without being free in solution.[295,296] If TAP transport is highly selective, then some cytosolic peptides may fail to enter the ER for presentation with class I, but if it is promiscuous, then some peptides may be transported that were better off not presented, such as those leading to autoimmunity.

The idea that other proteins may control accessibility of MHC class I-binding sites for peptides originally came from the observation that two rat strains with the same MHC type ($RT1.A^a$) were nevertheless not histocompatible, and CTL could recognize the difference

between them.[297] The difference, called a cim effect, for class I modification, occurred because different peptides were binding the same MHC in the two strains.[298,299] The rat has two alleles for a peptide transporter supplying peptides to MHC. The one called TAP2A has peptide specificity matching that of RT1.A^a and delivers a broad set of peptides for MHC binding. The other transporter allele, called TAP-2B, supplies a different set of peptides that are discordant with RT1.A^a, so fewer types of peptides are bound. Although RT1.A^a would prefer to bind peptides with Arg at position 9, it has to settle for peptides with hydrophobic termini as provided by TAP-2B,[300] thereby accounting for the apparent histocompatibility difference. Thus, the specificity of TAP transport was shown to provide a selective step in narrowing the potential repertoire of CTL epitopes.

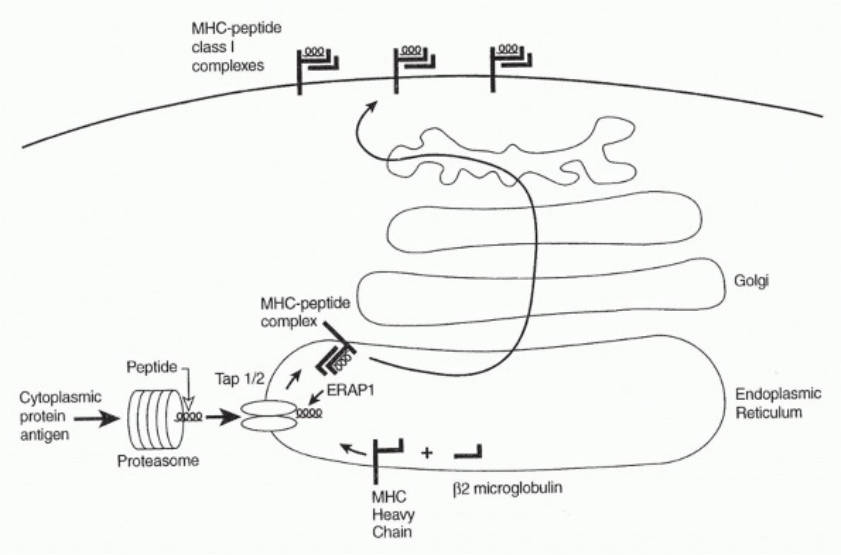

FIG. 23.9. Cytoplasmic Antigen-Processing Pathway leading to Major Histocompatibility Complex (MHC) Class I Presentation. Cytoplasmic antigen is degraded in the proteasome to fragments, which are transported into the endoplasmic reticulum by the transporter associated with antigen presentation (TAP) transporter. Peptide supplied by TAP forms a stable complex with MHC class I heavy chains and β2-microglobulin, and the complex is transported through the Golgi, where it achieves mature glycosylation, and out to the cell surface for presentation to class I-restricted T cells. Additional processing options by tripeptidyl amino peptidase II in the cytoplasm and endoplasmic reticulum aminopeptidase I in the endoplasmic reticulum, before and after TAP transport, allow greater flexibility in meeting the requirements of binding both TAP and MHC molecules.

To measure TAP specificity in other species, a transportable peptide bearing an N-linked glycosylation site was added to cells permeabilized by treatment with streptolysin. If the peptide was transported by TAP, it would enter the ER and cis Golgi, where it would be glycosylated.[301,302,303] The extent of glycosylation served as a measure of TAP function. When competitor peptides were added as well, TAP-mediated transport of the reporter peptide decreased, indicating saturation of peptide-binding sites. In this way, a series of related peptides could be tested for the ability to compete for TAP binding and transport in order to identify the requirements for TAP binding and transport.

TAP binding and transport depended strongly on peptide length.[303,304] Mouse TAP was shown to have a strong preference for peptides of nine residues or longer.[304] For human TAP, peptides shorter than seven amino acids long were not transported, regardless of sequence.[303] Peptides 8 to 11 amino acids long were almost all transported, with some variation in binding affinities depending on sequence.

Peptides 14 to 21 amino acids in length were transported selectively, whereas those longer than 24 amino acids were almost never transported intact. Thus, human TAP transport selected against peptides <7 or >24 amino acids in length, regardless of sequence. Unlike the rat, human and mouse TAP do not show allelic differences in peptide transport.

Although TAP can and must transport a wide variety of peptides, it may still have preferences for which peptides are transported most efficiently and which MHC types are provided with the peptides they need. For example, a self-peptide that naturally binds HLA-B27 was modified slightly to produce an N-linked glycosylation site, resulting in the sequence RRYQNSTEL.[303] Using the glycosylation of this peptide to measure transport, saturation of TAP by homologous peptides occurred with a 50% inhibitory concentration of < 1 μM. Other peptides with unrelated sequences also inhibited, often with equally high affinity. Not only did natural HLA-binding peptides compete but also did peptide variants lacking the MHC-binding motif at positions 2 and 9 (see subsequent discussion). Clearly, peptides binding different MHC types were transported by the same TAP protein, and even peptides that bound mouse MHC were transported by human TAP. In another example, using rat TAP proteins, peptides with Pro at position 2, 6, or 9 were found to be poor competitors for transport of a reference peptide.[302]

In a different approach, using a baculovirus system overexpressing TAP proteins in microsomes, the affinity of TAP binding was determined for a wide variety of synthetic peptides, allowing mapping of the important residues.[305,306] Binding, rather than transport, appears to be the major step determining TAP peptide selectivity.[307] Indeed, artificial neural networks have been developed to predict peptide binding to human TAP.[308] Using this scheme, it was found that peptides eluted from three different human class I molecules had higher predicted affinities for TAP than a control set of peptides with equal binding to those class I MHC molecules, supporting the hypothesis that TAP specificity contributes to the selection of the subset of peptides able to bind a class I molecule that actually bind in vivo.[308] Unlike MHC class I, there were no anchor positions at which a specific amino acid was required. However, there were several positions where substituting the wrong amino acid caused a marked reduction in TAP binding. In a typical MHC class I binding 9-mer, the strongest substitution effects were observed at position 9 (P9), followed by substitutions at P2 and P3, followed by P1. At the carboxy-terminal P9, the preferred residues were Tyr and Phe (as well as Arg and Lys), whereas Glu was worst, causing a 3 log reduction in binding. Similarly, substituting Pro at P2 caused a 1.5 to 2 log reduction in binding, as compared to preferred residues Arg, Val, and Ile.

These binding studies were extended to 231 peptides, which were evaluated for binding to both mouse and human TAP proteins.[309] Both TAP proteins showed strong positive selection favoring certain amino acids (Tyr and Phe) at position P9 and strong negative selection against others (Glu, Asp, and Ser) at P9. However, mouse TAP showed greater negative effects from basic amino acids (Arg or Lys) at P9. Both TAPs were sensitive to Pro at P1, P2, and P3, but human TAP was also sensitive to negative effects of amino acids Asp, Glu, and Gly at these positions. In both cases, TAP binding was insensitive to amino acid substitutions

at intermediate P4 through P8.

TAP preferences such as these would selectively transport some peptides more than others from cytoplasm to ER. Use of combinatorial peptide libraries independently confirmed that the critical residues influencing TAP transport were the first three N-terminal residues and the last C-terminal residue.[310]

Interestingly, these preferred residues are many of the same ones forming the MHC class I-binding motifs (P2 and P9). However, as the MHC-binding motifs differ from each other, it is not possible for TAP preferences to match them all. For example, the TAP preference for Arg at P2 and Phe, Tyr, Leu, Arg, or Lys at P9 overlaps with the binding motif of HLA-B27 and may favor the transport of peptide ligands for this MHC type. Remarkably, the variant B*2709, which does not prefer Tyr or Phe at P9, is not associated with autoimmune disease as in the more common form of HLA-B27. In contrast, HLA-B7 requires a Pro at P2, which greatly decreases TAP binding. Similarly, some peptides binding HLA-A2 have hydrophobic residues unfavorable for TAP binding, suggesting suboptimal compatibility between TAP and the most common HLA class I allele. Measurements with a series of naturally presented peptides from HLA-A2 and HLA-B27 indicated a mean 300-fold higher affinity of TAP for the HLA-B27 peptides than for those from HLA-A2, and some of the HLA-A2 peptides did not bind TAP at all.[308] How are these low-affinity peptides delivered to MHC? One suggestion is that peptide ligands for HLA-A2 and HLA-B7 may be transported as a larger precursor peptide containing the correct amino acids, which are then trimmed off to fit the MHC groove.

A series of studies support this mechanism, showing that longer peptide precursors are trimmed at the N-terminus by aminopeptidases in the ER to form HLA-binding peptides.[311] The ability to transport larger peptides, followed by trimming, could increase the range of permissible antigenic peptides, by facilitating transport of nonantigenic peptides, followed by trimming to the size and specificity needed for MHC binding. For example, following hepatitis B virus infection, certain peptide epitopes that are frequently recognized by CTL are nevertheless not bound or transported by TAP. By extending these peptides by one or two amino acids of the natural sequence at the amino end, their TAP binding was greatly enhanced, but at the expense of reduced MHC binding. When tested on permeabilized cells, the overall effect of the extended peptides was to increase MHC binding. Apparently, by improving TAP transport, these peptides were able to increase peptide delivery into the ER, where they were trimmed to produce peptides compatible with MHC binding.[312]

Similarly, it is known that peptides with a Pro at P2, needed to bind to certain MHC molecules but poorly transported, are produced from longer precursors that are transported by N-terminal trimming in the ER by aminopeptidases.[313] In fact, the inability of the aminopeptidase to cleave beyond a residue preceding a Pro naturally leads to trimming of peptides to produce ones with a Pro at P2. Alternatively, some of these peptides may derive from signal peptides and enter

the ER in a TAP-independent manner. As HLA-A2 tends to bind hydrophobic peptides, signal peptides, which are usually hydrophobic, may account for some HLA-A2-binding epitopes. The ER trimming enzyme has been identified as endoplasmic reticulum aminopeptidase I (ERAP I).[314,315,316] This enzyme is a 106 kD zinc metalloproteinase, and it is the major ER protease with broad specificity. It is inducible by interferon-γ and inhibited by the aminopeptidase inhibitor leucinethiol. Downregulation of ERAP I with small interfering ribonucleic acid in decreased expression of MHC class I, indicating that ERAP I contributes to the supply of peptides. ERAP I prefers peptides of 9 or 10 amino acids or longer and ignores peptides of 8 amino acids or fewer, which may allow it to generate antigenic peptides for

MHC binding without degrading them beyond recognition.

The aminopeptidase provides a way to relax the requirement for proteasomes to generate ends that can simultaneously bind TAP and MHC. In contrast, the fact that a comparable carboxypeptidase has not been identified suggests that carboxyl ends generated by proteasomal processing must be suitable for TAP transport and compatible with MHC binding. This requirement is quite stringent, as the carboxyl-terminal residue is the most important for TAP binding, and it is frequently an anchor residue for MHC as well.

The significance of selective peptide transport may be to limit immunity to self-peptides. If the match between HLA-B27 and TAP specificity is too good, it may contribute to the increased incidence of autoimmune disease associated with HLA-B27.[305] An effect of human TAP specificity in loading of peptides in viral infection has confirmed the biologic significance of TAP specificity.[312] TAP-binding specificity also limited the repertoire of alloantigenic peptides presented by HLA-B27.[317] Tapasin, which is involved in the TAP-binding process, may also contribute to selective MHC loading contributing to immunodominance by favoring binding of peptides with slow dissociation rates from MHC molecules.[318]

By combining the selectivity of proteasomal processing, TAP transport and MHC binding, it has been possible to generate models that correlate with known antigenic peptides.[319,320] These can be used to analyze the sequence of any given protein and to predict epitopes that may be recognized by T cells restricted to MHC class I. These may be important for analyzing the T-cell response to viral or neoplastic antigens and for generating synthetic vaccines capable of eliciting a T-cell response to these antigens. The importance of TAP proteins to antiviral immunity is shown by the fact that herpesviruses have targeted TAP-1 function as a way to interfere with antigen presentation to $CD8^+$ CTL. A herpes simplex virus immediate early viral protein called ICP47 binds to TAP and inhibits its function, causing reduced expression of new MHC class I molecules on the cell surface and inability to present viral or other antigens with MHC class I.[321,322,323] As a way to evade immune surveillance, this strategy could contribute to viral persistence in chronic infection and viral activation in recurrent disease as frequently occurs with herpes simplex virus-1 and herpes simplex virus-2. These findings also raise the possibility of making a live-attenuated ICP47-defective herpes simplex virus vaccine that would be more immunogenic than natural infection.

Transport Pathways Leading to Major Histocompatibility Complex Class II Presentation. Unlike the class I pathway, which delivers peptides to MHC, the MHC class II pathway transports MHC molecules to the endosomal compartment, where antigenic peptides are produced. During transport, the peptide-binding groove must be kept free of endogenous peptides. The cell uses one protein, called invariant chain (and its processed fragment CLIP), to block the binding site until needed, and another protein, HLA-DM, to facilitate release of CLIP peptides and their exchange for antigenic peptides as they become available.

MHC class II molecules assemble in the ER, where α and β chains form a complex with invariant chain.[324,325,326] Invariant chain binds MHC and blocks the peptide-binding groove, so endogenous peptides transported into the ER, for example by TAP, cannot bind.[325,327,328,329,330,331,332] The complex of α, β, and invariant chains, consisting of nine polypeptide chains in all,[333] is transported via the Golgi and directed by signals on invariant chain into endosome-/lysosome-like vesicles called MHC class II compartments. The compartments contain acid-activated proteases capable of digesting foreign proteins into antigenic peptides. In addition, they degrade invariant chain to a fragment called CLIP, corresponding to amino acids 80 to 103. As long as CLIP remains in the binding groove,

antigenic peptides cannot bind, so the rate of CLIP release limits the capacity of MHC to take up antigenic peptides.

Peptide loading can be measured by its effect on MHC structure. When an MHC class II molecule binds a peptide, it changes conformation, and certain monoclonal antibodies are specific for the peptide-bound conformation.[334] Also, the α-β complex becomes more stable after peptide binding, which can be detected by running the MHC on an SDS gel without boiling. The peptide bound form runs on gels as a large α-β dimer while MHC without peptides (but still bound to CLIP) is unstable under these conditions and falls apart to give α and β chain monomers on SDS gels.[335]

Mutant cell lines have been generated with a deletion between HLA-DP and HLA-DQ genes on chromosome 6.[334,336,337,338] These cells express normal levels of MHC class II structural proteins, HLA-DQ and HLA-DR, but fail to present protein antigens.[338] Some of their class II MHC proteins appear on the cell surface but more are retained in the MHC class II compartments. Biochemically, they still contain CLIP peptides,[339] rather than peptide antigens, and they have not achieved the conformation[334] or SDS stability of peptide-binding MHC class II complexes.[340] The defect was discovered to be due to loss of either of the two chains of a class II molecule, HLA-DM, and the phenotype can be corrected by adding back the missing gene.[341] In the presence of normal HLA-DM, MHC releases CLIP and binds antigenic peptides for presentation to T cells.

The importance of HLA-DM function for T-cell help in vivo was studied in H2-DM knockout mice.[342] These mice have reduced numbers of T cells, their class II MHC molecules reach the cell surface bearing high levels of CLIP peptide, and their B cells are unable to present certain antigens, such as ovalbumin, to T cells. When H2-DM knockout

mice were immunized with 4-hydroxy-5-nitrophenyl acetyl ovalbumin, specific IgG antibodies were reduced 20-fold, as compared to wild type. Germinal center formation and class switching were greatly reduced, and affinity maturation was not observed. The phenotype was more pronounced for some MHC types, such as I-A^b, than for others, such as I-A^k. Due to tighter binding of CLIP peptides, these MHC types may be more dependent on H2-DM to maintain empty class II molecules in a peptide receptive state.

In vitro studies with purified MHC class II molecules and biotin-labeled peptides have shown that HLA-DM can accelerate loading of exogenous peptides into HLA-DR-binding sites.[343,344] For example, loading of myelin basic protein fragment 90 to 102 was accomplished in 9 minutes with HLA-DM versus 60 minutes without it (Table 23.5). Other peptides were also loaded at the same rate, suggesting that the rate limiting step was the same for each: removal of CLIP peptides to expose the peptide binding sites on HLA-DR. The kinetic effect was optimal between pH 4.5 and 5.8, which is typical of the endosomal/lysosomal compartment where HLA-DM operates. HLA-DM did not affect the affinity, as measured by half-maximal binding, but it had a marked effect on the kinetics of binding.

Conversely, when biotinylated peptides were allowed to saturate HLA-DR-binding sites overnight, and then free peptides were removed, the off rate could be measured over time.[343,344] As shown in Table 23.5 (adapted from Sloan et al.[343]), the off rate for different peptides could be compared in the absence or presence of HLA-DM. The half-life for CLIP peptides was reduced from 11 hours to 20 minutes by adding HLA-DM. This could explain the enhanced loading of all other peptides, as they must wait for CLIP to come off. In the case of

antigenic peptides, myelin basic protein 90 to 112 was released 80-fold faster in the presence of DM than in its absence. However, another peptide, influenza hemagglutinin 307 to 319, was not affected at all. The differential effect on these antigenic peptides suggests that HLA-DM can serve a potential role in editing which peptides stay on MHC long enough to be presented and which are removed.[343] By releasing myelin basic protein preferentially and not the hemagglutinin peptide, HLA-DM would favor the stable MHC binding and presentation of hemagglutinin peptides over myelin basic protein peptides. The affinity of each peptide is determined by the fit between peptide and MHC groove, not by HLA-DM. However, DM can amplify the impact of the difference in affinity (ie, signal to noise ratio) by facilitating release of low-affinity peptides and allowing the high-affinity ones to remain. This editing function could have an important effect on which peptides get presented and elicit a T-cell response. HLA-DM could contribute to immunodominance of a peptide binding MHC with high affinity by releasing its lower affinity competitors. Alternatively, HLA-DM could contribute to self-tolerance by releasing self-peptides of low affinity before they could stimulate self-reactive T cells either at the time of positive selection (so they would fail to be positively selected) or in the periphery (so they would fail to be activated). When HLA-DM was engineered to be expressed on the cell surface, it also facilitated loading of exogenous peptides onto class II MHC molecules and affected the activation of T cells of different fine specificity for the same epitope.[345]

TABLE 23.5 Effect of Human Leukocyte Antigen-DM on Peptide on Rates and Off Rates for Binding to Human Leukocyte Antigen-DR1

Peptide	HLA-DM	Half-Time for Binding	Half-life for Release
CLIP (80-103)	-	60 min	11 hr
	+	9 min	0.3 hr
MBP (90-102)	-	62 min	86 hr
	+	9 min	1 hr
HA (307-319)	-	67 min	144 hr
	+	10 min	144 hr

CLIP, class II-associated invariant chain peptide; HA, hemagglutinin; HLA, human leukocyte antigen; MBP, myelin basic protein.

The on (association) and off (dissociation) rates of biotinylated peptide from purified soluble HLA-DR1 were measured by fluorescence assay, in the presence or absence of HLA-DM. The on rates of all three peptides are increased similarly in the presence of HLA-DM and probably reflect the rate-limiting dissociation of the bound CLIP fragment of the invariant chain. In contrast, once the peptides are bound, the off rates differ as a result of differences in affinity. Thus, HLA-DM catalyzes release of more weakly binding peptides and allows stable binding of higher affinity peptides.

In effect, this is an editing function of HLA-DM.

Major Histocompatibility Complex Binding and Assembly of a Stable Peptide-Major Histocompatibility Complex

Antigen Interaction with Major Histocompatibility Complex Molecules.

Perhaps the most selective step a potential antigenic site must pass is to bind with sufficiently high affinity to an appropriate MHC molecule.

The response specificity of T cells to antigens on APCs or target cells provides a number of hints that antigen interacts directly with MHC molecules of the APCs to form an antigenic complex recognized by T cells. First, genes coding for immune responsiveness (Ir genes) to a specific antigen are tightly linked to genes for MHC-encoded cell surface molecules.[127,171] Second, it became apparent that T-cell recognition of antigen is the step at which MHC restriction occurs.[127,179,219,346] For example, in vitro T-cell responses to small protein and polypeptide antigens were found to parallel in vivo responses controlled by Ir genes, and T cells were exquisitely sensitive to differences in MHC antigens of the APCs in all their antigen recognition functions. This observation in vitro made it possible to separate the MHC of the T cell from that of the APC. The T-cell response to antigenic determinants on each chain of insulin depended on the MHC antigens of the APC. This was particularly apparent when T cells from an (A × B)F1 animal responded to antigen presented by APCs of either the A or B parental MHC type.[219,347] Neither parental APC stimulated an allogeneic response from (A × B)F1 T cells, and the response to antigen was now limited by the MHC of the APCs. This ability of the APCs to limit what could be presented to the T cells was termed "determinant selection."[219,347] It became obvious that even in a single (A × B)F1 animal, distinct sets of antigen-specific T cells exist that respond to each antigenic determinant only in association with MHC type A or B.[348]

Experiments on the fine specificity of antigen-specific T-cell clones suggested that the MHC of the APCs could influence the T-cell response in more subtle ways than just allowing or inhibiting it. Determinant selection implied that a given processed peptide should contain both a site for MHC interaction and a distinct functional site for TCR binding. Thus, a protein with multiple determinants could be processed into different peptides, each with a different MHC restriction, consistent with the independent Ir gene control of the response to each antigenic determinant on the same protein.[181] For example, T-cell clones specific for myoglobin responded to different antigenic determinants on different peptide fragments of myoglobin[215]: Those specific for one of the epitopes were always restricted to I-A, whereas those specific for the other were always restricted to I-E. The simplest interpretation was that each antigenic peptide contained an MHC association site for interacting with I-A or I-E. At the level of Ir genes, mouse strains lacking a functional I-E molecule could respond to one of the sites only, and those with neither I-A nor I-E molecules capable of binding to any myoglobin peptide would be low responders to myoglobin.

Evidence for a discrete MHC association site on peptide antigens came from studies with pigeon cytochrome c. The murine T-cell response to pigeon cytochrome c and its carboxy-terminal peptide (81 to 104) depends on the I-E molecules of the APCs.[179] However, distinct

structural sites on the synthetic peptide antigen appear to constitute two functional sites: an epitope site for binding to the TCR and an “agretope” (for “antigen restriction tope”) site for interacting with the MHC molecule of the APC.[179,196,197,198] Amino acid substitutions for Lys at position 99 on the peptide destroyed the ability to stimulate T-cell clones specific for the peptide, whereas the difference between Ala and a deletion at position 103 determined T-cell stimulation in association with some MHC antigens but not others, independent of the T-cell fine specificity. In addition, immunizing with the peptides substituted at position 99 elicited new T-cell clones that responded to the substituted peptide but not the original and showed the same pattern of genetic restriction, correlated with the residue at position 103, as the clones specific for the original peptide. These results implied that the substitutions at position 99 had not affected the MHC association site but independently altered the epitope site that interacts directly with the TCR. In contrast, position 103 was a likely subsite for MHC interaction, without altering the TCR-binding site.

It remained to be shown that MHC molecules without any other cell surface protein were sufficient for presentation of processed peptide antigens. This was demonstrated by Watts et al.,[349] who showed that glass slides coated with lipid containing purified I-A molecules could present an ovalbumin peptide to an ovalbumin-specific T-cell hybridoma. This result meant that no other special steps were required other than antigen processing and MHC association. Likewise, Walden et al.[350] specifically stimulated T-cell hybridomas with liposomes containing nothing but antigen and MHC molecules. Also, Norcross et al.[351] transformed mouse L cells with the genes for the I-A α and β chains and converted the fibroblasts (which do not express their own class II molecules) into I-A-expressing cells. These cells were able to present several antigens to I-A-restricted T-cell clones and hybridomas[351] and similar I-E transfectants presented to I-E-restricted T cells.[215] Thus, whatever processing enzymes are required are already present in fibroblasts, and the only additional requirement for antigen-presenting function is the expression of I-A or I-E antigens.

The planar membrane technique has been applied to determine the minimum number of MHC-antigen complexes per APC necessary to induce T-cell activation.[352] After pulsing the presenting cells with antigen, the cells were studied for antigen-presenting activity, and some of the cells were lysed to produce a purified fraction containing MHC charged with antigenic peptides. These MHC-peptide complexes were used to reconstitute planar membranes, and their potency was compared to a reference MHC preparation pulsed with a high peptide concentration in vitro and presumed to be fully loaded. In this way, the relative peptide occupancy of MHC-binding sites corresponding to any level of antigen presentation could be determined. For B cells and macrophages, the threshold of antigen loading necessary for triggering T cells was 0.2% of I-E^d molecules occupied by peptide, corresponding to about 200 MHC-peptide complexes per presenting cell. For artificial presenting cells, such as L cells transfected with I-E^d, the threshold was 23 times greater or 4.6% of MHC occupied by peptide. Similarly, when MHC-peptide binding was measured directly, using radiolabeled peptide to determine the minimum level of MHC-peptide complexes required for T-cell triggering, B cells were capable of presenting antigen with as few as 200 to 300 MHC-peptide complexes per cell.[353] A similar number of peptide-MHC class I molecule complexes was reported to be required on a cell for recognition by $CD8^+$ cytotoxic T cells.[354] These results explain how newly generated peptide antigens can bind enough MHC molecules to stimulate a T-cell response, even in the presence of competing cellular antigens, as a low level of MHC occupancy is sufficient. In addition, this threshold of presentation may explain how multivalent protein antigens, such as viral particles, with 100 to 200 protein copies each,

can be over 10^3-fold more immunogenic than the same weight of protein monomers.[355,356,357] Studies on the number of TCRs needed for triggering, based on titrating peptide and recombinant soluble class I MHC molecules on plastic, suggested that interaction of three to five TCRs with MHC-peptide complexes was sufficient, consistent with several T cells interacting with one APC.[358,359] Biochemical evidence for the direct association between processed peptide and MHC molecules was demonstrated by competition between peptides for antigen presentation[225,360,361,362,363] and then more directly by equilibrium dialysis,[364] molecular sieve chromatography,[365] or affinity labeling.[366] Equilibrium dialysis (see Chapter 7) was performed by incubating detergent-solubilized class II molecules with fluoresceinated or radioactive antigenic peptides, followed by dialysis against a large volume of buffer. Peptide can pass in or out of the dialysis bag, but the class II molecules are trapped inside. In the absence of binding by class II molecules, the labeled peptide would distribute itself equally between the inside and outside of the dialysis

chamber. However, when the appropriate class II molecules were added to the chamber, extra peptide molecules were retained inside it due to formation of a complex with MHC class II. In this way, direct binding of antigen and MHC was shown, and an affinity constant was determined.[364,365]

TABLE 23.6 Correlation between Major Histocompatibility Complex Restriction and Binding to Major Histocompatibility Complex Molecules

Competitor Peptide		Ova + A^d	Myo + E^d	HEL + A^k	Cyto + E^k
Ova	323-339	++++	−	++	+
Myo	106-118	++++	−	++	+/-
Myo	132-153	−	++++	−	++
HEL	46-61	+	+	++++	+
Cytochrome c	88-104	++	+/-	++	++++

HEL, hen egg lysozyme.

Data from Früh et al.322

A second approach was to form the antigen-MHC complex over 48 hours, followed by rapid passage over a Sephadex G50 sizing column (Sigma-Aldrich). The bound peptide came off the column early because it is the size of class II molecules (about 58 kD), while free peptide was usually included in the column and eluted later, as it is only approximately 2 kD.[365] Peptide bound to specific and saturable sites on MHC. Competitive binding showed that different peptide antigens with the same MHC restriction bind to the same site on the MHC class II molecule.[367,368] For example, Table 23.6 shows the results with peptide antigens

that are known to be presented with I-A or I-E antigens of the D or K haplotype. We observe that Ova peptide 323 to 329, which is presented with I-A^d, also binds well to purified I-A^d, whereas nonradioactive peptide competes for the peptide-binding sites of the I-A^d molecule. Similarly, the other I-A^d-restricted peptide, myoglobin 106 to 118, competes with Ova 323 to 339 for the same site. However, myoglobin 132 to 153, which is not restricted to I-A^d, does not compete for it but does compete for its own restriction element, I-E^d. Similarly, pigeon cytochrome c competes best for its restriction element I-E^k rather than I-A^k or I-E^d, which do not present cytochrome. Conversely, recombinant Eβ genes have been used to map separate sites on a class II MHC molecule for binding to peptide antigen and to the TCR.[369]

Using these two biochemical methods, it has been possible to explain major losses of peptide antigenicity resulting from amino acid substitutions in terms of their adverse effect on epitope or agretope function. For example, the response of each of two ovalbumin-specific T-cell clones was mapped to peptide 325 to 335 by using a nested set of synthetic peptides. Five substitutions were made for each amino acid in the peptide, and the resulting 55 different peptides were each tested for the ability to stimulate the clone.[370] Presumably, those peptides that failed to stimulate could be defective at an epitope or an agretope functional site. In fact, only two amino acids (Val 327 and Ala 332) were essential for MHC interaction, and changes at either of these resulted in a loss of antigenicity for the clone. Seven other amino acids were critical for T-cell stimulation but did not affect MHC binding. Thus, these must be part of the functional epitope. Interestingly, certain substitutions for His 328, Ala 330, and Glu 333 had effects on MHC binding, whereas others had effects on T-cell stimulation without affecting MHC binding. These amino acids might participate in both agretope and epitope functional sites, or, alternatively, the substitutions may affect the conformation of the peptide as it binds, thus indirectly affecting T-cell recognition[371] (see following discussion). The fact that substitutions at 9 of 11 amino acids could be tolerated without affecting MHC binding is consistent with the determinant selection hypothesis in that multiple antigenic peptides are capable of interacting with the same antigen-binding site on the MHC molecule.

Similarly, by using a T-cell clone specific for peptide 52 to 61 of hen egg lysozyme, substitutions at each amino acid were analyzed for the ability to bind to I-A^k and stimulate the clone.[372] Four of eleven amino acid residues were silent, whereas substitutions at three positions resulted in reduced binding to I-A^k. Substitutions at the remaining three positions resulted in decreased T-cell stimulation without affecting MHC association. The epitope was very sensitive to substitutions, even conservative ones such as changing Leu 56 to Ile, norLeu, or Val. The results in both of these studies confirmed by competitive binding that the MHC molecule contains a single saturable site for peptide binding. This site must be capable of binding a broad range of antigenic peptides. In binding the MHC groove, antigenic peptides assume the extended conformation that exposes the epitope for recognition by the TCR.

Although a full set of general principles explaining the specificity of antigen presentation and T-cell recognition has not yet emerged, it is studies such as these, combined with complementary structural studies characterizing the antigen-interacting portions of MHC molecules[214,253,254,369,373,374,375,376,377,378,379,380] (see Chapters 21 and 22) and of TCRs[381,382,383,384,385,386,387] (see Chapter 11) that will ultimately lead to an understanding of these principles.

One observation that came out of this type of structurefunction study was that a single peptide can bind to a class II MHC molecule in more than one way, and thus be seen by

different T cells in different orientations or conformations.[371,388] The same conclusion can be reached from an entirely different type of study, in which mutations are introduced into the MHC molecule. Mutations in the floor of the peptide-binding groove, which cannot directly interact with the TCR, can differentially affect recognition of a peptide by one clone and not another.[389,390,391] In a particularly thoroughly studied case, it was clear that the quantitative level of peptide binding was not affected by the mutation, but rather the change in the floor of the groove imposed an altered conformation on the peptide that differentially affected recognition by different T cells.[391] If indeed the TCR cannot detect the mutation in the MHC molecule except indirectly by its effect on the peptide conformation, then

one is forced to conclude that different T cells have preferences for different conformations of the same peptide bound to (what appears to the T cell as) the same MHC molecule.

Another general observation to come from this type of study is that substitution of amino acids often affects presentation by MHC and recognition by T cells through introduction of dominant negative interactions or interfering groups, whereas only a few residues are actually essential for peptide binding.[392] Both for class II binding[392,393,394,395] and for class I MHC binding,[396] most residues can be replaced with Ala or sometimes Pro without losing MHC binding, as long as a few critical residues are retained. Of course, T-cell recognition may require retention of other residues. If many of the amino acid side chains are not necessary for binding to the MHC molecule, then one might expect side chains of noncritical amino acids to occasionally interfere with binding, either directly or through an effect on conformation. That is exactly what was observed for a helper epitope from the HIV-1 envelope protein when a heteroclitic peptide— that is, one that stimulated the T cells at much lower concentrations than did the wild-type peptide—was obtained by replacing a negatively charged Glu with Ala or with Gln, which has the same size but no charge.[392] An Asp, negatively charged but smaller, behaved like the Glu. Thus, this residue was not necessary for binding to the class II MHC molecule, but a negatively charged side chain interfered with binding to the MHC molecule as measured by competition studies. Information about residues that interfere with binding has allowed the refinement of sequence motifs for peptides binding to MHC molecules to permit more reliable prediction of binding[397] (see following discussion).

This observation also provides a novel approach to make more potent vaccines by “epitope enhancement,” the process of modifying the internal sequence of epitopes to make them more potent, for example, by increasing affinity for an MHC molecule or TCR, or able to induce more broadly cross-reactive T cells specific for multiple strains of a virus.[398,399,400,401] Proof of principle that this approach can make more potent peptide vaccines has recently been obtained.[401] The modified “enhanced” helper T-cell epitope from the HIV-1 envelope protein described previously,[392] with Ala substituted for Glu, was shown to be immunogenic at 10-to 100-fold lower doses for in vivo immunization than the wild-type HIV-1 peptide to induce a T-cell proliferative response specific for the wild-type peptide. Further, when a peptide vaccine construct using this helper epitope coupled to a CTL epitope[402,403] was modified with the same Glu-to-Ala substitution, it was more potent at inducing $CD8^+$ CTL specific for the CTL epitope than was the original vaccine construct, even though the CTL epitope was unchanged (Fig. 23.10).[401] The increased potency of the vaccine construct was shown to be due to improved class II MHC-restricted help by genetic mapping using congenic strains of mice expressing the same class I MHC molecule to present the CTL epitope and the same background genes but differing in class II MHC

molecules.[401] Thus, class II-restricted help makes an enormous difference in induction of class I-restricted CTL, and epitope enhancement can allow construction of more potent vaccines, providing greater protection against viral infection.[404] Further, the improved help was found to be qualitatively, not just quantitatively, different, skewed more toward Th1 cytokines.[404] The mechanism was found to involve greater induction of CD40 ligand on the helper T cells, resulting in greater interleukin 12 production by the antigen-presenting dendritic cells, which in turn polarized the helper cells toward Th1 phenotype.[404] The dendritic cells conditioned with the helper T cells and the higher affinity peptide and then purified were also more effective at activating CD8+ CTL precursors in the absence of helper cells, supporting a mechanism of help mediated

through activation of dendritic cells.[405,406,407] This study showed also that such help was mediated primarily through upregulation of interleukin 12 production and CD80 and CD86 expression on the dendritic cell.[404] A similar or overlapping HIV envelope epitope recognized by human CD4+ T cells when presented by HLA-DR13 has been mapped and has undergone epitope enhancement as well.[408] Understanding this mechanism of epitope enhancement may contribute to the design of improved vaccines.

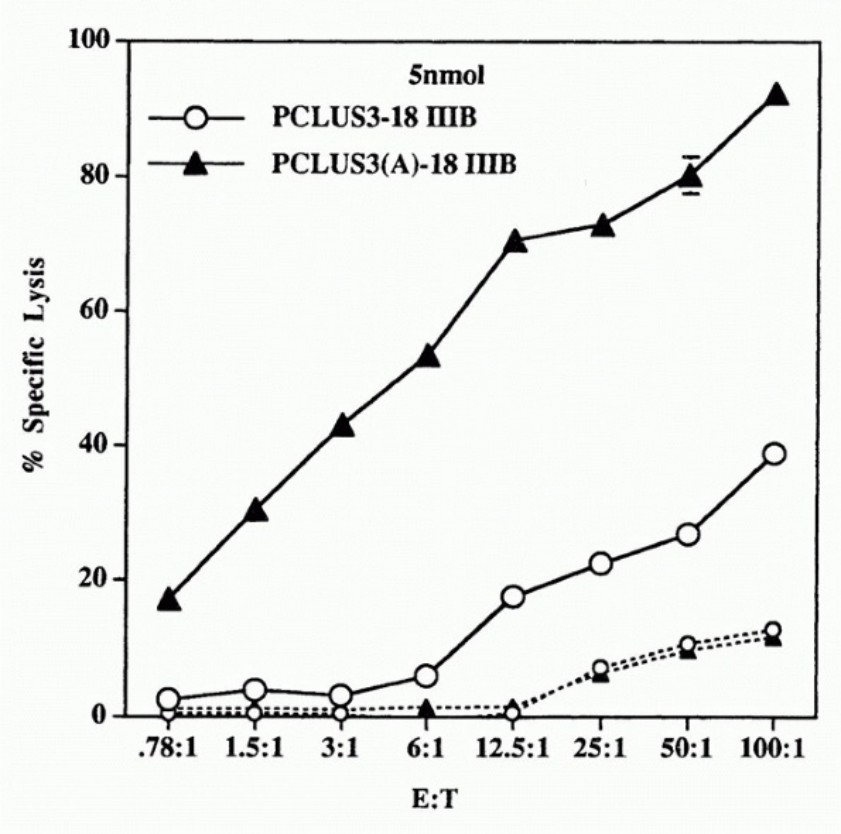

FIG. 23.10. Enhancement of Immunogenicity of a Peptide Vaccine for Induction of Class I Major Histocompatibility Complex (MHC)-Restricted Cytotoxic T-Lymphocytes by Modification of the Class II MHC-Binding Portion to Increase Cluster of Differentiation (CD)4+ T-Cell Help. Peptide vaccine PCLUS3-18 IIIB contains a class II MHC binding helper region, consisting of a cluster of overlapping determinants from the human immunodeficiency virsu-1 envelope protein gp160, and a class I MHC-binding cytolytic T cell (CTL) epitope, P18 IIIB. Modification of the helper

epitope to remove an adverse negative charge by replacement of a Glu with an Ala residue was shown to increase binding to the class II MHC molecule.[392] Here, introduction of the same modification of the helper epitope, to produce PCLUS3(A)-18IIIB, is shown to greatly increase immunogenicity in vivo for induction of CTL to the class I-binding P18IIIB portion. Immunization of A.AL mice with 5 nmol of either vaccine construct subcutaneously in montanide ISA 51 adjuvant, and stimulation of resulting spleen cells with P18IIIB for 1 week in culture, resulted in 33-fold more lytic units for lysing targets coated with P18IIIB when mice were immunized with the modified second-generation vaccine than when they were immunized with the original construct with the natural sequence. Thus, class II-restricted $CD4^+$ T-cell help has a major impact on induction of class I-restricted CTL, and this process of "epitope enhancement" can be used to make vaccines more potent than the natural viral antigens. Targets: BALB/c 3T3 fibroblasts with P18IIIB (*solid lines*) or no peptide (*dashed lines*). (Modified from Ahlers et al.[401] with permission.)

Similar epitope enhancement has been carried out for class I MHC-binding viral or tumor peptides as well,[409,410,411,412,413,414] and in one case has been found to result in greater clinical efficacy of a melanoma vaccine used for human immunotherapy.[415] Cautions have also been raised about the use of enhanced epitopes (sometimes also called agonistic or heteroclitic epitopes), in that the amino acid sequence modifications that affect MHC binding can also alter the conformation of the MHC-bound peptide and affect the specificity of T cells elicited.[416,417,418,419] The altered or enhanced peptides that elicit the most T cells specific for the wild-type epitope are the most effective at clearing tumors.[420] Thus, it is important in using epitope-enhanced peptides that the peptides still activate a large number of T cells that recognize the wild-type sequence. These results emphasize the importance of affinity for MHC molecules vaccine efficacy[421] and suggest that rational design of vaccines with higher affinity epitopes may produce more effective second-generation vaccines.[422,423] To that end, the discovery of sequence motifs predicting MHC molecule binding and the development of bioinformatics strategies to predict peptide affinity have proven a great impetus to the field.[424]

HLA, human leukocyte antigen; MHC, major histocompatibility complex.

Data from Goodman and Sercarz,234 Walden et al.,350 Sette et al.,370 Kurata and Berzofsky,371 Allen et al.,372 Brown et al.,373 and Bjorkman et al.374

In the case of class I MHC molecules, results defining sequence binding motifs generalize the conclusion that only a few critical “anchor” residues determine the specificity of binding to the MHC molecule (Table 23.7).[264,396,425,426,427,428,429] These motifs were defined by a detailed study of one peptide-MHC system[427] by sequencing the mixture of natural peptides eluted from a class I MHC molecule and finding that at

certain positions in the sequence, a single residue predominated within the pool of peptides,[425] and by separating and sequencing individual natural peptides eluted from a class I molecule and finding a conserved residue at certain positions.[426] The latter two studies also made the important observation that the natural peptides eluted from class I MHC molecules were all about the same length, eight or nine residues, and this was confirmed for a much larger collection of peptides eluted from HLA-A2 and analyzed by tandem mass spectrometry.[428] This finding was consistent with other studies demonstrating that a minimal nonapeptide was many orders of magnitude more potent than longer peptides in presentation by class I molecules to T cells.[430,431] This conservation of length was critical to the success of the approach of sequencing mixtures of peptides eluted from a class I molecule[425] because such a method requires that the conserved anchor residues all be at

the same distance from the N-terminus. The fact that Falk et al.[425] could find a single amino acid at certain positions, such as a Tyr at position 2 in peptides eluted from K^d, implies not only that most or all of the peptides bound to K^d had a Tyr that could be aligned but also that the peptides were already aligned as bound to the MHC molecule, with each one having just one residue N-terminal to the Tyr. This result implies that the position of the N-terminal residue is fixed in the MHC molecule. It is this fact that has made the identification of motifs for binding to class I molecules much more straightforward than finding motifs for binding class II molecules.

This conclusion has not only been confirmed but also explained by x-ray crystallographic data on class I peptide-MHC complexes.[376,377,378] It appears that both the N-terminal α-amino group and the C-terminal carboxyl group are fixed in pockets at either end of the MHC groove, independent of what amino acids are occupying those positions, and that the rest of the peptide spans these fixed points in a more or less extended conformation. The minimum length that can span the distance between these pockets is 8 residues, but 9 or 10 residues can be accommodated with a slight bulge or β turn in the middle of the peptide, explaining the narrow restriction on length. Between these ends, one or two pockets in the groove can accommodate the side chain of an amino acid, usually either at P2 binding in the B pocket or at P5 binding in the C pocket, depending on the particular MHC molecule. Additionally, the side chain of the C-terminal residue serves as an anchor in the F pocket at the end of the groove. These residues that fit into pockets correspond exactly to the “anchor” residues, at P2 or P5, and P8, P9, or P10, defined by the sequence motifs, and appear to be the primary determinants of specificity for peptide binding because the rest of the interactions are largely with peptide backbone atoms, including the α-amino and carboxyl groups, and therefore do not contribute to sequence specificity. This finding can explain both the breadth of peptides that can bind to a single MHC molecule because most of the binding involves only backbone atoms common to all peptides and also the exquisite specificity of binding is determined by the anchor residues that account for the Ir gene control of responsiveness.

In contrast, when natural self-peptides were eluted from class II MHC molecules,[252,432] the lengths were much more variable, ranging from 13 to 18 residues, and several variants of the same peptide were found with different lengths of extra sequence at one end or the other (“ragged ends”). This finding suggested that both ends of the peptide-binding groove of class II MHC molecules are open, in contrast to class I, so that additional lengths of peptide can hang out either side, and trimming does not have to be precise. However, a corollary is that the peptides eluted from class II molecules would not be aligned in a motif starting from the exact amino terminus and that was indeed what was found. Although a moderately conserved motif was found in some of the peptides eluted from the murine class II molecule I-A^d, consistent with the motif defined based on known antigenic peptides binding to I-A^d,[433] the motif was neither so clearly defined nor so highly conserved as in the class I case and required aligning of sequences to identify a core motif of about nine amino acid residues.[432] Subsequently, a number of motifs for peptides binding to human class II MHC molecules have been defined.[264,434,435,436,437,438,439] Unlike peptides eluted from MHC class I grooves, these class II-binding peptides may locate the core-binding motif at various distances from the amino or carboxyl end of the peptide.

The crystal structure of a peptide bound to a human class II MHC molecule, DR1, revealed that indeed the ends of the groove are open, and the peptide can extend beyond the groove in either direction.[254,440] In addition, the more broadly defined class II motifs in Table 23.7 can be explained by less stringent requirements for amino acid side chains to interact with

binding pockets in class II. In general, the MHC class II binding pockets are shallower than for class I, and a selected peptide derives less binding energy from each pocket. In fact, they form fewer H-bonds with the peptide side chains, and more H-bonds are directed at the peptide backbone, allowing a variety of different peptides to bind. Rather than requiring a specific amino acid at each position, the shallow binding pockets of MHC class II tend to exclude peptides based on unfavorable interactions, such as side chains too large to fit the binding pocket. Even one amino acid side chain that binds strongly to an MHC pocket is sufficient to anchor the peptide to MHC class II and set the frame for the interaction of the rest of the peptide with the MHC groove.

For example, binding of three peptides to the class II molecules I-A in mice or HLA-DQ in humans are shown in Figure 23.11. The first residue of the peptide motif is designated P1, the next is P2, and so on. The α-helical walls and β-sheet floor of the MHC class II groove (see Chapter 21) are peeled away to reveal the peptide backbone and side chains in relation to MHC-binding pockets. For the ovalbumin peptide $Ova^{323,324,325,326,327,328,329}$ binding to $I\text{-}A^{d}$, residues P1, P4, and P9 all point down into the binding pockets.[441] The best fit is between Val 327 and the P4 pocket, which creates mainly hydrophobic interactions with MHC and serves as the anchor residue. Residues P5 (His 328) and P8 (His 331) project upward for binding to the TCR. The shallow P4 pocket can tolerate only small hydrophobic side chains, such as Val, so it dictates which peptides can bind here. The other MHC

pockets, P1 and P9, accommodate many different residues, so they have little effect on which peptides can be presented by $I\text{-}A^{d}$.

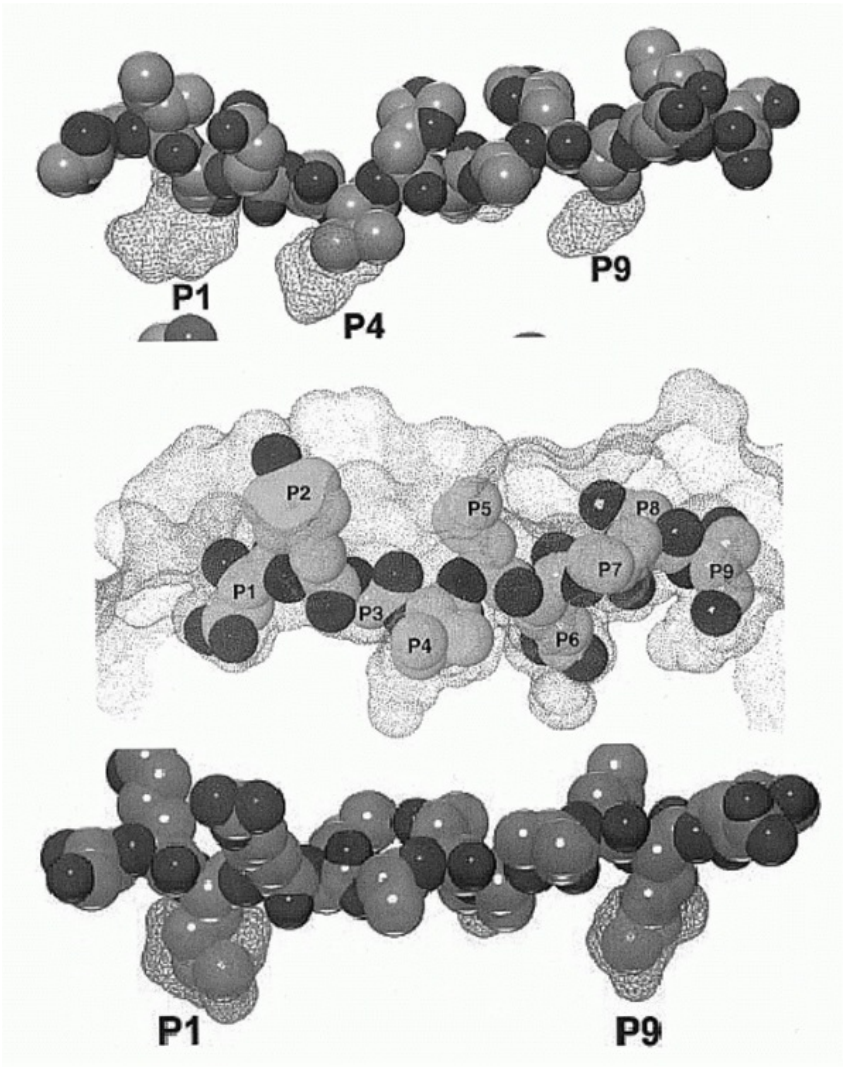

FIG. 23.11. Interaction of Peptides with the Binding Groove of Major Histocompatibility Complex Class II, as Determined by X-ray Crystallography. Anchor residue side chains fill binding pockets to a greater or lesser extent, supplemented by H-bonds to the peptide backbone. Examples include I-A^d with ovalbumin peptide 323 to 334 *(Top)*,[441] I-A^k with hen egg lysozyme 52 to 60 *(Middle)*,[442] and HLA-DR3 with invariant chain class II-associated invariant chain peptide *(Bottom)*.[443]

For hen egg lysozyme peptide[50,51,52,53,54,55,56,57,58,59,60,61,62] binding to I-A^k, interactions with MHC are observed for P1, P4, P6, and P9.[442] The P1 interaction is very different from I-A^d, as the P1 pocket is a perfect fit for Asp and has an arginine at the end of the tunnel to neutralize charge. This structure explains why nearly all peptides presented by I-A^k must have Asp at this position. In contrast, the P4 and P9 pockets are partially filled and will tolerate a number of different side chains at these positions. The P6 pocket requires a Glu or Gln here, even though the MHC residues deep in the pocket are acidic. It is presumed that one of the Glu residues must be protonated to allow Glu binding at this position. This arrangement of the peptide leaves P2, P5, and P8 exposed to solvent in the crystal structure and to the TCR during antigen presentation.

For the CLIP peptide binding to HLA-DR3, deep pockets at P1 and P9 are more fully occupied by the peptide side chains.[443] The pH-dependent binding is important because CLIP must be stable at neutral pH and unstable at acid pH in the presence of HLA-DM in order to perform its function.

Based on affinity for MHC, these interactions explain the peptide-binding motifs for MHC class II that select which peptides can be presented to T cells. In addition, these interactions orient the peptide in the MHC groove and determine which residues are accessible for recognition by the TCR.

T-Cell Receptor Recognition

The last hurdle that a potential antigenic determinant must surmount is recognition by a TCR within the repertoire of the individual responding. This repertoire may be limited by the availability of combinations of V, D, and J genes (see Chapter 11) in the genome that can combine to form an appropriate receptor, given the lack of somatic hypermutation in TCRs in contrast to antibodies,[383,444] and then by self-tolerance, as mediated by thymic or peripheral negative selection, or by limits on the repertoire that is positively selected in the thymus on existing self-peptide-MHC complexes. The available repertoire may also be influenced by prior exposure to cross-reactive antigens. In general, however, it has been hard to find holes in the repertoire.[445] Indeed, studies examining large panels of peptides binding to particular class I molecules for correlations between peptide affinity for MHC and T-cell responses have failed to find high-affinity peptides for which no T-cell response can be raised, whereas not all lower affinity peptides elicit a response.[446,447] These results suggest that if the peptide can bind well enough to the MHC molecule, there is virtually always a T cell that can see the complex. However, the array of other MHC molecules present can influence the breadth of the T-cell repertoire.[448] Furthermore, when TCR repertoires of mice and humans were compared for peptides presented by HLA-A2.1, they seemed to be capable of seeing the same spectrum of peptides.[449] Eleven peptides from hepatitis C virus proteins, each of which had a motif for binding to HLA-A2.1, were tested for recognition by CTL from HLA-A2.1 transgenic mice and human HLA-A2.1 positive patients infected with hepatitis C virus. The same four peptides that were recognized by the T cells from the mice were the ones recognized by the human T cells, whereas the others were not recognized well by either murine or human T cells. The selection of which peptides were recognized seemed to be determined by binding to the HLA-A2.1 molecule rather than by the availability of T cells. Thus, despite the differences in TCR genes in mice and humans, the repertoires are plastic enough that if a peptide passes the other three hurdles of processing, transport, and binding to MHC molecules, T cells can be elicited to respond to it in either species.[449] Likewise, no hole in the helper T-cell repertoire could be found to explain low responders to the recombinant hepatitis B vaccine.[450]

On the other hand, evidence exists that MHC binding is not the whole story. Schaeffer et al.[451] examined 14 overlapping peptides covering the sequence of staphylococcal nuclease with different class II MHC molecules, constituting 54 different peptide-MHC combinations. Clearly, MHC binding plays a major role because 12 out of 13 immunogenic peptides were high or intermediate binders to MHC molecules, whereas only 1 of 37 poor binders were immunogenic. Of high-affinity binders, five out of five peptides

were immunogenic. However, for intermediate affinity MHC-binding peptides, only 7 out of 12 were immunogenic. Similar results were found for the class I MHC molecule HLA-B*0702, in which it was found that 7 of 7 high-affinity binders but only 9 out of 12 intermediate affinity

binders, were immunogenic.[447] Thus, MHC binding alone is not sufficient to ensure immunogenicity. The T-cell repertoire was one factor suggested that might limit the spectrum of immunogenic peptides.

Indeed, examples for selection at the level of the TCR repertoire exist. A particularly elegant example described by Moudgil et al.[452] is one in which a peptide (46 to 61) of mouse lysozyme presented by I-A^k is recognized T cells from CBA/J and B10.A mice, expressing I-A^k and I-E^k, but not by T cells from B10.A(4R) mice expressing only I-A^k, even though the APC from B10.A(4R) mice can present the peptide to T cells from the other strains. T cells from the B10.A(4R) mice can respond to variant 46 to 61 peptides in which the C-terminal Arg is replaced by Ala, Leu, Phe, Asn, or Lys, indicating that the C-terminal Arg is hindering recognition, but not binding by I-A^k, and in this case, not processing as the B10.A(4R) APC can present the peptide. It appears that the hindrance interferes with recognition by TCRs available in B10.A(4R) mice, but not TCRs available in B10.A or CBA/J mice, or in (B10.A(4R) × CBA/J)F1 mice. Because the B10.A mice are congenic with the B10.A(4R) mice, the difference is not one of non-MHC-linked genes such as TCR structural genes or non-MHC self-antigens producing self-tolerance. Further, because the F1 mice respond, the difference is not due to a hole in the repertoire produced by a self-antigen of the B10.A(4R) mice. It was concluded that the CBA/J and B10.A mice contain an additional repertoire, positively selected on I-E^k or possibly an H-2D/L class I molecule, in which these strains differ, which can recognize the 46 to 61 peptide despite the hindering Arg at the C-terminus. An alternative related explanation is that strains that express I-E^k or D^k or D^d/L^d have an additional repertoire of TCRs positively selected on I-A^k-presenting self-peptides from processing of these other MHC molecules in the thymus. This example illustrates a case in point that subtle differences in TCRs, presumably caused in this case by positive selection, can lead to responsiveness or nonresponsiveness to a determinant that has already passed all of the three earlier hurdles, processing, transport, and MHC binding. Of course, there are some holes related to selftolerance, primarily related to the loss of response to dominant determinants[453] and especially loss of high-avidity T cells.[454,455,456,457] Interestingly, not only is there no loss of response to cryptic determinants but also T cells recognizing cryptic determinants of mouse lysozyme can be positively selected on other nonmouse lysozyme self-ligands in a lysozyme knockout mouse.[453] The selective loss of high-avidity T cells to immunodominant determinants has suggested a strategy to apply epitope enhancement to modify subdominant lower affinity tumor antigen peptides to increase their affinity for MHC molecules, and thereby make them more immunogenic in order by to take advantage of a repertoire not already crippled by loss of the high-avidity clones.[458]

Another elegant example of T-cell repertoire limitations on immunodominance comes from a study of mice deficient in LMP-2, and so unable to make immunoproteasomes. Reduced response to one normally immunodominant influenza epitope was found by T-cell adoptive transfer studies to be due to an alteration in the T-cell repertoire, presumably because of altered processing of self-peptides in the thymus.[281]

A recent study found another mechanism by which the T-cell repertoire contributes to immunodominance. It was found that the relative immunodominance of a dominant determinant of the HIV envelope protein among different strains of H-2D mice all presenting the same peptide-H-2D^d complex correlated with the avidity of the T cells responding in those strains.[459] The mechanism found was that highavidity T cells proliferate faster than low-avidity ones when exposed to antigen and therefore dominate the response. This

mechanism differs from those at earlier steps that progressively constrain the response, and thereby narrow the repertoire to dominant epitopes, whereas this mechanism selectively expands the dominant repertoire. This mechanism may also explain other recent findings such as the higher affinity of dominant compared to subdominant TCRs specific for human cytomegalovirus.[460] Because highavidity T cells are better able to clear virus infection,[461,462] a recent study even suggests that the driving force for MHC polymorphism is to create a large enough repertoire to select for high-avidity T cells.[463]

Several critical parameters have been reported to be involved in more effective T-cell activation during TCR-peptide-MHC interaction. In some situations, TCR avidity for the peptide-MHC complex appears to play a more critical role than dissociation rate[464] and a threshold for maximal activity may even be defined,[465] whereas in other situations, the half-life of the TCR-peptide-MHC interaction seems most critical.[466,467,468] Moreover, in situ in two-dimensional surface interactions, a rapid on-rate may compensate for a faster off-rate (shorter half-life) and allow effective TCR-peptide-MHC engagement, suggesting the total cumulative duration time (including multiple repeat engagements) may be most critical.[469,470,471,472]

As more is understood about the molecular basis of TCR recognition, with crystallographic data now available,[386,387,473] it becomes possible to apply epitope enhancement in a rational way to the affinity of the peptide-MHC complex to the TCR, as was described for the peptide affinity for MHC molecules. Sequence modifications in the peptide that increase the affinity for the TCR were shown to be more effective at expanding in vivo the T cells specific for tumor antigens.[474,475,476] Most of these modifications were found empirically, but a systematic study of substitutions throughout a number of peptides revealed a pattern in which peptides with conservative substitutions at P3, P5, or P7 were most likely to yield increased TCR affinity, narrowing the candidate list of peptides that require empirical screening.[477] This strategy provides a second type of epitope enhancement, derived from basic immunologic principles, to produce more effective vaccines.

The advent of DNA vaccines has made it possible to link a series T-cell epitopes in tandem and express them in the form of a multiepitope vaccine. These chimeric proteins have the

potential advantages of focusing the immune response on biologically important epitopes, combining T helper epitopes with CTL epitopes, using epitopes with high affinity for MHC, and linking the epitopes in any desired order to optimize immunogenicity. Ideally, antigen processing throughout the construct would produce multiple epitopes that could be presented independently. In the case of HIV, where antigenic variation is so common, these vaccines could be designed to overcome variation by including epitopes that are conserved within each geographical region (clades).

For example, Létourneau et al.[478] expressed a string of HIV sequence fragments from the gag, pol, vif, and env genes that were highly conserved within their own clades. As they progressed from one fragment to the next, they alternated sequences from different HIV clades: Immunity to multiple epitopes would produce broad based immunity across clades. Fourteen fragments were linked in tandem. Each fragment contained multiple T-cell epitopes, for a total of 270 known epitopes recognized with human MHC. In addition, T cells from most patients infected with HIV responded to peptide pools from the vaccine, indicating that the epitopes were processed and presented to T cells. But when the multiepitope vaccine was given as a DNA vaccine followed by two viral vector boosts, it elicited relatively weak T-cell

responses to two out of six peptide pools in HLA-A2 transgenic mice.

For these constructs to function as multiepitope vaccines, antigen processing between epitopes is required. In any given string, all of the epitopes are expressed equally, but different locations might be processed differently. In order to elicit T-cell immunity to multiple epitopes at the same time, there must be efficient processing and presenting of epitopes in all parts of the string. For example, Depla et al.[479] created a vaccine with 30 epitopes from hepatitis B virus that were restricted to five different MHC class I types. The immune response to the combined antigen was compared to individual peptides as an indication of the effect of antigen processing on presentation of internal epitopes. For two MHC types, the same 5 out of 12 epitopes were immunogenic, regardless of whether they were presented as a string of epitopes or as free peptides. However, for three other MHC types, whereas 14 out of 18 epitopes were immunogenic as peptides, only 3 out of 18 were immunogenic in the multiepitope vaccine. This difference suggests inefficient antigen processing at multiple sites, either because of failure to process the epitopes correctly or due to excessive degradation.

One way to control processing was suggested by Livingston et al.[480,481] These authors found that the first amino acid following each epitope is an important marker for antigen processing. They demonstrated that poor presentation of an internal epitope can be corrected by adding a spacer of as little as one amino acid between epitopes to improve the yield of processed peptides. The most favorable amino acid spacers were Lys, Arg, Asn, and Gln, followed by Cys, Gly, Ala, Thr, or Phe. The least active spacer residues were Asp, Val, Met, or Leu.[480,481] For example, an epitope from hepatitis B virus core antigen was poorly immunogenic when it was located next to a Phe residue, but its immunogenicity was enhanced by four logs when Lys was substituted for Phe at this position. These amino acid preferences may reflect the major protease activities of proteasomes: The most targeted amino acids could improve the yield of intact epitopes.

This strategy was used to construct a multiepitope vaccine from HIV antigens.[482] Twenty-one epitopes were identified, based on the T-cell response of infected humans, and these were linked together in a multiepitope DNA vaccine. Spacers of one to four amino acids were inserted between epitopes to optimize antigen processing. The DNA vaccine was used to immunize HLA transgenic mice, and the response to each epitope was compared to peptide vaccinated mice. For two HLA types, A2 and A3, the peptide and multiepitope vaccines were nearly equal, suggesting efficient processing. In addition, for HLA-A2, the potency of the T-cell response to different epitopes was largely independent of their position in the vaccine sequence, suggesting efficient antigen processing at various points throughout the chimeric protein. But for a third HLA type, B7, despite a normal peptide response, the multiepitope vaccine failed to elicit immunity to four out of seven epitopes tested, indicating that processing was limiting the response to these residues.

Design of an effective multiepitope vaccine depends on finding the optimal balance between antigen processing and epitope survival. Antigen processing between epitopes generates antigenic peptides, but processing within the epitope would destroy its antigenicity. Delamarre et al.[483] have compared pairs of proteins with the same sequence but different conformations, resulting in different susceptibilities to lysosomal processing. Ribonuclease (RNAse) A was relatively stable to lysosomal extracts of dendritic cells, whereas RNAse S was degraded quickly. Of these two forms of the same protein, RNAse A was a far more potent immunogen, as measured by T-cell proliferation or Delayed Type Hypersensitivity (DTH). Similarly, horseradish peroxidase is stable to lysosomal proteases in the native form, but is quickly degraded in the apo form. Native horse radish peroxidase (HRP) was a much more potent immunogen than the unstable apo form. These results indicate the harmful effect

of excessive processing on T-cell stimulation and immunogenicity.

Multiepitope immunogens have been designed to elicit CTLs by stimulating T helper cells and CTLs simultaneously. These immunogens have combined T helper and CTL epitopes in a variety of ways. Some vaccines contain at least one T helper epitope and one CTL epitope on each polypeptide chain.[484] Others have expressed them separately: A polypeptide consisting of multiple T helper epitopes was coadministered with a DNA plasmid coding for multiple CTL epitopes.[485] A third way would be to express alternating T helper and CTL epitopes in tandem in the same multiepitope vaccine, either as DNA or polypeptide. The T-cell response to paired T helper epitopes was generally weak,[484] whereas the response to a string of multiple T helper epitopes was reportedly stronger, although it did not confer any improvement on the immune response to CTL epitopes expressed separately.[485]

As with T-cell help for B cells, a multiepitope vaccine for CTLs should combine T helper and CTL epitopes in the same construct.[402] It would deliver both epitopes into

the same APC, to facilitate helper T cell effects on CTL induction. But the epitopes should target different cellular compartments, leading to the main processing pathways: T helper epitopes should travel to endosomes for processing and presentation with MHC class II. CTL epitopes should traffic to the cytoplasm for proteasomal processing and presentation with MHC class I.

Defining the Role of Individual Amino Acids and Effects of Altered Peptide Ligands

Once an antigenic peptide is identified, the next step is to map key amino acid residues by making a series of variant peptides, each of which differs from the native sequence by a single amino acid substitution, as previously described in the section on MHC binding. One approach, called an alanine scan, substitutes Ala for the natural amino acid at each position in the peptide or uses Ser or Gly to replace naturally occurring Ala. Ala is used because the side chain is only a methyl group, so it replaces whatever functional side chain is present with the smallest one other than that of Gly, which is not used because of its effects on conformation. Thus, one can ask whether loss of the naturally occurring side chain affects function, without the introduction of a new side chain that might itself affect function. Generally, each peptide will have several amino acids where Ala substitution destroys antigenicity. Some of these correspond to contact residues for the TCR, whereas others are contact residues for MHC. In many cases, the MHC-binding residues can be determined by testing the substituted peptides in a competitive MHC-binding assay (discussed previously). The amino acid substitutions that knockout T-cell proliferation but not MHC binding are presumed to be in the epitope recognized by the TCR directly, and these can be studied with additional substitutions. For example, this technique was used to compare the residues interacting with the MHC molecule or TCR when the same HIV-1 V3 loop peptide P18 (residues 308 to 322) was presented by three different MHC molecules, a human class I molecule, a mouse class I molecule, and a mouse class II molecule (Fig. 23.12).[486,487] Interestingly, there was a striking concordance of function of several of the residues as presented by all three MHC molecules (see Fig. 23.12). For example, Pro and Phe interacted with the MHC in all three cases, and the same Val interacted with the TCR in all three cases. Also, the same Arg in the middle of the peptide interacted with both the mouse class I and II molecules, and the C-terminal Ile was an anchor residue for both human and murine class I molecules.[486,487]

In the case of autoimmune T cells, these techniques have been used to study the number

and variety of epitopes recognized by self-reactive T cells. In the nonobese diabetic mouse, the β chain of insulin is a major target of T cells recovered from pancreatic islets.[488] Alanine scanning of β chain peptide 9 to 23 revealed two patterns of T-cell recognition for the same peptide. Some T cells recognize peptide 9 to 16, whereas others respond to peptide 13 to 23. Each epitope appears to have distinct sites for MHC and TCR binding, even though they come from the same peptide chain. Similarly, in systemic lupus erythematosus, human T cells specific for the Sm antigen are narrowly restricted to a few epitopes that are found on a small group of proteins.[489] On the Sm-B antigen, three epitopes were recognized. On Sm-D antigen, there were two. In each case, alanine scans showed that the same epitopes were recognized by distinct T-cell clones. These results are consistent with the hypotheses that the autoimmune response to insulin or to Sm antigen may be induced by abnormal exposure of a very few cryptic epitopes, or they may depend on selective loss of tolerance for a limited number of epitopes shared by a small subset of self-proteins.

TCRs may distinguish different chemical classes of amino acid side chains. An example of structural differences between amino acid side chains recognized by the TCR comes from an analysis of non-cross-reactive CTL that distinguishes homologous peptides from the V3 loop of different strains of HIV-1 envelope protein. The residue at P8 in the minimal determinant was identified as a key

“epitopic” TCR contact residue in both strain IIIB, which has a Val at this position, and strain MN, which has a Tyr at this position.[486,490,491] CTLs specific for strain IIIB do not recognize the MN sequence but will recognize peptides identical to MN except for the substitution of any aliphatic amino acid at that position, such as Val, Leu, or Ile.[400] In contrast, CTL specific for the MN strain do not recognize the IIIB sequence but will recognize the IIIB peptide if the Val at this position is replaced by a Tyr.[490] Moreover, they will see any MN variant in which the Tyr is replaced by another aromatic amino acid, such as Phe, Trp, or His.[400] Thus, the two non-cross-reactive TCRs see similar peptides but discriminate strongly between peptides with amino acids with aliphatic versus aromatic side chains. On the other hand, they do not distinguish strongly among different aliphatic residues or among different aromatic residues. Interestingly, however, in each category, the least active is the bulkiest member of the category, Ile and Trp, respectively, suggesting that these residues must fit into a pocket of limited size in the TCR.

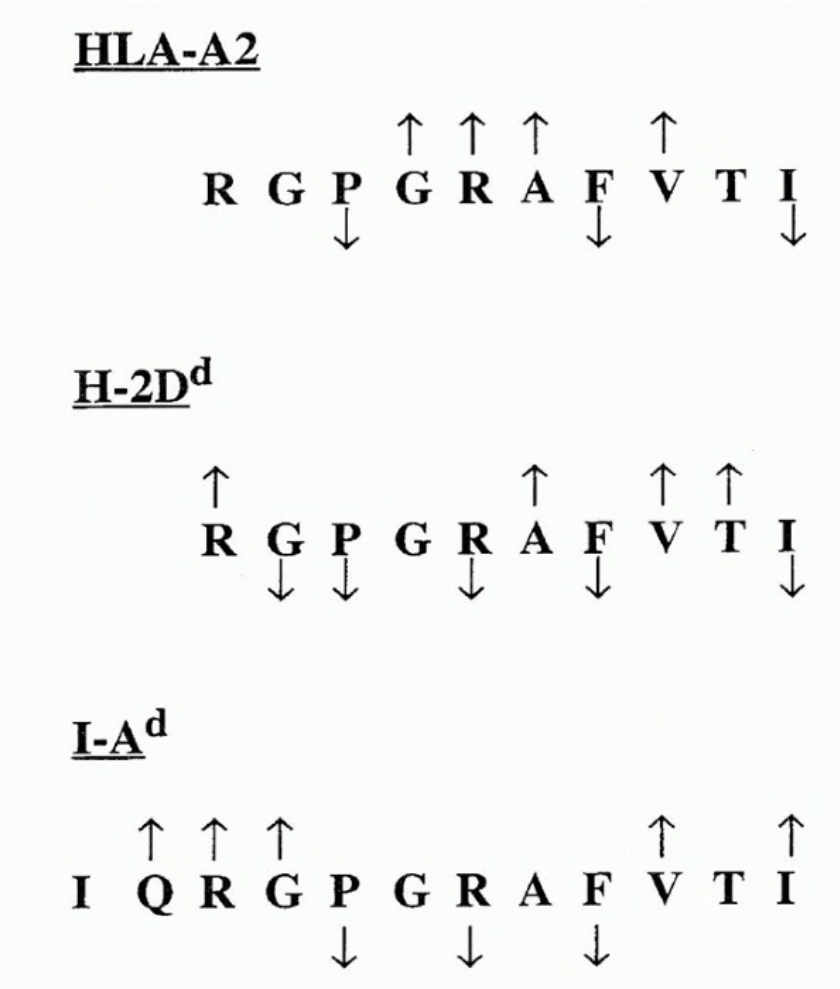

FIG. 23.12. Comparison of the Major Histocompatibility Complex (MHC)-Interacting ("Agretopic") and T-Cell Receptor (TCR)-Interacting ("Epitopic") Residues of the Same Human Immunodeficiency Virus (HIV)-1 Envelope V3 Loop Peptide as It Is Presented by Human Class I, Murine Class I, and Murine Class II MHC Molecules to Cluster of Differentiation (CD)8$^+$ Cytolytic T Cell and CD4+ Helper T Cells. The sequence of the optimal binding portion of peptide P18 IIIB from the HIV-1 envelope protein V3 loop for each MHC molecule, in single letter amino acid code, is shown. *Arrows pointing up* indicate residues determined to interact with the TCR, and *arrows pointing down* indicate residues determined to interact with the MHC molecule. Mapping of residue function for binding to the human class I MHC molecule HLA-A2.1 was described in Alexander-Miller et al.,[487] and binding to the murine class I molecule H-2D^d and the murine class II molecule I-A^d was described in Takeshita et al.[486] Note the common use of the Pro and Phe for binding all three MHC molecules and the use of the key Val residue for binding all the TCRs. Also, the murine MHC molecules both use the central Arg residue as a contact residue, whereas both class I molecules use the C-terminal Ile residue as an anchor residue. Thus, there is a surprising degree of concordance.

The interaction of peptide ligand with TCR can be studied by introducing single substitutions of conservative amino acids at these contact residues, such as Glu for Asp, Ser for Thr, or Gln for Asn. The TCR readily distinguishes among peptides with these minor differences at a

single residue, and the results have been revealing. Depending on affinity for the TCR, closely related (altered) peptides can elicit very different responses in T cells. Thus, although a substituted peptide may be very weak or nonstimulatory by itself, it may still act as a partial agonist or even a strong antagonist of an ongoing T-cell response. Antagonistic peptides can be demonstrated by pulsing APCs with native peptide antigen first so that one is not measuring competition for binding to MHC molecules, followed by pulsing with a 10-fold or greater excess of the antagonist before adding T cells. In the case of influenza hemagglutinin peptide 307 to 319 presented with HLA-DR1, peptide analogues such as Gln substituted for Asn 313 inhibited the proliferation of a human T-cell clone, even though they did not stimulate the clone. Anergy was not induced, and the antagonist peptide had to be present throughout the culture to inhibit the response.[492,493] Thus, lack of antagonist activity is another feature of the interaction between peptide (in complex with MHC molecule) and TCR that is required for the peptide to be a stimulatory antigenic determinant.

Partial agonists were first demonstrated using T-cell clones specific for an allelic form of mouse hemoglobin. These T cells were from CE/J mice, which express the Hb^s allele of mouse hemoglobin, after immunization with the Hb^d allele. The minimum antigenic peptide corresponds to amino acids 67 to 76 of the Hb^d sequence and differs from Hb^s at P72, P73, and P76.[494] Peptides substituted at each residue from amino acid 69 to 76 were tested for T-cell proliferation and cytokine release. Some substitutions, such as Gln for Asn at P72, blocked T-cell stimulation completely in both assays. Other substituted peptides, such as Asp for Glu at P73, lost T-cell proliferation but still stimulated interleukin 4 release, and these are considered partial agonists (Fig. 23.13).[495] Lack of stimulation was not due to failure to bind MHC, as both substituted peptides gave reasonable binding in a competitive-binding assay.[496] Similar alteration of cytokine profile by altering the peptide ligand can be seen in other systems.[493,497,498]

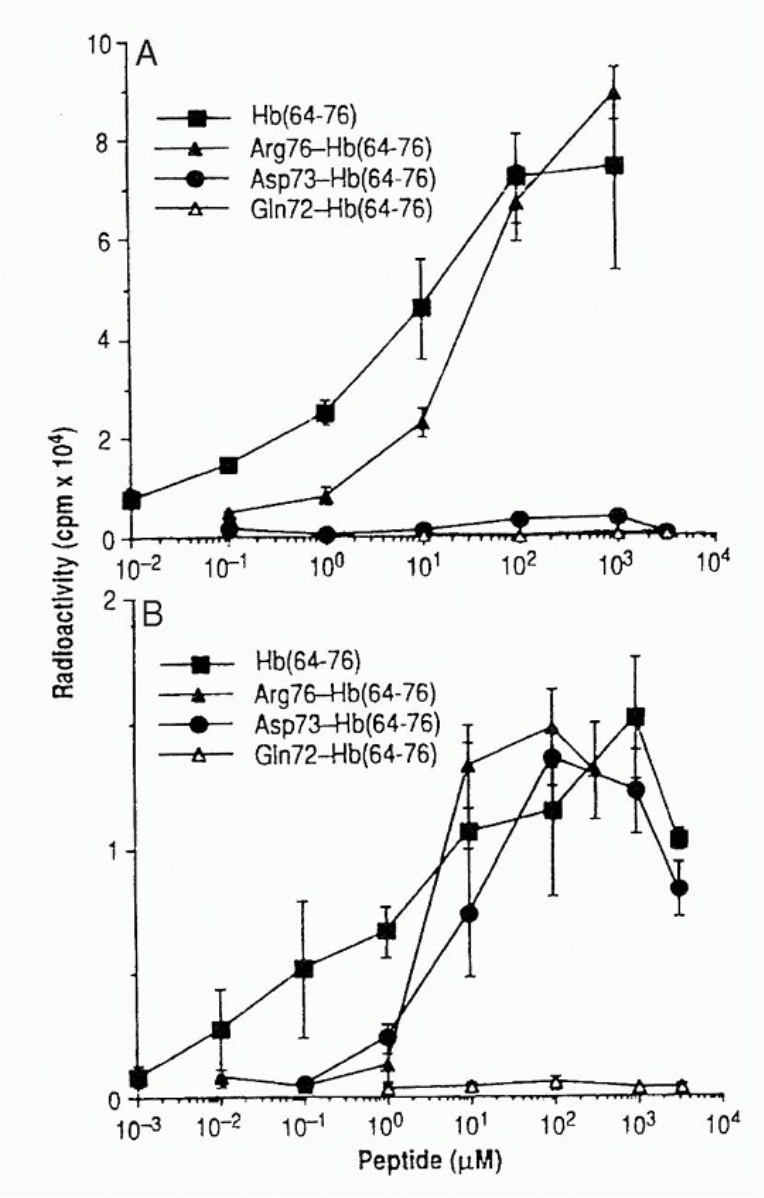

FIG. 23.13. Differential Effect of Altered Peptide Ligands on the Response to Peptide 64 to 76 from Hemoglobin. A: Proliferative response of a T-cell line incubated with antigen-presenting cells and the natural Hb (64-76) peptide or with peptides substituted at positions 72, 73, or 76. **B:** Interleukin 4 release by the T-cell line under the same conditions. The peptide substituted with Asp for Glu at position 73 is unable to induce T-cell proliferation, but it can still induce production of interleukin 4, so it is a partial agonist. In contrast, substitution of Gln for Asn at position 72 knocks out both responses equally. Modified from Evavold and Allen,[495] with permission.

For one of the Hb 64 to 76 specific T-cell clones, PL.17, substitutions at amino acids 70, 72, 73, or 76 reduced antigenic potency by 1000-fold or more, even though conservative amino acids were substituted. Although substitution of Ser for Ala 70 prevented T-cell stimulation in both assays, there was clearly some response to this peptide, as it induced expression of the interleukin 2 receptor.[499] In addition, once T cells were exposed to the Ser 70 peptide, they became unresponsive to subsequent exposure to the natural Hb^d peptide. This phenomenon closely resembled T-cell anergy and persisted for a week or more. The Ser 70 substitution

alters a contact residue of the peptide for the TCR of clone PL.17 and affects its affinity. Other T-cell clones, however, can respond to this peptide presented on the same MHC molecule (I-E^k). Other Hb^d peptides substituted at this position, such as Met and Gly 70, also induced anergy but not proliferation, whereas nonconservative substitutions such as Phe, Asn, Asp, and His 70 induced neither.[500]

Another well-studied example is influenza hemagglutinin peptide 306 to 318 as presented on human HLA-DR1. Based on the known crystal structure of the peptide-MHC complex,[253] amino acid substitutions could be targeted to contact residues for the TCR at P307, P309, P310, P312, P315, and P318.[501] At each position, nonconservative substitutions often rendered the peptide inactive, whereas conservative substitutions at several sites either gave full antigenicity or gave progressively lower stimulatory activity, down to 1000-fold less than native peptide while retaining the ability to induce anergy. For example, substituting His or Gly for Lys 307 gave 1000-fold reduced stimulation of T-cell proliferation but full ability to induce tolerance. Similarly, substituting His for Lys 315 gave complete loss of stimulation but nearly full anergy inducing activity. As before, induction of the interleukin 2 receptor (CD25) was a sign of T-cell activation by these altered peptide ligands, even when they did not induce proliferation. Unlike these peptides, the antagonists do not induce interleukin receptors or secretion, and they do not cause long-lasting tolerance. Overall, a number of altered peptide ligands have now been identified that, in appropriate complexes with MHC molecules, induce anergy or act as antagonists of the TCR and block activation by agonist ligands by delivering an abortive signal.[493]

Several methods have been found to anergize T cells to a specific antigen for up to a week, and all have the common theme of delivering a partial signal via the TCR, resulting in tolerance rather than stimulation. The first method was to expose the T cells to peptide plus APCs treated with the carbodiimide cross-linker ECDI.[502] This treatment may prevent accessory molecules on the presenting cell from interacting with the TCR complex or costimulatory signals from contributing to T-cell activation. The second method was to present peptide on presenting cells with mutated I-E molecules.[503,504] The third method was to use altered peptide ligands that act as TCR antagonists as described previously.[493,500,501] The final method was to block CD4 function with a monoclonal antibody, which would delay the recruitment of CD4 to the engaged TCR.[505] Because generation of a complete stimulatory signal requires the interaction of TCR and accessory molecules, modifications that affect either component can block signaling. An altered peptide ligand, with decreased affinity for the TCR, may form an unstable complex, which cannot stay together long enough to recruit accessory molecules and generate a complete signal.[505,506] Altered peptide ligands with low affinity for the TCR can also act as partial agonists that can compete with optimal agonists and reduce T-cell stimulation based on a similar mechanism (short dwell time of peptide-MHC complex on the TCR).[199]

Abnormal TCR signaling can be demonstrated by following the activity of protein kinases. Normal signaling produces phosphorylation of TCR subunits, such as ζ chain, as well as phosphorylation and activation of receptor-associated tyrosine kinases, such as ZAP-70. These kinases generate the downstream signal needed for T-cell activation. However, in each case studied, partial antigen signaling resulted in ζ chain phosphorylation without phosphorylation or activation of ZAP-70,[500,504,505] so downstream activation did not occur. This abnormal pattern occurred regardless of the method of anergy induction.

Partial signaling may be important for T-cell survival during negative selection in the thymus or in maintaining peripheral tolerance. By responding to self-antigens as if they were altered ligands presented in the thymus, T cells could use anergy induction as a successful strategy for avoiding clonal deletion. Similarly, peripheral tolerance may be an important mechanism for preventing autoimmune disease. Immunotherapy with altered peptide ligands could be envisioned as a way to block an ongoing response or induce tolerance to a specific antigen, such as the synovium in arthritis, or foreign MHC antigens in allograft rejection. However, a potential pitfall is that different T cells recognize the same peptide differently, so a peptide that is seen as an altered peptide ligand by some T-cell clones may be seen as a complete antigen by others. In addition, the choice of peptide would vary with MHC type. To be effective, an altered peptide ligand should antagonize or anergize polyclonal T cells and should work with each patient's MHC type.

A similar mechanism may be invoked to explain the generally weak immunogenicity of tumor antigens. According to this hypothesis, the only T cells capable of responding to self-antigens on tumors may have low-affinity receptors for them. In effect, the natural sequence is the altered ligand that induces tolerance. In some cases, this anergy can be overcome with modified peptides that have greater affinity for the TCR and induce a full stimulatory signal, resulting in an effective immune response to the tumor antigens,[474] as previously described under epitope enhancement.

Prediction of T-Cell Epitopes

The fact that T cells recognize processed fragments of antigens presented by MHC molecules leads to the ironic situation that T-cell recognition of antigen, which is more complex than antibody recognition due to the ternary complex needed between TCR, antigen, and MHC molecule, may actually be focused on simpler structures of the antigen than those seen by most antibodies specific for native protein antigens. In contrast to the assembled topographic antigenic sites seen by many antibodies,[50,51] T cells specific for processed antigens are limited to seeing short segments of continuous sequence.[177,233] Therefore, the tertiary structure of the protein plays little if any role in the structure of the epitope recognized by T cells, except as it may influence processing. However, the structure of the T-cell antigenic site itself must be limited to primary (sequence) and secondary structure, the latter depending only on local rather than long-range interactions. This limitation greatly simplifies the problem of identifying structural properties important to T-cell recognition because one can deal with sequence information, which can now be obtained from DNA without having a purified protein, and with the secondary structure implicit therein without having to obtain an x-ray crystallographic three-dimensional structure of the native protein—a much more difficult task.

Because the key feature necessary for a peptide to be recognized by T cells is its ability to bind to an MHC molecule, most approaches for predicting T-cell epitopes are based on

predicting binding to MHC molecules. These approaches, which have been reviewed,[424,507,508,509,510] can be divided into those that focus on specific individual MHC molecules one at a time, such as motif-based methods, and those that look for general structural properties of peptide sequences. We shall discuss first the methods based on general properties and then those directed to individual MHC molecules.

The first structural feature of amino acid sequences found associated with T-cell epitopes that remains in use today is helical amphipathicity,[227,511,512,513,514] which is statistically significant independent of the tendency to form a helix per se.[512] Because the x-ray

crystallographic structures of both MHC class I[376,377,378,515] and II molecules[253,443] have consistently shown peptides to be bound in extended, not α-helical, conformation, helicity per se has been abandoned as an associated structural feature of T-cell epitopes. However, as discussed in the following text, other explanations of amphipathic structures have been discovered that do not require the peptide to be bound to the MHC molecule as an α helix. Amphipathicity is the property of having hydrophobic and hydrophilic regions separated in space. It was observed that the immunodominant T-cell epitopes of myoglobin and cytochrome c corresponded to amphipathic helices.[185,189,516] DeLisi and Berzofsky[511] developed an algorithm to search for segments of protein sequence that could fold as amphipathic helices based on the idea that the hydrophobicity of the amino acids in the sequence must oscillate as one goes around an amphipathic helix. For the hydrophobic residues to line up on one side and the hydrophilic residues on the other, the periodicity of this oscillation must be approximately the same as the structural periodicity of the helix, about 100 degrees per residue (360 degrees per 3.6 residues per turn) (Fig. 23.14).

A microcomputer program implementing this analysis was published.[514] Margalit et al.[227] optimized the original approach,[511] correctly identifying 18 of the 23 immunodominant helper T cell antigenic sites from the 12 proteins in an expanded database ($p < .001$)[227] (see Table 23.4). Indeed, when the database was expanded to twice and then four times its original size, the correlation remained highly significant, and the fraction of sites predicted remained relatively stable (34/48 sites = 71%, $p < .003$; 61/92 sites = 66%, $p < .001$).[517,518] A similar correlation was found for 65% of peptides presented by class I MHC molecules.[518] A primary sequence pattern found in a substantial number of T-cell epitopes by Rothbard and Taylor[519] was consistent with one turn of an amphipathic helix. Also, another approach, called the “strip-of-the-helix” algorithm, which searches for helices with a hydrophobic strip down one face, found a correlation between amphipathic helices and determinants presented by both class II and I MHC molecules.[513,520]

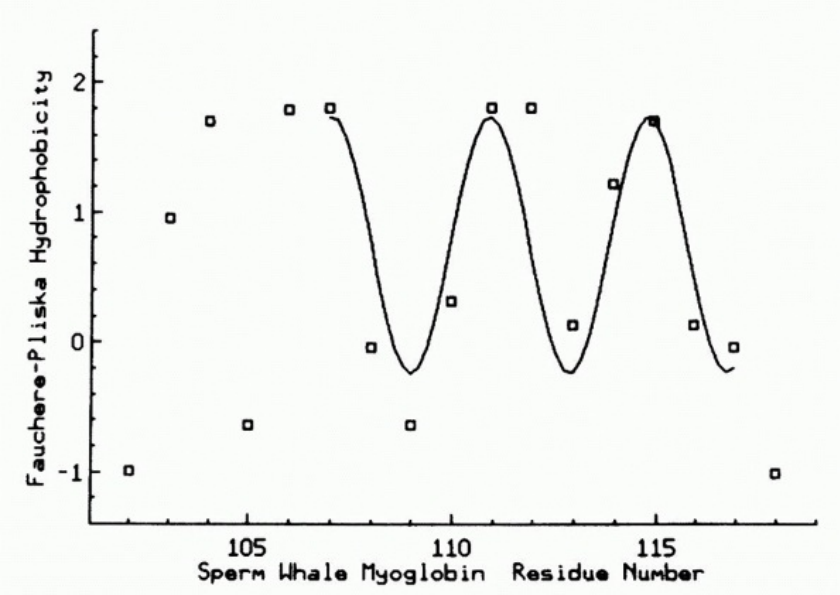

FIG 23.14. Plot of hydrophobicity of each amino acid in sperm whale myoglobin 102 to 118, according to the scale of Fauchère and Pliska,[604] as a function of amino acid sequence, showing least-squares fit of a sinusoidal function to the sequence of

hydrophobicities from 107 to 117. (From Berzofsky et al.,[180] with permission.)

Newer data suggest at least two explanations, not mutually exclusive, for this correlation in the absence of helical structure found in the peptides bound to MHC molecules.[521] First, crystal structures of peptides bound to class II MHC molecules have found that the peptides are bound in an extended conformation, but with a -130-degree twist like that of a type II polyproline helix,[253,443] and can be quite amphipathic because of this twist.[253] Although the -130-degree twist is distinct from that of an α helix, it gives a periodicity similar enough to be detected. Second, it was observed that spacing of the anchor residues in the motifs for peptides binding to class I and II MHC molecules was consistent with the spacing of turns of an α helix, for example, at P2 and P9 (seven residues apart like two turns of a helix) or at P5 and P9 (spaced like one turn of a helix).[521] Because the anchor residues are most often hydrophobic, this pattern resulted in an amphipathic periodicity pattern like that of an amphipathic α helix for just the anchor residues alone, seen in most motifs.[521] Thus, if the other residues have a random pattern, the anchor residue spacing alone, which is enforced by the spacing of the pockets in the MHC molecules that bind these anchor residues, will produce the amphipathic helical signal, even though the peptide is bound in an extended conformation. This amphipathic helical periodicity has held up as a correlate for peptides defined as T-cell epitopes[521] and has continued to be a useful predictive tool for identifying potential epitopes, successful in a number of studies, when one does not want to focus on individual MHC alleles or wants to find regions of high epitope density. Other structural properties such as coil content and exposure have been used as general predictors of MHC class II binding.[522]

Other approaches to predicting T-cell epitopes are generally based on sequences found to bind to specific MHC molecules.[424,507,508,509,510,523,524,525] The simplest approach is to apply standard sequence search algorithms to known protein sequences to locate motifs for peptides binding to particular MHC molecules, using collections of motifs identified in the literature.[264] This approach showed early success for epitopes in proteins from *Listeria monocytogenes*[526] and malaria,[527] but it also became apparent that only about 30% of sequences bearing motifs actually bound to the corresponding MHC molecules.[526,528,529] This discrepancy may relate to adverse interactions created by nonanchor residues[392,397,530] and

could be overcome to some extent by generating extended motifs taking into account the role of each residue in the sequence.[397,530]

To determine whether one could locate regions of proteins with high densities of motifs for binding multiple MHC molecules, Meister et al.[531] developed the algorithm Epimer, which determined the density of motifs per length of sequence. A surprising result was that the motifs were not uniformly distributed but clustered. This clustering may reflect the fact that many motifs are related, and that the same anchor residues are shared by several motifs, perhaps because MHC molecules are also related and their variable segments that define some of the binding pockets are sometimes exchanged by gene conversion events.[532] This hypothesis has now been confirmed and extended by studies showing that each anchor pocket can be grouped into families of MHC molecules sharing similar pockets and therefore anchor residues, but the families for the B, C, and F pockets do not coincide, so there is a

reassortment between pockets.[533,534] These observations allow prediction of motifs for additional MHC molecules. In the case of HIV, the densities of motifs for class I MHC binding were anomalous at both the low and high ends of the spectrum.[535] Clustering at the high end may be due to anchor sharing and showed no correlation with conserved or variable regions of the sequence. However, at the low end, long stretches with low motif density occurred preferentially in variable regions, suggesting that the virus was mutating to escape the CTL immune system.[535] This clustering may be useful in vaccine development because identification of sequences containing overlapping motifs for multiple MHC molecules may define promiscuously presented peptides that would elicit responses in a broad segment of the population.[531]

Another type of MHC allele-specific approach is the use of matrices defining the positive or negative contribution of each amino acid possible at each position in the sequence toward binding to an MHC molecule. A positive or negative value is assigned to each of the 20 possible amino acids that can occur at each position in a peptide sequence, and these are summed to give the estimated potential of that peptide for binding. The values in the matrix are derived from either experimental binding studies using peptide panels with single positions substituted with each possible amino acid,[439,536,537,538,539] or from comparisons of peptides known to bind in a compilation of the literature, if the number known is sufficiently large.[507,540] One improvement described is an amino acid similarity matrix that disfavors substitutions with opposite charge.[541] Davenport et al.[542,543] also developed a motif method based on Edman degradation sequencing of pooled peptides eluted from MHC molecules. All of these methods have had some success in predicting peptides binding to particular MHC molecules,[507] but they all require the assumption that each position in a peptide must be acting independently of its neighbors, which is a reasonable first approximation, but exceptions are known.[544,545] The more experimental data that goes into generating the matrix, the more reliable the predictions. Therefore, the predictive success may be greater for some of the more common HLA molecules for which more data exists. This matrix approach has been used for both class I and II MHC molecules. Current predictive matrix algorithms, compared to experimental screening, have been found to detect the vast majority of $CD8^+$ T-cell epitopes detected experimentally, for example, in vaccinia virus, in which the top-ranked 300 peptides using four different algorithms predicted 40 per 49 epitopes found.[546]

A potentially very useful observation is the finding that HLA class I molecules can be grouped into families (HLA supertypes) that share similar binding motifs.[438,536,547,548] The broader motifs that encompass several MHC molecules have been called supermotifs. For example, HLA-A*0301, A*1101, A*3101, A*3401, A*6601, A*6801, and A*7401 all fall into the HLA-A3 superfamily.[547] A peptide that carried this supermotif should be active in a broader range of individuals than one which was presented by a single HLA molecule. Moreover, as several HLA supertypes have been defined, it should be possible to design a vaccine effective in a large fraction of the population with only a limited number of well-selected antigenic determinants.[549]

Another approach for predicting peptides that bind to MHC molecules is based on free energy calculations of peptides docked into the groove of a known MHC structure, for which the crystallographic coordinates are known, or on structural modeling of the MHC molecule by homologous extension from another MHC molecule, when the crystal structure is not known, followed by peptide docking calculations.[550,551,552] It is important to use free energy rather

than energy, as the latter alone cannot find the most stable orientation of a side chain and cannot correctly rank order different side chains at the same position. This approach correctly predicts the structure of several known peptide-MHC complexes when starting with the crystal structure of a different complex, in each case to within 1.2 to 1.6 Å all-atom root-mean square deviation.[551] Using this structural modeling can allow one to extend motifs to nonanchor positions for cases where only anchor residue motifs are known and can allow one to predict new motifs for MHC molecules whose motifs have not yet been determined.

Another approach to predicting MHC-binding sequences uses a technique called threading that has been developed for predicting peptide secondary structure, based on threading a sequence through a series of known secondary structures, and calculating the energies of each structure. Altuvia et al.[553,554] showed that threading could be applied to peptides in the groove of MHC molecules, because when several peptides that bind to the same MHC molecule are compared crystallographically, the conformation of the peptides is fairly similar, as for example in several peptides cyrstallized bound to HLA-A2.1.[515] In testing the threading approach, Altuvia et al.[553,554] showed that known antigenic peptides are highly ranked among all peptides in a given protein sequence, and the rank order of peptides in competitive binding studies could be correctly predicted. The advantage of this approach is that it is independent of known binding motifs and can identify peptides that bind despite lack of the common motif for the MHC molecule in question. It can

also be used to rank a set of peptides all containing a known motif. For both class I and II MHC-binding peptides, a number of structure-based predictive approaches have been developed as well.[522,555,556,557,558]

Finally, artificial neural networks can be trained on a set of peptides that bind to a given MHC molecule to recognize patterns present in binding peptides.[559,560] When the predictions of the artificial neural networks are tested, the results can be used to further train the artificial neural networks to improve the predictive capability in an iterative fashion.

Recently, predictive algorithms for proteasomal cleavage sites[561,562] and TAP-transported peptides[319,563] have been developed. Combining these into approaches to predict epitopes based on all the steps a peptide must pass through, cleavage, transport, and MHC binding (except for TCR binding), has led to the most recent comprehensive algorithms for epitope prediction that can achieve up to 72% sensitivity.[286,320,508,564,565,566,567,568]

As all these methods are further developed and refined, they promise to allow accurate prediction of peptides that will bind to different MHC molecules and thus allow the design of vaccines without empirical binding studies until the end of the process. In addition, empirical high throughput methods for epitope mapping have been developed to speed the latter.[569] Further, localization of clusters of adjacent or overlapping binding sequences in a short segment of protein sequence can also be useful for selecting sequences that will be broadly recognized. Predictive algorithms for locating T-cell epitopes also have the potential use to reduce immunogenicity of therapeutic proteins (such as hormones, cytokines, and monoclonal antibodies) against which one would not want an immune response to develop.[570,571] For this purpose and others, it is useful to be able to predict all the epitopes likely to be recognized not just with a single MHC allele but with all of a person's MHC molecules or even those of a larger population; such methods have also been developed.[572]

RELATIONSHIP BETWEEN HELPER T-CELL EPITOPES AND B-CELL

EPITOPES ON A COMPLEX PROTEIN ANTIGEN

As we have seen, the factors that determine the location of antigenic sites for T and B cells, with the possible exception of self-tolerance, are largely different. Indeed, if B cells (with their surface antibody) bind sites that tend to be especially exposed or protruding—sites that are also more accessible and susceptible to proteolytic enzymes—then there is reason to think that T cells may have a lower probability of being able to recognize these same sites, which may be more likely to be destroyed during processing. Certainly, assembled topographic sites will be destroyed during processing. On the other hand, there are examples in which T cells and antibodies seem to see the same, or very closely overlapping, sites on a protein,[43,185,215,573,574,575] although fine specificity analysis usually indicates that the antibody and T cell fine specificities are not identical. The question dealt with here is whether there are any functional or regulatory factors in T cell-B cell cooperation that would produce a relationship between helper T cell specificity and B cell specificity for the same protein antigen.

Early evidence that helper T cells might influence the specificity of the antibodies produced came from a number of studies showing that Ir genes, which appeared to act through effects of T-cell help, could influence the specificity of antibodies produced to a given antigen.[181,576,577,578,579,580,581,582,583] It was hard to imagine how MHC-encoded Ir genes could determine which epitopes of a protein elicit antibodies, when such antibodies are generally not MHC restricted. One explanation suggested was that the Ir genes first select which helper T cells are activated, and these in turn influence which B cells, specific for particular epitopes, could be activated.[130] Because, for cognate help, the B cell has to present the antigen in association with an MHC molecule to the helper T cell, the Ir gene control of antibody specificity must operate at least partly at this step by selecting which helper T cell can be activated by and help a given B cell. Conversely, if the helper T cell selects a subset of B cells to be activated on the basis of their antibody specificity, then there is a reciprocal interaction between T and B cells influencing each other's specificity. Therefore this hypothesis was called “T-B reciprocity.”[130] Steric constraints on the epitopes that could be used by helper T cells to help a B cell specific for another particular epitope of the same protein were also proposed by Sercarz et al.[584]

The concept was first tested by limiting the fine specificity of helper T cells to one or a few epitopes and then determining the effect on the specificities of antibodies produced in response to the whole molecule. This was accomplished by inducing T-cell tolerance to certain epitopes[585] or using T cells from animals immune to peptide fragments of the protein.[128,586,587] In each case, the limitation on the helper T-cell specificity repertoire influenced the repertoire of antibodies produced.

One purpose of the B-cell surface Ig is to take up the specific antigen with high affinity, which is then internalized by receptor-mediated endocytosis and processed like any other antigen.[588,589,590,591,592,593,594,595] Therefore, the explanation was proposed that the surface Ig, which acts as the receptor to mediate endocytosis, sterically influences the rate at which different parts of the antigen are processed because what the B cell is processing is not free antigen but a monoclonal antibody-antigen immune complex.[130] This concept presupposes that many antibody-antigen complexes are stable near pH 6 in the endosome, and that what matters is the kinetics of production of large fragments, rather than the products of complete digestion, when both the antigen and the antibody may be degraded to single amino acids. Such protection from proteolysis of antigen epitopes by bound antibody can be demonstrated at least in vitro.[57] More recently, the effect of antigen-specific B-cell

surface Ig on the fragments produced by proteolytic processing of antigen was elegantly demonstrated by Davidson and Watts.[596] They demonstrated that the pattern of fragmentation of tetanus toxoid, as measured by SDS-polyacrylamide gel electrophoresis, produced during processing by B-lymphoblastoid clones specific for tetanus toxoid varied among B-cell clones depending on their specificity for different epitopes within the antigen.

Binding to the antibody may also influence which fragments are shuttled to the surface and which are shunted into true lysosomes for total degradation. Thus, different B cells bearing different surface Ig would preferentially process the antigen differently to put more of some potential fragments than others on their surface in contrast to nonspecific presenting cells that would process the antigen indifferently. By this mechanism, it is proposed that B-cell specificity leads to selective antigen presentation to helper T cells and, therefore, to selective help from T cells specific for some epitopes more than from T cells specific for others.[130]

To test this hypothesis, Ozaki and Berzofsky[129] made populations of B cells effectively monoclonal for purposes of antigen presentation by coating polyclonal B cells with a conjugate of monoclonal antimyoglobin coupled to anti-IgM antibodies. B cells coated with one such conjugate presented myoglobin less well to one myoglobin-specific T-cell clone than to others. B cells coated with other conjugates presented myoglobin to this clone equally well as to other clones. Therefore, the limitation on myoglobin presentation by this B cell to this T-cell clone depended on the specificity of both the monoclonal antibody coating the B cell and the receptor of the T-cell clone. It happened in this case that both the monoclonal antibody and the T-cell clone were specific for the same or closely overlapping epitopes. Therefore, it appears that the site bound by the B-cell surface Ig is less well presented to T cells. This finding is also consistent with a recent study of chimeric proteins in which one or more copies of an ovalbumin helper T-cell determinant were inserted in different positions.[597] Although the position of the ovalbumin determinants did not affect the antibody response to one epitope, the position did matter for antibody production to an epitope of the chimeric protein derived from insulin-like growth factor I. An ovalbumin determinant inserted distal to this epitope was much more effective in providing help than one inserted adjacent to the same epitope, when both constructs were used as immunogens, even though both constructs elicited similar levels of ovalbumin-specific T-cell proliferation in the presence of nonspecific presenting cells in vitro as a control for nonspecific effects of flanking residues on processing and presentation of the helper T-cell determinants. However, circumstantial evidence from the Ir gene studies mentioned previously suggests that T cells may preferentially help B cells that bind with some degree of proximity to the T-cell epitope, as there was a correlation between T cell and antibody specificity for large fragments of protein antigens under Ir gene control.[127,130,181,579,580,583] Therefore, antibodies may have both positive and negative selective effects on processing. Further studies on presentation of β-galactosidase-monoclonal antibody complexes by nonspecific APCs suggest similar conclusions.[598,599] Presumably, the conjugates are taken up via Ig fragment c (Fc) receptors on the presenting cells and processed differentially according to the site bound by the antibody so that they are presented differentially to different T-cell clones. Thus, non-B-presenting cells can be made to mimic specific B-presenting cells. This also suggests that circulating antibody may have a role in the selection of which T cells are activated in a subsequent exposure to antigen.

The issue of whether bound antibody enhanced or suppressed presentation of specific determinants to T cells was explored further by Watts et al.[600] and Simitsek et al.[601] They first found that a particular tetanus toxoid-specific Epstein-Barr virus-transformed human B-

cell clone 11.3 failed to present the tetanus toxoid epitope 1174 to 1189 to specific T cells, whereas it presented another epitope as well as did other B cells, and another B-cell clone presented the 1174 to 1189 epitope well. Moreover, the free 11.3 antibody also inhibited presentation of this epitope to T cells at the same time that it enhanced presentation of other epitopes by Fc receptor facilitated uptake.[600] They subsequently found that the same 11.3 B cell and antibody actually enhanced presentation of another epitope of tetanus toxoid, 1273 to 1284, by about 10-fold, even though both epitopes were within the footprint of the antibody as determined by protection from proteolytic digestion.[601] The enhancement could be mediated also by free antibody as well as Fab fragments thereof, indicating that the mechanism did not involve Fc receptor facilitated uptake. Furthermore, the 11.3 antibody had no effect on presentation of another determinant in the same tetanus toxoid C fragment, 947 to 967, which was not within the footprint of the antibody, and another antibody to the C fragment did not enhance presentation of 1273 to 1284. The authors concluded that the same antibody or surface Ig can protect two determinants from proteolysis but sterically hinder the binding of one to class II MHC molecules while facilitating the binding of the other.[601] The facilitation may involve protection from degradation. This antibody-mediated enhancement of presentation of selected epitopes to helper T cells can greatly lower the threshold for induction of a T-cell response and may thereby elicit responses to otherwise subdominant epitopes. It can also contribute to epitope spreading, for example, in autoimmune disease, in which an initial response to one dominant determinant leads to a subsequent response to other subdominant determinants, perhaps by helping for antibody production, which in turn facilitates presentation of the other determinants.

Taken together, these results support the concept of T-B reciprocity in which helper T cells and B cells each influence the specificity of the other's expressed repertoire.[130] This mechanism may also provide an explanation for some of the cases in which Ir genes have been found to control antibody idiotype.[602,603] These relationships probably play a significant role in regulating the fine specificity of immune response of both arms of the immune system. Therefore, they will also be of importance in the design of synthetic or recombinant fragment vaccines that incorporate both T- and B-cell epitopes to elicit an antibody response.

CONCLUSION

Overall, antibodies and T cells recognize different structural features in different contexts or environments, and thus complement each other to detect the spectrum of foreign (or self-) antigens encountered. Antibodies recognize three-dimensional structures on the exposed surface of molecules either in solution or on a cell surface.

Therefore, they are dependent on the conformation of the antigen and can recognize structures that are assembled on the surface of the antigen molecule by the way it folds but that are not contiguous in the primary sequence. However, they do not generally recognize structures buried within protein molecules or inside cells. In contrast, T cells are designed to recognize short segments of primary amino acid sequence of protein antigens, and thus are not dependent on the conformation of the original protein unless it affects processing. Furthermore, T cells particularly provide internal surveillance of proteins inside cells, recognizing peptide fragments of these presented by MHC molecules that carry these fragments to the cell surface. This surveillance of intracellular proteins requires a number of hurdles including proteolytic processing of the antigen into fragments, transport of these into the compartments where they are loaded onto MHC molecules, binding with appropriate specificity to the combining site of specific MHC molecules, and then finally recognition by an

appropriate TCR. These hurdles limit the number of amino acid sequences that can be recognized and account in part for immunodominance. Furthermore, the two major subsets of T cells also complement each other by recognizing exogenous and endogenous proteins processed and transported through different pathways and presented by difference classes of MHC molecules. Thus, the two major classes of T cells complement the types of structures and the locales surveyed by antibodies. For example, in the case of viruses, antibodies can detect intact virions and shed viral proteins in solution as well as viral proteins expressed on the surface of infected cells; $CD4^+$ T cells can recognize viral proteins taken up by APCs and processed in an endosomal pathway and $CD8^+$ T cells can detect proteins synthesized within the infected cell, whether or not they are ever expressed intact on the cell surface or secreted. Together, they provide the immune system with a strategy to detect all forms of foreign invaders as well as to protect the host through different effector mechanisms.

Chapter 24

Fc Receptors and Their Role in Immune Regulation and Inflammation

Jeffrey V. Ravetch

Falk Nimmerjahn

HISTORICAL BACKGROUND

Cellular receptors for immunoglobulins (Igs) were anticipated by the description of cytophilic antibodies of the IgG class, identified by Boyden and Sorkin in 1960.[1] These antibodies conferred upon normal cells, like macrophages, the capacity to specifically absorb antigen. Using sheep red blood cells (RBCs) as the antigen resulted in rosette formation between the cytophilic antisheep RBC antibodies and macrophages and provided a convenient means of visualization of the binding of cytophilic antibodies with normal cells. Subsequent studies by Berken and Benacerraf[2] suggested that the crystallized fragment (Fc) of the cytophilic antibody interacted with a cell surface receptor on macrophages. Similar studies on B-lymphocytes extended the generality of these receptors and led to the term *Fc receptor* (FcR) to denote the surface molecules on lymphoid and myeloid cells that are capable of interacting with the Fc of immunoglobulin molecules.[3] Studies on IgE, IgM, and IgA demonstrated the existence of distinct receptors for those isotypes as well on various immune cell types. Detailed biochemical characterization of Fc receptors was inaugurated by the studies of Kulczycki et al.[4] on the high-affinity IgE FcR of mast cells, revealing a hetero-oligomeric $\alpha\beta\gamma_2$ subunit structure. A distinction between FcRs for the IgE and IgG isotypes emerged with the observation of the very high (10^{10} M^{-1}) binding affinity of IgE for its receptor in comparison with the low binding (10^6 M^{-1}) of IgG1 to its receptor. This distinction led to the realization that the functional IgG1 ligand was exclusively in the form of an immune complex (IC), whereas IgE binding occurred through monomer interaction with its receptor. This difference in binding affinity had significant functional implications for the structures of these receptors and mechanisms by which each isotype activated its target cell. Determination of the structure of these receptors was facilitated by their molecular cloning, beginning with the IgG FcRs[5,6] and followed by the IgE FcR.[7] Two distinct types of IgG receptors, differing in their transmembrane and cytoplasmic sequences, were identified that offered a molecular explanation for the apparent contradictory activation and inhibitory activities attributed to IgG FcRs. The primary structure of the subunits of the high-affinity IgE FcR revealed homology in the ligand binding α subunit to its IgG counterparts. However, the extent of similarity between these receptors became apparent with the observation that the γ chain subunit was common to both IgG and IgE FcRs, providing both assembly and signaling functions to these activation receptors.[8,9] This common structure suggested a functional link between IC diseases and allergic reactions, a prediction that was confirmed through mouse knockout studies of IgG FcRs.[10,11] The FcRs, through their dependence on the immunoreceptor tyrosine-based activation motif (ITAM) pathway of cellular activation, belonged to the family of immunoreceptors that included the antigen receptors on B and T cells. Three-dimensional crystal structures have been solved for the low-affinity IgG FcRs[12,13] and the high-affinity IgE FcR,[14] alone and in complex with their Ig ligands,[15,16] further establishing the close structural link between these Ig receptors.

The functional roles of IgG FcRs were suggested by the distribution of these receptors on both lymphoid and myeloid cells.[17] On myeloid cells, they were presumed to mediate effector cell activation, resulting in phagocytosis, antibody-dependent cellular cytotoxicity (ADCC), and release of inflammatory mediators. However, the well-known ability of the classical pathway of complement to generate activated fragments in response to ICs capable of inducing inflammatory responses by myeloid cells complicated the interpretation of the physiological role of IgG FcRs. Thus, the contribution of IgG FcRs to the mechanism of IC-mediated inflammation, as distinct from the role of complement, remained uncertain. Insight into this distinction was gained through the generation of mouse strains specifically deficient or blocked in either FcRs[10,18,19,20] or components of the classical complement pathway.[21] Studies on IC-mediated inflammatory responses in these animals, such as the Arthus reaction, led to the realization that IgG FcRs and not the classical pathway of complement activation were the functional mediators of inflammatory responses triggered by ICs.[20,22,23] The situation for IgE was less confounding, and the identification and characterization of a high-affinity receptor for this isotype on mast cells offered a plausible explanation for many of the inflammatory features of allergic reactions,[24] validated later by mouse knockouts of this receptor. IgG ICs had also been observed to mediate suppression of B-cell responses; thus, the presence of an IgG FcR activity on B cells provided a possible, but uncharacterized, mechanism for this inhibitory activity. Molecular characterization of this inhibitory activity for the B-cell FcR, FcRIIB, resulted in the first detailed description of an inhibitory motif, now termed the immunoreceptor tyrosine-based inhibitory motif (ITIM),[25,26] and the signaling pathway by which it abrogates ITAM-triggered activation. The ITIM mechanism is now

recognized as ubiquitous and has resulted in the recognition of a large family of inhibitory receptors on immune cells that function to maintain proper

thresholds for activation and abrogate activation responses to terminate an immune reaction.[27]

FcRs are now recognized as central mediators of antibody-triggered responses, coupling the innate and adaptive immune responses in effector cell activation.[28] In addition to these specialized roles, the IgG FcRs have served as an example of the emerging class of balanced immunoreceptors, in which activation and inhibition are tightly coupled in response to ligand binding. Perturbations in either arm of the response have been shown to lead to pathological consequences and have been taken as a paradigm of how these systems are likely to work for those paired immunoreceptors with unknown ligand-binding functions. The newly described roles for FcRs in maintaining peripheral tolerance, shaping the antibody repertoire, regulating antigen-presenting cell (APC) maturation, and promoting mast cell survival indicate the diversity of functions that these receptors possess and their central role in modulating both afferent and efferent responses in the immune response.

This chapter focuses primarily on the IgG and IgE FcRs, for which substantial data on their structure, function, regulation, and role in a variety of physiological and pathological conditions are now available. The similarity in structure and signaling between those receptors and other members of this family, such as the IgA FcR and the recently discovered Fc-receptor for mouse and human IgM (FcμR), is also discussed. These FcRs will be referred to as “canonical Fc receptors,” reflecting their shared structural and functional properties. In contrast, lectins such as SIGN-R1 and DC-SIGN, which bind IgG Fc when sialylated, represent a novel class of FcRs with distinct structures and functions and will be discussed in detail in the following. Other Ig receptors with specialized functions in the transport of Igs, such as the FcRn[29] and the poly-Ig FcR,[30] will not be discussed here.

STRUCTURE AND EXPRESSION

Molecular Genetics

Two general classes of canonical FcRs are now recognized: the activation receptors, characterized by the presence of a cytoplasmic ITAM sequence associated with the receptor, and the inhibitory receptor, characterized by the presence of an ITIM sequence. These two classes of receptors function in concert and are usually found coexpressed on the cell surface. Thus coengagement of both signaling pathways is the rule, setting thresholds for and ultimately determining the physiological outcome of effector cell responses. Among the factors that determine this threshold level are the actual affinities of the individual activating and inhibitory receptors for a specific IgG ligand and the expression level of the receptor pairs on immune effector cells. Importantly, the affinity of different antibody isotypes and subclasses for their respective activating and inhibitory FcRs varies significantly, thus explaining the differential activity of antibody isotypes in vivo.[20,31,32] In addition, alleles of specific FcRs have been described that alter their affinity for individual subclasses thus accounting for the variable responses seen in a population to an antibody (see subsequent discussion). Noncanonical FcRs such as the IgM receptors FcμR, Fca/μR, the poly-Ig receptor, and the sialylated IgG Fc receptors SIGN-R1 and DC-SIGN, contain neither ITAM nor ITIM motifs.

Subunit Composition

Canonical FcRs are typically type I integral membrane glycoproteins consisting of, at the least, a ligand recognition *α* subunit that confers isotype specificity for the receptor. *α* subunits for IgG, IgE, IgM, and IgA have been described.[17,33,34,35] These subunits typically consist of two extracellular domains of the IgV type superfamily, a single transmembrane domain and a relatively short intracytoplasmic domain. In activation FcRs, a signaling subunit of the *γ* family is often found, resulting in an $\alpha\gamma_2$ complex. The inhibitory FcγRIIB molecule, in contrast, is expressed as a single-chain receptor. The *α* subunits have apparent molecular weights of between 40 and 75 kDa, and share significant amino acid sequence homology in their extracellular domains. Alternatively, spliced forms of FcγRIIB modify the intracytoplasmic domain of this molecule. For example, the B2 form lacks sequences that inhibit internalization and thus demonstrates enhanced internalization of ICs, in comparison with FcγRIIB1. However, all the splice variants contain the ITIM motif, a necessary and sufficient domain for mediating inhibitory signaling. The conservation of this sequence in mice and humans, its presence in all splice variants, and the hyperresponsive phenotypes generated in mice deficient in this receptor all support inhibition as the central function of FcγRIIB. The specific structures of the *α* subunits of the canonical FcRs are shown in Figure 24.1. The notable exceptions to the general structure just outlined are seen for the high-affinity FcγRI*α* subunit, which has three extracellular domains; the activation FcγRIIA*α* subunit, which does not require additional subunits for assembly or signaling; and the glycosylphosphatidyl-inositol (GPI)-linked FcγRIIIB, which attaches to the cell surface through a GPI linkage, rather than through a transmembrane domain.

The *γ* subunit is found associated with activation IgG, IgE, and IgA FcRs, as well as with non-FcR molecules, such as paired Ig-like receptor A (PIR-A) and natural killer (NK) cell cytotoxicity receptors, but not with IgM receptors, nor the lectins SIGN-R1 and DC-SIGN.[36,37,38] It is required for assembly of the *α* subunits of these receptors by protecting these subunits from degradation in the endoplasmic reticulum. The *γ*chain is found as a disulfide-linked homodimer, with a short extracellular domain containing the cysteine involved in dimerization, a transmembrane domain, and an intracytoplasmic domain containing the ITAM. An aspartic acid residue found in the transmembrane domain of the *γ*chain is often associated with a basic amino acid residue in the transmembrane domain of the *α* subunit.

The γsubunit belongs to a gene family that includes the T-cell receptor-associated ζ chain and the NK receptor DAP-10- and DAP-12-associated molecules.[39] FcγRIIIA can associate with the ζ chain, resulting in the $\alpha\zeta_2$ complex found in human NK cells.

A third subunit is found associated with the activation FcRs FcεRI and FcγRIII, the β subunit. This 33-kDa subunit has four transmembrane-spanning domains and amino and carboxy intracytoplasmic domains, belonging to the cluster

P.585

of differentiation (CD)20 family of tetraspan molecules.[24] An ITAM sequence is found in the intracytoplasmic carboxy domain. In mast cells and basophils, the β chain assembles into an $\alpha\beta\gamma_2$ complex with the α chain belonging to either FcγRIII or FcεRI. Its presence is required for assembly of FcεRI in rodents. In humans, however, $\alpha\gamma_2$ complexes of FcεRI are found in monocytes, Langerhans cells, and dendritic cells (DCs), in addition to the $\alpha\beta\gamma_2$ complexes found in mast cells and basophils. The ITAM motif found in the β subunit is not an autonomous activation sequence but functions as a signaling amplifier of the ITAM found in the γsubunits.[40]

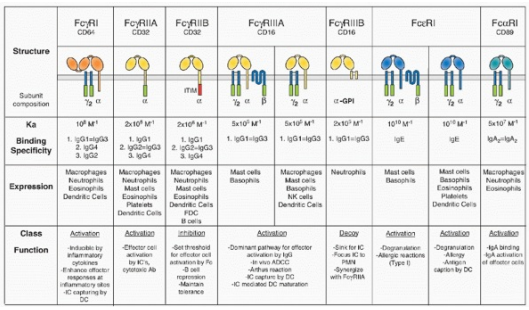

FIG. 24.1. Summary of Fc Receptor Structures, Expression Patterns, and in Vivo Functions. The immunoreceptor tyrosine-based activation motif signaling motif is indicated by the *green rectangle*; the immunoreceptor tyrosine-based inhibitor motif is indicated as a *red rectangle*. Alleles of FcγRIIA and FcγRIIIB and their binding properties are discussed in the text.

Gene Organization, Linkage, and Polymorphisms

All α subunits of canonical FcRs share a common gene organization, which indicates that the evolution of this family of receptors resulted from gene duplication from a common ancestor.[41] Sequence divergence then resulted in the acquisition of distinctive specificities for these related sequences. Most of the genes belonging to the expanded FcR family, including the recently identified Fcμ-receptor, the Fcα/μR, the poly-Ig receptor, the group of FcR-homologous or -like (FCRL) proteins, the α chains of FcγRI, FcγRII, FcγRIII, and FcεRI including the common FcR-γ chain (Fig. 24.2), are found on the long arm of chromosome 1.[34,35,42,43,44] This region is syntenic with a comparable region on mouse chromosome 1; however, FcγRIα and several FCRLs are found on mouse chromosome 3. In humans, the α subunit of the IgA receptor is found on chromosome 19 as is the lectin DC-SIGN (CD209) and the β subunit is on chromosome 11. The FcγRII-FcγRIII locus on chromosome 1 is further linked to a variety of lupus susceptibility genes found in that region, including the *Sle1* cluster.[45] A locus linked to atopy has been identified at 11q12-13 and further delineated polymorphisms of the β chain (I181V and V183L) that are associated with a heightened risk of atopy. However, a direct functional association of these polymorphisms with the known biological activities of the β chain has not been found.[46]

Polymorphisms in the α chains of the FcγRs have been described, most notably in FcγRIIA and FcγRIIIA; these polymorphisms result in differences in binding affinity to specific IgG subclasses.[47] For example, a histidine at position 131 in FcγRIIA results in higher affinity binding to IgG2 and IgG3 than does an arginine at that position. Similarly, FcγRIIIA with valine at position 158 of the α chain has a higher binding affinity for IgG1 and 3 than does the polymorphic form with phenylalanine at that position. These polymorphisms translate into a more robust ADCC response for the FcγRIIIA val/val and the FcγRIIA his/his haplotype in vitro and has been positively correlated with a better clinical response to antitumor antibodies inclunding the CD20-specific antibody rituximab, the Her2/neu-specific antibody trastuzumab, and the epidermal growth factor receptor-specific antibody cetuximab in human lymphoma, metastatic breast cancer, and colorectal cancer patient cohorts, respectively.[48,49,50,51,52,53] This data is consistent with previous results obtained with rituximab

P.586

and trastuzumab in mouse models, demonstrating an important role of cellular FcγRs for the activity of these therapeutic antibodies in vivo.[54,55] Four amino acids are polymorphic for FcγRIIIB at positions 18, 47, 64, and 88, which contribute to the neutrophil antigen polymorphisms for this receptor. Several studies have attempted to link specific FcR polymorphisms or copy number variations to autoimmune diseases, specifically to systemic lupus erythematosus (SLE).[56] Recent studies have reported associations in susceptibility to SLE in both murine and human populations with levels of FcγRIIB

expression or alleles of FcγRIIB.[57] Reduced expression of FcγRIIB on activated B cells, such as memory cells, has been seen in patients with SLE and chronic inflammatory demyelinating polyneuropathy (CIDP), and is associated with a promoter polymorphism.[58,59] In mouse strains that develop a spontaneous, lupus-like disease, restoring the level of FcγRIIB expression on their B cells to a wild-type level reverses disease.[60,61] A higher incidence of an allele of FcγRIIB has been reported in several populations with autoimmune disease. This allele, found in the transmembrane domain of the receptor, is suggested to result in a hypomorphic phenotype, similar to the reduced expression observed.[57] Of note, despite increasing the risk for development of SLE, this FcγRIIB allele seems to decrease the likelihood of malaria infections and the severity of disease and can be found at increased frequencies in areas of the world where malaria is endemic.[62,63]

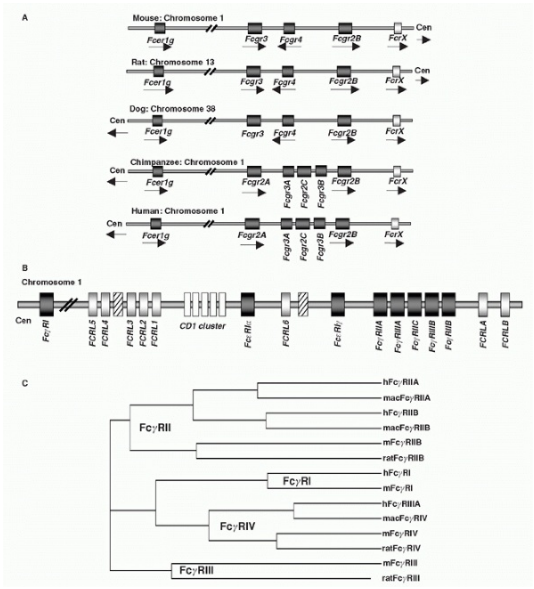

FIG. 24.2. Chromosomal Organization of Fc Receptor (FcR) and FcR-Like Genes. A: Localization of FcR genes in different species. **B:** The human FcR locus on chromosome 1. Classical FcR genes are shown in *dark grey*, FCRL genes as *light grey*, and the CD1 gene cluster on chromosome 1 as *white boxes*. Pseudogenes are indicated as hatched boxes. (adapted from Davis et al.[44]). **C:** The cladogramm shows the alignment of selective classical FcRs of humans (*h*), macaques (*mac*), mice (*m*), and rats.

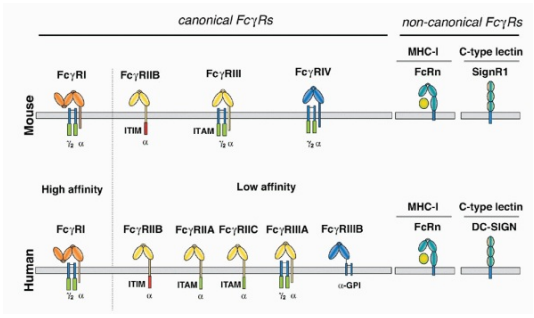

FIG. 24.3. Comparison of the Human and Mouse Canonical and Noncanonical Fcγ-Receptor Protein Family. In both species, canonical FcγRs can be distinguished by their affinity for the antibody Fc-portion (high or low affinity) and by the signaling pathways they trigger (activating versus inhibitory). The noncanonical neonatal FcR belongs to the family of major histocompatibility class I proteins and regulates immunoglobulin (Ig)G half life. Mouse SIGNR1 or human DC-SIGN are C-type lectin proteins that can only bind to IgG glycoforms rich in terminal sialic acid residues and are involved in the anti-inflammatory activity of IgG.

Species Comparisons

Detailed comparisons between the canonical FcRs in mice and humans have revealed several notable differences in both structure and expression of these molecules (Figs. 24.1, 24.2, 24.3). Whereas IgG, IgM, and IgE FcRs are conserved in these species, IgA FcRs are not. To date, a murine homolog for the IgA FcR has not been identified. In general, murine

and human IgG FcRs display comparable degrees of heterogeneity and complexity.[41,64] Specific differences, however, have been noted. For example, FcγRI is encoded by a single gene in the mouse, in comparison with three genes in the human.[43] Two genes for activation FcRs, FcγRIIA and C, are found in the human and not rodents, which is notable because of their unusual single-chain activation structure.[65] Both mice and human encode a gene referred to as FcγRIIIA, although recent studies have identified a novel mouse FcR with higher homology to the human FcγRIIIA called FcγRIV.[31,64,66] As mentioned previously, FcγRIIIB is unique among FcRs in being expressed as a GPI-anchored protein (see Fig. 24.3). Its expression is limited to human neutrophils, in comparison with FcγRIIIA, which is expressed widely on cells of the myeloid lineage, such as macrophages, NK cells, mast cells, and DCs. Finally, both mice and humans have only a single gene encoding the inhibitory FcγRIIB molecule. Among the noncanonical FcRs, the lectin DC-SIGN is the functional homologue of the murine SIGN-R1 molecule with respect to its ability to bind sialylated IgG Fc and mediate an antiinflammatory response.[67,68] While the overall structure of these proteins are similar (see Fig. 24.3), their patterns of expression are quite distinct. SIGN-R1 expression is restricted to marginal zone macrophages of the spleen and lymph node, whereas DC-SIGN expression is seen on myeloid DCs and macrophages in a variety of tissues, including spleen, bone marrow, and lymph node.[69]

The genes for the IgE FcR are conserved in mice and humans. The difference that is observed relates to the requirement for the β chain to achieve surface expression

in mice, precluding the expression of the $\alpha\gamma_2$ complex.[24] In humans, this form of the receptor is widely expressed on monocytes, Langerhans cells, and DCs, and is likely to be found on mast cells and basophils as well. This difference in FcεRI subunit composition is likely to result in functional differences as well. Although these specific interspecies differences are important, the fundamental organization of the canonical FcR system, with activation and inhibitory signaling through a shared ligand specificity coupled to opposing signaling pathways, is well conserved, as is the role of the noncanonical FcRs in mediating the immunomodulatory functions of sialylated IgG. Thus, conclusions regarding the function of this expanded FcR system in immunity by the analysis of murine models are relevant to an understanding of the role of these receptors to human immunity as well.

Expression

Canonical FcRs are expressed widely on cells of the myeloid lineage, including monocytes, macrophages, DCs, mast cells, basophils, neutrophils, eosinophils, and NK cells.[17,33] In addition, B cells and follicular DCs (FDCs) express the inhibitory FcγRIIB receptor, whereas T cells are generally negative for FcγR expression, but may express the Fc-receptor for IgM. Interestingly, the majority of FCRL proteins are expressed during varying stages of B-cell development. Despite their homology to the canonical FcRs, however, the FCRL proteins seem not to bind to Igs, rendering FcγRIIB the only IgG binding FcR on B cells. The specific expression pattern for each FcR varies, and these patterns are summarized in Figure 24.1. Because canonical FcRs represent a balanced system of activation and inhibition, the general rule of coexpression of FcRs of these classes is maintained. B cells use the B-cell antigen receptor as the activation coreceptor for FcγRIIB, whereas NK cells appear to utilize NK inhibitory receptors to modulate FcγRIIIA activation. The decoy FcγR, FcγRIIIB, is expressed exclusively on human neutrophils, on which it functions to concentrate and focus ICs without directly triggering cell activation, perhaps also playing role in neutrophil recruitment.[70] The FcγRIIA-FcγRIIB pair functions on neutrophils to modulate IC activation. FcεRI can be modulated by FcγRIIB, as demonstrated both in vitro and in vivo; mice deficient in FcγRIIB display enhanced IgE-triggered anaphylaxis[71] by virtue of the ability of IgE to bind with high affinity to FcεRI and with low affinity for FcγRIIB. Other mast cell inhibitory receptors, such as glycoprotein 49B1, modulate mast cell sensitivity to IgE: mice deficient in this molecule display enhanced anaphylactic responses to IgE stimulation.[72] Expression of the common *γ* chain is broad: it has been found on all myeloid and lymphoid cells examined to date. In contrast, the *β* chain appears to be quite restricted in its expression: it has been found only on mast cells and basophils.

Regulation of canonical FcR expression can occur at several levels. In general, cytokines involved in activation of inflammatory responses induce expression of activation FcγRs, whereas inhibitory cytokines downregulate these activation receptors. Transcriptional regulation of *α* chain levels has been documented for a variety of cytokines, including interferon-*γ*, interleukin (IL)-4, and transforming growth factor *β*.[73,74] In addition, complement component C5a binding to its receptor, C5aR, results in the induction of expression of activation FcγRs.[75] Induction of FcγRI, FcγRIIA, and FcγRIIIA *α* and *γ*chains in myeloid cells occurs upon interferon-*γ*treatment: IL-4 generally inhibits expression of these activation receptors but induces expression of the inhibitory FcγRIIB. Administration of intravenous gamma globulin, a widely used treatment for inflammatory diseases, has been shown to induce expression of the inhibitory FcγRIIB on effector macrophages and B cells in mice and humans.[59,76,77,78] This induction is not direct but mediated through other, noncanonical FcR pathways including molecules such as SIGNR1 and its human orthologe DC-SIGN (see Fig. 24.7). Engagement of these receptors by sialylated IgG results in an intrinsic Th2 pathway, ultimately leading to the expression of IL-4, which induces FcRIIB expression on inflammatory macrophages.[67,68,79,80] The situation in B cells is likely to be more complex, whereby regulation of FcγRIIB is critical for the maintenance of peripheral tolerance. Germinal center B cells downregulate FcγRIIB, perhaps in response to IL-4 production by T cells. Regulation of FcR expression has also been documented to occur upon binding of ligand. IgE regulates the expression of FcεRI by stabilizing the intracellular pool of receptor

upon receptor engagement.[81] Thus, high IgE levels result in the induction of surface expression of FcεRI. However, this same mechanism of regulation is not seen for FcγRs: mice deficient in IgG have FcγR levels comparable with those of wild-type animals. Competition for limiting subunits also contributes to regulation of receptor expression. In mast cells, it appears that the level of γ chain is limiting. Competition between α chains for the limiting concentration of γ chain has been documented in mouse knockouts, whereby levels of one receptor increase if the α chain of the other receptor is reduced.[82] This type of reciprocal regulation has recently also been observed for FcγRs in neutrophils and is likely to be significant in the cross-regulation of FcRs by different isotypes of Ig.[83]

Three-Dimensional Structure

The crystal structures of FcγRIIA, FcγRIIB, FcγRIIIA, and FcεRI have been solved, as have the cocrystals of FcγRIIIA-IgG1 Fc and FcεRI-IgE Fc[84] (Fig. 24.4). These studies demonstrate that the receptors have a common structure in which the two extracellular Ig domains fold in a strongly bent overall structure, arranged into a heart-shaped domain structure. A 1:1 stoichiometry between the receptor and ligand is observed, with the receptor inserted into the cleft formed by the two chains of the Fc fragment (Cγ2 or Cε3). The binding region of the FcR to Fc fragments consists mainly of rather flexible loops that rearrange upon complex formation. Only domain 2 and the linker region connecting domains 1 and 2 interact in the complex with different regions of both chains of the Fc. Conserved tryptophans located on the FcRs interact with proline to form a "proline sandwich." A solvent-exposed hydrophobic residue at position 155 is conserved among all FcRs and represents a binding site for the important IgG1 residue Leu 235 (not

found in IgE). Specificity is generated among the receptor-ligand pairs in a variable region connecting the two extracellular domains that is in contact with the lower hinge region of the Fc fragment (residues 234 to 238), a region not conserved among the IgGs and IgE. The binding region of FcRs to their Ig ligands does not overlap with other Fc binding molecules such as protein A, protein G, and FcRn.

FIG. 24.4. Ribbon Diagram of Crystallizable Fragment (Fc) Receptor III-Immunoglobulin (IG)G1 Fc Structure. The carbohydrate moiety attached to both CH2 domains of the IgG Fc-fragment is shown as a stick and ball model. The extracellular domains of Fc receptor III are shown, together with the Fc fragment of IgG1. See text for details. Adapted from Sondermann et al.,[15] with permission.

The structure of the FcR bound to its ligand reveal that the antigen-binding fragment (Fab) arms are quite sharply bent and may adopt a perpendicular orientation toward the Fc. This arrangement would give the Fab arms maximal flexibility to bind antigen when the Fc fragment is oriented parallel to the membrane of the FcR-expressing cell. The asymmetrical interaction of the two Fc chains with a single FcR prevents a single antibody molecule from triggering dimerization of receptors and initiating signaling. Instead, dimerization is initiated by the interaction of antigen with the Fab arms, thus linking adaptive responses to effector cell triggering. Of note, the majority of the IgG-FcγR cocrystals have been generated with FcγRs produced in bacteria and therefore in an aglycosylated form. In general glycosylation at Asn

297 is critical for FcγR binding; modulation of FcγR binding by glycan modification has been observed for several classes of glycan modifications, including sialylation, fucosylation, and branching N-acetyl glucosamine.[85,86] The first IgG-FcγR cocrystal structure with differentially glycosylated IgG variants demonstrated that carbohydrate-carbohydrate interactions between IgG and FcγR are essential for high-affinity recognition of afucosylated IgG glycovariants by FcγRIIIA.[87] In contrast, low-affinity binding of FcγRIIIA to fucosylated IgG is independent of these carbohydrate interactions. These novel insights may offer new ways of optimizing IgG-FcγR interactions for enhanced therapeutic activity of IgG.

IN VITRO ACTIVITY

Binding Properties

As outlined in Figures 24.1 and 24.3, Ig binding to canonical FcRs falls into either high- or low-affinity binding classes. The high-affinity binding class is typified by FcεRI, with a binding affinity of 10^{10} M^{-1} for IgE, which ensures a monomeric interaction between IgE and its receptor. FcγRI binds with relatively high affinity for IgG1 and IgG3 (human) and IgG2a (mouse) with an affinity constant of 10^{8} M^{-1}. In contrast to these high-affinity FcRs, the low-affinity receptors, such as the human FcγRIIA, FcγRIIB, FcγRIIIA, FcγRIIIB, and FcαRI, and the mouse FcγRIIB, FcγRIII, and FcγRIV bind with affinities ranging from 5×10^{5} M^{-1} (FcγRIII) to 5×10^{7} M^{-1}. This low-affinity binding ensures that these receptors interact with ICs and not monomeric ligands. As described subsequently, this dependence on high-avidity and low-affinity interactions ensures that these receptors are activated only by physiologically relevant ICs and not by circulating monomeric Ig, thus avoiding inappropriate activation of effector responses. In general, low-affinity FcγRs bind IgG1 and IgG3 preferentially; their binding to IgG2 and IgG4 is of even lower affinity. As mentioned previously, polymorphisms in FcγRIIA and FcγRIIIA affect binding to IgG2 and IgG1, respectively, which may have significance in vivo in predicting responses to specific cytotoxic antibodies (Table 24.1). The isolated consideration of the affinity of antibody isotypes to their activating FcγRs is not sufficient, however, to explain the differences in in vivo activity. More importantly, the ratio of the affinities of an antibody isotype to the activating FcγRs compared to the inhibitory FcγRIIB (termed A/I-ratio) predicts antibody activity more consistently.[20,64] Thus, antibody isotypes with a high A/I-ratio, such as mouse IgG2a and IgG2b, will show a greater activity than counterparts with a lower ratio (see Table 24.1). The sugar moiety of the antibody Fc-portion is essential for FcR binding and the presence or absence of certain sugar residues can significantly impact on antibody-FcR binding.[20,80,88,89] The absence of fucose, for example, will selectively increase the affinity of human IgG1 or mouse IgG2b for human FcγRIIIa or mouse FcγRIV, respectively. In contrast, the presence of terminal sialic acid on the N-linked Fc glycan reduces affinities for FcRs by an order of magnitude with a concomitant reduction in in vivo activity.[80] Subunit interactions have also

been reported to influence affinity for ligand, as demonstrated for the common γchain associating with FcγRIIIA.[90] Its affinity for IgG1 is higher than the GPI-anchored form of this receptor, FcγRIIIB.

Binding constants were obtained by surface plasmon resonance analysis with immobilized antibodies (FITC-isotype switch variants) and soluble Fc receptors (FcRs) produced by transient transfection in 293T cells. Shown are the association constants (K_A in M^{-1}) of soluble FcR binding to the indicated antibody isotypes as determined by surface plasmon resonance analysis.31,174,175,176 IG, immunoglobulin; n.b., no detectable binding or binding that is too low to be evaluated; n.d., that no surface plasmon resonance or other quantitative data are available.

[a] The two numbers indicate the A/I ratios for the low and high affinity allele of FcγRIII

[b] Indicates detectable but very low binding that did not allow to determine exact binding constants by surface plasmon resonance.

The crystal structures of IgG1-FcγRIIIA and IgE-FcεRI reveal similarities in the binding properties of these two complexes. Of significance is the 1:1 stoichiometry of the complexes, which ensures that a single receptor binds to a single immunoglobulin molecule.[15,16] This property in turn ensures that activation occurs upon cross-linking of receptor complexes by multivalent ligands. Two binding sites on the receptor interact asymmetrically with two sites on the Fc molecule. The FcR inserts into the cleft formed by the two chains of the Fc molecule, burying a binding surface of 895 Å for each binding site. Alterations in the Fc structure that reduce the cleft, such as deglycosylation of IgG, inhibit FcR binding. Four distinct regions have been defined in the Fc domains involved in FcR interactions. For IgE, this includes residues 334 to 336, 362 to 365, 393 to 396, and 424. The homologous regions for IgG are residues 234 to 239, 265 to 269, 297 to 299, and 327 to 332. Interactions of these residues occur with the carboxy-terminal domain 2 of the respective FcRs. In view of the similarities of these complexes and the homologies among the receptors and their ligands, an obvious question that arises concerns the molecular basis for specificity. Attempts to resolve that question have relied on mutagenesis studies of the ligands and domain exchanges between receptors. For example, exchange of the FG loop in domain 2 of Fcε to Fcγ receptors confers detectable IgE binding; similarly, variation in this loop in FcγRs may provide interactions that determine IgG specificity for these receptors. Mutagenesis of IgG1 revealed that a common set of residues is involved in binding to all FcγRs, but FcγRII and FcγRIII also utilize distinct residues.[91] Several IgG1 residues not found at the IgG-FcR interface by crystallographic determination had a profound effect on binding, which indicates the greater complexity of these interactions in solution.

The implications of these structural studies are that the Fc domain of IgG may be selectively mutated to direct its binding to specific FcγRs. Fc mutants that selectively engage activation FcγRs (IIIA and IIA) while minimally interacting with inhibitory and decoy FcγRs (IIB and IIIB) would confer optimal cytotoxic potential for tumoricidal applications. Indications that such Fc engineering is possible are suggested by IgG mutants with selective binding to FcγRIII or FcγRII.[92,93,94]

Effector Cell Activation

The critical step in triggering effector cell response by canonical FcRs is mediated by the cross-linking of these receptors by Ig. This can occur either by interactions of low-affinity, high-avidity IgG ICs or of IgG opsonized cells with activation FcγRs or by the cross-linking of monomeric IgG or IgE bound to FcγRI or FcεR, respectively, by multivalent antigens binding to the Fab of the antibody. Crosslinking of ITAM-bearing FcRs results in common cellular responses, determined by the cell type, rather than the FcR. Thus, for example, FcεRI or FcγRIII cross-linking of mast cells results in degranulation of these cells, whereas crosslinking of macrophage expressed FcαRI or FcγRIII by opsonized cells triggers phagocytosis. These functions underlie the functional similarity of activation FcRs in which crosslinking mediates cellular responses by ITAM-mediated tyrosine kinase cascades. In addition to degranulation and phagocytosis, activation FcR cross-linking has been demonstrated to induce ADCC, the oxidative burst, and the release of cytokines and other inflammatory cell mediators. A sustained calcium influx is associated with these functions, as is transcription of genes associated with the activated state.

Cellular activation initiated by ITAM-bearing activation FcRs can be enhanced by coengagement with integrin and complement receptors. Although the ability of these receptors to mediate phagocytosis, for example, are

modest, synergistic interactions with FcRs result in sustained activation and enhancement. Synergistic interactions between activation FcRs and toll receptors, mannose receptors, and other pattern-recognition molecules have also been reported in vitro and suggest that interplay between the innate and adaptive effector mechanisms of an immune response are involved in mediating efficient protection from microbial pathogens.

In contrast to the activation of effector cell responses triggered by cross-linking of ITAM-bearing FcRs in vitro, cross-linking of an ITIM-bearing inhibitory receptor to an ITAM-bearing receptor results in the arrest of these effector responses. Homoaggregation of FcγRIIB by its crosslinking on effector cells by ICs does not result in cellular responses; rather, it is the coengagement of ITAM- and ITIM-bearing receptors that results in the functional generation of an inhibitory signal. In vitro, it is possible to ligate any ITAM-bearing receptor to any ITIM-bearing receptor with a resulting inhibitory response. This activity is used functionally to define putative ITIMs and has proved to be a useful device in dissecting the signaling

pathways induced by ITAM-ITIM coligation.

B-Lymphocyte Suppression

B-cell stimulation through the B-cell antigen receptor can be arrested by the coligation of FcγRIIB to the B-cell receptor (BCR). This occurs naturally when ICs, retained on FDCs in the germinal center, interact with both the BCR and FcγRIIB during the affinity maturation of an antibody response. In vitro suppression of B-cell activation has been demonstrated by coligation of BCR and FcγRIIB, resulting in arrest of calcium influx and proliferative responses triggered by the BCR,[25,95] the result of recruitment of the SH2-containing inositol 5′-phosphatase (SHIP)-1.[96] Calcium release from the endoplasmic reticulum is not affected, and there is thus an initial rise in intracellular calcium; however, this calcium flux is not sustained, because SHIP recruitment blocks calcium influx by uncoupling of the capacitance channel. Homoaggregation of FcγRIIB by ICs can trigger apoptosis in B cells, as demonstrated in the DT40 B-cell line and in murine splenocyte preparations.[97] This activity is retained in ITIM mutants and is dependent on the transmembrane sequence of FcγRIIB. Consistent with this, other studies showed that a SHIP-independent but BTK-, JNK1-, and cABL-dependent pathway is involved in induction of apoptosis upon FcγRIIB homoaggregation.[98] The potent inhibitory effect of FcγRIIB on B-cell activation has recently been used therapeutically to suppress autoantibody production by B cells. By engineering the Fcfragment of CD19-specific antibodies to have increased affinity to FcγRIIB, resulting in an enhanced coengagment of the inhibitory FcγRIIB with the BCR signaling complex, it was possible to suppress humoral immunity in mice and to shut down autoantibody production by B cells.[94] In contrast to mature B cells, which coexpress the BCR and FcγRIIB, plasma cells responsible for high-level antibody production downregulate BCR expression but maintain FcγRIIB expression. It was suggested that crossliniking of FcγRIIB by ICs on bone marrow plasma cells might be involved in inducing apoptosis in a fraction of plasma cells thereby creating niches for newly generated plasma cells during exposure to a new antigenic stimulus.[99]

SIGNALING

Immunoreceptor Tyrosine-Based Activation Motif Pathways

The general features of signal transduction through ITAM receptors are conserved among all members of this family, including T-cell receptors, BCRs, and various FcRs. The 19 amino acid-conserved ITAM is necessary and sufficient to generate an activation response, as demonstrated by the analysis of chimeric receptors. With a single exception, FcRs associate with accessory subunits that contain these signaling motifs. As described previously, the common *γ*chain contains an ITAM and is associated with FcεRI, FcγRI, FcγRIII, FcγRIV, and FcαRI. In addition, both FcεRI and FcγRIII may associate with the *β* subunit in mast cells. The ITAM found in the *β* chain does not function as an autonomous activation cassette, as has been found for most other ITAMs. Rather, it functions to amplify the activation response generated by the *γ* chain ITAM by increasing the local concentration of Lyn available for activation upon aggregation of the receptor.[40] FcγRIIA contains an ITAM in the cytoplasmic domain of its ligand recognition *α* subunit and is thus able to activate in the absence of any associated subunit.

Upon sustained receptor aggregation, Src family kinases that may be associated with the receptor in an inactive form become activated and rapidly tyrosine-phosphorylate the ITAM sequences, creating SH2 sites for the docking and subsequent activation of Syk kinases. Ligands that rapidly dissociate from their receptors result in nonproductive signaling complexes that fail to couple to downstream events and behave as antagonists.[100] The specific Src kinase involved for each FcR depends on the receptor and cell type in which it is studied. Thus, Lyn is associated with the FcεRI pathway in mast cells, Lck is associated with FcγRIIIA in NK cells, and both of these kinases as well as Hck are associated with FcγRI and FcγRIIA in macrophages. After activation of the Src kinase, tyrosine phosphorylation of the ITAM motif rapidly ensues, leading to the recruitment and activation of Syk kinases. This two-step process is absolutely necessary to transduce the aggregation signal to a sustainable intracellular response. Once activated, Syk kinases lead to the phosphorylation or recruitment of a variety of intracellular substrates, including PI3K, Btk and other Tec family kinases, phospholipase C-*γ*(PLC*γ*), and adaptor proteins such as SLP-76 and BLNK. The Ras pathway is also activated through Sos bound to Grb2 that is recruited upon phosphorylation of Shc. Ras phosphorylates Raf, which in turn leads to MEK kinase and MAP kinase activation. A summary of these intracellular pathways is shown in Figure 24.5A. A crucial step in this sequential activation cascade occurs with the activation of PI3K by Syk. By generating phosphatidyl inositol polyphosphates, such as PIP_3, PI3K leads to the recruitment of pleckstrin homology (PH) domain-expressing proteins such as Btk and PLC*γ*, which in turn leads to the

generation of inositol triphosphate and diacylglycerol, intermediates crucial to the mobilization of intracellular calcium and activation of protein kinase C, respectively.

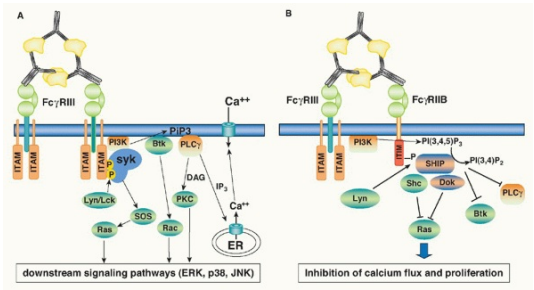

FIG. 24.5. Signaling by Activation and Inhibitory Fc Receptors (FcRs). A: FcγRIII signaling in natural killer cells is shown as an example of the activation class of FcRs. Cross-linking by an immune complex initiates the signaling cascade. The specific Src family kinase varies, depending on the cell type. **B:** FcR signaling in macrophages is shown as an example of simultaneous triggering of activation and inhibitory FcRs.

Immunoreceptor Tyrosine-Based Inhibitory Motif Pathways

The inhibitory motif, embedded in the cytoplasmic domain of the single-chain FcγRIIB molecule, was defined as a 13 amino acid sequence AENTITYSLLKHP, shown to be both necessary and sufficient to mediate the inhibition of BCR-generated calcium mobilization and cellular proliferation.[25,26] Significantly, phosphorylation of the tyrosine of this motif was shown to occur upon BCR coligation and was required for its inhibitory activity. This modification generated an SH2 recognition domain that is the binding site for the inhibitory signaling molecule SHIP.[96,101] In addition to its expression on B cells, where it is the only IgG FcR, FcγRIIB is widely expressed on macrophages, neutrophils, mast cells, DCs, and FDCs, absent only from T and NK cells. Studies on FcγRIIB provided the impetus to identify similar sequences in other surface molecules that mediated cellular inhibition and resulted in the description of the ITIM, a general feature of inhibitory receptors.

FcγRIIB displays multiple inhibitory activities. Coengagement of FcγRIIB to an ITAM-containing receptor leads to tyrosine phosphorylation of the ITIM by the Lyn kinase, recruitment of SHIP, and the inhibition of ITAM-triggered calcium mobilization and cellular proliferation (see Fig. 24.5B).[96,102,103] These two activities result from different signaling pathways; calcium inhibition requires the phosphatase activity of SHIP to hydrolyze PIP_3 and the ensuing dissociation of PH domain-containing proteins such as Btk and PLCγ.[104] The net effect is to block calcium influx and prevent sustained calcium signaling. Calciumdependent processes such as degranulation, phagocytosis, ADCC, cytokine release, and proinflammatory activation are all blocked. Arrest of proliferation in B cells is also dependent on the ITIM pathway, through the activation of the adaptor protein Dok and subsequent inactivation of MAP kinases.[105,106] The role of SHIP in this process has not been fully defined, inasmuch as it can affect proliferation in several ways. SHIP, through its catalytic phosphatase domain, can prevent activation of the PH domain survival factor Akt by hydrolysis of PIP_3.[107,108] SHIP also contains phosphotyrosine-binding domains that could act to recruit Dok to the membrane and provide access to the Lyn kinase that is involved in its activation. Dok-deficient B cells are unable to mediate FcγRIIB-triggered arrest of BCR-induced proliferation, while retaining their ability to inhibit a calcium influx, which demonstrates the dissociation of these two ITIM-dependent pathways.

Another inhibitory activity displayed by FcγRIIB is independent of the ITIM sequence and is displayed upon homoaggregation of the receptor. Under these conditions of FcγRIIB clustering, a proapoptotic signal is generated through the transmembrane sequence. This proapoptotic signal is blocked by recruitment of SHIP, which occurs upon coligation of FcγRIIB to the BCR, because of the Btk requirement for this apoptotic pathway.[97] This novel activity

has been reported only in B cells and has been proposed to act as a means of maintaining peripheral tolerance for B cells that have undergone somatic hypermutation. The in vivo relevance of this pathway remains to be proven.

IN VIVO FUNCTIONS

FcγReceptors in the Afferent Response

The ability of IgG ICs to influence the afferent response has been known since the 1950s and can be either enhancing or suppressive, depending on the precise combination of antibody and antigen and the mode of administration.[109] Investigators have attempted to define the molecular mechanisms behind these activities with the availability of defined mouse strains with mutations in activation or inhibitory FcRs and through the use of specific blocking antibodies to individual receptors. Direct effects on B cells stem from the ability of the inhibitory FcγRIIB molecule to influence the state of B-cell activation and survival. Because antigen is retained in the form of ICs on FDCs, it can interact with B cells by coengaging FcγRIIB with BCR, modulating the activation state of the cell. Mice deficient in this inhibitory receptor develop anti-deoxyribonucleic acid (DNA) and antichromatin antibodies and die of a fatal, autoimmune glomerulonephritis at 8 months of age. The phenotype is strain dependent and is not seen in BALB/c or 129 strains of mice.[110] Combining FcγRIIB deficiency with

defects in other inhibitory receptor pathways, such as PD-1, results in autoantibodies with different specifities and distinct pathological presentation. Thus, PD-1-deficient Balb/c mice develop cardiomyopathy resulting from anticardiac myosin antibodies. PD-1/FcγRIIB double deficient BALB/c mice develop antiuroepithelial antibodies and hydronephrosis.[111] FcγRIIB thus acts as a modifier of autoimmune disease, a conclusion further supported by studies that determined the contribution of the C57BL/6 background to the spontaneous lupus-like disease observed in those mice. The B6 background, by virtue of an incomplete light chain editing pathway, provides a source of autoreactive B cells in the periphery, which, when combined with defects in the inhibitory FcγRIIB pathway, leads to the accumulation of autoantibodies, pathogenic ICs, and disease.[112] Further support for this conclusion is provided by the observations that autoimmune disease-prone strains of mice, such as New Zealand black (NZB), BXSB, SB/Le, MRL, and nonobese diabetic, have reduced surface expression of FcγRIIB on activated B cells, attributed to DNA polymorphisms in the promoter region of the gene encoding this receptor.[113,114] This reduced expression of FcγRIIB is thus suggested to contribute to the increased susceptibility of these animals to the development of autoantibodies and autoimmune disease. Direct evidence that this is indeed the case comes from studies where FcγRIIB expression levels have been restored by retrovirus-mediated gene transfer in BXSB, NZM, and FcγRIIB knockout animals. These mice had dramatically reduced levels of autoreactive antibodies and were protected from the development of fatal autoimmune disease.[60] Consistent with these results obtained in mouse model systems, human patients with SLE and CIDP were demonstrated to have a reduced FcγRIIB expression level on B cells.[58,59]

Moreover, if FcγRIIB indeed functions in vivo to maintain peripheral tolerance, then its loss should allow for the emergence of autoantibodies when otherwise resistant animals are challenged with potentially crossreactive antigens. This hypothesis has been validated in models of collagen-induced arthritis and Goodpasture syndrome. FcγRIIB-deficient mice, with the nonpermissive H-2^b haplotype, develop arthritis when immunized with bovine type II collagen.[115] The loss of FcγRIIB thus bypasses the requirement for the specific H-2^q and H-2^r alleles previously demonstrated to be necessary in this model by allowing FcγRIIB-deficient autoreactive B-cell clones to expand and produce pathogenic autoantibodies. When the permissive DBA/1 strain (H-2^q) is made deficient in FcγRIIB, autoantibody development is augmented and disease is greatly enhanced. In a similar manner, immunization of H-2^b mice deficient in FcγRIIB with bovine type IV collagen results in crossreactive autoantibodies to murine type IV collagen, with dramatic pathogenic effects.[115,116] These mice develop hemorrhagic lung disease and glomerulonephritis with a “ribbon deposition” pattern of ICs in the glomeruli. These characteristics are indicative of Goodpasture syndrome, a human disease not previously modeled in an animal species.

Expression of the inhibitory FcγRIIB on B cells thus provides a mechanism for the suppressive effects of ICs on antibody production. Although FcγRIIB is expressed throughout peripheral B-cell development, recent data suggest that it represents a late checkpoint controlling the expansion of autoreactive IgG-positive plasma cells. In contrast, deficiency of the inhibitory receptor did not impact the generation of autoreactive IgM antibodies.[112] Taking the considerably higher pathogenic potential of IgG compared to IgM antibodies into account, this late stage of FcγRIIB-mediated regulation seems to be sufficient to prevent severe autoreactive processes.

The enhancing property of ICs on the afferent response is likely to arise from the expression of FcRs on APCs, such as DCs.[117,118,119] DCs express all three classes of IgG FcRs as well as FcεRI. Although in vitro studies have suggested that triggering of activation FcRs can induce DC maturation, the in vivo significance of this pathway has not been established.[120] The ability of FcRs, particularly FcγRI, to internalize ICs could provide a mechanism for enhanced presentation and augmented antibody responses, whereas the presence of the inhibitory FcγRIIB molecule appears to reduce the enhancing effect. Mice deficient in FcγRIIB display enhanced antibody responses to soluble antibody-antigen complexes, in some cases dramatically so, which is likely to result from enhanced presentation.[121,122] In addition, in vitro studies suggest that internalization through specific FcRs on APCs may influence the epitopes presented and T-cell response generated as a result. At present, a growing body of data suggests that FcRs are indeed involved in enhancement of the afferent response, by influencing antigen presentation and cognate T-cell interactions. FcγRIIB-deficient DCs pulsed ex vivo with antigen in the form of ICs induce a strong and protective cytotoxic immune response after transfer into naïve mice.[123] In contrast, wild-type DCs induce a much smaller and nonprotective response, indicating that the threshold set by co-crosslinking of the inhibitory and activating FcRs

prevents complete DC maturation. Moreover, blocking of IC binding to FcγRIIB on human DCs with an FcγRIIB-specific antibody resulted in spontaneous maturation of the cells by ICs present in low amounts in human serum.[124,125] Taken together, these data indicate that the inhibitory receptor is an important regulator of DC activation. As the DC maturation state will determine whether an activating or a tolerogenic signal will be delivered to T cells, FcRs might be important factors for the maintenance of peripheral tolerance in the cellular immune system. Transiently blocking FcγRIIB activity with monoclonal antibodies in vivo might thus be an interesting strategy to optimize immunotherapeutic and vaccination approaches. Further defining the precise role of each FcR expressed on APCs will require conditional knockouts of these molecules on specific DC populations to resolve the contribution of these systems to the generation of an appropriate antibody response.

FcγReceptors in the Efferent Response

The first canonical FcR knockout to be described was for the common activation subunit, the γchain, which resulted in the loss of surface assembly and signaling of FcγRI, FcγRIII and FcγRIV as well as FcεRI (10). Mice deficient in the common γ chain were systematically studied in diverse models of inflammation and found to be unable to mediate IgG-triggered inflammatory responses for cytotoxic or IC reaction; attributed to low-affinity activation receptors, the high-affinity FcγRI played a minimal role in the in vivo inflammatory response triggered by IgG.[22,126,127,128] The results were further confirmed by comparisons of mice deficient or blocked for either FcγRI, FcγRIII, or FcγRIV.[19,20,32,129] The loss of FcεRI ablated IgE-mediated anaphylaxis; this was demonstrated independently by gene disruption in the α subunit of that receptor.[11] Subsequent studies on mice deficient in the inhibitory FcγRIIB molecule established the opposing action of this receptor, in which mice deficient in that receptor displayed enhanced B-cell responses, autoimmunity, and augmented IgG-mediated inflammation in a subclass and effector cell-dependent manner.[18,20,32,55,128] The general finding, which is discussed in detail subsequently, illustrates that IgGs initiate their effector responses in vivo through coengagement of activating and inhibitory FcRs. The physiological response is thus the net of the opposing activation and inhibitory signaling pathways that each receptor triggers and is determined by the level of expression of each receptor and the selective avidity of the IgG ligand (see Table 24.1). This also explains the longstanding observation that different IgG isotypes have a differential activity in vivo (Fig. 24.6A). The absence of a murine homolog for FcαRI has precluded similar studies for that receptor. Studies on mice bearing a human transgene of FcαRI suggest that this receptor is involved in IgA nephropathy (Berger disease).[130]

Type I: Immediate Hypersensitivity

Both cutaneous and systemic models of passive anaphylaxis, induced by IgE, were studied in FcRγchain-deficient mice and were found to be absent, a finding fully consistent with the observations obtained in FcεRI-deficient mice and confirming the role of the high-affinity IgE receptor in mediating IgE-induced anaphylactic responses.[10,11,40,131] FcγRIIB-deficient mice, challenged in this model, displayed an unexpected enhancement of IgE-mediated anaphylaxis, which suggests a physiological interaction between this inhibitory receptor and FcεRI.[71] The molecular basis for this modulation of FcεRI signaling by FcγRIIB has not been

determined, although previous studies have indicated that IgE can bind with low affinity to FcγRII/FcγIII, which suggests that there exists a mechanism for coengagement of these receptors. Deletion of the mast cell inhibitory receptor glycoprotein 49B1 also results in enhanced IgE-induced anaphylaxis.[72] In addition to FcεRI, mast cells also express the IgG FcγRIIB and FcγRIII, but not FcγRIV. Passive systemic anaphylaxis induced by IgG was attenuated in FcRγ chain-deficient and FcγRIII-deficient mice, which indicates the capacity of IgG and FcγRIII to mediate mast cell activation in vivo. FcγRIIB-deficient mice displayed enhanced IgG-induced anaphylaxis. Active anaphylaxis, induced by immunization with antigen in alum, was enhanced in FcεRI-, FcγRIIB-, and glycoprotein 49B1-deficient mice and attenuated in FcRγ- and FcγRIII-deficient mice. All these animals displayed antigen-specific antibodies for IgE and IgGs, which indicates that the active anaphylaxis seen was attributed primarily to IgG antibodies. The reason for the enhancement of anaphylactic responses in FcεRI-deficient animals resulted from the increased expression of FcγRIII on mast cells in these mice, normally limited by competition of α chains for the available pool of the common γchain.[82] In the absence of FcεRI α chain, FcRγ chain is available to associate with FcγRIII α chain and assemble on the cell surface as a functional signaling receptor. A similar type of regulation was also described for expression of FcγRIII and FcγRIV on mouse neutrophils, where deletion of one receptor resulted in enhanced expression of the other γ-chain-dependent molecule.[83] These studies indicated the importance of the γchain in regulating the level of surface expression of FcεRI and FcγRIII. Because γ chain is also associated with other members of the activation/inhibition paired receptors expressed on mast cells, such as PIR-A/PIR-B, the intracellular competition between these diverse α subunits and the common γ chain determines the level of surface expression of individual receptors and thus their ability to respond to specific biological stimuli. The absolute level of surface expression of FcRs on mast cells is clearly of therapeutic significance in both IgE- and IgG-mediated inflammatory responses; modulation of γ chain expression could thus represent a new therapeutic avenue for intervention in diseases such as anaphylaxis and asthma.

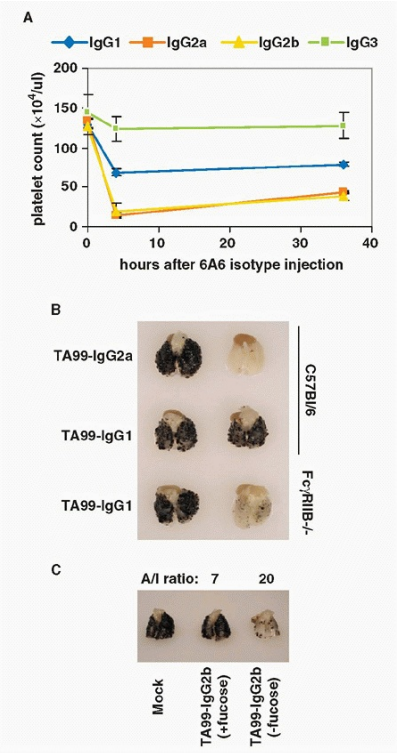

FIG. 24.6. Antibody Activity is Determined by Activating and Inhibitory Fc Receptors (FcRs). A: Mice were injected with the same amount of different 6A6 antibody isotypes, which recognize an integrin on mouse platelets and lead to FcR-dependent clearance of platelets from the blood as observed by the drop in platelet count after antibody injection. **B:** Wild-type or FcγRIIB knockout mice were injected intravenously with B16 melanoma cells on day 0 and with IgG1 and IgG2a isotype switch variants of the monoclonal antibody TA99 on alternate days. **C:** Mice were injected with antitumor antibodies containing or lacking branching fucose residues, thereby enhancing binding to activating FcRs and changing the A/I ratio (see text for details). Lungs were harvested on day 14. Adapted from Nimmerjahn and Ravetch,[20] with permission.

Type II Inflammation: Cytotoxic Immunoglobulin G

Cytotoxic IgGs are found in a variety of autoimmune disorders and have been developed for therapeutic indications in the treatment of infectious and neoplastic diseases. The mechanisms by which these antibodies trigger cytotoxicity in vivo have been investigated in FcR knockout mice. Anti-RBC antibodies trigger erythrophagocytosis of IgG-opsonized RBCs in an FcR-dependent manner; γ chain-deficient mice were protected from the pathogenic effect of these antibodies, whereas complement C3-deficient mice were indistinguishable from wild-type animals in their ability to clear the targeted RBCs.[132,133] FcγRIII plays the exclusive role in this process for the mouse IgG1 isotype. Murine IgG2a anti-RBC antibodies utilize primarily the FcγRIV receptor pathway despite the singular ability of murine IgG2a antibodies to bind as monomers to FcγRI. These and other studies suggest that the role of the high-affinity FcγRI in IgG-mediated inflammation is likely to be restricted to augmenting the effector response (determined by FcγRIII and IV) in situations that involve high concentrations of murine IgG2a antibodies which are found at localized inflammatory sites where FcγRI expression is induced on recruited macrophages.

Experimental models of immune thrombocytopenic purpura (ITP) in which murine IgG1 antiplatelet antibodies trigger thrombocytopenia and yielded results similar to those of the anti-RBC studies cited previously. The specific FcγR involved depended on the subclass of antibody used. IgG1 antibodies mediated their activity exclusively through FcγRIII, while IgG2a and 2b were FcγRIV dependent. In contrast, FcγRI- or C3-deficient mice were fully susceptible to antibody-induced thrombocytopenia.[20,31] FcγRIIB-deficient mice showed an isotype-specific enhancement of antibody-mediated platelet depletion, with the strongest impact on IgG1 and much smaller increases for IgG2a and IgG2b isotypes. This is consistent with the affinities of these isotypes for their specific activating and the inhibitory receptor, which will determine antibody activity in vivo (see Table 24.1). In a passive protection model of *Cryptococcus neoformans*-induced disease, passive immunization with mouse IgG1, IgG2a, and IgG2b antibodies resulted in protection in wild-type animals but not in FcRγchain-deficient animals.[134]

IgG antibodies raised to murine glomerular basement membrane preparations induce acute glomerulonephritis in a model of Goodpasture disease in wild-type but not FcRγ- or FcγRIV-deficient animals.[77,135,136] FcγRIIB-deficient animals displayed enhanced disease in this model, which indicates that the effector cells involved were constitutively expressing significant levels of FcγRIIB. Similar results were obtained when DBA/1 animals were

immunized with bovine type II collagen to induce arthritis. Deficiency of FcRγ chain protected these mice from the pathogenic effects of the anticollagen antibodies that were generated.[137] As mentioned previously, deficiency of FcγRIIB in the DBA/1 collagen-induced arthritis model resulted in enhanced disease, through increased autoantibody production and elevated effector responses.

A dramatic example of the importance of these pathways in determining the in vivo activity of cytotoxic antibodies was obtained in models of antitumor antibody response. In a syngenic murine model of metastatic melanoma, a murine IgG2a antimelanocyte antibody was able to reduce tumor metastasis in wild-type animals but was ineffective in FcRγ- or FcγRIV-deficient mice.[20,83,138] In the absence of FcγRIIB, the activity of an IgG1 antibody, matched in its antigen binding domain, was enhanced, which indicates that the in vivo cytotoxic activity of the antibody was the net of activation and inhibitory receptor engagement[20,55] (see Fig. 24.6B). These studies, together with similar studies performed with antiplatelet antibodies or defucosylated antibodies, demonstrated that the in vivo activity of a cytotoxic antibody could be predicted by a simple equilibrium binding model in which the ratio of the monomeric affinity constants for

the activation and inhibitory Fc receptors (A/I ratio) are the dominant parameters, as demonstrated for T-cell receptor-major histocompability complex interactions.[139] An example for the enhanced cytotoxic activity of an antitumor antibody due to increased affinity for activating FcRs is shown in Figure 24.6C. The generation of an afucosylated antitumor antibody resulted in an increase of the A/I ratio of 7 to 20 for this IgG subclass, resulting in enhanced antitumor activity in vivo. Xenograft models of human tumors transplated into nude mice demonstrated, for a variety of tumors and cytotoxic antibodies, the requirement for FcR effector activity. For example, human breast carcinoma or lymphoma lines transplanted into nude mice and treated with either the humanized IgG1 or chimerized IgG1 antibodies (trastuzumab and rituximab), respectively, revealed that the ability of these antibodies to modulate tumor growth was abrogated in FcRγ chain-deficient mice. A point mutation that eliminated FcR binding of the anti-Her2/neu murine IgG1 antibody 4D5 abolished the in vivo cytotoxic activity of the antibody against a human xenograft but did not affect the in vitro growth inhibitory activity; this again illustrates the difference between in vivo and in vitro mechanisms. Similar results were obtained for T-cell lymphoma xenograft models and anti-CD2 antibodies, among others.[140,141] The general conclusions that can be drawn from these studies support a dominant role for the low-affinity activating FcγRs in mediating cytotoxicity by IgG antibodies. FcγRIIB restricts the effector response for those antibodies with low A/I ratios and in situations in which the effector cell expresses this inhibitory molecule.

The relevance of these murine in vivo studies to the treatment of human populations with antitumor cytotoxic antibodies has been demonstrated in two studies that investigated the differential responses of patients treated with anti-CD20 (rituximab) for lymphoma.[48,52] Both studies demonstrated a highly significant correlation between patient response, as measured by the time to relapse, and alleles of FcγRIIIA. In patients with an allele of this low-affinity activation receptor (158V) that confers higher binding affinity for human IgG1 Fc, improved outcome was observed, as compared to those with a lower binding allele of this receptor (158F). In addition, lymphoma patients with the high affinity allele showed a significantly better clinical response after receiving antiidiotype vaccination.[51]

Type III Responses: Immune Complex-Mediated Inflammation

The classic example of this reaction, the Arthus reaction, has been studied in a variety of FcR- and complement-deficient animals. The initial studies were performed by using the cutaneous reverse passive Arthus reaction, in which antibody was injected intradermally and antigen was given intravenously. An inflammatory response, characterized by edema, hemorrhage, and neutrophil infiltration, developed within 2 hours. This reaction was elicited in a variety of complement- and FcR-deficient animals. The results from several independent studies confirmed the initial observations: that IgG ICs triggered cutaneous inflammatory reactions even in the absence of complement but displayed an absolute requirement for FcγR activation.[22] FcγRIIB modulated the magnitude of the response, with enhanced Arthus reactions observed in FcγRIIB-deficient strains.[18] The effector cell in the cutaneous reaction was determined to be the mast cell, as demonstrated by the use of mast cell-deficient strains and by mast cell reconstitution studies.[131] The generality of this result was demonstrated in similar reactions performed in the lung, illustrating the FcR dependence and relative complement independence of this response.[116] Thus, all studies have demonstrated an absolute dependence on FcR expression in the Arthus reaction. One model for IC-induced arthritis, the KRN/nonobese diabetic model, in which IgG1 anti-GPI antibodies are responsible for IC deposition in the synovium,[142] has been shown to depend on both FcγRIII and C3 but not on components of the classical complement pathway, such as C1q and C4; transfer of serum to animals deleted for FcγRIII or C3 prevented the development of disease.[143,144] Deficiency in the late components of complement, such as C5a or its receptor, have also been reported to result in a partial reduction in the magnitude of the response in IC-induced lung inflammation[145] and to result in a complete block in the KRN/nonobese diabetic arthritis model. The likely mechanism by which C5a exerts its effects is through upregulation of activating FcγRs, resulting in an amplification loop.[75] C5a is generated in this system as a result of FcR activation of effector cells and is independent of the classical, alternative, and mannan-binding protein pathways. Binding of C5a to the C5aR results in upregulation of activation receptors on these effector macrophages, thus augmenting the inflammatory response triggered by FcRs. These studies have led to a

revision of the hypotheses about the mechanism of IC-mediated inflammation, typified by the Arthus reaction, in which there is an absolute requirement for activating FcγRs in initiating mast cell activation by ICs. FcγR activation is, in turn, modulated by the inhibitory receptor FcγRIIB. The A/I value of a specific IgG antibody and the densities of these opposing signaling receptors determines the concentration threshold for IC activation and the magnitude of the effector response that can be obtained. The classical pathway of complement activation is not required; however, C5a activation, through the FcγR pathway, may enhance the response under some circumstances through an amplifying loop. The release of inflammatory mediators such as vasoactive amines, chemokines, and cytokines leads to the hallmarks of this reaction: edema, hemorrhage, and neutrophil infiltration at the site of IC deposition.

The significance of the FcR pathway in initiating IC inflammation in autoimmune disease was further established by investigating a spontaneous murine model of lupus, the B/W F1 mouse. The Arthus reaction results predicted the absolute requirement of activation FcγR in initiating inflammation and tissue damage in IC diseases such as lupus. The FcRγchain deletion was backcrossed onto the NZB and New Zealand white strains for eight generations, and the intercrossed progeny were segregated into B/W FcRγ-/- and FcRγ+/-. Anti-DNA antibodies and circulating ICs developed in all animals; IC and complement C3 deposition was similarly observed in all animals. However, mice deficient in the common γchain showed no evidence of glomerulonephritis

and had normal life expectancy, despite comparable levels of circulating ICs and glomerular deposition of these complexes along with complement C3. Mice heterozygous for the γchain mutation were indistinguishable from B/W F1 animals with wild-type γchains in developing glomerulonephritis and displaying reduced viability.[127] This spontaneous model supports the conclusions stated previously about the absolute requirement for FcγRIII in the activation of inflammatory disease by ICs: in the absence of this receptor, deposited ICs and C3 are not sufficient to trigger effector cell activation, which indicates that it is possible to uncouple pathogenic ICs from inflammatory disease by removing activating FcR engagement. Similar conclusions were reached in a murine model of Goodpasture disease where IC deposition, composed of mouse IgG2b antibodies, resulted in a fulminant glomerulonephritis.[77] Blocking the relevant activation FcR, FcγRIV, with a monoclonal antibody, protected the animals from fatal disease. These results further indicate that intervention in the effector stage of IC diseases, such as lupus and rheumatoid arthritis, would be accomplished by blocking activation FcγRs to prevent initiation of effector cell responses.

Immunoglobulin G-Dependent Neutralization and Induction of Agonistic Signaling

In contrast to these FcR-dependent activities, IgG molecules, by virtue of their exquisite specifity for discrete antigens, are expected to mediate FcγR-independent effects, such as neutralization of bacterial toxins or viruses. Here, IgG molecules would prevent the toxin or microorganism from binding to its cellular receptor, thereby protecting the host from the pathogenic effects of the infecting microbe. This picture changed, however, as it was demonstrated that both IgG-mediated toxin and virus neutralization can be dependent on cellular FcRs in vivo. Thus, neutralization of the anthrax toxin (called protective antigen component) by anti-protective antigen antibodies required FcR expression in vivo and anti-protective antigen antibodies that differed only by their Fc subclasses showed a hierarchy of protection with IgG2a and IgG2b antibodies affording a better protection than IgG1 antibodies, consistent with previous observation for cytotoxic IgG.[146,147] Similar results were obtained for the mechanism of activity of neutralizing antibodies protecting from influenza or human immunodeficiency virus infection.[148,149] These results suggest that current in vitro assays using only the pathogen-specific antibody, a target cell line might miss an important component required for antibody activity in vivo, and that novel assays including the FcR-dependent component might provide a better predictability of IgG activity.[150]

Beyond the central function of IgG in host defense, agonistic antibodies triggering signaling pathways in target cells are being evaluated for their therapeutic potential. For example, agonistic antibodies for tumor necrosis factor receptor family members such as anti-CD40 or anti-DR5 (drozitumab) are under evaluation for their ability to enhance tumor cell clearance by both direct and indirect mechanisms. Interestingly, the apoptosis inducing activity of anti-DR5 agonistic antibodies was found to be dependent on FcRs in vivo.[151] A similar dependence on FcRs for in vivo activity was demonstrated for agonistic anti-Fas antibodies.[152] A variety of CD40-specific agonistic antibodies have been used to deliver costimulatory signals to augment and sustain T-cell responses to result in tumor clearance.[151] Recent studies showed that the inhibitory FcγRIIB was essential for this agonistic activity and could not be replaced by activation FcγRs.[153,154] Although the exact mechanism of these FcR-dependent pathways remain to be established, these findings open the path toward generating improved agonistic anti-tumor necrosis factor receptor antibodies by Fc engineering. Consistent with this notion, a recent study showed that generating anti-CD40 antibodies with enhanced FcγRIIB binding considerably augmented their in vivo adjuvant activity.[154]

DISEASE ASSOCIATIONS

Autoimmunity and Tolerance

In view of their functional capacity to link autoantibodies to effector cells, FcRs have naturally been considered to have a pathogenic role in the development of autoimmune diseases. Several studies have attempted to correlate specific polymorphisms in FcγRIIA, FcγRIIIA, or

FcγRIIIB with incidence or severity of lupus or rheumatoid arthritis.[155] In view of the heterogeneity of these diseases, it is perhaps not surprising that inconsistent results have been obtained. Alleles that increase the ability of FcγRIIA to bind IgG2 or FcγRIIIA to bind IgG1 might be expected to correlate with disease severity in some populations. Indeed, these types of associations have been reported in some studies but not in others.[156] These variable results have often been explained as an indication that other genes may be in linkage disequilibrium with the FcR alleles under investigation. This is a plausible explanation when viewed in light of the autoimmunity susceptibility genes mapping in or near the region of the FcR genes, chromosome 1q21-24.[157] This region of chromosome 1 has been implicated in a variety of human and murine linkage studies. For example, the Sle1 alleles derived from NZB flank the FcγRIIB gene and form a linkage group with the ability to break tolerance to nuclear antigens, resulting in production of antichromatin antibodies. Epistatic interactions between FcγRIIB and lupus susceptibility genes have been demonstrated in the murine lupus model of B6.RIIB. Crossing the *yaa* gene to this strain accelerates the development of disease; 50% survival is decreased from 8 months to 4 months, with 100% fatality by 8 months. This increase in severity correlates with a change in the specificity of the autoantibodies, from diffuse antinuclear antibodies to antibodies that stain with a punctate, nucleolar pattern on antinuclear antibody staining. Recently, it has been shown that the yaa susceptibility locus contains a duplication of the toll-like receptor 7 gene in the pseudoautosomal region of the y-chromosome ([158]). Moreover, toll-like receptor 7 and toll-like receptor 9 with their ability to recognize potential self-antigens such as ribonucleic acid or DNA, respectively, were shown to be important components in the generation of pathogenic autoreactive antibodies.[159,160] Compared to other Yaa-independent SLE susceptibility loci, FcγRIIB may be a dominant factor for the development of autoantibodies

and the systemic activation of the immune system as demonstrated by a study using NZB/BXSB F1 animals congenic for the wild-type *fcgr2b* gene. In these mice, a dramatic reduction in the production of autoantibodies and immune cell activation was noted compared to mice with impaired FcγRIIB expression.[161] These data are consistent with studies that overexpressed FcγRIIB in autoimmune-prone mouse strains resulting in suppression of autoantibody production.[60,61]

Two types of polymorphisms in the FcγRIIB gene have been associated with SLE. Promoter polymorphisms have been described resulting in reduced expression of FcγRIIB on activated B cells in both mouse and human SLE and CIDP populations.[59,113,162] In addition, a polymorphism in the transmembrane domain of FcγRIIB has been identified that is associated with susceptibility to SLE in Japanese populations. This polymorphism results in an FcγRIIB protein with reduced ability to enter lipid rafts and thus behaves as a hypomorphic allele for inhibitory function.[163]

Together, these studies point to FcγRIIB as a susceptibility factor in the development of autoimmunity with the ability to interact with other susceptibility factors to modify both the afferent and efferent limbs of the autoimmune response.

Inflammation

Antibody-mediated inflammatory diseases have been clearly demonstrated to involve the coupling of pathogenic autoantibodies or ICs to cellular FcRs. Therapeutics targeted to disrupt these interactions are in development, beginning with a monoclonal antibody to human IgE that functions to reduce IgE binding to its high-affinity receptor and thereby prevent allergic and anaphylactic reactions.[164] Because IgE is required for the survival of mast cells as well as in the regulation of FcεRI expression, reduction in IgE has synergistic effects on the ligand, receptor, and effector cell. The success of this approach will undoubtedly lead to other approaches that target the receptor or its signaling pathway. Blocking FcγRIIIA or IIA is expected to mimic the phenotype of FcRgamma-deficient animals in models of IgG-induced disease. Early attempts to use this approach in ITP were promising but limited by the crossreactivity to receptors on neutrophils, which led to neutropenia and the development of immune response to the murine antibody.[165] Development of second-generation anti-FcγRIIIA antibodies with greater specificity and reduced toxicity now appears to be a viable approach for the treatment of autoimmune diseases. Moreover, using small molecules to inhibit signaling molecules such as Syk seems to have promising effects in preventing autoantibody dependent platelet depletion in mice and humans.[166]

An alternative approach to limiting the activation of FcRs is to utilize the endogenous inhibitory pathway to abrogate IgE or IgG activation of their cognate receptors through coligation to FcγRIIB. This mechanism has been proposed to explain the ability to induce desensitization for the treatment of allergic diseases.[33,167] Inducing production of IgG antibodies to an allergen may facilitate cross-linking of FcγRIIB to FcεRI. A similar approach involving anti-CD19 antibodies containing an engineered Fc-fragment with enhanced binding to FcγRIIB has been successfully used to shut down autoantibody production by human B cells in a xenograft mouse model system.[168] The ability to exploit the inhibitory pathway to reduce the activity of activation FcγRs has been demonstrated to account for some of the anti-inflammatory activity associated with high-dose intravenous gamma globulin (IVIG), which consists of the pooled IgG fraction of serum from thousands of donors.[76] The use of IVIG for the treatment of ITP and other autoimmune diseases is well established, although the mechanism of action has been elusive. In murine models of ITP, arthritis, and nephritis, it has been demonstrated that protection by IVIG is dependent on the presence of FcγRIIB; deletion of FcγRIIB or blocking FcγRIIB by a monoclonal antibody eliminates the ability of IVIG to protect the animal against an inflammatory response.[76,78,80] IVIG was demonstrated to lead

to the in vivo induction of FcγRIIB on splenic effector macrophages, which would raise the threshold required for platelet clearance by activating FcγRs on these cells.[20,31,78,83] A similar upregulation of the human inhibitory FcγRIIB was demonstrated in patients with CIDP receiving IVIG treatment as a first-line therapy.[59] Recently, it has become clear that the sialic acid-rich fraction of IgG antibodies in the IVIG preparation is responsible for the anti-inflammatory activity and FcγRIIB upregulation, enabling for the first time the generation of a recombinant IVIG replacement consisting of a sialic acid-rich IgG Fc fragment.[79,80] Human and mouse sialic acid-rich IgG has a reduced affinity for classical FcRs and acquires the capacity to bind to SIGNR1 strongly expressed on mouse splenic marginal zone macrophages.[68,80] By using SIGNR1-deficient mice expressing human DC-SIGN, it was demonstrated that human DC-SIGN expressed on macrophages or DCs can substitute for mouse SIGNR1 affording a candidate molecule essential for the anti-inflammatory activity of IVIG in humans.[67] Both molecules belong to the C-type lectin family and have been implicated in recognition of pathogenic microorganisms including human immunodeficiency virus and *Mycobacterium tuberculosis*.[169] Therefore, SIGNR1 and human DC-SIGN can be considered as noncanonical FcRs recognizing specific IgG glycovariants and, together with the family of toll-like receptors, provide a prime example for the dual usage of one molecule in the recognition of self- and non-self-ligands. Moreover, infusion of sialic acid-rich IgG resulted in an IL33-dependent expansion of basophils and IL4 production. IL4 is one of the interleukins known to upregulate FcγRIIB on innate immune effector cells, consistent with the upregulation of FcγRIIB noted in mouse model systems and humans. Together with previous data on the dependence of FcγRIIB upregulation on colony-stimulating factor-1-dependent macrophages, so called sensor macrophages, this suggests the following model for the anti-inflammatory activity of IVIG (Fig. 24.7). In this model, sialic acid-rich IVIG binds to mouse SIGNR1 or human DC-SIGN on sensor macrophages or DCs, which results in the production of IL33 that in turn leads to IL4 production by basophils, inducing the upregulation of FcγRIIB on effector macrophages, thereby raising the threshold for activation.[67] There is evidence that this

anti-inflammatory pathway triggered by IgG glycovariants rich in terminal sialic acid residues is of general importance for maintaining immune homeostasis. Thus, patients with rheumatoid arthritis and autoimmune-prone mouse strains have reduced levels of serum IgG-rich containing terminal sialic acid and galactose residues during active phases of the disease.[170,171] A similar reduction of this anti-inflammatory IgG variant is observed during aging, consistent with an increased probability to develop autoimmune disease.[172] This downmodulation of sialic acid-rich IgG was also observed during normal immunization conditions in mice, suggesting the general importance of this phenomenon during proinflammatory conditions.[80] The opposite type of regulation is seen in women with rheumatoid arthritis during pregnancy.[173] Parallelling the decreased frequency of arthritic flares an increased level of IgG glycoforms rich in terminal galactose and sialic acid residues was observed. In addition, inducing expression of FcγRIIB might be a clinically feasible approach and could be effective at modulating pathogenic autoantibodies from activation effector cell responses through activating FcRs.

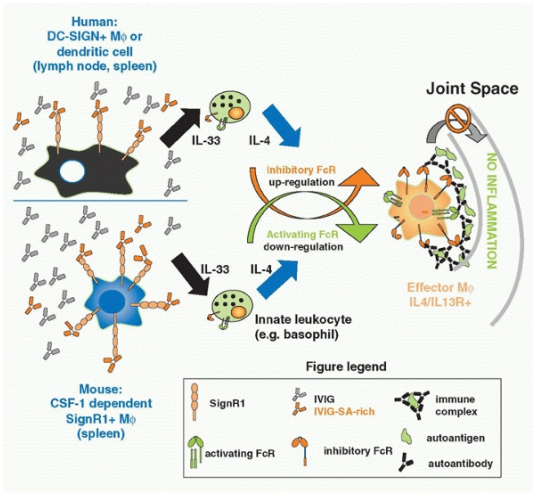

FIG. 24.7. Model for the Anti-inflammatory Activity of Intravenous Gamma Globulin (IVIG) in Mice and Humans. Sialic acid-rich antibodies in the IVIG preparation lose affinity for classical FcγRs and acquire the capacity to bind to molecules such as mouse SIGNR1 or human DC-SIGN on the surface of colonystimulating factor-1-dependent sensor macrophages or dendritic cells. This results in the production of IL33 and the expansion of innate leukocytes such as basophils followed by IL4 release resulting in the upregulation of the inhibitory FcγRIIB and downmodulation of activating FcγRs on effector macrophages inhibiting the release of inflammatory mediators and tissue destruction.

Studies on the Fc*α*RI receptor have demonstrated a role for this molecule in the

pathogenesis of IgA nephropathy, in which circulating macromolecular complexes are deposited in the mesangium, resulting in hematuria and eventually leading to renal failure. Soluble FcαRI is found in the circulating IgA complexes, which suggests a role for the receptor in the formation of these pathogenic complexes. A transgenic mouse expressing FcαRI spontaneously develops IgA nephropathy resulting from the interaction of polymeric mouse IgA and the human FcαRI receptor to release soluble receptor-IgA complexes, which leads to deposition in the mesangium and the sequelae of IgA neuropathy.

CONCLUSION

Receptors for the Fc of immunoglobulins provide an essential link between the humoral and adaptive response, translating the specificity of antibody diversity into cellular responses. The canonical FcRs mediate their biological responses through the coupling of Fc recognition to ITAM-/ITIM-based signaling motifs. A diverse array of biological responses depends on the FcR system, influencing both the afferent and efferent limbs of the immune response. Detailed biochemical, structural, and molecular biological data have provided a detailed understanding of how these receptors are regulated, are assembled, bind their ligand, and transduce specific cellular signals. FcRs play a significant role in vivo in maintaining peripheral tolerance by limiting the accumulation of autoreactive B cells that escape central tolerance checkpoints, such as light chain editing or potentially arise during somatic hypermutation in germinal centers, in modulating T-cell responses by regulating both antigen presentation and maturation by DCs, and in mediating the coupling of antigen recognition to effector-cell activation. They are the primary pathways by which pathogenic IgG and IgE antibodies trigger inflammatory responses in vivo. Allergic reactions, cytotoxic IgG responses, and IC-mediated inflammation are all critically dependent on FcR cross-linking and have resulted in a fundamental revision of the mechanisms

underlying such classic immunological responses as the Arthus reaction. Blocking of these receptors uncouples the pathogenic potential of autoantibodies and represents an important new therapeutic target for the development of anti-inflammatory therapeutic agents. Central to the correct functioning of these responses is the balance that is maintained through the pairing of activation and inhibitory receptors that coengage the IgG ligand; perturbations in either component can result in pathological responses. The study of FcRs defined the ubiquitous inhibitory motif, the ITIM, and has provided a paradigm for how these pathways modulate ITAM-based activation responses. Studies in mice deficient in individual FcRs have provided the necessary insights for defining comparable activities in human autoimmune diseases and suggest ways in which manipulation of the IgG-FcR interaction may lead to new classes of therapeutics for the treatment of these diseases. Modulation of the inhibitory response, a novel activity associated with IVIG to account for some of its anti-inflammatory activity in vivo, represents a novel approach to the regulation of Igmediated inflammation and suggests that therapeutic agents based on those pathways are likely to be effective. It seems clear that this anti-inflammatory pathway is of general importance for maintaining immune homeostasis, suggesting that IgG glycoforms rich in terminal sialic acid residues might be considered as a molecular switch either keeping the immune system in a resting state or, during infection or autoimmune responses, loosening the brakes thereby allowing full blown inflammation. In this pathway, noncanonical FcRs including SignR1 and human DC-SIGN recognizing specific IgG glycoforms are of central importance. Conversely, engineering of therapeutic antibodies targeted to eliminate infectious or neoplastic disease will probably benefit from optimization of their Fc domains for interaction with specific canonical FcRs.

Chapter 25

Type I Cytokines and Interferons, and Their Receptors

Warren J. Leonard

OVERVIEW AND ISSUES OF NOMENCLATURE

Cytokines are proteins that are secreted by cells and transduce signals via specific cell surface receptors on either the cytokine-producing cell (autocrine actions) or on other target cells (paracrine actions). From this operational type of description, it is clear that the distinction between cytokines, growth factors, and hormones may be imprecise. In general, cytokines and growth factors are similar, except that the term cytokine most often refers to molecules involved in host defense that have actions on leukocytes, whereas the term growth factor more often refers to molecules acting on other somatic cell types. Cytokines most often act locally. For example, in the interaction between a T cell and an antigen-presenting cell, cytokines are produced and usually exert potent actions locally, with rather limited biologic halflives in the circulation. In contrast, hormones are released and then disseminated via the bloodstream throughout the body, with actions on distal target organs. Nevertheless, this distinction between cytokines and hormones is not absolute, with certain cytokines acting at longer distances as well.

In the immune system, terms such as *monokines* and *lymphokines* were originally devised to identify the cellular source for cytokines.[1] Specifically, monokines included molecules such as interleukin (IL)-1, which was first recognized to be produced by monocytes, and lymphokines included molecules such as IL-2, which was first described as a T-cell growth factor produced by T lymphocytes. The monokine/lymphokine nomenclature can be problematic; however, when a cytokine is synthesized by more than one type of cell. This resulted in the adoption of the term cytokine, as proposed by Stanley Cohen in 1974.[2,3] The term cytokine refers to a protein made by a cell (“cyto”) that acts (“kine”) on target cells. Cytokines can have very broad ranges of actions, including on cell development, differentiation, growth, cytolytic activity of effector cells, survival, apoptosis, and chemotaxis.

Many cytokines are referred to as *interleukins* to indicate molecules that are produced by one leukocyte and act on another.[4] However, this term is also problematic as some interleukins (eg, IL-1 and IL-6) are additionally produced by cells other than leukocytes and/or exert actions on cell types beyond the immune system. For example, IL-7 is produced by stromal and epithelial cells rather than by typical leukocytes. Furthermore, nomenclature can be inconsistent. For example, IL-7 is highly related to another cytokine that is denoted as thymic stromal lymphopoietin (TSLP) rather than as an interleukin (see section on IL-7 and Thymic Stromal Lymphopoietin), even though both can be produced by stromal and epithelial cells and share a receptor component as well as select actions on lymphocytes. The more descriptive name of TSLP correctly describes its production by thymic stroma but obscures its production by skin epithelial cells, and that major target cells include dendritic cells (DCs) and cluster of differentiation (CD)4+ T cells.

Among the many classes of cytokines, the “type I” cytokines are distinctive in their sharing a similar four α-helical bundle structure, as detailed in the section on Type I Cytokines

—Structural Considerations, and correspondingly, their receptors share characteristic features that have led to their description as the cytokine receptor superfamily, hematopoietin receptors, or type I cytokine receptors.[5,6,7,8] Although many interleukins are type I cytokines, some are not. For example, two of the major "proinflammatory cytokines," IL-1 and IL-6, are interleukins, but IL-6 is a type I cytokine, whereas IL-1 is not. One interleukin, IL-8, is a CXC family chemokine, an entirely different type of molecule involved in chemotaxis. Moreover, IL-10, IL-19, IL-20, IL-22, IL-24, IL-26, IL-28A, IL-28B, and IL-29 are more similar to interferons (IFNs) and are denoted as type II cytokines.

In summary, the term inter leuk in indicates a relationship to leukocytes, whereas the identification of a cytokine as a type I or type II cytokine indicates general properties of its three-dimensional structure. Knowing that a molecule is a type I cytokine is instructive as it indicates a likely general structure for the cytokine receptor as well as the mechanism of signal transduction. In contrast, the identification of a molecule as an interleukin provides little information other than that it often, but not always, is a type I or type II cytokine of immunologic interest.

In addition to molecules of primarily immunologic interest, other important proteins, such as growth hormone, prolactin, erythropoietin (Epo), thrombopoietin, and leptin, are type I cytokines and their receptors are type I cytokine receptors. Despite having their major actions outside the immune system, these cytokines nevertheless share important signal transduction pathways with type I cytokines of immunologic interest. By focusing on type I cytokines and IFNs and their receptors, this chapter necessarily focuses on cytokines that are evolutionarily related and share common signaling pathways, instead of focusing on common functions per se. For example, although IL-6 has overlapping actions with IL-1 and tumor necrosis factor (TNF)-α, these latter proinflammatory cytokines are not discussed in this chapter

because they are not type I cytokines, and the signaling pathways they use are distinct from those used by IL-6. This illustrates the important concept that similar end functions can be mediated via more than one type of signaling pathway. This is not to minimize the observation that many type I cytokines in fact do have similar/overlapping functions, as detailed in the section on "cytokine redundancy."

The field of IFN research is older than the cytokine field, but both fields more recently have developed in parallel. In fact, one can consider the IFNs to be the first cytokines that were identified. IFN was discovered as an antiviral activity in 1957. This turned out to be type I IFN (IFNα/β). Type II IFN (IFNγ) was discovered in 1965. Over time, it was recognized that type I cytokines and IFNs/type II cytokines share a number of common features, including signaling pathways.

An unfortunate nomenclature issue exists that should be noted. There are specialized popuplations of T cells that include T helper 1 (Th1) and T helper 2 (Th2) cells (see following discussion), which produced specialized sets of cytokines, such as IFNγ by Th1 and IL-4 by Th2 cells. These are sometimes called type 1 and type 2 cytokines (for Th1 and Th2 cytokines); unfortunately, this jargon can result in confusion as IL-4 is a type I (ie, four α-helical bundle) cytokine that is functionally a type 2 cytokine (in that it is produced by Th2 cells), where IFNγ is a type II structure cytokine produced by Th1 cells.

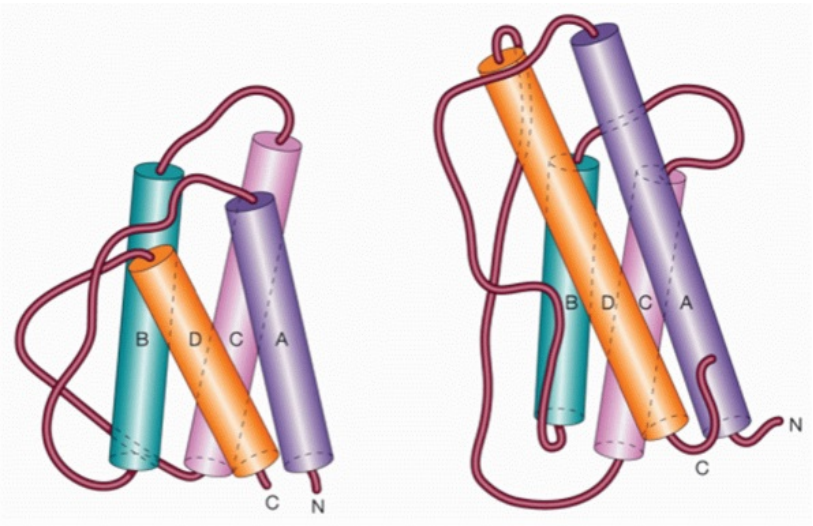

FIG. 25.1. Schematic of Four α-Helical Bundle Cytokines. Schematic drawing showing typical short-chain and long-chain four helical bundle cytokines. Although these both exhibit an "up-up-down-down" topology to their four α helices, note that in the short-chain cytokines, the AB loop is in behind the CD loop, whereas in the long-chain cytokines the situation is reversed. See text. The figure was provided by Dr. Alex Wlodawer, National Cancer Institute.

TYPE I CYTOKINES AND THEIR RECEPTORS

Type I Cytokines—Structural Considerations

Type I cytokines typically share only limited amino acid sequence identity, but strikingly, all type I cytokines whose structures have been solved by nuclear magnetic resonance and/or x-ray crystallographic methods achieve similar three-dimensional structures,[5,6,7,8,9] and those whose structures have not yet been solved are believed to share similar three-dimensional structures. Type I cytokines contain four α helices and thus are designated as four α-helical bundle cytokines (Fig. 25.1). Within their structures, the first two and last two α helices are each connected by long overhand loops, resulting in an "up-up-down-down" topologic structure, as the first two helices (A and B) can be oriented in an "up" orientation and the last two helices (C and D) can be oriented in a "down" orientation, as viewed from the N- to C-terminal direction. As shown in Figure 25.1, the N- and C-termini of the cytokines are positioned on the same part of the molecule.

Type I cytokines are either "short chain" or "long chain" four α-helical bundle cytokines based on the lengths of the α helices.[8] Some of the short-chain cytokines include IL-2,

IL-3, IL-4, IL-5, granulocyte macrophage-colony stimulating factor (GM-CSF), IL-7, IL-9, IL-13, IL-15, IL-21, macrophagecolony stimulating factor (M-CSF), stem cell factor (SCF), and TSLP, whereas long-chain cytokines include growth hormone, prolactin, Epo, thrombopoietin, leptin, IL-6, IL-11, leukemia inhibitory factor (LIF), oncostatin M (OSM), ciliary neurotrophic factor (CNTF), cardiotrophin-1 (CT-1), novel neurotrophin-1 (NNT-1)/B cell-stimulating factor-3 (BSF-3)/cardiotrophin-like factor (CLC), and granulocytecolony stimulating factor (G-CSF) (Table 25.1).[8,10,11] The α helices are approximately 15 amino acids long in short-chain helical cytokines and 25 amino acids long in long-chain cytokines. Additional differences include differences in the angles between the pairs of helices, and the AB loop is "under" the CD loop in the short cytokines but "over" the CD loop in the long cytokines (see Fig.

25.1).[7,8,12] Moreover, short-chain cytokines have β structures in the AB and CD loops, whereas long-chain cytokines do not.

TABLE 25.1 Four Helical Bundle Cytokines

Short-Chain Cytokines	Long-Chain Cytokines
IL-2	IL-6
IL-4	IL-11
IL-7	Oncostatin M
IL-9	Leukemia inhibitory factor
IL-13	CNTF
IL-15	Cardiotropin-1
IL-21	NNT-1/BSF-3
TSLP	
IL-3	Growth hormone
IL-5[a]	Prolactin
GM-CSF	Erythropoietin
	Thrombopoietin
M-CSF[a,b]	Leptin
SCF[b]	G-CSF

BSF-3, B cell-stimulating factor-3; CNTF, ciliary neurotrophic factor; G-CSF, granulocytecolony stimulating factor; GM-CSF, granulocyte macrophage-colony stimulating factor; IL, interleukin; M-CSF, macrophage-colony stimulating factor; NNT-1, novel neurotrophin-1; SCF, stem cell factor; TSLP, thymic stromal lymphopoietin.

[a] Dimers.

[b] Different from the other four helical bundle cytokines in that the M-CSF and SCF receptors (CSF-1R and c-kit, respectively) have intrinsic tyrosine kinase activity and are not type I cytokine receptors.

The division of type I cytokines into short-chain and longchain cytokines has evolutionary considerations and correlates with grouping of their receptor chains for these two subfamilies of type I cytokines. An analysis of short-chain cytokines has revealed that 61 residues comprise the family framework, including most of the 31 residues that contribute to the buried inner core. The similarities and differences in the structures of IL-2, IL-4, and GM-CSF have been analyzed. 5 Among these cytokines, there is considerable variation in the intrachain disulfide bonds that stabilize the structures. For example, IL-4 has three intrachain disulfide bonds, GM-CSF has two, and IL-2 has only one. In IL-4, the first disulfide bond (between Cys 24 and Cys 65) connects loop AB to BC, the second disulfide bond (between Cys 46 and Cys 99) connects helix B and loop CD, and the third disulfide bond (between Cys 3 and Cys 127) connects the residue preceding helix B with helix D. In GM-CSF, the N-terminus of helix B and the N-terminus of β strand CD are connected by one disulfide bond, whereas the other disulfide bond connects the C-terminus of helix C and a strand following helix D. In IL-2, a single essential disulfide bond between Cys 58 and Cys 105 connects helix B to strand CD. Thus, each cytokine has evolved distinctive disulfide bonds to stabilize its structure, although it is typical that helix B is connected to the loop between helices C and D. The structures formed by helices A and D are more conserved than those formed by helices B and C, primarily due to the interhelical angles; helix D and the connecting region are the most highly conserved elements among the three cytokines.[5] This is of particular interest, as the regions of type I cytokines that are most important for cytokine receptor interactions (based on analogy to the growth hormone receptor structure, see subsequent discussion) include helices A and D and residues in the AB and CD loops, whereas helices B and C do not form direct contacts.[5]

Variations on these typical four α-helical bundle structures can occur. For example, IL-5 is unusual in that it is a dimer, wherein the ends containing the N- and C-termini are juxtaposed, and helix D is “exchanged” between the two covalently attached monomers so that helix D of each molecule actually forms part of the four helix bundle of the other.[13] M-CSF is also a dimer, but no exchange of helix D occurs.[12]

The IFNs form related albeit distinctive structures from type I cytokines and are designated as type II cytokines.[8] IFNβ has an extra helix that is positioned in place of the CD strand.[14] IFNγ is a dimer, each of which consists of six α helices[15] (Fig. 25.2). Two of these helices are interchanged, including one from each four α-helical bundle.[12,15] IL-10, which is closely related to IFNγ, has a similar structure,[16] as

presumably do the more recently identified IL-10-like molecules, including IL-19, IL-20, IL-22, IL-24, IL-26, IL-28A, IL-28B, and IL-29. Interestingly, although not universally the case, most four α-helical bundle cytokines have four exons, with helix A in exon 1, helices B and C in exon 3, and helix D in exon 4.[7] A related organization is found for IFNγ, as well as for the long-chain helical cytokines, growth hormone, and G-CSF. However, there are exceptions, for example, IL-15 is divided into nine exons, whereas the IFNαs and IFNβ are encoded by single exons.

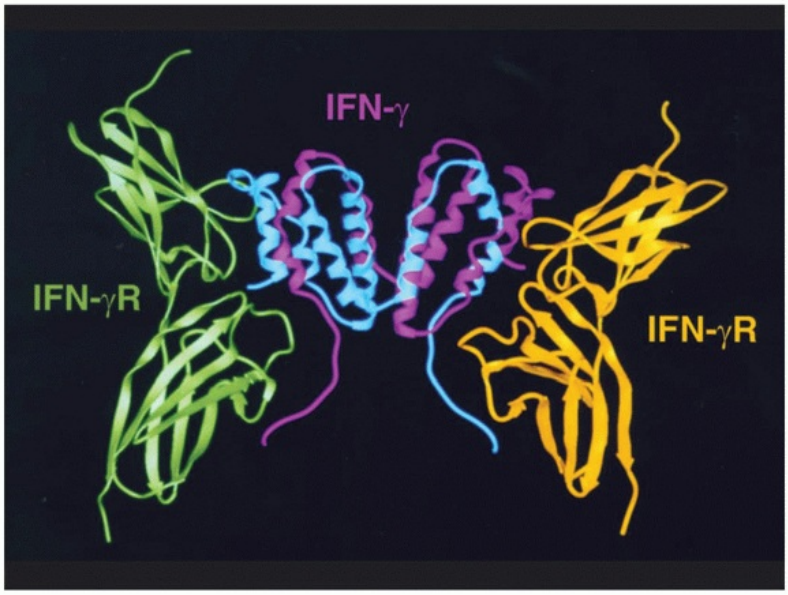

FIG. 25.2. Structure of the Interferon γReceptor (IFNγR). Shown are ribbon diagrams of the structures of the IFNγ/IFNγR complex as an example of a type II cytokine/cytokine receptor. In the IFNγR, only IFNGR-1 complexed to the IFNγ dimer is shown, as the full structure with IFNGR-2 is not available. See text for discussion of the structure. The IFNγ-IFNGR-1 structure is from Walter et al.[401] The figure was provided by Dr. Alex Wlodawer, National Cancer Institute.

Receptors for Type I Cytokines

The first report suggesting that type I cytokines interacted with receptors with similar features identified similarities in the sequences of the erythropoietin receptor and the IL-2 receptor β chain,[17] and subsequent analysis of a large number of type I cytokine receptors established these receptors as a superfamily.[18] Type I cytokine receptors are generally type I membrane-spanning glycoproteins (N-terminus extracellular, C-terminus intracellular). The only exceptions are proteins such as the CNTF receptor α chain (see the following discussion), which lacks a cytoplasmic domain and instead has a glycosylphosphatidylinositol (GPI) anchor; however, the orientation of this protein is otherwise similar to that of a type I membrane protein. In their extracellular domains, a number of conserved features have been noted (Table 25.2). These include four conserved cysteine residues that are involved in intrachain disulfide bonding, and a tryptophan residue, located two amino acids C-terminal to the second conserved cysteine. In addition, a membrane proximal WSXWS (Trp-Ser-X-Trp-Ser) motif is generally conserved, although again exceptions exist, for example, in the growth hormone receptor, the motif is a substantially different YGEFS (Tyr-Gly-Glu-Phe-Ser) sequence, and in the IL-23R, it is WQPWS (Trp-Gln-Pro-Trp-Ser). In some cases, such as the common cytokine receptor β chain, β_C, shared by the IL-3, IL-5, and GM-CSF receptors (see subsequent discussion), the extracellular domain is extended, with a duplication of the domains containing the four conserved cysteines and the WSXWS motif. Another shared feature of type I cytokine receptors is the presence of fibronectin type III domains.

The two pairs of conserved cysteine residues are typically encoded in two adjacent exons, and the exon containing the WSXWS motif is typically just 5′ to the exon encoding the transmembrane domain. Although serines can be encoded by six different codons (ie, sixfold degeneracy in codon usage), only two of these (AGC and AGT) dominate as the codons used for the serines in WSXWS. All of these features indicate a common ancestral type I

cytokine receptor.

TABLE 25.2 Features Common to Type I Cytokine Receptors

2. WSXWS motif
3. Fibronectin type III modules

Cytoplasmic domain

1. Box 1/Box 2 regions—The Box 1 region is a proline-rich region that is involved in the interaction of Janus family tyrosine kinases.

Overall, analogous to limited sequence identity between type I cytokines, there is only limited sequence identity among type I receptor molecules. Nevertheless, they appear to form similar structures, based on the known structures for the receptors for growth hormone, prolactin, erythropoietin, IL-4, IL-13, IL-6, and IL-2[9,19,20,21,22,23,24,25] as well as the modeling of other cytokine receptor molecules based on the known structures. The cytokines and their receptors have presumably coevolved, with the differences in amino acid sequences between different cytokines allowing for their distinctive interactions with their cognate receptor chains. Despite amino acid differences, there are also several sets of cytokines that coevolved to interact with shared receptor chains, which form type I cytokine and cytokine receptor subfamilies.[8,11]

In addition to these noted similarities in the extracellular domains, there are sequence similarities that are conserved in the cytoplasmic domain of cytokine receptors. In particular, membrane proximal "Box 1/Box 2" regions are conserved (see Table 25.2), with the proline-rich Box 1 region being the most conserved.[26] This will be discussed in greater detail related to its role in the binding of JAK kinases.

Type I Cytokine Receptors Are Homodimers, Heterodimers, or Higher Order Receptor Oligomers

The first cytokine receptor structure solved was that for growth hormone (Fig. 25.3).[19] Prior to x-ray crystallographic analysis, it was believed that growth hormone bound to its

receptor with a stoichiometry of 1:1, but x-ray crystal solution structure revealed that a single growth hormone molecule interacts with a dimer of the growth hormone receptor, in which each receptor monomer contributes a total of seven β strands. Perhaps the most striking finding is that totally different parts of growth hormone interact with the same general region of each receptor monomer. The three-dimensional structure for the growth hormone/growth hormone receptor complex is shown in Figure 25.3. Solving the structure also clarified the basis for the assembly of the growth hormone receptor complex.[19] Growth hormone first interacts with one receptor monomer via a relatively large and high-affinity interaction surface (site I), spanning ~1230 $Å^2$. A second receptor monomer then interacts with the growth

hormone/growth hormone receptor complex via two contact points: one on growth hormone (spanning ~900 $Å^2$) (site II) and the other on the first receptor monomer (spanning ~500 $Å^2$) (site III), located much more proximal to the cell membrane. Thus, three extracellular interactions are responsible for the formation and stabilization of the growth hormone/growth hormone receptor complex. Mutations in critical residues in site I should prevent growth hormone binding to its receptor, whereas inactivating mutations in site II can be predicted to prevent dimerization and signal transduction, suggesting a basis by which different classes of antagonists might be identified.

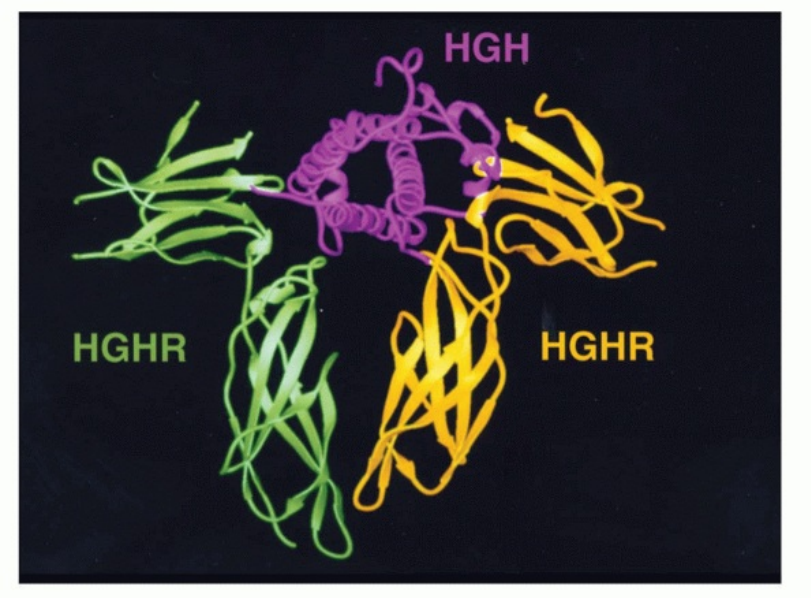

FIG. 25.3. Structure of the Growth Hormone Receptor. Shown are ribbon diagrams of the structure of the growth hormone receptor as an example of a type I cytokine receptor. For growth hormone, both growth hormone receptor monomers are shown. See text for discussion of the structures. The growth hormone/growth hormone receptor structure is from de Vos et al.[19] The figure was provided by Dr. Alex Wlodawer, National Cancer Institute.

The growth hormone/growth hormone receptor structure revealed that the growth hormone receptor extracellular domain is composed of two fibronectin type III modules, each of which is approximately 100 amino acids long and contains seven β strands, resulting in the formation of an immunoglobulin (Ig)-like structure. The contact surface between ligand and receptor occurs in the hinge region that separates these two fibronectin type III modules. Analysis of a growth hormone-prolactin receptor complex revealed a similar structure for the prolactin receptor.[20]

The growth hormone/growth hormone receptor structure served as a paradigm for the structures of other type I cytokine receptors. As a receptor homodimer, it immediately served as a model for other homodimers, such as the Epo receptor, whose structure was solved[21] using a small protein mimetic (20 amino acid long peptide) of Epo.[27] The Epo receptor structure is similar to that of the growth hormone receptor, although the “site III” stem region interaction surface in the Epo receptor is much smaller than that in the growth hormone receptor, comprising only 75 $Å^2$.[21]

In addition to the structural similarities for the growth hormone and Epo receptors and

perhaps other homodimeric type I cytokine receptors, a similar structure was achieved by the heterodimeric growth hormone/growth hormone receptor/prolactin receptor structure,[20] in which one of the growth hormone receptor monomers is replaced by a prolactin receptor molecule. Thus, the two surfaces of growth hormone interact either with two identical monomers of growth hormone receptor or with two nonidentical monomers in the case of the growth hormone receptor/prolactin receptor heterodimer.

It seems reasonable that cytokine-receptor systems with a homodimeric receptor are evolutionarily older than those with heterodimeric receptors, and that the coordination of two different receptor chains in heterodimeric receptors would have evolved in order to allow higher levels of specialization. In this regard, it is interesting that growth hormone and Epo, whose actions are vital for growth and erythropoiesis, bind to receptor homodimers, whereas the heterodimeric structures that typify the immune system are perhaps more “specialized” functions that arose later in evolution.

Interestingly, all type I cytokines known to interact with homodimers (growth hormone, prolactin, Epo, and G-CSF) are long-chain helical cytokines, although other long-chain helical cytokines (eg, cytokines whose receptors contain gp130; see following discussion) interact with heteromeric receptors. The short-chain cytokines that signal through homodimers are SCF and M-CSF, but in these cases, the receptors (c-kit and CSF-1R, respectively) are different from type I cytokine receptors in that they contain intrinsic tyrosine kinase domains. Thus, SCF and M-CSF are not typical type I cytokines and all other short-chain cytokines signal through heterodimers or more complex receptor structures (eg, IL-2 and IL-15 receptors have three components).

Heterodimeric receptors are involved when site II on a cytokine has evolved to a point where it interacts with a different receptor molecule than site I does. This latter situation is the case for many cytokines, including all short-chain type I cytokines except for SCF and M-CSF. Overall, several sets of type I cytokines fall into distinct groups, wherein each group shares at least one common receptor component. This phenomenon is observed for certain sets of both shortchain and long-chain four α-helical bundle cytokines, and depending on the set of cytokines, the shared chain interacts either with site I or site II.

The structures of the low- and high-affinity forms of the IL-2 receptor have now been solved[9,23,28]; these are the first complete structures for a short-chain cytokine/receptor complex.[29] Moreover, they are of added interest in that the low-affinity receptor involves the interaction of IL-2 with IL-2Rα, which is not a type I cytokine receptor protein but instead is a distinctive sushi-domain containing protein, whereas the high-affinity receptor includes not only IL-2Rα but also IL-2Rβ and γ_C, which are both type I cytokine receptor proteins that are shared either with IL-15 (IL-2Rβ) or with IL-4, IL-7, IL-9, IL-15, and IL-21 (γ_C),[30] as discussed in the following text. In the structure of IL-2 bound to its high-affinity receptor (Fig. 25.4), there is a long peptide connecting the IL-2Rα globular head and transmembrane segment, allowing the binding site on this protein to extend relatively far from the cell surface in order to bind the dorsal surface of IL-2. Both the IL-2/IL-2Rα and IL-2/IL-2Rβ contacts are independent, and IL-2Rα does not appear to contact either IL-2Rβ or γ_C; however, IL-2/IL-2Rβ forms a composite surface with γ_C, somewhat analogous to the composite surface formed by growth hormone and one growth hormone receptor monomer for binding to a second monomer. As anticipated, the surface interaction between IL-2 and γ_C is smaller than that between IL-2 and either of the other chains. In addition to the heterodimeric IL-2 receptor structure,[23] the IL-6[31,32] and LIF[33] receptor complexes,

the IL-4/IL-13 receptor[34] complexes, and GM-CSF receptor structure[35] have been solved.

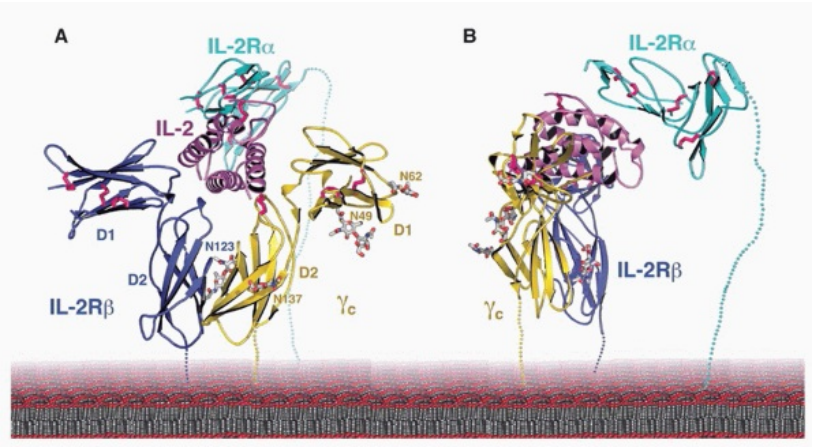

FIG. 25.4. Structure of the High-Affinity Interleukin (IL)-2 Receptor. This is the first structure for a short-chain type I cytokine complexed to its complete receptor. It is particularly interesting in that it includes the sushi-domain containing IL-2Rα chain as well. Reprinted from Wang et al.,[23] with permission of Dr. Garcia and *Science* magazine.

TYPE I CYTOKINE RECEPTOR FAMILIES AND THEIR RELATIONS

Cytokines that Share the Common Cytokine Receptor γChain (Interleukin-2, Interleukin-4, Interleukin-7, Interleukin-9, Interleukin-15, and Interleukin-21)

The receptors for six different immunologically important cytokines, IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21, share the common cytokine receptor γ chain, γ_c (CD132).[11,30,36,37,38,39,40,41,42,43,44,45] These cytokines are all short-chain four α-helical bundle cytokines; basic features of these cytokines are summarized in Table 25.3. The properties of these cytokines and their distinctive receptor chains are summarized in the following text, followed by a discussion of the discovery that they share a common receptor component and the implications thereof.

IL-2 is important not only for its function but also historically, as it was the first type I cytokine that was cloned,[46] the first type I cytokine for which a receptor component was cloned,[47,48] and the first short-chain type I cytokine whose receptor structure was solved.[23] Many general principles have derived from studies of this cytokine, including its being the first cytokine that was demonstrated to act in a growth factor-like fashion through specific high-affinity receptors, analogous to the growth factors being studied by endocrinologists and biochemists.[49,50]

Mature IL-2 is a 133 amino acid long peptide that can act as a major T-cell growth factor, in keeping with its original discovery as a T-cell growth factor.[51] Although IL-2 is not produced by resting T cells, it is rapidly and potently induced following antigen encounter with resting CD4+ T cells, and transcription and synthesis of IL-2 are often used as indicators of T-cell receptor (TCR)-mediated cellular activation. Although the antigen determines the specificity of the T-cell immune response, the interaction of IL-2 with high-affinity IL-2 receptors regulates the magnitude and duration of the subsequent response, based on the amount of IL-2 produced, the levels of high-affinity receptors expressed, and the duration of IL-2 production and receptor expression. IL-2 can act in either an autocrine or paracrine fashion, depending on whether the producing cell is also the responding cell or whether the responding cell is a nonproducing cell. The gene encoding IL-2 is located on chromosome

4,[52] and like many other helical cytokines, its gene consists of four exons.[7] IL-2 binds to three different classes of receptors. These are formed by different combinations of three different chains, IL-2Rα,[47,48,53] IL-2Rβ,[54,55,56,57] and a protein initially called IL-2Rγ[36] but now known as the common cytokine receptor γ chain, γ_c.[11,30,37] These different classes of IL-2 receptors are discussed in the following text.

In addition to its being a T-cell growth factor, IL-2 has other important actions as well (see Table 25.3).[29] For example, it can increase Ig synthesis and J chain transcription in B cells,[50,58,59] potently augment the cytolytic activity of

natural killer (NK) cells,[60,61,62] induce the cytolytic activity of lymphokine activated killer cells, promote the elimination of autoreactive cells in a process known as antigen-induced (or activation-induced) cell death,[29,50,63] and promote the differentiation of regulatory T (T_{reg}) cells,[64,65] cells that suppress inappropriate responses and are important for immunologic tolerance. Low-dose IL-2 is sufficient to promote T_{reg}-cell survival, and thereby, for example, can protect mice from developing autoimmune diabetes.[66] Interestingly, IL-2 can also prime CD8+ T cells during a primary response to undergo enhanced proliferation in vivo during a secondary response,[67,68] and autocrine IL-2 is believed to be required for secondary expansion of CD8+ memory T cells.[69] There appears to be a complex interplay between IL-2 and inflammatory signals to regulate effector and memory cytolytic T-lymphocytes generation in lymphocytic choriomeningitis virus infection, with persistent IL-2 promoting effector rather than memory cytotoxic T-lymphocyte development.[70,71] In *Listeria monocytogenesis* infection, Th1 effector memory cells highly express the transcription factor T-Bet and IL-2Rα, and IL-2Rα appears to be critical for the development of these cells.[72] Presumably because of its critical role in T_{reg} development, the absence of IL-2, IL-2Rα, or IL-2Rβ leads to autoimmunity. Interestingly, the production of IL-2 by mast cells has been reported to contribute to the suppression of chronic allergic dermatitis by its increasing the relative number of T_{reg} cells at the site of inflammation.[73]

TABLE 25.3 Features of Cytokines Whose Receptors Share γ_c

Cytokine	Major Source	Size[a]	Actions	Chromosome Location (h/m)	Genomic Org
IL-2	Activated T cells (Th1 cells)	h153 aa/20aa m169aa/20aa 15.5 kDa	T-cell growth factor B-cell growth, Ig production, J chain expression Induces LAK activity Induces tumor infiltrating lymphocyte activity Augments NK activity Critical roles in antigen-induced cell	4q26-27/3	Four exons

			death Stimulates macrophage/monocyte Antitumor effects Promotes T_{reg} development Promotes Th1 and Th2 differentiation Inhibits Th17 differentiation		
IL-4	Activated T cells (Th2 cells) CD4+NK1.1+ natural T cells	h153/24 aa m140 aa/20 aa 18 kDa	B-cell proliferation Ig class switch: IgG1, IgE production Augment MHC II, Fcε receptors, IL-4Rα, and IL-2Rβ expression Th2 cell differentiation Antitumor effects	5q31.1/11	Four exons
IL-7	Stromal cells	h177 aa/25aa m154aa/25aa 17-25 kDa	Thymocyte growth T-cell growth Pre-B-cell growth in mice but not human Survival and growth of peripheral T cells CD4+ and CD8+ T-cell homeostasis	8q12-13/3	Six exons
IL-9	Activated Th cells	h144aa/18aa m144aa/18aa 14 kDa	Th helper clones Erythroid progenitors B cells Mast cells/allergic responses Fetal thymocytes	5q31-35/13	Five exons
IL-15	Monocytes and many cells outside the immune system[b]	h162aa/48aa m162aa/48aa 14-15 kDa	Mast cell growth NK cell development and activity T-cell proliferation CD8+ T-cell homeostasis	4q31/8	Nine exons
IL-21	Activated CD4+ T cells	h162aa/31 aa m146aa/24 aa	Comitogen for T-cell proliferation Inhibits B-cell proliferation to anti-IgM + IL-4 Augments B-cell proliferation to anti-CD40	4q67-27/3	Five exons

	Conflicting reports related to NK cells Cooperates with IL-7 and IL-15 to expand CD8 cells Antitumor effects Drives terminal B-cell differentiation to plasma cells Proapoptotic for B and NK cells Promotes Tfh differentiation Promotes Th17 differentiation

CD, cluster of differentiation; Ig, immunoglobulin; IL, interleukin; LAK, lymphokine activated killer; MHC, major histocompatibility complex; NK, natural killer; Tfh, T follicular helper; Th, T helper; T_{reg}, regulatory T.

[a] h and m refer to human and mouse, respectively. The number of amino acids refers to the length of the open reading frame/length of signal peptide. The number of amino acids in the mature protein is therefore the difference between these numbers. Note that for IL-15, residues 1 to 29 have been identified as a signal peptide and 30 to 48 as a propeptide.

[b] More IL-15 messenger ribonucleic acid is produced in skeletal muscle, kidney, placenta, and lung than in thymus or spleen. It is important to note, however, that IL-15 messenger ribonucleic acid is widely expressed without concomitant production of IL-15 protein so that the source of biologically meaningful IL-15 may be more limited.

IL-2 is also important in inducing or inhibiting Th differentiation. It is required for efficient Th1 74 and Th2 differentiation,[75,76,77,78] which are populations of T helper cells first described based on patterns of cytokine production by mouse T cells.[79] This theme was then extended to human cells as well,[80,81,82,83,84] although there are some variations in humans and mice in terms of the degree of how tightly restricted cytokine expression is. IFNγ is the cytokine most reliably produced by Th1 cells; IL-2 is also produced by these cells, although without as rigorous an association. In contrast, IL-4, IL-5, IL-6, IL-9, IL-10, and IL-13 are produced by Th2 cells. In both species, certain type I cytokines (eg, IL-3 and GM-CSF) are produced by both Th1 and Th2 cells. IL-12 and the transcription factors signal transducer and activator of transcription (STAT)4 and T-Bet are the major transcription factors promoting Th1 differentiation, whereas IL-4 and the transcription factor STAT6 drive Th2 differentiation. For Th1 cells, IL-2 acts by STAT5-dependent induction and expression of IL-12Rβ1/IL-12Rβ2 and T-Bet,[74] whereas for Th2 differentiation, IL-2 via STAT5 promotes IL-4[75,76] and IL-4Rα[77] expression. In addition, IL-2 also affects chromatin remodeling at the *Ifng* locus during Th1 differentiation.[85] IL-2 also inhibits Th17 differentiation,[86] in part via downregulation of IL-6Rα/gp130 expression[74] and by inducing T-bet,[74,87] which prevents Runx1-mediated activation of RORγt, a transcription factor that drives Th17 differentiation.[87]

Like IL-2, IL-4 is produced primarily by activated CD4+ T cells.[88,89] IL-4 is also produced by

CD4+NK1.1+ “natural” T cells, denoted as natural killer T (NKT) cells,[90] and by mast cells and basophils.[88] IL-4 is the major B-cell growth factor, and it promotes Ig class switch, enhancing the production and secretion of mouse IgG1 (human IgG4) and being essential for the production of IgE.[88] IL-4 is involved in the physiologic response to parasites, including helminths, and for allergen sensitization. IL-4 induces expression of class II major histocompatibility complex molecules and increases cell surface expression of the CD23 (the low-affinity IgE receptor) on B cells. In addition to its actions on B cells, IL-4 can also act as a T-cell growth factor, inducing proliferation in both human and mouse T cells, and is critical for normal differentiation of Th2 cells.[89] Moreover, when IL-4 and transforming growth factor (TGF)-β are combined, cells that produce IL-9 (Th9) cells are induced (see following discussion). When combined with phorbol 2-myristate 3-acetate, IL-4 is also a potent comitogen for thymocytes. Importantly, IL-4 can inhibit certain responses of cells to IL-2.[91] Moreover, IL-4 can exert actions on macrophages, hematopoietic precursor cells, stromal cells, and fibroblasts.[92] The gene encoding IL-4 is located on human chromosome 5 (5q23.3-31.2) and mouse chromosome 11,[92,93] in the same region as IL-3, IL-5, IL-13, and GM-CSF. The type I IL-4 receptor is expressed on T cells and other hematopoietic cells consists of the 140 kDa IL-4Rα protein[88,94,95,96] and γ_C.[38,39] Expression of IL-4Rα tends to be quite low, and cells that potently respond to IL-4 often express only a few hundred receptors per cell. In addition to the type I IL-4 receptor, an alternate form of the receptor (the type II IL-4 receptor), containing IL-4Rα and IL-13Rα1, although not expressed on mature T cells, is expressed on many other cell types and can transduce IL-4 signals into these cells. For example, IL-13Rα1 is expressed on neonatal Th1 cells and the type II IL-4 receptor has been implicated as mediating apoptosis of these cells.[97]

IL-7 is not produced by lymphocytes but instead is a 152 amino acid long cytokine that is produced by stromal cells and certain other cells.[98,99,100] Based on the analysis of patients with X-linked severe combined immunodeficiency (SCID), JAK3-deficient SCID, and IL-7Rα-deficient SCID, IL-7 receptor-dependent signaling is essential for T-cell development in humans (discussed subsequently). The major role of IL-7 is to enhance thymocyte survival, growth, and differentiation[101,102,103,104,105] as well as low-affinity peptide-induced proliferation, and thus it promotes homeostatic proliferation of naive and memory CD8+ T cells.[100,105,106,107] Additionally, IL-7 can regulate the homeostasis of CD4+ memory T cells[108,109] and also can stimulate the growth of mature T cells.[30,105,110,111] Although IL-7, as noted previously, is believed to primarily be a stromal factor, IL-7 has also been noted to be produced by the liver and kidney but not spleen or lymph nodes after toll-like receptor (TLR) signaling. Although basal liver production is low, after TLR signaling, hepatic IL-7 can promote CD4 and CD8 T-cell survival and promotes antigen-specific T-cell responses.[112] In addition, in the mouse, IL-7 is vital for the growth of mouse pre-B cells,[96,98,103,104,111] and transient IL-7 signaling can inhibit Ig heavy chain gene rearrangements.[113] IL-7 via STAT5 has also been shown to inhibit Ig-κ recombination in pro-B cells.[114] In contrast to its requirement for B-cell development in the mouse, there is normal B-cell development in patients with defective IL-7 signaling, as is found in patients with X-linked SCID, JAK3-deficient

SCID, and IL-7Rα-deficient SCID (see following discussion). Thus, human B cells can develop normally in the absence of IL-7 responsiveness, demonstrating that in humans, IL-7 is not vital for the growth of human pre-B cells,[30,115] and it remains unknown whether IL-7 plays important roles in human B-cell biology. Interestingly, IL-7 also acts on DCs, and this

appears to limit the homeostatic proliferation of T cells under lymphopenic conditions.[100,116] Clinically, IL-7 has been of interest in terms of its ability to induce T-cell proliferation and to thereby increase T-cell numbers, with a greater effect on CD8+ than on CD4+ T cells, as well as to augment the diversity of the TCR repertoire[117]; IL-7 also can increase antigen-specific responses following vaccination[100] and can promote antiviral immunity, apparently in part due to its induction of IL-22 and repression of SOCS3.[118] The gene encoding IL-7 is located on human chromosome 8q12 to 8q13[119] and mouse chromosome 3. The functional IL-7 receptor contains the 75 kDa IL-7Rα[120] and γ_c.[37,40] Interestingly, signaling via the TCR, IL-2 or IL-7 can downregulate IL-7Rα expression,[121,122] with PI 3-kinase/AKT and GFI1B being implicated in its downregulation in T cells.[122,123,124] The downregulation of IL-7Rα not only can both decrease responsiveness of cells but can also increase the availability of the cytokine for other cells that are poised to respond.[11] Induction of IL-7Rα requires PU.1 in B cells[125] and another Ets family protein, GABP, in T cells.[123]

IL-9 was originally described as a mouse T-cell growth factor[126] that is produced by activated T cells and can support the growth of T-helper clones but not of cytolytic clones.[127] In contrast to IL-2, its production is delayed, suggesting its involvement in later, perhaps secondary signals. In the mouse, IL-9 can exert proliferative effects on erythroid progenitors, B cells, B-1 cells, mast cells, and fetal thymocytes. IL-9 is identical to mast cell growth-enhancing activity, a factor present in conditioned medium from splenocytes,[128] and synergizes with IL-3 for maximal mast cell proliferation. IL-9 is highly expressed in the lung of patients with asthma,[129] and overexpression leads to airway inflammation and Th2 cytokine production.[130] Interestingly, IL-9 is substantially made in the lung by innate lymphoid cells, and in these cells neutralizing antibodies to IL-9 lowered expression of IL-13 and IL-5, supporting a link between IL-9 and the regulation of the Th2 response.[131] Consistent with the action of IL-9 on thymocytes in vitro, IL-9 transgenic mice develop thymic lymphomas, and IL-9 is a major antiapoptotic factor for such tumors.[132] Nevertheless, IL-9 knockout mice have normal T-cell development[133]; instead, they exhibit a defect in pulmonary goblet cell hyperplasia and mastocytosis following challenge with *Schistosoma mansoni* eggs, a synchronous pulmonary granuloma formation model. However, there was no defect in eosinophilia or granuloma formation.[133] Mice expressing an IL-9 transgene in the lung exhibit airway inflammation and bronchial hyperresponsiveness; nevertheless, IL-9-/- mice exhibit normal eosinophilia and airway hyperreactivity in an ovalbumin-induced inflammatory model.[134,135,136] Thus, although IL-9 can contribute to allergic/pulmonary responses, there are compensatory cytokines that substitute for IL-9 in at least certain settings. IL-9 can be produced by the Th9 populations of cells, which can be induced by IL-4 plus TGF-β in a fashion that is dependent on PU.1 and interferon regulatory factor (IRF)-4.[137] Interestingly, the addition of IL-25 further enhances the production of IL-9.[138] IL-9-producing cells are typically IL-9+IL-10+Foxp3-effector T cells and can be derived from Th2 cells.[139,140] Overall, IL-9 is believed to play a key role in allergic responses; additionally, given the ability of both Th17 and T_{reg} cells to produce IL-9 during autoimmunity and transplantation, it will be interesting to further clarify the role of IL-9 in autoimmunity.[141] Currently, there is some confusion, as one study showed that antibody blockade of IL-9 or IL-9Rα blocks experimental autoimmune encephalomyelitis (EAE) disease progression,[142] whereas another study showed that IL-9Rα knockout mice develop more severe EAE.[138] While mouse IL-9 is active on human cells, human IL-9 is not biologically active on mouse cells (the opposite situation

from that for IL-2). Human IL-9 is located on chromosome 5q31 to 5q35,[143] which is also the location for the genes encoding IL-3, IL-4, IL-5, IL-13, and GM-CSF. In contrast, mouse IL-9 is "isolated" on chromosome 13, while IL-3, IL-4, IL-5, IL-13, and GM-CSF are clustered on chromosome 11. IL-9 binds to the 64 kDa IL-9Rα binding protein, which is similar in size to γ_c,[144] and the functional IL-9 receptor consists of IL-9Rα plus γ_c.[30,41,42]

IL-15 was identified as a T-cell growth factor that also unexpectedly was expressed in the supernatant of a human T-lymphotropic virus type I (HTLV-I)-transformed T-cell line.[145,146] Although IL-15 messenger ribonucleic acid (RNA) is produced by a range of nonlymphocytic cell types, it is difficult to detect physiologic levels of IL-15 protein.[147] Its main site of synthesis appears to be DCs and monocytes, and unlike IL-2, IL-15 is not produced by activated T cells.[148] IL-15 receptors are widely expressed; although IL-15 is perhaps most important for the development of NK cells[149,150,151] and CD8+ memory T cells,[150,151] it also has both paracrine and autocrine actions on DCs, including promoting the survival of these cells.[11] Interestingly, it also regulates the TCR repertoire of γδ intraepithelial lymphocytes[152] and cross talk between different types of DCs.[153] The receptor for IL-15 on T cells contains IL-2Rβ,[43,147,154] γ_c,[43] and an IL-15-specific protein, IL-15Rα. IL-15Rα shares a number of structural similarities with IL-2Rα, including that it is a sushi domaincontaining protein (IL-2Rα has two sushi domains, whereas IL-15Rα has one),[155] and the *IL2RA* and *IL15RA* genes are closely positioned on human chromosome 10p14.[156] A distinctive feature of IL-15 signaling is that it signals substantially by a process called *transpresentation,* wherein IL-15Rα on the surface of dendritic cells or monocytes will transpresent IL-15 to responding cells such as CD8+ T cells or NK cells that express IL-2Rβ + γ_c.[148,157] IL-15Rα has a longer cytoplasmic domain than IL-2Rα and appears to be critical for IL-15Rα function, although potentially not for transpresentation.[158] Interestingly, transpresentation can be utilized by IL-2 as well.[159] The very high affinity of IL-15Rα for IL-15 is explained by a large number of ionic interactions mediated by the sushi domain.[160] Note that these responding cells can also express IL-15Rα. In contrast to IL-2, which is a growth factor as well as a mediator of antigen-induced (or activationinduced) cell death and promoter of T_{reg} differentiation, the

role of IL-15 appears to be more focused on growth of CD8+ T cells,[161] maintaining long-lasting, high-avidity T-cell responses to foreign pathogens (ie, CD8+ T-cell memory).[148,162] This ability has suggested it could have potential as a vaccine adjuvant.[163] Overall, the fact that IL-15 promotes the proliferation and differentiation of B, T, and NK cells; the cytolytic activity of CD8 T cells; and the maturation of dendritic cells, yet, unlike IL-2, fails to stimulate immunosuppressive T_{reg} cells indicates that it has an array of properties that make it potentially promising as an anticancer therapeutic agent; as a result, a number of ongoing clinical trials are now in progress.[164]

IL-21 is the most recently identified member of the IL-2 family of cytokines. IL-21 can bind to specific receptors and exert actions on T, B, NK cells, DCs, and macrophages.[165] It augments T-cell proliferation as a comitogen,[166] can cooperate with IL-7 or IL-15 to drive the expansion of freshly isolated mouse CD8+ T cells, and it can augment the antitumor activity of CD8+ T cells.[167] IL-21 promotes the differentiation of Th17 cells[168,169] as well as the generation of T follicular helper cells.[170] In the case of Th17 differentiation, IL-21 is part of an IL-6 to IL-21 to IL-23 signaling cascade[169,171,172] to drive the differentiation of these

cells in an RORγ-dependent manner.[173] Polarization of Th17 cells is dependent on TCR stimulation, TGF-β, and IL-6 but is independent of IL-23, which instead may be required for maintaining/expanding these cells.[174,175,176,177]

The actions of IL-21 on B cells are particularly complex. It augments B-cell proliferation when combined with anti-CD40 or lipopolysaccharide (LPS) but inhibits proliferation in response to anti-IgM + IL-4[166]; this inhibition is reversed if anti-CD40 is additionally provided. It induces apoptosis of incompletely activated B cells, perhaps serving a role analogous to that of IL-2 in activation-induced cell death of T cells to eliminate incompletely activated cells.[165] In contrast, IL-21 drives terminal differentiation to plasma cells of more fully activated cells. Strikingly, IL-21 can drive plasma cell differentiation of both peripheral memory B cells and cord blood B cells, at least in part explained by its ability to induce expression of BLIMP1.[178,179] Strikingly, IL-21 regulates not only BLIMP-1 but also a broad range of genes via a functional cooperation between STAT3 and IRF4.[180] In IL-21R knockout mice, following immunization, IgG1 is diminished related to a role for IL-21 in class switching to IgG1 and IgG3, whereas IgE is elevated, related to the ability of IL-21 to inhibit Cε transcription[181] and/or to its ability to augment the apoptosis of IgE-producing B cells. Analysis of IL-21R/IL-4 double knockout mice has revealed that IL-21 cooperates with IL-4 to globally regulate Ig production in that these mice exhibit a panhypogammaglobulinemia, mimicking the T-cell phenotype in humans with X-linked SCID.[182] IL-21 can also cooperate with IL-15 and Flt-3 ligand to increase development of NK cells[166] and augment antitumor activity[183]; however, it was also reported to oppose the actions of IL-15[184] and can also direct NK cell apoptosis. Interestingly, IL-21 exerts potent antitumor effects, including against large established solid tumors.[11,165] In the pMEL-1 CD8 TCR transgenic system, the effector cells recognize a melanoma antigen. When cells are adoptively transferred into tumor-bearing mice and animals are vaccinated with the cognate antigen, the addition of IL-21 or IL-21 plus IL-15 has potent antitumor effects.[167] Moreover, treatment of cells with IL-21 in vitro prior to adoptive transfer results in markedly enhanced antitumor effects in vivo, conferring a distinctive differentiation program from that conferred by IL-2.[185] IL-21 is now in phase II clinical trials for cancer. In addition to its anticancer activity, IL-21 can also promote autoimmunity. Elevated IL-21 levels have been reported in the BXSB-*Yaa* mouse model of systemic lupus erythematosus,[178] and elevated IL-21 levels have been found in a subset of humans with systemic lupus erythematosus (P. Lipsky, personal communication). Elevated IL-21 has also been associated with other autoimmune processes, including in the non-obese diabetic (NOD) mouse.[181] More importantly, in mouse models of type 1 diabetes, lupus, and experimental allergic uveitis, no autoimmune disease develops on an IL-21R knockout background.[186,187,188] IL-21 unexpectedly can also be immunosuppressive via its induction of IL-10.[189,190] Consistent with this, an IL-21/IL-10/STAT3 pathway is required for normal development of memory CD8+ T cells after lymphocytic choriomeningitis virus (LCMV) infection[191]; similarly, STAT3, presumably by an overlapping mechanism is important for human T-cell memory development, as evidenced by studies in patients with autosomal dominant hyper-IgE syndrome, which is caused by dominant negative mutations in STAT3.[192] IL-21 has complex roles in viral responses. For LCMV, IL-21 is required to control chronic infection,[193] whereas IL-21 mediates the pathogenic response after infection with pneumonia virus of mice.[194] Interestingly, for hepatitis B virus, IL-21 appears to be critical in determining the age-dependent effectiveness of immune responses, wherein decreased IL-21 production in younger individuals hinders the generation of critical lymphoid responses to the virus, whereas more robust IL-21 production in adults is associated with viral clearance that

occurs in 95% of patients.[195]

The receptor for IL-21 consists of IL-21R plus γ_C.[30,44] IL-21R is most related to IL-2Rβ, and like IL-2Rβ, its expression is induced following cellular stimulation with anti-CD3 or phytohemagglutinin, and in addition, its expression is augmented in T cells following transformation with HTLV-I.[196] Both human and mouse IL-21 can act on cells of the other species. IL-21 is on human chromosome 4q26 to 4q27, while its receptor is on chromosome 16p11, immediately downstream of the *IL4R* gene.

Thus, IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 collectively exhibit partially overlapping roles related to T cells, NK cells, B cells, and mast cells, and together would be expected to play vital roles for normal development and/or function of these cellular lineages. As discussed in the following, IL-2, IL-7, IL-9, and IL-15 utilize primarily STAT5A and STAT5B; IL-4 activates primarily STAT6; and IL-21 activates STAT1, STAT3, STAT5A, and STAT5B, with STAT3 being the dominant STAT for this cytokine.[11] The fact that these six cytokines share γ_C is of particular interest, especially as the gene encoding γ_C is mutated in patients with the most common form of severe combined immunodeficiency in humans.

X-Linked Severe Combined Immunodeficiency Disease Results from Mutations in the Gene Encoding γ_C

The γ chain was originally identified as a third component of the IL-2 receptor[36] after it became clear that IL-2 receptor α and β chains alone were not sufficient to transduce an IL-2 signal. The hypothesis that the γ chain was a shared component of receptors for cytokines in addition to IL-2 was motivated from a comparison of the clinical phenotypes in humans that result from defective expression of IL-2 versus. the γ chain. In 1993, it was discovered that mutations in the gene encoding the γ chain resulted in X-linked SCID (the disease is also designated as SCIDX1).[30,197] X-linked SCID is characterized by profoundly diminished numbers of T cells and NK cells[30,45,197,198,199,200,201] (Table 25.4). Although the B cells are normal in number, they are nonfunctional, apparently due to a lack of T-cell help as well as an intrinsic B-cell defect.[45,200,202] In contrast to the profoundly decreased number of T cells in patients with X-linked SCID, IL-2-deficient patients[203,204] and mice[205] have normal numbers of T cells (the phenotypes of mice deficient in type I and type II cytokines and their receptor, JAK kinases, and STAT proteins are summarized in Table 25.15). This observation indicated that defective IL-2 signaling was unlikely to be responsible for X-linked SCID, making the finding that the gene encoding the γ chain was mutated in X-linked SCID all the more unexpected. Thus, the conundrum was why a defect in a component of a receptor would cause a more severe than a defect in the corresponding cytokine. This led to the hypothesis that the γ chain was critical for other cytokine receptors as well.[197] In this model, defective IL-2 signaling either did not contribute to the defects in X-linked SCID or these defects were explained by the simultaneous inactivation of multiple signaling pathways.[45,197] Indeed, it was found that the γ chain was also an essential component of both the IL-4 and IL-7 receptors on T cells,[37,38,39,40] leading to it being renamed as the common cytokine receptor γ chain, γ_C.[37,38] IL-9, IL-15, and IL-21 were subsequently also shown to share γ_C[30] (Fig. 25.5).

The sharing of γ_C by six different cytokine receptors revealed that X-linked SCID is a disease of defective cytokine signaling. The major deficiencies in X-linked SCID can be attributed to defects related to different cytokines. Based on the dramatically diminished T-cell

development not only in IL-7-deficient[104] or IL-7Rα-deficient[103] mice but also in *IL-7R*-deficient humans with T-B+NK+ SCID,[206,207] yet normal T-cell development in mice deficient in IL-2,[205] IL-4,[208,209] both IL-2 and IL-4,[210] IL-9,[133] IL-15,[151] IL-15Rα,[150] IL-21R,[182,184] and most if not all of the defect in T-cell development in patients with X-linked SCID can be attributed to defective IL-7 signaling.[30] In addition to profoundly diminished numbers of T cells, humans with X-linked SCID lack NK cells. As discussed previously, NK-cell development is defective in IL-15- and IL-15Rα-deficient mice, indicating that it is defective IL-15 signaling that is responsible for the defective NK-cell development in X-linked SCID.[30]

TABLE 25.4 Features of X-Linked Severe Combined Immunodeficiency

1. Absent or profoundly diminished numbers of T cells and mitogen responses
2. Absence of NK cells
3. Normal numbers of B cells, but defective B-cell responses
4. IgM can be normal but greatly diminished Igs of other classes
5. XSCID carrier females exhibit nonrandom X-inactivation patterns in their T cells and NK cells; the X-inactivation pattern is random in surface IgM-positive B cells but nonrandom in more terminally differentiated B cells.

Ig, immunoglobulin; NK, natural killer; XSCID, X-linked severe combined immunodeficiency.

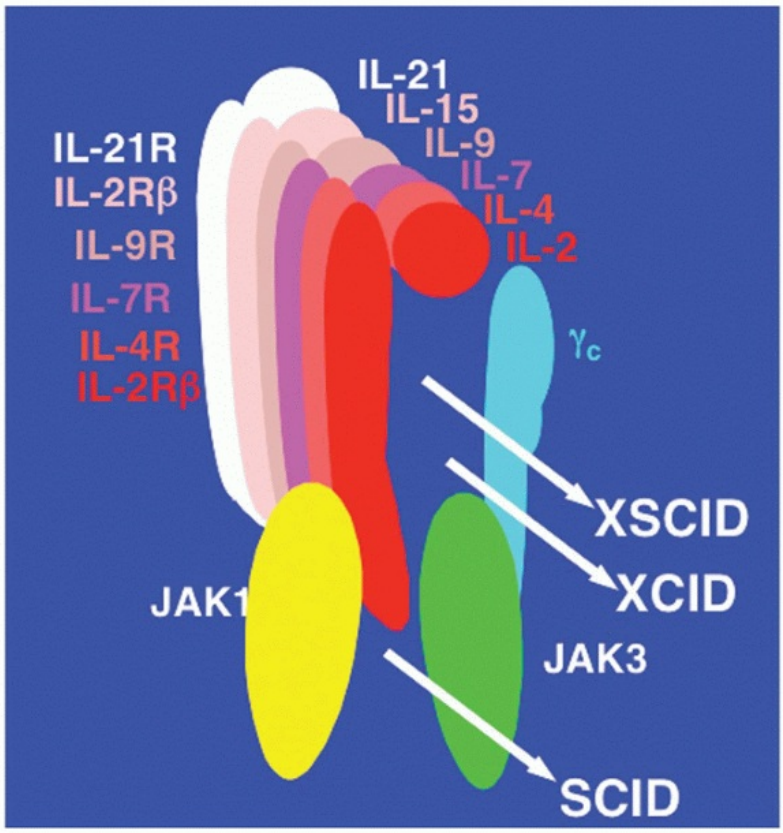

FIG. 25.5. Schematic of the Receptors for Interleukin (IL)-2, IL-4, IL-7, IL-9, IL-15, and IL-21, Showing Interactions with JAK1 and JAK3. The figure shows that IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 all share γ_C. IL-2Rα and IL-15Rα are not shown. Whereas the distinctive chains associate with JAK1, γ_C associates with JAK3. Mutations in γ_C cause X-linked severe combined immunodeficiency or more moderate forms of X-linked immunodeficiency. Mutations in JAK3 cause an autosomal recessive form of severe combined immunodeficiency (see text).

In contrast to the greatly diminished number of T cells and absent NK cells in patients with X-linked SCID, B-cell numbers are normal. This is in contrast to the greatly diminished numbers of B cells in γ_C-deficient mice[211,212] as well as mice deficient in either IL-7 or IL-7Rα, indicating that IL-7 is not required for pre-B-cell development in humans and underscoring a major difference for IL-7 in human versus mouse biology. Indeed, patients with *IL-7R*-deficient SCID have a T-B+NK+ form of SCID.[206,207] Although B cells develop in patients with X-linked SCID, they are nonfunctional. This is due in part to a lack of T-cell help (given the near absence of T cells in X-linked SCID), but a variety of data indicate an intrinsic B-cell defect as well.[30] As discussed

previously, analysis of IL-4/IL-21R double knockout mice indicate that defective signaling by IL-4 and IL-21 appear to explain the intrinsic B-cell defect in X-linked SCID.[182]

Rationale for the Sharing of γ_C

Why should there have been evolutionary pressure to maintain the sharing of γ_C, given the obvious increased risk associated with sharing a receptor component when it is mutated? There are at least two different types of models.[45,213] First, the sharing of γ_C could be a

basis for shared actions. For example, given that IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 can each act as T-cell growth factors, at least in vitro, it is possible that γ_c might couple to signal transducing molecule(s) that promote T-cell growth. Second, the sharing of γ_c might represent a means by which one cytokine using γ_c can modulate the signals of the others. To understand this model, it is important to recognize that, in contrast to antigen receptor complexes, cytokine receptor components individually are targeted to the cell surface, and the formation/stability of receptor complexes is promoted or stabilized by ligand binding, as noted in the discussion of growth hormone, wherein the second receptor monomer recognizes the combined surface of growth hormone and the first growth hormone receptor monomer[19] or for the IL-2 receptor where γ_c "sees" a combined IL-2/IL-2Rβ surface.[23] This latter finding is consistent with γ_c originally having been coprecipitated with IL-2Rβ in the presence but not in the absence of IL-2,[214] and dimerization of IL-2Rβ and γ_c is known to be required for efficient signaling.[215,216] Thus, receptor heterodimerization at a minimum is stabilized by the cytokine and physiologically may be absolutely dependent on the presence of the cytokine. In the absence of stable preformed cytokine receptor complexes between γ_c and the other receptor chains, one can envision that γ_c might be differentially recruited to different receptors based on the relative amount of a cytokine or its binding efficiency. In a situation where γ_c is limiting, a cytokine might then not only induce its own action but could also simultaneously inhibit the action of another cytokine that was less efficient at recruiting γ_c to its cognate receptor complex.

An analysis of mice deficient in IL-2,[205] IL-2Rα,[217] IL-2Rβ,[218] and γ_c[211,212] provides the interesting observation that although the mice lacking γ_c have defective signaling in six different cytokine pathways, mice deficient in IL-2, IL-2Rα, and IL-2Rβ appear to be less healthy than the γ_c-knockout mice with more markedly activated T cells and autoimmunity that is not evident in γ_c-deficient mice. This is at least in part explained by the fact that IL-2-deficient mice lack T_{reg} cells and thus develop autoimmune disease,[65] whereas γ_c-deficient mice lack T cells due to defective IL-7 signaling and thus lack effector T cells. These and other data indicate that γ_c plays a major role in regulating lymphoid homeostasis, as originally indicated.[219]

TABLE 25.5 Features of Cytokines whose Receptors Share the Common β Chain, β_c

Cytokine	Major Source	Size	Cellular Targets	Chromosome Location (h/m)	Exons
IL-3	T cells	h152/19aa m166/26 aa 22-34 kDa	Multiple lineages	5q31.1/11	5
IL-5	T cells	h139/22aa m133/21 45 kDa dimer	Eosinophils B cells (?)	5 q31.1/11	4

GM-CSF	T cells	h144/17aa m141/17aa 23 kDa	Granulocytes Macrophages	5q31.1/11	4

GM-CSF, granulocyte macrophage-colony stimulating factor; IL, interleukin.

Cytokines whose Receptors Share the Common β Chain, β_c (Interleukin-3, Interleukin-5, and Granulocyte Macrophage-Colony Stimulating Factor)

The hematopoietic cytokines, IL-3, IL-5, and GM-CSF (Table 25.5) are all synthesized by T cells and exert effects on cells of hematopoietic lineage.[220,221,222] These cytokines are vital for proliferation as well as differentiation of myeloid precursor cells. Of these three cytokines, IL-3 is the most pluripotent[221] and historically was also called multi-CSF, reflecting the large number of lineages on which it can act. It can act to promote proliferation, survival, and development of multipotent hematopoietic progenitor cells and of cells that have become dedicated to a range of different lineages, including granulocyte, macrophage, eosinophil, mast cell, basophil, megakaryocyte, and erythroid lineages. It induces a range of effects, including, for example, inducing the production off IL-4 by basophils.[223] IL-3 also can exert end-function effects, such as enhancing phagocytosis and cytotoxicity. GM-CSF is mainly restricted to the granulocyte and monocyte/macrophage lineages, but its actions are nevertheless still quite broad.[220] It is both a growth and survival factor. In addition, it can expand the number of antigen-presenting cells, such as DCs, and thereby may greatly expand the ability of the host to respond to antigen. IL-23 and RORγt can augment GM-CSF production in Th cells, whereas IL-12, IFNγ, and IL-27 negatively regulate its expression, and GM-CSF is now known to be required for the initiation of autoimmune neuroinflammation in experimental autoimmune encephalitis. Collectively, these results suggest that GM-CSF is important for encephalitogenic actions of both Th1 and Th17 cells.[224,225] GM-CSF mediates autoimmune effects at least in part by enhancing IL-6-dependent

Th17 cell development and survival.[226] Whereas IL-3 and GM-CSF can act on eosinophils, they act at much earlier stages than IL-5, presumably expanding the number of eosinophil-committed precursors cells. IL-5 stimulates the eosinophilic lineage and eosinophil release from the bone marrow and is essential for expanding eosinophils after helminth infections,[227,228] and can mediate the killing of *S. mansoni*. IL-5 can also induce Ig production in B cells activated by contact with activated Th cells in mouse systems, and IL-5 and IL-5Rα knockout mice have diminished CD5+ B1 cells and decreased thymocytes until approximately 6 weeks of age.[227,228] Interestingly, the production of IL-5 by memory Th2 cells is driven by GATA3 but downregulated by expression of eomesodermin, which interacts with GATA3. Most memory Th2 cells produce the transcription factor Eomes, but the $CD62^{lo}CXCR3^{lo}$ population has decreased Eomes and is the population of cells that produces IL-5.[229]

On cells that express receptors for more than one of these cytokines, such as eosinophilic progenitors that express receptors for IL-3, IL-5, and GM-CSF, or on mouse pre-B cells, which express receptors for IL-3 and IL-5, the signals induced are indistinguishable.[221,222] Thus, the differential lineage specificities of these cytokines are determined by the cellular distribution of their receptors rather than by fundamental differences in the signals that are induced by each cytokine. These observations are explained by studies demonstrating that each of these three cytokines has its own unique 60 to 80 kDa α chain (ie, IL-3Rα, IL-5Rα,

and GM-CSFRα),[230,231,232,233,234,235,236] but that they share a common 120 to 130 kDa β chain, β_C.[222,237,238,239] The α chains are the principal binding proteins for the cytokines, whereas the shared β_C subunit augments binding affinity but does not exhibit binding activity in the absence of the proper α chain. The α chains have relatively short cytoplasmic domains (approximately 55 amino acids long for IL-3Rα, IL-5Rα, and GM-CSFRα) and are not believed to play major roles in signaling function, whereas β_C, with its cytoplasmic domain of 432 amino acids, is the primary determinant of the signal. As a result, there is a relative compartmentalization of binding and signaling function for these cytokines, although the cytoplasmic domains of the GM-CSFRα and IL-5Rα chains (and by analogy, perhaps the IL-3Rα chain), as well as β_C, appear to be capable of at least modulating the growth signals in transfected cells.[222,240,241,242] In any case, the sharing of β_C helps to explain why the signals induced by IL-3, IL-5, and GM-CSF are similar on cells that can respond to more than one of these cytokines. The situation for the β_C family of cytokines is therefore quite different from the receptors for γ_C family cytokines, wherein the chains with the largest cytoplasmic domains (IL-2Rβ, IL-4Rα, IL-7Rα, IL-9Rα, and IL-21R) not only contribute most to signaling specificity but also are the proteins principally involved in ligand binding (note that for IL-2 and IL-15, IL-2Rα and IL-15Rα, respectively, serve important roles as well). The shared chain, γ_C, serves a vital accessory function (hence the development of X-linked SCID when the *IL2RG* gene is mutated), but it contributes less to cytokine binding and does not provide an obvious basis for signaling specificity (see subsequent discussion).

An interesting feature of the β_C family of hematopoietic cytokines is that there appears to be considerable redundancy of function so that knockout mice that lack the ability to respond to all three cytokines (GM-CSF, IL-3, and IL-5) due to deletion of β_C as well as the mouse IL-3-specific β_C-like protein (discussed in the following text) nevertheless exhibit relatively normal hematopoiesis. These observations do not minimize the potency of these particular cytokines but instead underscore a substantial redundancy for a particularly important set of functions.[221,222,243] It is also noteworthy that β_C-deficient mice exhibit defective host responses to infectious challenge, suggesting that these hematopoietic cytokines play a vital role in promoting immune function.

Cytokines whose Receptors Share gp130 (Interleukin-6, Interleukin-11, Oncostatin M, Ciliary Neurotropic Factor, Leukemia Inhibitory Factor, Cardiotrophin-1, Novel Neurotrophin-1/B Cell-Stimulating Factor-3/Cardiotrophin-Like Factor, and Interleukin-27)

There are now eight cytokines that are known to utilize gp130 as a signal transducing molecule.[244,245,246,247,248,249,250,251,252,253,254,255] Some of the properties of these cytokines are summarized in Table 25.6. This family is often referred to as the IL-6 family of cytokines and includes IL-6, IL-11, OSM, LIF, CNTF, CT-1, NNT/BSF-3/CLC, and IL-27. This group of cytokines comprises molecules with a diverse range of actions, ranging beyond the hematopoietic and

immune systems to the central nervous and cardiovascular systems, making them even more "multifunctional" than the γ_C and β_C families of cytokines, whose actions are more restricted to the lymphoid and hematopoietic systems.

TABLE 25.6 Cytokines whose Receptors Share gp130[a]

Cytokine	Chromosome Location (h/m)
IL-6	7p21/5
IL-11	19q13.3-13.4/7
LIF	22q12.1-12.2/11
OSM	22q12.1-12.2/11
CNTF	11q12.2/19
CT-1	16p11.1-11.2/7
NNT-1/BSF-3/CLC	11q13/19
IL-27	

Overlapping actions of several gp130 cytokines

	IL-6	IL-11	LIF	OSM	CNTF	CT-1
Growth of myeloma cells	+	-	+	+	+	?
Maintenance of embryonic stem cell pluripotency	-	-	+	+	+	+
Induction of hepatic acute phase proteins	+	+	+	+	+	+
Induction of cardiac hypertrophy	-	+	+	+	+/-	+
Induction of osteoclast formation	-	+	+	+	?	?
Enhanced neuronal survival/differentiaion	+	+	+	+	+	+
Inhibit adipogenesis	?	+	+	?	?	?

BSF-3, B cell-stimulating factor-3; CLC, cardiotrophin-like factor; CNTF, ciliary neurotrophic factor; CT-1, cardiotrophin-1; IL, interleukin; LIF, leukemia inhibitory factor; NNT-1, novel neurotrophin-1; OSM, oncostatin M.

[a]Most of the data in this table are derived from Yin et al.248

Note that NNT-1 can support survival of chicken embryonic and sympathetic neurons, can induce amyloid A, and analogous to IL-6 can induce B-cell hyperplasia.

IL-6 was originally identified and then cloned as a B-cell differentiation factor that stimulated terminal differentiation/maturation of B cells into antibody-producing plasma cells.[256,257,258] However, IL-6 also can exert effects for T-cell growth and differentiation (and thus is a thymocyte "comitogen"), induce myeloid differentiation into macrophages, induce acute-phase protein synthesis of hepatocytes, and exert actions on keratinocytes, mesangial cells, hematopoietic stem cells, the development of osteoclasts, and neural differentiation of PC12 cells.[250] IL-6 is also a mediator of amplified lymphocyte trafficking during febrile inflammatory responses, which is dependent on IL-6-mediated activation of L-selectin.[259] IL-6 binds to an 80 kDa IL-6 binding protein, denoted IL-6Rα, which has a comparatively short 82 amino acid long cytoplasmic domain.[257,260] This IL-6-IL-6Rα complex then interacts with and recruits the 130 kDa signal transducing molecule, gp130, which together with IL-6Rα can form a functional IL-6 receptor.[250] From a structural perspective, gp130 contains a total of six fibronectin type III modules, with the four conserved cysteine residues and the WSXWS motif being located in the second and third of these modules, starting from the N-terminus. As such, these regions are topologically positioned at greater distance external to the cell membrane than is the case for the other type I cytokine receptors discussed previously.

The IL-6 system illustrates a novel twist related to the properties of their principal binding proteins: The cytoplasmic domain of IL-6Rα is superfluous for signaling; a soluble form of the IL-6Rα extracellular domain is in fact sufficient for ligand binding and coordination with gp130, a process termed *IL-6 transsignaling*.[261] Thus, in the presence of soluble IL-6Rα and IL-6, many cell types that express gp130 but not IL-6Rα are capable of signaling in response to IL-6. It was observed that IL-6 signaling requires the dimerization of gp130 and that the overall complex containing two molecules each of IL-6, IL-6Rα, and gp130 (a dimer of a trimer or a hexamer),[32,262,263,264,265] providing a possible paradigm for the stoichiometry of subunits for other members of the IL-6 family of cytokines.[24]

IL-11 was identified as a factor produced by a stromal cell line in response to stimulation with IL-1.[266,267] It has a number of effects on hematopoiesis, particularly in combination with IL-3 and SCF. Because IL-11 exhibited "IL-6-like activities," a complementary deoxyribonucleic acid (DNA) was isolated based on the presence of IL-6-like activity in the presence of antibodies to IL-6.[268] Other actions of IL-11 include the ability to stimulate the proliferation of lymphoid and hematopoietic progenitor cells, stimulate megakaryocytic progenitors and megakaryocyte maturation, and stimulate erythroid progenitors (an action not shared by IL-6).[266,267] Overall, it acts on T cells, B cells, hematopoietic cells, epithelium, endothelial cells, and osteoclasts.[269] Like IL-6, IL-11 induces acute-phase proteins and augments antigen-specific B-cell responses, but it does not stimulate human myeloma cells.[266,267,268,270] Subsequently, adipogenesis inhibitory factor was cloned and found to be identical to IL-11,[271] revealing another action of IL-11. IL-11 is also produced by lung eosinophils and various structural cells in the lung and is expressed in patients with modest-to-severe asthma.[272] IL-11 signals via a receptor complex containing both IL-11Rα[273] and gp130.[244] Interestingly, IL-11Rα messenger RNA can be alternatively spliced to yield a form lacking the cytoplasmic domain, and like IL-6Rα, a soluble form of IL-11Rα can coordinate with IL-11 to transsignal in cells expressing gp130.[274] Studies on the stoichiometry of the IL-11 receptor complex failed to reveal dimerization of gp130 to itself or LIFRβ. Thus, assuming that it forms a hexameric receptor complex, only five of the members are known: two molecules of IL-11 and IL-11Rα, respectively, and one of gp130, suggesting that another

component may still be found.[275] IL-11 and STAT3 are expressed in gastrointestinal cancers associated with inflammation, suggesting a possible link to cancer.[269]

LIF is another multifunctional cytokine originally cloned based on the activity associated with its name.[276] LIF can suppress the differentiation of pluripotent embryonic stem cells, inhibit adipogenesis (like IL-11), and induce monocyte differentiation of the M1 murine leukemia cell line, thus mimicking a number of the actions of IL-6.[277] In addition, it exerts a number of actions in the central nervous system, and LIF was shown to be identical to cholinergic neural differentiation factor.[278] and can induce acetylcholine synthesis while simultaneously suppressing catecholamine production, thereby inducing cholinergic function while suppressing noradrenergic function.[278] LIF has been shown to be essential for embryo implantation.[279] LIF binds to a receptor (LIFRβ) that is structurally related to gp130,[280] but the functional LIF receptor (LIFR) receptor requires the heterodimerization of LIFRβ and gp130 as well.[246] Interestingly, whereas IL-6 promotes Th17 differentiation, this is inhibited by LIF, apparently based on LIF's ability to activate ERKs and to augment the expression of SOCS-3, which can inhibit STAT3 activation.[281] Interestingly, LIF can also promote the differentiation of T_{reg} cells and may exhibit therapeutic potential in multiple sclerosis.[282] LIF maintains mouse embryonic stem cells, but LIF is not capable of maintaining human embryonic stem cells or mouse epiblast stem cells in the pluripotent state.[283]

CNTF was discovered based on its ability to promote neuronal survival.[284,285] CNTF signals through a receptor comprising LIFRβ and gp130 but requires a specific binding protein,[286,287] now denoted CNTF receptor (CNTFR)α. Interestingly, CNTFRα lacks transmembrane and cytoplasmic domains and instead is a GPI-linked receptor molecule. CNTFRα appears to provide a receptor-cytokine surface with which gp130 and LIFRβ can interact. Thus, CNTF is like IL-6 in that each requires initial binding to a receptor component (CNTFRα or IL-6Rα) that does not require its own cytoplasmic domain for signaling. Whereas IL-6 signaling involves homodimerization of gp130, CNTF signaling involves the heterodimerization of LIFRβ and gp130. In fact, the functional CNTFR appears to be a hexameric structure containing two molecules of CNTF, two of CNTFRα, and one each of gp130 and LIFRβ.[288] The receptor is expressed largely within the nervous system and in skeletal muscle, accounting for largely restricted actions of CNTF.[286]

OSM is a growth regulator that was originally identified based on its ability to inhibit the growth of A375 human melanoma cells.[289,290] OSM is a potent growth factor for Kaposi sarcoma in patients with acquired immunodeficiency syndrome.[291,292] Not only OSM can bind directly to gp130 and signals through a receptor combination of gp130 and LIFRβ[246] but also has an alternative receptor comprising a specific OSM receptor subunit (OSMRβ) and gp130.[293] These are now known as the type I and type II OSM receptors (OSMRs), respectively. OSM can enhance the development of both endothelial cells and hematopoietic cells, possibly by increasing hamangioblasts, a common precursor for endothelial and hematopoietic cells.[251]

CT-1 was initially isolated based on its actions on cardiac muscle cells.[294] However, it is now clear that it is a multifunctional cytokine with hematopoietic, neuronal, and developmental effects, in addition to its effects on cardiac development and hypertrophy.[295,296] Like OSM and LIF, CT-1 can also signal through a heterodimer of LIFRβ and gp130.[249] Interestingly, the CT-1 receptor on motor neurons may involve a third receptor

component, possibly GPI linked.[297,298]

NNT-1/BSF-3, like CNTF, can also support the survival of chicken embryonic sympathetic and motor neurons.[253] Interestingly, in mice, NNT-1/BSF-3 can augment the effects of IL-1 and IL-6 and is a B-cell-stimulating factor (hence the term BSF-3). The NNT-1 receptor contains LIFRβ and gp130.[253] NNT-1 is also known as CLC, and this forms a complex with a soluble receptor protein known as cytokine-like factor-1. Together, this complex is a second ligand for CNTFR.[299] It appears that CLC can also interact directly with soluble CNTFR to form a related cytokine.[254]

IL-27 is an IL-6-related cytokine[300] that represents a dimer of the p28 protein (also known as IL-30) and EB13 (Epstein-Barr virus-induced gene 3) (also known as IL-27B), which can induce proliferation of naive CD4+ T cells. p28 can exist by itself independently of EB13 and is capable of antagonizing gp130-mediated signaling by IL-6, and indeed, overexpression of p28 in transgenic mice prevents normal development of germinal centers and antibody production.[301] Together with IL-12, IL-23, CLC/cytokine-like factor-1, and CLC/soluble CNTFR, this is one of five cytokines that represent dimers including a type I cytokine and a soluble receptor-like protein. IL-27 signals via gp130 and the WSX-1/TCCR receptor,[300] which is discussed in the section on diseases of cytokine receptors and related molecules. IL-27 has proinflammatory and anti-inflammatory effects. Although it was suggested to promote Th1 responses, it is clear that it can also antagonize such responses, and IL-27 can promote effector responses of both CD4+ and CD8+ T cells, of NK cells, and it additionally stimulates mast cells. The anti-inflammatory effects of IL-27 are indicated by the absence of WSX-1 resulting in increased mast cell and macrophage responses.[302,303]

Thus, eight cytokines (IL-6, IL-11, LIF, CNTF, OSM, CT-1, NNT-1/BSF-3, and IL-27) all have receptors that are dependent on gp130.[304] These can be divided into two sets of cytokines: those known to not require LIFRβ (IL-6, IL-11, and IL-27) and those that use both gp130 and LIFRβ (LIF, CT-1, OSM, CNTF, and NNT-1/BSF-3) (Table 25.7), with OSM having two forms of receptors, each of which contains gp130 but only one of which contains LIFRβ. When cytokines share essentially the same receptor, one can hypothesize that two cytokines might exert identical actions on cells that can respond to both cytokines. It is clear that the presence of IL-6Rα, IL-11Rα, and CNTFRα (either on the cell surface or as a soluble receptor form, discussed subsequently) determines whether a cell can respond to IL-6, IL-11, and CNTF. This raises the interesting question as to whether functional homologues of these proteins will also exist for LIF, OSM, CT-1, NNT-1/BSF-3, and IL-27.

TABLE 25.7 Composition of Receptors for the Interleukin-6 Family of Cytokines

Cytokines whose receptors do not contain LIFRβ	
IL-6	IL-6Rα + gp130
IL-11	IL-11Rα + gp130
OSM	OSMRβ + gp130
Cytokines whose receptors contain LIFRβ	
LIF	LIFRβ + gp130

OSM	LIFRβ + gp130
CNTF	CNTFRα + LIFRβ + gp130
CT-1	LIFRβ + gp130 + ?CT1Rα
NNT-1/BSF-3 /CLC + CLF-1	CNTFRα + LIFRβ + gp130
CLC + soluble CNTFRα	LIFRβ + gp130
Cytokines whose receptors contain OSMRβ	
OSM	OSMRβ + gp130
IL-31	IL-31R + OSMRβ

BSF-3, B cell-stimulating factor-3; CLC, cardiotrophin-like factor; CLF-1, cytokinelike factor-1; CNTF, ciliary neurotrophic factor; CNTFR, CNTF receptor; CT-1, cardiotrophin-1; IL, interleukin; LIF, leukemia inhibitory factor; NNT-1, novel neurotrophin-1; OSM, oncostatin M.

Note that the sharing of CNTFRα by CNTF and the dimeric NNT-1/BSF-3/CLC - CLF-1 ligand helps to explain why the phenotype in CNTF-/- mice is less severe than that found in CNTFRα-/- mice.

Significance of the Sharing of Receptor Chains

Interestingly, γ_C, β_C, and gp130 all contribute to signaling, but none of these shared cytokine receptor proteins has primary binding activity for any known cytokine. Instead, they each increase binding affinity in the context of the primary binding protein for each cytokine. Consequently, the capacity of a cell to respond to a given cytokine is determined by the unique binding chain(s), but signaling pathways can be shared.

Other Receptors with Similarities to gp130 (Granulocyte-Colony Stimulating Factor Receptor, OB-R, Interleukin-12Rβ1, Interleukin-12Rβ2, and Interleukin-31R)

As noted previously, LIFRβ and OSMRβ bear some similarities to gp130.[293] In addition, the G-CSF receptor, the leptin receptor (also denoted OB-R, for obesity receptor), IL-12/IL-23 receptor components, and IL-31R all resemble gp130. The amino acid identity among these different receptors, compared pairwise, ranges from 18% to 32%, with LIFRβ and OSMRβ being the most similar. Although G-CSF is granulocyte-colony stimulating factor, it may have

a broader role. For example, G-CSF has been shown to stimulate myoblast proliferation and thereby to affect skeletal muscle formation,[305] indicating broad pleiotropic actions by this cytokine.

Leptin

Leptin is the product of the obesity (ob) gene, an adipose tissue-derived cytokine that plays a

role in body weight homeostasis.[306,307,308] Additionally, leptin affects thymic homeostasis, increasing thymocyte number and having antiapoptotic effects in the thymus and periphery. It is proinflammatory, promoting Th1 differentiation, and augmenting the production of TNF-α, IL-1, and IL-6 by monocytes/macrophages.[308] The leptin receptor, OB-R, was cloned and found to be most closely related to the gp130 signal transducer, G-CSF receptor, and LIFRβ .[309] Interestingly, this receptor is encoded by the "diabetes gene," which is mutated in db/db mice.[310]

Interleukin-12, IL-23, and IL-35

As noted previously, IL-12 is the major inducer of Th1 cells. IL-12 is primarily produced by phagocytic cells in response to bacterial and intracellular parasites, such as *Toxoplasma gondii*, but it is also produced by other antigen-presenting cells, such as B cells.[311] IL-12 potently induces the production of IFNγ by NK cells and T cells and is also a growth factor for preactivated but not resting NK and T cells. IL-12 was originally discovered as NK cell stimulatory factor.[312] IL-12 can also induce the production of IL-2, IL-3, GM-CSF, IL-9, TNF-α, and M-CSF, although inducing IFNγ is perhaps its most important known action.[311,313,314] As is discussed in the section on immunodeficiency diseases, IL-12 is essential for the proper clearing of mycobacterial infections. It is interesting that Th2 cells do not respond to IL-12; the lack of responsiveness of these cells to IL-12 results from their loss of expression of the IL-12Rβ2 subunit of the IL-12 receptor.[315] Apparently, IL-4 inhibits IL-12Rβ2 expression, whereas IL-2[74] and IFNγ[315] induce its expression. The abilities of mice to survive infections is critically linked to the Th patterns of cytokines. For example, the ability to survive *T. gondii* infection is dependent on IFNγ/IL-12 production (a Th1 pattern).[83]

IL-12 can be thought of as having vital roles in both innate immunity and acquired immune responses. It is rapidly produced by NK cells and then T cells in response to antigens or foreign pathogens. This rapid response facilitates the activation of first-line defense against infections. In addition, however, IL-12 is also required for the subsequent differentiation of specialized T-cell populations, including its STAT4-dependent priming of Th1 cells for optimal production of IFNγ and IL-2. IL-12 can act synergistically with hematopoietic growth factors, such as IL-3 and SCF, to support the proliferation and survival of hematpoietic stem cells.[311] Structurally, IL-12 is a covalently linked dimer of 35 (IL-12A) and 40 (IL-12B) kDa peptides[311]; thus, successful production of IL-12 requires that a cell transcribe both the p35 and p40 genes.[316] Interestingly, whereas p35 bears sequence similarity to IL-6 and G-CSF, p40 is homologous to the extracellular domains of IL-6Rα, CNTFRα, and G-CSF receptor and bears some of the features typical of type I receptors, including four conserved cysteines, a conserved tryptophan, and a WSEWAS motif, which has similarity to the typical WSXWS motif.[311] Moreover, as both IL-12 receptor (IL-12Rβ1 and IL-12Rβ2) chains bear some similarity to gp130,[312,316,317] one can think of p40 as a functional homologue of the soluble p80 IL-6Rα chain. Thus, for this cytokine, part of the "receptor" has become part of the cytokine. Interestingly, all cells that produce IL-12 synthesize much more p40 than p35, suggesting that the careful control of signaling is at the level of the "primordial" p35 cytokine part of IL-12. p40 is on human chromosome 5q31 to 5q33 while p35 is on 3p12 tp 3p13.2.[311] As noted previously, it is interesting that IL-2 induces expression of IL-12Rβ1 and IL-12Rβ2.

IL-23 is similar to IL-12 in that it also contains p40.[318] However, rather than also containing p35, IL-23 is a dimer of a p40 and p19 (IL-23A). IL-23 signals via a receptor that contains IL-12Rβ1 but not IL-12Rβ2.[319] Instead, another receptor chain, denoted IL-23R, is the second component of the IL-23R[320]; both IL-12Rβ2 and IL-23R are located on chromosome 1 within

150 kb of each other.[320] Both IL-12 and IL-23 activate JAK2 and TYK2. IL-12 and IL-23 can activate STAT1, STAT3, STAT4, and STAT5. STAT4 is the dominant STAT protein activated by IL-12.[320] Interestingly, as compared to human IL-23R, mouse IL-23R contains a 20 amino acid duplicated region that spans the WQPWS motif. IL-23 appears to play a vital role in the maintenance, rather than in the initial differentiation of Th17 cells (IL-17-producing cells), and IL-23 is essential for resistance to certain diseases, such as EAE, which were originally believed to be Th1-mediated diseases, as elimination of IL-23 by eliminating either the p40 subunit shared by IL-12 and IL-23 or by eliminating p19 confers resistance to EAE.[175,321] Whereas IL-23 promotes Th17 cell numbers, IL-27 can negatively regulate their development.[321] In the CD40-mediated model of inflammatory bowel disease, IL-12 p35 secretion controlled wasting disease and serum cytokine production but did not affect mucosal pathology, which instead was associated with IL-23/p19.[322] Interestingly, IL-23R has been identified as an inflammatory bowel disease gene,[323] and IL-23 can drive intestinal inflammation via direct actions on T cells.[324] Separate from Th17 cells, a population of innate lymphoid cells that produce IL-17, IL-22, and IFNγ in response to IL-23 have been identified as the mediators of inflammatory bowel disease.[325] IL-23 and its receptor are nevertheless critical for the terminal differentiation of Th17 cells.[169,326] IL-27 is a related cytokine (discussed previously), but it can act as an inhibitor of Th1 responses associated with intracellular infections such as *T. gondii*. Whereas host defense to *T. gondii* is dependent on IL-12 and IFNγ, IL-27-deficient mice control the parasite replication but develop a lethal inflammatory disease that is dependent on CD4+ T cells. Additionally, IL-27 can inhibit Th2 actions.[303]

IL-35 is produced by T_{reg} cells and plays a role in immunosuppression. It is a heterodimer of IL-12A (p35) and IL-27B (EBI3).[327] IL-35 treatment of naive mouse or human T cells induces regulatory cells that have been called iTR35 cells[328] and promote tolerance and tumor progression.

Interleukin-31

IL-31 is a four α-helical bundle cytokine that fits into the greater IL-6 extended family in that its receptor consists of IL-31RA and the OSMRβ.[329] IL-31R is a gp130-like type 1 receptor, with four splice variants. IL-31 is produced primarily by activated T cells and when overexpressed results in pruritis, alopecia, and skin lesions, indicating a potential role in dermatitis.[329,330]

Other Examples of Shared Receptor Molecules

Interleukin-7 and Thymic Stromal Lymphopoietin Share Interleukin-7 Receptor α Chain

In addition to IL-7, a second stromal factor, TSLP has been identified that shares at least some actions with IL-7.[11,331,332,333] The TSLP receptor is a heterodimer of TSLPR and IL-7Rα.[334,335] Interestingly, TSLPR is 24% identical to γ_c, making it the cytokine receptor most like γ_c.[334] Human and mouse TSLP share only 43% amino acid identity, and human and mouse TSLP receptors share only 39% identity.[336] This is very low for human and mouse orthologues of cytokine receptors, for example, human and mouse γ_c are 70% identical.[337] In addition to their wide sequence divergence, mouse and human TSLP were originally suggested to substantially differ in their actions. Mouse TSLP was first reported to be a B-cell differentiation factor that is important for the development of IgM+ immature B cells from pre-

B cells and to also be a weak thymic comitogen. In contrast, human TSLP appeared not to exert effects on these lineages but was found to be an epithelial-derived cytokine that potently activated DCs related to Th2 allergic responses, an action not then known to be shared by mouse TSLP.[338,339,340] However, it is now clear that mouse TSLP can also activate DCs and that it plays a critical role in both atopic disease and asthma in mouse models, and that these effects of TSLP are mediated via actions on both DCs and CD4+ T cells.[341,342,343,344,345,346,347] TSLP can also promote immunity to helminth parasites,[333] and TSLP is also important for mucosal healing in the dextran sulfate sodium-induced colitis model.[348] Interestingly, human TSLP is expressed by Hassall corpuscles[349] and was suggested to promote selection of T_{reg} cells in human thymus, thus contributing to central tolerance.[350] It is striking, however, that mice lacking TSLP receptor have normal numbers of T_{reg} cells, indicating that TSLP is not absolutely essential for this function, and that other molecules can at least substitute for TSLP. Indeed, IL-7 is such a molecule.[350a] TSLP is now known to be produced by a range of cell types, including epithelial cells, fibroblasts, keratinocytes, stromal cells, basophils, mast cells, and DCs,[11] and to in turn act on multiple lineages, including DCs, CD4+ and CD8+ T cells, mast cells, NKT cells, eosinophils, and B cells.[11,333,351] Interestingly, TSLP promotes Th2 differentiation and has been shown to promote metastasis in breast cancer and pancreatic cancer.[352,353,354] From a signaling perspective, whereas IL-7 activates JAK1 and JAK3, TSLP activates JAK1 and JAK2, making it the only type 1 cytokine to use this combination of JAK kinases to activate STAT5.[347] Although IFNγ also uses JAK1 and JAK2, it instead activates STAT1.[355]

Two Types of Interleukin-4 Receptors, One of which also Responds to Interleukin-13

As detailed previously, on T cells, IL-4 acts through a receptor comprising IL-4Rα and γ_C (the type I IL-4 receptor)[38,39]; however, IL-4 can also signal through type II IL-4 receptors comprising IL-4Rα and IL-13Rα1 but not γ_C.[356] IL-13 is another cytokine that shares some actions with IL-4 and was originally described as a T-cell-derived cytokine capable of inhibiting inflammation,[357] although it is now clear that other cells such as NK cells and mast cells can also produce IL-13. IL-13 can induce identical signals to IL-4 on non-T cells that respond to IL-4 but lacks effects on mature T cells, as these cells do not bind IL-13.[358,359] The shared actions of IL-4 and IL-13 include the ability to 1) decrease expression of inflammatory cytokines, 2) induce major histocompatibility complex class II expression, 3) induce CD23 expression and IgE production by B cells in humans, 4) inhibit IL-2-induced proliferation of chronic lymphocytic leukemia cells of B-cell origin, and 5) costimulate with anti-CD40 antibodies. This is explained by the observation that the type II IL-4 receptor consists of IL-4Rα plus IL-13Rα1,[360,361] with both IL-4 and IL-13 inducing indistinguishable signals on cells expressing this receptor. Interestingly, IL-4 binds primarily to IL-4Rα and IL-13 binds primarily to IL-13Rα1. This situation may be analogous to the situation for LIF, CT-1, and OSM, which can all act through receptors containing LIFRβ and gp130 but differ in their abilities to directly interact with each of these receptor proteins. An additional IL-13 binding protein, IL-13Rα2, has much higher binding affinity for IL-13 than does IL-13Rα1.[362] IL-13Rα2 is nonfunctional in terms of signaling and instead acts as a “decoy” receptor.

Although IL-13 was originally believed to be substantially redundant with IL-4, it has important distinctive actions as well. IL-13 may be vital in asthma, as blocking IL-13 can inhibit pathophysiologic changes of asthma.[363,364] It also is clear that IL-13 regulates eosinophilic infiltration, airway hyperresponsiveness, and mucus secretion, and that it is a potent mediator

of fibrosis.[357] Moreover, IL-13 that is produced by innate natural helper cells in the lung contributes to asthma.[365] The phenotype of IL-13 knockout mice suggested a role for IL-13 the ability to expel helminths,[366] and it is clear that IL-13 specifically can modulate resistance to intracellular organisms, including *Leishmania major* and *Listeria monocytogenes*.[357] IL-13 has also been identified as a factor that is secreted by and can stimulate the growth of Hodgkin and Reed-Sternberg cells.[367]

Although IL-4 and IL-13 are both critical for host defense to helminths, the use of reporter mice revealed that Th2 cells produce both cytokines. Tfh cells in lymph nodes as well as basophils make IL-4, whereas innate helper type 2 cells secrete IL-13. Thus, although both are produced during helminth infection, there are distinctive sites of production, correlating with distinctive roles.[368]

An Example of Multiple Affinities of Binding for a Single Cytokine: Three Classes of Interleukin-2 Receptors

Although cytokines typically signal via a single class of highaffinity cell surface receptor, more complex situations exist.

The IL-2 system provides the very interesting illustration of a system with three classes of affinities of receptors (Table 25.8). In addition to the high-affinity receptor (IL-2Rα + IL-2Rβ + γ_c, $K_d \approx 10^{-11}$ M), there are both low-affinity (IL-2Rα alone, $K_d \approx 10^{-8}$ M) and intermediate-affinity (IL-2Rβ + γ_c, $K_d \approx 10^{-9}$ M) receptors.[29,50] Low- and high-affinity receptors are expressed on activated lymphocytes, whereas intermediate-affinity receptors are found on resting lymphocytes, particularly on NK cells. Both intermediate- and high-affinity receptors can signal, suggesting that IL-2Rβ and γ_c are necessary and sufficient for signaling, in keeping with the theme of dimerization indicated previously. Given that the intermediate-affinity form is functional, what then is the rationale for having a high-affinity IL-2 receptor that also contains IL-2Rα? This is a particularly important question in view of the fact IL-2Rα has an extremely short cytoplasmic domain that does not appear to play a role in signaling. The importance of IL-2Rα is clearly demonstrated by the severely abnormal phenotype of IL-2Rα-deficient mice, which exhibit autoimmunity, inflammatory bowel disease, and premature death,[217] and by the observation that IL-2Rα mutations can cause an autoimmune syndrome in humans as well.[369] A clue to the importance of IL-2Rα comes from the kinetics of association of IL-2 with each chain. Although the IL-2Rα appears to lack a direct signaling function, it has a very fast on-rate for IL-2 binding.[370] Thus, the combination of this rapid onrate with the slow off-rate from IL-2Rβ/γ_c dimers results in high-affinity binding that is vital for responding to the very low concentrations of IL-2 that are physiologically present in vivo. Moreover, as activated T cells express approximately 10 times as many low-affinity than high-affinity receptors, IL-2Rα may serve as an efficient means of recruitment and concentration of IL-2 on the cell surface, allowing more efficient formation of IL-2/IL-2Rβ/γ_c signaling complexes.

TABLE 25.8 Classes of Interleukin-2 Receptors

Affinity	K_d	Where Expressed	Composition	Functional
	10^{-8}			

Low	10^{-8} M	Activated cells	IL-2Rα	No
Intermediate	10^{-9} M	Resting cells	IL-2Rβ and γ_C	Yes
High	10^{-11} M	Activated cells	IL-2Rα, IL-2Rβ, and γ_C	Yes

IL, interleukin

As noted previously, IL-2Rα is not a type I cytokine receptor and in fact has homology to the recognition domain of complement factor B.[371] Subsequently, the IL-15 receptor α chain was shown to also have a similar structure to IL-2Rα,[155] with both IL-2Rα and IL-15Rα having what are called "sushi" domains, which contribute to ligand binding. The fact that IL-2 and IL-15 both have related α chains is consistent with the close relationship between IL-2 and IL-15, and that the receptors for both IL-2 and IL-15 contain both IL-2Rβ and γ_C.

As IL-2Rα cannot transduce a signal by itself, the detection of IL-2Rα on the cell surface does not necessarily reflect IL-2 responsiveness. Because IL-2Rα was discovered before IL-2Rβ and γ_C, many papers in the literature have evaluated IL-2 receptor expression based on IL-2Rα expression alone, and this may not reflect IL-2 responsiveness. IL-2Rα is also expressed on a subpopulation of double negative thymocytes, but it remains unclear if IL-2 physiologically acts on these cells. Each of the components of the IL-2 receptor is located on a different chromosome: Human IL-2Rα is located on chromosome 10p14 to 10p15,[372] IL-2Rβ is at 22q,[373,374] and γ_C is at Xq13.1,[197] while the mouse homologues are located at chromosomes 2, 15, and X.

Erythropoietin, Thrombopoietin, and Stem Cell Factor

Epo was the first cytokine that was biochemically purified and is vital for erythropoiesis, whereas thrombopoietin is critical for thrombopoiesis. These cytokines each bind to receptors that are homodimers.[21,375] Interestingly, Epo signaling may depend in part on the functional cooperation of the Epo receptor and c-kit, the receptor for SCF.[376] This latter receptor has intrinsic tyrosine kinase activity and is not a type I cytokine receptor. Epo was the first cytokine with demonstrated clinical efficacy, for example, in renal insufficiency. Although it is dominantly associated with erythrocyte production, Epo receptors have been found more broadly on immune cells. Recently, Epo has been shown to have effects on a number of cell types, blocking NF-κB p65 and resulting in inhibition of the induction of TNF-α and inducible nitric oxide synthase in activated macrophages, with diminished control of *Salmonella* infection, whereas in a model of chemical-induced colitis, such inhibition of NF-κB-dependent immune modulators limits tissue damage and disease severity.[377] It will therefore be important to determine the full scope of immunologic actions that are mediated by Epo.

CYTOKINE AND CYTOKINE RECEPTOR PLEIOTROPY AND REDUNDANCY

It is well recognized that many cytokines exhibit the phenomena of cytokine "pleiotropy" and "redundancy."[304] Cytokine pleiotropy refers to the ability of a cytokine to exert many different types of responses, often on different cell types, whereas cytokine redundancy refers to the fact that many different cytokines can induce similar actions. One set of cytokines that exhibit cytokine pleiotropy is the γ_C family of cytokines. For example, IL-2 can induce T-cell growth,

augment B-cell Ig synthesis, increase the cytolytic activity of lymphokineactivated killer and NK cells, and play an essential role in mediating activation-induced cell death; IL-4 can induce B-cell growth and Ig class switch; and IL-7 not only plays a major role in thymocyte development but also can stimulate mature T cells, and at least in the mouse, can act as a pre-B-cell growth factor. The gp130 family cytokines also exhibit broad actions. For example, IL-6 exerts effects ranging from that of

a comitogen for thymocyte activation to that of a mediator of the acute-phase response in liver. Regarding cytokine redundancy, it has already been highlighted that IL-2, IL-4, IL-7, and IL-15 receptors contain γ_C can act as T-cell growth factors, and that IL-3 has actions that overlap with IL-5 and GM-CSF.

The recognition that cytokines not only have overlapping actions but also share receptor components, led to the concepts of "cytokine receptor pleiotropy" and "cytokine receptor redundancy."[304] The first of these terms can be defined by the ability of a single cytokine receptor subunit to function in more than one receptor. Thus, examples include the sharing of γ_C, β_C, gp130, IL-4Rα, LIFRβ, and OSMRβ, as summarized previously, as well as the sharing of IL-2Rβ by IL-2 and IL-15 receptors, the sharing of IL-4Rα and IL-13Rα in type II IL-4 receptors and IL-13 receptors, and the sharing of IL-7Rα by the IL-7 and TSLP receptors. Another way of viewing receptor pleiotropy is that certain receptor chains are useful "modules" that function in more than one context.

The final term, cytokine receptor subunit redundancy, is the one with fewest examples. There is one well-documented example in mice but not in humans. IL-3 signals through IL-3Rα plus either β_C or an alternative unique IL-3Rβ that shares 91% amino acid identity with β_C and appears to be a completely functionally redundant protein for IL-3 signaling, but IL-3Rβ cannot substitute for β_C in the context of IL-5 or GM-CSF signaling.[239] Other potential examples exist. For example, in type I and type II IL-4 receptors, IL-4Rα coordinates with either γ_C or IL-13Rα1, respectively, and there are two types of OSM receptors, both of which contain gp130, but one of which contains a specific OSM receptor while the other contains LIFRβ. What remains unknown, however, is whether the signals mediated by these different types of receptors are truly identical so that there is redundancy, or whether there are distinctive features to the signals that IL-4 and OSM induce via the different receptors. Indeed, mice lacking IL-13Rα1 have exacerbated Th2 responses and is essential for allergen-induced airway hyperreactivity, suggesting that type 2 IL-4 receptor signaling (either via IL-4 or IL-13) is not identical to that mediated by the type 1 IL-4 receptor (via IL-4).[378]

In addition to these examples related to type I cytokines, the IL-10 subfamily of type II cytokines is interesting in that IL-10Rβ (IL-10R1), IL-20Rα (IL-10R1), IL-20Rβ (IL-20R2), and IL-22Rα (IL-22R) are each shared receptor components, collectively affecting signaling in response to IL-10, IL-19, IL-20, IL-22, and IL-24.[304,379] Specifically, IL-10 signals via a receptor containing IL-10R1 and IL-10R2, IL-19 signals via a receptor containing IL-20R1 and IL-20R2, IL-20 signals via receptors containing IL-20R2 and either IL-20R1 or IL-22R, IL-22 signals via receptors containing IL-22R and IL-10R2, and IL-24 signals through receptors containing IL-20R2 plus either IL-20R1 or IL-22R. Two other IL-10 family members, IL-28 and IL-29, both signal via IL-28R + IL-10R2.[380] Interestingly, IL-10 is believed to be a dimer; IL-26 may also be a dimer, but the other family members are monomers.[379]

SOLUBLE RECEPTORS

Soluble forms of many cytokine receptors have been identified, including those for IL-1, IL-2, IL-4, IL-5, IL-6, IL-7, IL-13Rα2, GM-CSF, type I and type II IFNs, IL-22, and TNF.[381,382,383] As is clear from this list of cytokines, soluble receptors are not restricted to receptors for type

I cytokines, and in the case of IL-2, the principal soluble receptor protein is IL-2Rα, which is not a type I cytokine receptor. Soluble receptors can be created by alternative splicing that truncates the protein N-terminal to the transmembrane domain, resulting in a secreted protein rather than a membrane-anchored membrane in the case of IL-4Rα, IL-5Rα, IL-6Rα, IL-7Rα, IFNAR-2, and GM-CSFRα. Alternatively, they can be created by proteolytic cleavage of the membrane receptor as is found for the receptors for IL-2Rα and TNFRI and TNFRII[382] (Table 25.9). Although it is conceivable that a distinct gene might encode the soluble forms of a receptor, no examples have been reported. In the cases where proteolytic cleavage occurs, the identity of the proteases has not been identified. The major questions related to these soluble receptors are as follows: 1) Do they have physiologic or pathophysiologic functions? 2) How do their affinities compare to the corresponding cell surface receptor? 3) Do they have diagnostic, prognostic, and therapeutic applications?

Unfortunately, there is little information available on the in vivo role of soluble receptors. In general, when analyzed using in vitro studies, soluble receptors can compete with their corresponding cell surface receptors, thereby serving negative regulatory roles. For example, this appears to be the case for the IL-22 soluble receptor. However, soluble IL-6Rα exerts an agonistic role because, as summarized previously, IL-6 signaling occurs equally well via gp130 when the soluble rather than transmembrane form of IL-6Rα interacts with IL-6. Nevertheless, a mutated form of IL-6Rα that cannot interact with gp130 but still binds IL-6 can effectively inhibit the actions of IL-6.[384] In the case of IL-2Rα, there is no reported physiologic function for soluble IL-2Rα, as the affinity of the released receptor is, as expected, similar to that of the low-affinity receptor ($K_d \approx 10^{-8}$ M), making it unlikely to effectively compete with the high-affinity cell surface receptor ($K_d \approx 10^{-11}$ M). However, this and other soluble receptors could serve as cytokine carrier proteins and potentially could increase stability of a cytokine by protecting it from proteolysis.[382] This theoretically could be similar to the role of IL-2/anti-IL-2 conjugates in exhibiting higher activity.[385] Moreover, there are potential diagnostic and prognostic uses for measuring the level of shed receptors (Table 25.10).

TABLE 25.9 Soluble Cytokine Receptors

Generated by Alternative Splicing	Generated by Proteolytic Cleavage of Mature Receptor
sIL-4Rα	sIL-2Rα
sIL-5Rα	sTNFR
sIL-6Rα	
sIL-7Rα	
sGM-CSFRα	
sIFNAR-2	

GM-CSF, granulocyte macrophage-colony stimulating factor; IL, interleukin; TNFR, tumor necrosis factor receptor.

TABLE 25.10 Soluble Interleukin-2 Receptors in Human Disease

Malignancies
Hematologic
Adult T-cell leukemia
Hairy cell leukemia
Acute lymphocytic leukemia
Chronic lymphocytic leukemia (B cell)
Acute myelogenous leukemia
Chronic myelogenous leukemia (especially in blast crisis)
Malignant lymphomas
Hodgkin disease
Non-Hodgkin lymphomas
Nonhematologic
Adenocarcinoma of lung, breast, pancreas
Small cell bronchogenic carcinoma
Ovarian, cervical, and endometrial cancers
Nasopharyngeal carcinoma
Melanoma
Infections
Human immunodeficiency virus
Tuberculosis
Rubeola

Infectious mononucleosis
Other diseases
End-stage renal disease
Rheumatoid arthritis
Systemic lupus erythematosus
Scleroderma
Sarcoidosis
After transplantation
After interleukin-2 administration

In adults, the mean sIL-2Rα levels are 280 ± 161 units/mL (levels tend to be higher in pediatric populations). The situations where the levels exceed 5000 units/mL are adult T-cell leukemia, hairy cell leukemia, chronic myelogenous leukemia, and after interleukin-2 administration. The situations where levels are between 1000 and 5000 units/mL include acute myelogenous leukemia, chronic lymphocytic leukemia, non-Hodgkin lymphomas, acquired immunodeficiency syndrome associated with Kaposi sarcoma, tuberculosis, rubeola, and end-stage renal disease. Data are from Kurman et al.381 and Fernandex-Botran et al.382

INTERFERONS (TYPE II CYTOKINES) AND THEIR RECEPTORS

IFNs represent an evolutionarily conserved family (Table 25.11) of cytokines that are related to the IL-10 family of type II cytokines. IFNs were discovered in 1957 on the basis of their antiviral activity and were the first cytokines that were discovered.[386] IFNs are known as either type I or type II IFNs,[387,388,389,390,391,392,393,394,395,396] where type I interferons include IFNα (originally known as leukocyte IFN) and IFNβ (originally known as fibroblast IFN), and IFNε, IFNκ, IFNω, IFNδ, and IFNτ. IFNδ and IFNτ are absent in humans. IFNω is closely related to the IFNαs and was formerly designated as an IFNα. There are multiple (at least 12) IFNαs in mice and humans. In contrast, the other type I IFNs, IFNβ and IFNω, are each encoded by single human and mouse genes near the IFNα cluster, and in addition, there are multiple pseudogenes most closely related to IFNα and IFNω. The type I IFNs are clustered on human chromosome 9 and mouse chromosome 4. Type II interferon is IFNγ,[314] which is encoded by a single gene on human chromosome 12 and mouse chromosome 10. IFNα/β is produced after viral infection in many cell types, although plasmacytoid DCs appear to be the largest producers of IFNα/β. These type I IFNs inhibit viral replication and induce the apoptosis of virally infected cells. In addition, IFNα/β mediate the activation of macrophages and NK cells, and they additionally affect the proliferation and survival of CD8+ T cells.

TABLE 25.11 Type II Cytokines

		Chromosomal Location (h/m)
Type I IFNs		
IFNα	Many genes	9p22/4
IFNβ	Single gene	9p21/4
IFNω	Single gene	9p21/4
IFNτ	Many genes	
Type II IFN		
IFNγ	Single gene	12q14/10
IL-10 family cytokines		
IL-10	Single gene	1q31-32/1
IL-19	Single gene	1q32/1
IL-20	Single gene	1q32/1
IL-22	Single gene	12q14-15/10
IL-24	Single gene	1q32/1
IL-26	Single gene	12q14-15/
IL-28	Single gene	19q13/7
IL-29	Single gene	19q13

IFN, interferon; IL, interleukin.

The grouping of the IFNαs and IFNβ together as type I IFNs is logical not only because of the similar amino acid sequences and structures of these IFNs but also based on the fact that they share the same receptor and induce essentially the same signals.[397,398] Although DNA array analysis does show some differences in the genes induced by IFNα and IFNβ, the basis for these differences are unclear.[399] These signals include not only antiproliferative and antiviral activities but also the ability to stimulate cytolytic activity in lymphoyctes, NK cells, and macrophages. In contrast, IFNγ has a distinct receptor. Type I and type II IFN receptors share a sufficient degree of similarity to each other so as to form a family.[400] The structure of the IFNγ receptor[401] is shown in Figure 25.2. IFN receptors are referred to as type II cytokine receptors, and there are substantial differences between these receptors and the type I cytokine receptors.[8] Because both type I and type II IFNs bind to type II cytokine receptors,

IFNs are occasionally referred to as type II cytokines but more generally are referred to as IFNs. Based on the similarity of the

IL-10 receptor to the IFNγ receptors,[8] IL-10 was designated as a type II cytokine, and indeed when its x-ray crystal was determined, IL-10 was found to be topologically related to IFNγ.[16] As noted previously, more recently a series of IL-10-related cytokines has been identified, including IL-19, IL-20, IL-22, IL-24, IL-26, IL-28A, IL-28B, and IL-29, and these are also designated as type II cytokines, with IL-28A, IL28B, and IL-29 also known as IFNλs. Among type II cytokines, IFNγ has helices similar to those of the type I short-chain helical cytokines, but its short helices that occupy the AB and CD loops positions exhibit the long-chain cytokine-like AB over CD topology. IL-10 and IFNαβ have long-chain structures.[8] Thus, the theme of short-chain and long-chain type I cytokines also extends to the IFNs and the IL-10 family of type II cytokines.

Type I IFNs signal through a receptor known as the type I IFN receptor.[388,392,394,396,397] The receptor consists of at least two chains.[402,403,404,405] In contrast to the α and β chain nomenclature typical for type I cytokine receptors, IFN receptor chains are officially denoted as IFNAR-1 (previously also denoted IFN-αR1, IFNAR1, and IFN-Rα) and IFNAR-2 (previously also known as IFNα/β receptor, IFNαR2, IFNAR2, and IFNRβ).[406] IFNAR-2 has both short and long forms as well as a soluble form.[407] The long form has a much larger cytoplasmic domain and serves a more important role in signal transduction. Whereas IFNAR-1 cannot bind IFNα, IFNAR-2 binds with low affinity, and the combination of both chains results in high-affinity binding[407] and function. As detailed in the following, IFNAR-1 binds the Janus family tyrosine kinase TYK2, whereas IFNAR-2 binds JAK1. In addition to these cellular receptors, it is interesting that vaccinia virus and other orthopoxviruses encode a soluble form of type I IFN receptor that is related to the IL-1 receptors and that is capable of binding IFNα, IFNβ, and IFNω.[408,409] This form of IFN receptor is therefore not a member of the type II cytokine family but instead is an Ig superfamily protein. IFNαs are typically species specific, although IFNα8 is a human type I IFN that can bind to the mouse receptor. IFNAR-1 confers species specificity of binding. As noted previously, type I IFNs are induced by viral infection. Infection with viruses results in the generation of nonself RNAs in the cell, which are recognized by retinoic acid inducible gene-I (RIG-I)-like receptors, which include RIG-I, MDA5, and LGP2, each of which contains a helicase domain. Retinoic acid inducible gene-I-like receptors are essential for the production of tpe I interferons as well as IL-6, and cells lacking both RIG-I and MDA5 are completely defective in the production of type I IFNs.[410]

IFNγ was first recognized in 1965 as immune IFN, named as IFNγ in 1980, cloned in 1982, and then confirmed to be the same as primary macrophage activating factor.[388,397,411,412,413] In addition to its antiviral activity, IFNγ also has a range of actions on proinflammatory and anti-inflammatory host responses.[393] For example, IFNγ can prime macrophages to manifest antimicrobial and antitumor effects. Moreover, following IL-12-mediated differentiation of Th1 cells, IFNγ is a major secreted product. This production is critical for host response to a range of infectious pathogens, including, for example, *T. gondii*. IFNγ inhibits the generation of Th2 cells as well as Th17 cells. IFNγ is produced by a range of cells, including T_{reg} cells and in this context appears to result in apoptosis of naive cells and Th2 effector T cells. It is produced by NK cells and can mediate NK-dependent lysis of tumor cells, augment IgG2a isotype switching of B cells, and activate DCs. Moreover, IFNγ can either contribute to disease protection or can be protective, depending on the context.[413] Finally, IFNγ- or anti-IFNγ-based therapy are being tried in a range of conditions.[314]

IFNγ is encoded by four exons on chromosome 12. IFNγ forms a functional homodimer with an apparent molecular weight of 34 kDa, whereas little of the monomeric form can be detected and it is not biologically active. Each IFNγ monomer has six α helices, four of which resemble the shortchain helical cytokines, and there is no β sheet structure. The subunits interact in an antiparallel fashion. In contrast to the ability of many different cells to produce IFNα, IFNγ is more restricted, with it being produced primarily by NK cells, CD8+ T cells, and the Th1 subclass of CD4+ T cells.[388] Many signals, including antigen stimulation, IL-12, and IL-18, can induce the production of IFNγ. IFNγ exerts its effects through specific receptors that are expressed on all types of cells except erythrocytes. Interestingly, even platelets express IFNγ receptors, raising the possibility that they can serve a function in transporting IFNγ in the circulation.[388] The functional human receptor consists of two chains[414]: IFNGR-1, formerly also denoted IFNγR1 or IFNγRα[406,415] a 90 kDa protein whose gene is located on human chromosome 6q16 to 6q22 and mouse chromosome 10,[412] and IFNGR-2, also denoted as IFNγRβ,[416,417] located on human chromosome 21q22.1 and mouse chromosome 16.[412] IFNGR-1 is required for ligand binding, whereas IFNGR-2 plays a role in signaling. JAK1 associates with the Leu-Pro-Lys-Ser sequence in the membrane proximal region of the cytoplasmic domain of IFNGR-1,[418] whereas JAK2 binds to IFNGR-2.[419] The fact that IFNγ is a homodimer explains how its binding induces the homodimerization of IFNGR-1, which then allows the recruitment of IFNGR-2. Thus, the functional IFNγ receptor is believed to contain two molecules each of IFNGR-1 and IFNGR-2. Normal IFNγ production is dependent on IL-12, and defective IFNγ signaling is associated with failure to appropriately clear mycobacterial and other infections (discussed subsequently).

Both type I and type II IFNs are important for cancer immunoediting, a process in which neoplastic growth is suppressed by the immune system and tumor immunogenicity is shaped. IFNγ can suppress tumor development, but type I IFNs are required to initiate the antitumor response, at least in part via actions on DCs.[420]

Interleukin-10, a Type II Cytokine, and the Related Cytokines Interleukin-19, Interleukin-20, Interleukin-22, Interleukin-24, Interleukin-26, Interleukin-28A, Interleukin-28B, and Interleukin-29

IL-10 is a type II cytokine that originally was identified as cytokine synthesis inhibitory factor,[380,421,422] produced by Th2 cells. However, it then was observed to be produced by T_{reg} cells as well, and it is now clear that IL-10 is much

more broadly expressed, including by Th1, Th17 cells, B cells, macrophages, NKT, NK, T_{reg}, monocytes, and myeloid DCs but not plasmacytoid DCs, keratinocytes, as well as mast cells and eosinophils.[423,424] IL-10 production by T_{reg} cells helps to explain their suppressive effects, and IL-10 production by T_{reg} cells is required for their suppression of Th17-mediated inflammation.[425] The IL-10 gene contains five exons and is located on chromosome 1 in both mice and humans.[422] IL-10 has an open reading frame of 178 amino acids, including the signal peptide, and the mature protein is 18 kDa. Human IL-10 receptor maps to 11q23.3. IL-10 can inhibit the production of a number of cytokines, including IL-2, IL-3, IFNγ, GM-CSF, and TNF-α. Production of IL-10 is substantially dependent on the transcription factor E4BP4 (also called NFIL-3).[426] IL-10 production is induced by pathogen-derived products, with TLR2 signaling being critical for its induction by antigen-presenting cells and macrophages, although TLR-independent induction of IL-10 has also been observed.[423] Interestingly, IL-21 has been shown to be a potent inducer of IL-10 and to mediate IL-27 and part of the IL-6-

mediated induction of IL-10 as well.[189,190] IL-10 inhibits monocyte/macrophage/DC-dependent T-cell proliferation, in part, by markedly decreasing synthesis of a variety of cytokines, expression of costimulatory molecules, and chemokines, to name just some of its inhibitory effects.[380] In addition to these indirect effects on T cells, IL-10 can exert direct stimulatory effects on thymocytes and T cells in vitro and promote the development of B1 cells and activity of NK cells. IL-10-deficient mice develop a form of inflammatory bowel disease that is similar to Crohn disease.[422,427] Interestingly, the BCRF1 protein that is encoded by Epstein-Barr virus is very similar to IL-10 and shares many of its biologic properties as a macrophage "deactivating" factor and as a costimulator of proliferation of B cells.[428] The Epstein-Barr virus IL-10 homologue is a selective agonist, although its binding to the IL-10 receptor is somewhat impaired.[428] IL-10 is a major inhibitor of Th1 functions.[422] Although it was originally suggested that IL-10 might also favor Th2 development, IL-4 is the major mediator of Th2 cell development, and IL-10 instead plays a major role in limiting and terminating inflammatory responses.[422]

The IL-10 receptor is most closely related to IFN receptors, making it a type II cytokine receptor[429,430] and corresponding to the close structural relationship of IL-10 to IFNγ. The receptor for IL-10 consists of an IL-10R1 chain and IL-10R2[422]; this latter protein is the same as CRF2-4, which was first identified as an "orphan" IFN receptor family member that is located on chromosome 21 within 35 kb of IFNGR-2.[431,432] The major STAT protein used by IL-10 is STAT3.[423]

A series of IL-10-related cytokines have been been identified, including IL-19, IL-20, IL-22, IL-24, IL-26, IL-28A, IL-28B, and IL-29.[379,424,433,434,435,436,437] IL-19 was discovered as a gene that was induced in LPS-stimulated monocytes. IL-19 has been suggested to potentially be involved in the pathogenesis of chronic inflammatory diseases, such as psoriasis. Like IL-19, IL-20 is produced by myeloid cells; it was also found to be produced by epidermal cells, with overexpression resulting in aberrant epidermal differentiation. IL-20 is believed to have a role in psoriasis, and in psoriatic skin, expression of IL-20 is primarily detected in DCs.[379,438] IL-20 also appears to contribute to rheumatoid arthritis, atherosclerosis, and stroke; recently, IL-20 has been implicated in bone loss, with elevated IL-20 in patients with osteopenia and osteoporosis in in ovariectomized mice. Moreover, IL-20R1-deficient mice have increased bone density as did treatment with anti-IL-20.[439]

IL-22 was found as an IL-9-induced cytokine that can in turn induce acute-phase reactant production by hepatocytes and accordingly that it might be involved in inflammatory responses. It was first observed to be produced by activated Th1 cells but was subsequently noted to be more broadly produced by CD4+ and CD8+ T cells, NK cells, lymphoid tissueinducer cells and mucosal RORγt+NKp46+ cells in humans and mice,[440,441,442] and to be produced by Th17 cells. IL-22 is often coexpressed with IL-10, and STAT3, the Notch pathway, and the aryl hydrocarbon receptor promoter production of these cytokines; in contrast, TGF-β, ICOS, and IL-27 augment IL-10 production yet inhibit IL-22.[424] IL-22 mediates cross talk between leukocytes and tissue epithelia, with target cells primarily in the digestive and respiratory systems, but it also can act on keratinocytes, can promote innate immunity,[443] and can cooperate with IL-17A to effect epithelial and healing responses. In particular, IL-22 can contribute to epithelial resistance to injury after microbial infection of the gut or lungs, and thereby may play a role in host defense and tissue repair.[442] Interestingly, the transcription factor c-Maf mediates suppression of IL-22 production by TGF-β.[444]

IL-24 was originally discovered as melanoma differentiation-associated antigen 7. IL-24 is

induced in peripheral blood mononuclear cells by mitogen stimulation and is produced not only by Th2 cells but also by myeloid cells. Overexpression of IL-24 can induce apoptosis in a wide range of tumor cells, including, for example, melanoma and malignant gliomas, and infection with adenoviral-drive melanoma differentiation-associated antigen 7 can sensitize tumors to ionizing radiation.[380] Like IL-19, IL-20, and IL-22, IL-24 is expressed in psoriatic but not normal skin and like these other cytokines, functional receptors are highly expressed on keratinocytes. IL-10, IL-19, IL-20, IL-22, and IL-24 are all increased in synovial fluid cells in rheumatoid arthritis and thus are potential mediators of this autoimmune disease. IL-20 and IL-22 in particular may be associated with lupus.[379]

IL-26 was originally discovered as AK155. Relatively little is known regarding the function of IL-26.

IL-28A and IL-28B (IFNλ1 and IFNλ2) and IL-29 (IFNλ3) are also called type III IFNs and are induced in plasmacytoid DCs by viral infection and exhibit antiviral activity, analogous to type I IFNs; nevertheless, they bind to a receptor consisting of IL-10R2 and IL-28R[445] and differ in terms of potency and kinetics from IFNα.[379] IL-28A, IL-28B, and IL-29 induce relatively weak antiviral responses, and the IL-28R chain is relatively restricted in its expression, as compared to the IFNα receptor. IL-28A appears to enhance antiviral activity induced by TLR3 and TLR9 and to be important for host defense to influenza A.[379] Interestingly, the genes encoding IL-10, IL-19, IL-20, and IL-24 colocalize at human chromosome 1q32, whereas those encoding IL-22

and IL-26 are at 12q14 to 12q15 near the *IFNG* gene, and IL-28 and IL-29 are at 19q13.[380,446] Thus, these type II cytokines can be subdivided into three different groups based at least in part on chromosome localization.

Overall, IL-10 family cytokines are diverse and can be subdivided into the IL-19, IL-20, IL-22, IL-24, and IL-26 subfamily that acts on tissue epithelial cells and in the case of IL-20 in wound healing, whereas IL-28A, IL-28A, and IL-29 exhibit antiviral activity and are more IFN-like in their biology.[379]

SPECIES SPECIFICITY OF CYTOKINES

There are no general rules for the species specificity of human and mouse cytokines, and how the cytokines and their receptor chains have coevolved. To provide illustrative examples of each situation, human IL-2 can stimulate both human and mouse cells, whereas mouse IL-2 exhibits little action on human cells.[59] Conversely, human IL-12 does not work on mouse cells, whereas mouse IL-12 is biologically active on both mouse and human cells.[311] This selective property of IL-12 is dependent on the species origin of p35. Finally, IL-4 exhibits rather strict specificity so that human and mouse IL-4 only induce responses on human and mouse cells, respectively.[92,93] As noted previously, IFNαs are generally specifies specific, although IFNα8 is not. In addition to these examples, varying degrees of relative species specificity have been demonstrated, depending on the cytokine. Thus, a cytokine may or may not be restricted in its specificity to its own species, and if it does occur, cross-species activity may have attenuated potency.

SIGNALING THROUGH INTERFERON AND CYTOKINE RECEPTORS

Our understanding of signaling through IFN and cytokine receptors has tremendously increased in the past few years. Multiple signaling pathways/molecules have been observed for various cytokines. Collectively, these include the JAK-STAT pathway, IRF family proteins, Ras/mitogen-activated protein (MAP) kinase pathway, Src and Zap70 and related proteins, PI 3-kinase, IRS-1 and IRS-2, and phosphatases. Each of these pathways will be discussed in

turn. The JAK-STAT pathways are important for both type I and IFNs/type II cytokines, while the IRF proteins play central functions more so for the IFNs than type I cytokines.

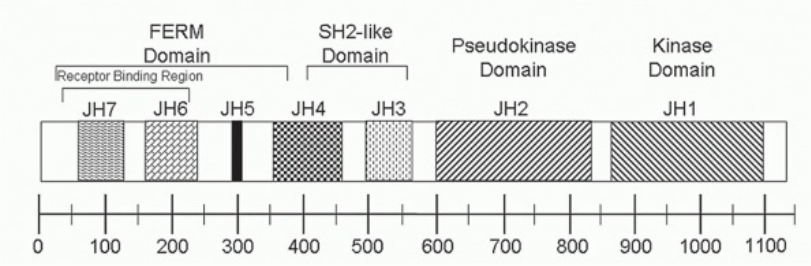

FIG. 25.6. Schematic of JAK Kinases. Shown are the locations of the seven JH domains. JH1 is the catalytic domain. JH2 is the pseudokinase domain, the presence of which prompted the naming of this family as Janus family tyrosine kinases. As noted in the text, the JH nomenclature has limitations and in fact masks the presence of an SH2 domain that spans parts of the JH4 and JH3 domains. Also shown is the conserved tyrosine (Y1007 in JAK2) whose phosphorylation is required for maximal catalytic activity.

OVERVIEW OF JAKS AND STATS

The JAK-STAT pathway[30,355,397,447,448,449] is particularly exciting in that it serves as a rapid mechanism by which signals can be transduced from the membrane to the nucleus. JAK kinases are known as Janus family tyrosine kinases, and the acronym "STAT" denotes signal transducer and activator of transcription. STAT proteins are substrates for JAK kinases. A tremendous amount of information is now available on JAKs and STATs that demonstrate their importance related to development, differentiation, proliferation, cellular transformation, and tumorigenesis.

JAKs

The JAK kinases are 116 to 140 kDa, and comprise approximately 1150 amino acids.[355,397] The seven regions of conserved sequences in JAK kinases, denoted JH1 to JH7, are depicted in Figure 25.6. One of the hallmark features of these kinases is that in addition to the presence of a catalytic tyrosine kinase domain (JH1), there is also a pseudokinase region (JH2). The name Janus kinase reflects the two faces of the mythological Roman god, with one face representing the true kinase and the other the pseudokinase. Although the JH nomenclature was used historically, it has obvious limitations in that except for the JH1 catalytic and JH2 pseudokinase domains, and it remains unclear whether or not the other JH regions correspond to discrete domains. Modeling has indicated five important regions, including an N-terminal domain, a FERM (4.1, ezrin, radixin, moesin) domain, and SH2, kinase-like (which spans two of the JH domains), and kinase domains.[450]

There are four mammalian JAK kinases, JAK1,[451] JAK2,[452] JAK3,[453,454] and TYK2,[455] each of which was identified as part

of a study intended to identify new kinases.[355] At least one JAK kinase is activated by every IFN and cytokine, and some cytokines activate two or three JAK kinases.[355,397,447,448] Table 25.12 lists a number of features of each JAK kinase, whereas Table 25.13 summarizes the JAK kinases that are activated by a variety of cytokines.

TABLE 25.12 Features of Janus Family Kinases

Kinase	Inducible versus Constitutive	Size	Chromosomal Location (H/M)
JAK1	Constitutive	135 kDa	1p31.3/4
JAK2	Constitutive	130 kDa	9p23-24/19
JAK3	Inducible	116 kDa	19p13/8
TYK2	Constitutive	140 kDa	19p13.2/9

Because JAK1, JAK2, and TYK2 are ubiquitously expressed, each cell type expresses either three or in some cases all four JAK kinases (eg, lymphoid cells that also express JAK3). The JAK kinases that are activated by a specific cytokine are those that can bind to its receptor's cytoplasmic domain. JAK kinases physically bind to the membrane proximal Box 1/Box 2 region of the cytoplasmic domains,[454,455,456,457,458,459] and the N-terminal region of the JAK is required for this function.[460,461,462] In cytokine receptors, the Box 1 region is proline rich,[26] suggesting that JAK kinases may have SH3-like domains in their N-terminal regions to mediate these interactions. As each cytokine or IFN receptor is a homodimer, heterodimer, or higher order oligomer, it is reasonable to assume that at least two JAK molecules (either two molecules of one JAK or one molecule each of two different JAKs) will be activated, as one JAK will be associated with each receptor chain. In accord with their ubiquitous expression, JAK1, JAK2, and TYK2 are activated by a variety of different sets of cytokines (see Tables 25.12 and 25.13). For example, JAK1 is activated not only by type I and II IFNs but also by the γ_C family of cytokines (eg, IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21), whereas JAK2 is activated not only by IFNγ but also by growth hormone, Epo, prolactin, and the hematopoietic cytokines, IL-3, IL-5, and GM-CSF.[355,447] TYK2 is somewhat more restricted in that it is activated by IFNα/β and IL-12/IL-23; the significance of its activation by gp130 family cytokines is less clear. Interestingly, JAK1, JAK2, and TYK2 are recruited by each of the cytokine receptors that share gp130 as a signal transducing molecule, raising the question as to whether these cytokines require all three JAK kinases for optimal function or whether any one or two is/are sufficient. At least for IL-6, JAK1 is vital,[463,464] whereas the importance of JAK2 and TYK2 is less clear.

TABLE 25.13 Cytokines and the JAKs They Activate

Cytokine	JAK Kinase(s) Activated
IFNα/β	JAK1, TYK2

IFNγ	JAK1, JAK2
Growth hormone	JAK2
Prolactin	JAK2
Erythopoietin	JAK2
Thrombopoietin	JAK2
IL-10	JAK1, TYK2
IL-12, IL-23	JAK2, TYK2
G-CSF	JAK1, JAK2
γ_C family	
IL-2, IL-4,[a] IL-7, IL-9, IL-15, IL-21	JAK1, JAK3
β_C family	
IL-3, IL-5, GM-CSF	JAK2,?JAK1
gp130 family	
IL-6, IL-11, CNTF, LIF, OSM, CT-1	JAK1, JAK2, TYK2
TSLP	JAK1, JAK2

CNTF, ciliary neurotrophic factor; CT-1, cardiotrophin-1; G-CSF, granulocyte-colony stimulating factor; GM-CSF, granulocyte macrophage-colony stimulating factor; IFN, interferon; IL, interleukin; LIF, leukemia inhibitory factor; OSM, oncostatin M; TSLP, thymic stromal lymphopoietin.

[a] Note that IL-4 activates JAK1 and JAK3 when it acts through the type I IL-4 receptor (IL-4Rα + γ_C, found for example on T cells). However, JAK3 is not activated when IL-4 signals through the type II IL-4 receptors (IL-4Rα + IL-13Rα1, a form of receptor that is expressed on a number of non-T cells, including fibroblasts).

JAK3 is different from the other JAK kinases in that it is much more inducible. Moreover, JAK3 is only activated by cytokines whose receptors contain γ_C.[30,45] Interestingly, each cytokine whose receptor contains γ_C activates not only JAK3 but also JAK1. The basis for the activation of both JAK1 and JAK3 by IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 is that JAK1 associates with each of the distinctive signaling chains (IL-2Rβ, IL-4Rα, IL-7Rα, IL-9Rα, and IL-21R), whereas JAK3 associates with γ_C.[30,45] Although this could be a coincidental result of coevolution of these cytokine systems, these observations raise the possibility that JAK1 is

the JAK kinase that most efficiently functionally cooperates with JAK3.

Given the wide range of cytokines that activate any particular JAK kinase and that in some cases multiple cytokines can activate the same set of JAKs, it is clear that the JAK kinases by themselves do not determine signaling specificity. For example, IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 all activate JAK1 and JAK3 but induce a range of actions. Moreover, JAK2 is the only JAK kinase that is activated by growth hormone and erythropoietin, cytokines with different target cells and biologic functions. Interestingly, JAK2 is the JAK that interacts with all cytokine receptors that form homodimers. Given that homodimeric receptors are likely the oldest cytokine receptors in evolution, this suggests that JAK2 might be the "primordial" JAK kinase from which others evolved.

Importance of JAK Kinases in Signaling

In addition to the activation of JAK kinases by multiples cytokines and IFNs, a variety of other data indicate their importance for signaling. One of the vital series of experiments that led to the establishment of the critical role of JAK kinases in IFN signaling involved a group of mutant cell lines that were defective for IFN signaling, but wherein signaling could be rescued by genetic complementation.[397] Defective signaling in response to IFNα and IFNβ was found in a mutant fibroblast cell line (U1 cells) lacking TYK2; defective signaling in response to IFNα,

IFNβ, and IFNγ was found in a mutant cell line lacking JAK1 (U4 cells), and defective IFNγ signaling was found in cells lacking JAK2.[397] A variety of other data have indicated the importance of JAK kinases in cytokine signaling pathways. First, dominant negative JAK2 inhibits signaling by erythropoietin and growth hormone,[465,466] while a dominant negative JAK3 inhibits signaling in response to IL-2[467]; as noted previoulsy, JAK1 is vital for IL-6 signaling. Second, humans[468,469] and mice[470,471,472] deficient in JAK3 exhibit developmental and signaling defects. Third, humans with an activating mutation in JAK2 develop polycythemia vera,[473] and a JAK2 inhibitor inhibited the growth of acute lymphoblastic leukemia cells in vitro.[474] Fourth, a patient with mutation in TYK2 developed a form of immunodeficiency.[475] Fifth, in Drosophila, the *hopscotch* gene encodes a JAK kinase, wherein loss-of-function alleles result in lethality and decreased proliferation, whereas a gain-offunction allele, *hopscotch Tumorous-lethal* results in melanotic tumors and hypertrophy of the hematopoietic organs.[476,477] Sixth, in zebrafish, JAK1 is vital for normal cell migration and anterior specification.[478] Seventh, as discussed in the following, JAK kinases are constitutively activated in many cell lines infected with a number of viruses, including HTLV-I, v-Abl, spleen focus-forming virus, and with v-Src.[479,480,481,482] These data together underscore the vital roles of JAKs in cytokine signaling. Depending on the function of the particular cytokine (eg, development, differentiation, or proliferation), the particular JAK kinases potentially may be involved in a variety of processes, and when dysregulated, in at least certain settings, they appear to contribute to cellular transformation.

JAK3 Mutations Result in an Autosomal Recessive Form of Severe Combined Immunodeficiency that is Indistinguishable from X-Linked Severe Combined Immunodeficiency

A very large number of different mutations in γ_c have been observed in X-linked SCID. As might be expected, in cases where it has been examined, amino acid substitutions in the extracellular domain result in defective cytokine binding. In contrast, mutations or truncations in the γ_c cytoplasmic domain result in defective signaling. Analysis of a family in which a number of males exhibit a moderate form of X-linked combined immunodeficiency revealed

that this disease also resulted from a mutation in γ_c[41] (Leu 271 → Gln) that resulted in a decrease, but not total loss of JAK3 association, in contrast to the loss of JAK3 interaction seen with mutations in the γ_c cytoplasmic domain that cause X-linked SCID. Thus, the severity of the immunodeficiency inversely correlated with the degree of JAK3 activation.[30,45] Moreover, it was predicted that JAK3 was required for T-cell and NK-cell development, and that mutations in JAK3 might result in a clinical phenotype indistinguishable from that in X-linked SCID.[41] Indeed, this is the case in humans.[468,469] As one would hypothesize, many mutations in JAK3 have been identified.[355] Presumably, any mutation that interferes with its ability to interact with γ_c, with its catalytic activity, or with recruitment of substrates could result in clinical disease, ranging from moderate-tosevere immunodeficiency. Analogous to the similarity of X-linked SCID and JAK3-deficient SCID, mice deficient in either γ_c or JAK3 also have indistinguishable phenotypes.[211,212,470,471,472] These in vivo data underscore the vital role of JAK3 in mediating γ_c-dependent functions and suggested that JAK3 is essential for most, if not all, γ_c functions. Some in vitro data indicate that γ_c may do more than to recruit JAK3,[467,483] and interestingly, γ_c can interact with calpain,[484] but the recruitment of JAK3 is clearly essential, and the defects in T-cell and NK-cell development associated with γ_c or JAK3 deficiency are indistinguishable. Because JAK3 deficiency is not clinically or phenotypically more severe than γ_c deficiency in humans and mice, it seems likely that γ_c is the major, if not only, protein with which JAK3 associates. Moreover, as had been predicted based on the association of γ_c with JAK3,[41] JAK3 inhibitors are immunosuppressive, and one JAK inhibitor has now been approved by the FDA.[485] Although JAK3 was suggested to associate with CD40,[486] a functional role for JAK3 in CD40 signaling has been questioned.[487] The phenotypes of mice lacking each of the four JAK kinases are summarized in Table 25.14.

JAK2 Mutations and Translocations

The JAK2V617F mutations has now been identified in most of patients with polycythemia vera,[473,488] some of whom have homozygous and some have heterozygous mutations. The homozygous patients had duplications of the mutated allele. This mutation results in a constitutively activated kinase and presumably confers factor-independent growth, something that has been demonstrated in transfected cell lines. Moreover, patients with polycythemia exhibit erythropoietin-independent BFU-E. Furthermore, the *JAK2* locus is involved in a chromosomal translocation to create the TEL-JAK2 protein that is causally related to a human leukemia,[489] further underscoring the relationship of JAK2 to the growth of hematopoietic cells.

TYK2 Mutations and Human Immunodeficiency

A mutation in TYK2 has now been identified in a patient with primary immunodeficiency.[475] The patient had clinical defects more severe than anticipated from TYK2-deficient mice, with increased susceptibility to viral infections and atypical mycobacterial infections and defective signaling in response to IL-23, IL-6, and IL-10. Additionally, the patient had hyper-IgE production, which perhaps corresponds to enhanced Th2 cell-mediated allergic inflammation in TYK2-/- mice.[490] Because this was a single patient, it remains to be determined if other individuals with TYK2 deficiency will have this full range of clinical problems.

ACTIVATION OF JAKS AND THE JAK-STAT PARADIGM

The paradigm of JAK-STAT activation is shown in Figure 25.7, which also shows activation of

other pathways, such as the Ras-MAP kinase and PI 3-kinase/AKT/p70 S6

P.626

P.627

P.628

kinase pathways. Following IFN or cytokine engagement, dimerization or higher order oligomerization of receptor complexes is induced. This in turn allows the juxtapositioning of JAK kinases, facilitating transphosphorylation and activation. In receptors with only two chains, the direct transphosphorylation of one JAK by the other seems likely to occur. In more complex receptors, such as the IFNγ system, because the receptor is a heterotetramer with two IFNGR-1 chains that each bind JAK1 and two IFNGR-2 chains that each bind JAK2, it is not clear if JAK1 and JAK2 transactivate each other or if one of the JAK kinases plays a dominant role. Indeed, one study suggests that JAK2 may phosphorylate both itself and JAK1, thereby increasing the catalytic activities of both kinases.[491] JAK1 in turn then phosphorylates IFNGR-1, allowing the recruitment of STAT1. In this model, it is additionally suggested that JAK2 phosphorylates STAT1.[491] Interestingly, a kinase-dead mutant of JAK1 was able to mediate the induction of certain IFNγ-induced genes, indicating a potential "structural" role for JAK1, but catalytically active JAK1 was essential for the establishment of the antiviral state,[491] emphasizing the essential role of both JAK1 and JAK2 for normal IFNγ function.

TABLE 25.14 Phenotypes of Mice Deficient in Type I and Type II Cytokines, Their Receptors, JAKs and STATs

Type I Cytokines and Their Receptors	
γ_c family	
IL-2[205,692,693]	Normal thymic and peripheral T-cell development. Decreased polyclonal T-cell responses in vitro, but more normal in vivo responses to pathogenic challenges. Autoimmunity with marked changes in levels of serum immunoglobulin isotypes. Ulcerative colitis-like inflammatory bowel disease.
IL-4[208,209]	Defective Th2 cytokine responses and class switch; defective IgG1 and IgE production.
IL-2/IL-4[210]	Some features of both IL-2 and IL-4 knockout mice. No gross abnormalities of T-cell development.
IL-7[104]	Greatly diminished thymic and peripheral T-cell development and B lymphopoiesis, resulting in profound lymphopenia.
IL-9[133,135]	No T-cell defect. Defect in pulmonary goblet cell hyperplasia and mastocytosis following

	challenge with *Schistoma mansoni* eggs. No defect in eosinophilia or granuloma formation.
IL-15151	Defective NK-cell development. Defect in CD8 memory T-cell homeostasis.
IL-2Rα217	Normal initial lymphoid development, but massive enlargement of peripheral lymphoid organs, polyclonal T- and B-cell expansions, and activated T cells, with impaired activation-induced cell death. Autoimmunity with increasing age, including hemolytic anemia and inflammatory bowel disease.
IL-2Rβ218	Severe autoimmunity including autoimmune hemolytic anemia. Death within approximately 3 months. Deregulated T-cell activation. Dysregulated B-cell differentiation and altered Ig profile.
γ_c211,212	Greatly diminished thymic development but double negative, double positives, and single positives all represented. Age-dependent accumulation of peripheral $CD4_+$ T cells with an activated memory phenotype. Greatly diminished numbers of conventional B cells, although B1 cells are present. No NK cells or γδ cells. Absent gut-associated lymphoid tissue, including Peyer patches.
IL-4Rα694	Like IL-4-/- mice, they have defective Th2 cytokine responses and class switch; defective IgG1 and IgE production. In addition, they cannot expel *Nippostrongylus brasiliensis*, presumably because of defective IL-13 signaling.
IL-7Rα103	Greatly diminished thymic and peripheral T-cell development and B lymphopoiesis, resulting in profound lymphopenia.
IL-15Rα150	Defective NK cell development. Defect in CD8 memory T-cell homeostasis.
IL-13366,695	Defective Th2 cell development and the ability to expel helminths. Impaired diarrhea to OVA.
IL-4/IL-13 DKO695	Produce almost no IgE, highly resistant to OVA-induced diarrhea.

IL-13Rα1378,695	Exacerbated Th2 responses, with diminished mortality after infection with *S. mansoni* and greater susceptibility to *N. brasiliensis*. However, partially impaired allergic diarrhea to OVA.
IL-21R182,184	Decreased IgG1, elevated IgE.
IL-21R/IL-4 DKO182	Panhypogammaglobulinemia (mimicks the B-cell phenotype in humans with XSCID).
β_c family	
IL-5227	Decreased basal level of eosinophils and defective induction of eosinophils following infectious challenge. Developmental defect in $CD5_+$ B1 cells. Normal antibody and cytotoxic T-cell responses.
GM-CSF696,697	Normal basal hematopoiesis. Unexpected abnormalities of the lung; abnormal pulmonary homeostasis.
IL-3Rβ698	No defects (due to redundant function of β_C).
β_C243,698	Defective responses to IL-5 and GM-CSF but normal responses to IL-3 (due to redundant function of IL-3Rβ). Diminished eosinophils: both basal levels and in responses to infectious challenge. Unexpected abnormalities of the lung characterized by pulmonary proteinosis and reduced phagocytosis by alveolar macrophages. In other words, the defects are a combination of those found in the IL-5- and GM-CSF-deficient mice.
IL-3Rβ + β_C DKO698	Same phenotype as β_C-deficient mice, except that they cannot respond to IL-3.
gp130 family	
IL-6699	Impaired acute-phase responses following infection or tissue damage. Decreased numbers of hematopoietic progenitor cells.
gp130700,701	Embryonic lethal. Extreme hypoplastic development of the myocardium; although

	the ventricular wall was very thin, trabeculation within the ventricle chamber was normal. Hematologic abnormalities characterized by greatly reduced CFU-S and somewhat reduced CFU-Gm and BFU-E. Markedly diminished size of thymus and numbers of thymocytes. Reduced primordial germ cells in embryonic gonads. Diminished size of placenta.
LIF702,703,704	Decreased hematopoietic progenitor cells. Normal sympathetic neurons but deficient neurotransmitter switch in vitro. Defective blastocyst implantation.
LIFRβ705,706	Postnatal lethality. Normal hematopoietic and germ cell compartments but multiple neurologic, skeletal, placental, and metabolic defects. The greater severity than found in LIF-deficient mice reflects that LIFRβ is shared by several cytokines, including CNTF, LIF, OSM, and CT-1.
CNTF707	Progressive atrophy and loss of motor neurons.
CNTFRα708	Severe motor neuron deficient resulting in perinatal mortality. The more severe phenotype than in CNTF-deficient mice was unexpected and suggests another cytokine may utilize CNTFRα.
IL-11Rα709	Blastocysts can implant but decidualization cannot occur, associated with failure of pregnancy. Fetal lethal phenotype.
IL-12 p40710	Impaired but not completely lacking in their ability to produce IFNγ and to mount a Th1 response in vivo. Elevated secretion of IL-4; normal production of IL-2 and IL-10. Substantially decreased CTL responses. Resistant to infection with intracellular pathogens.
IL-12Rβ1711	Defective IL-12 signaling. IL-2 but not IL-12 could augment NK activity. Defective IFNγ production in response to ConA or anti-CD3. Severe defect in Th1 differentiation.
IL-12 p35175,712	Selective loss of IL-12 function without loss of IL-23. Less resistant to infection than p40

	and IL-12Rβ1 KO.
IL-12Rβ2713	Selective loss of IL-12 function without loss of IL-23. Less resistant to infection than p40 and IL-12Rβ1 KO.
IL-23 p19175,714	Complete resistance to EAE, defective DTH response.
EBI3715	Increased pathologic features of colitis and shorter survival than in p28 KO mice, indicating that IL-35 rather IL-27 is protective.
IL-27 p28715	Decreased pathologic features of colitis and longer survival than in EBI3 KO mice, indicating that IL-35 rather than IL-27 is protective.
Epo, Tpo, G-CSF, and M-CSF	
Epo716	Embryonic lethal. Complete block of fetal liver erythropoiesis, resulting in severe anemia, yet normal development of BFU-E and CFU-E progenitor cells.
EpoR717	Same as Epo-deficient mice.
TpoR718	Decreased megakaryocytes and platelets, but other hematopoietic cells are present in normal numbers.
G-CSF719 Neutropenia and impaired neutrophil mobility. Diminished granulocytes and macrophage precursors.	
M-CSF720,721	Osteopetrosis, absence of teeth. Females are infertile, suggesting an unexpected role for M-CSF.
M-CSF + GM-CSF721	A combination of defects of both M-CSF and GM-CSF, with osteopetrosis and alveolar proteinosis. Early death of pneumonia.
Type II cytokines and their receptors	
IFNAR1722,723,724	Normal development. Defective immune defense against most viral infections tested,

	including lymphocytic choriomeningitis virus, Semliki Forest virus, Theiler virus, vesicular stomatitis virus. Normal resistance to *Listeria monocytogenes*, *Leishmania major*, *Mycobacterium bovis*, and *Mycobacterium avium*.
IFNγ[725,726,727]	Normal lymphoid development. Impaired resistance to *Listeria monocytogenes*, *Leishmania major*, *M. bovis,* and *M. avium*. Can mount curative responses to a number of viruses. $CD4_+$ effector cells default to the Th2 pathway after infection with *Leishmania*. Succumb to infection with *Toxoplasmosis gondii*.
IFNGR1[723,724,728]	Normal lymphoid development. Impaired resistance to *Listeria monocytogenes, Leishmania major, M. bovis,* and *M. avium* Can mount curative responses to a number of viruses.
IL-10[422,427]	Normal lymphocyte development and antibody responses. Chronic enterocolitis, anemia, and growth retardation. Augmented inflammatory responses.
IL-19[729]	Increased susceptibility to dextran sulfate sodium-induced colitis, increased accumulation of macrophages, and production of proinflammatory cytokines and IFNγ.
IL-20R1[39]	Increased bone density with defective osteoclast differentiation.
IL-20R2[730]	Anti-TCR stimulation results in elevated IL-2 and IFNγ production, with increased antigen-specific CD4 and CD8 cells that produce IFNγ, but diminished IL-10.
IL-22[731]	Increased susceptibility to infection with *Citrobacter rodentium*, with augmented bacterial burden, intestinal epithelial damage, and mortality.
IL-28A[732]	Normal clearance of a range of viruses but diminished antiviral activity in response to TLR3 and TLR9 agonists. Expression of IL-28α on nonhematopoietic cells appears to be the most critical.

STATs and JAKs

STAT1[557,558]	Defective responses to both type I and type II IFNs. Defective response to certain viruses and bacterial antigens.
STAT2[559]	Defective signaling in response to type I IFNs; interestingly, the defect in not as severe in STAT2-deficient macrophages as it is in STAT2-deficient fibroblasts.
STAT3[560,561,562,563,564]	Embryonic lethal. Embryos implant but cannot grow. The fact that this phenotype is even more severe than that seen with gp130 suggests a role for STAT3 via a gp130-independent cytokine. By Cre-lox methodology, *STAT3* was also selectively targeted in T cells, which exhibit defective IL-2-induced proliferation that correlates with a defect in IL-2-induced IL-2Rα expression; as expected, T cells also exhibit defective signaling in response to IL-6. *STAT3*-deficient neutrophils and macrophages show defective IL-10 signaling. STAT3 is also essential for normal involution of the mammary epithelium, for wound healing, and for normal hair cycle processes. *STAT3*-deficient DCs exhibit defective Flt3L-dependent expansion of DCs.
STAT4[566,567]	Defective Th1 development. Essentially, the same phenotype as in IL-12-deficient mice, including defective IL-12-mediated boosting of NK cell cytolytic activity.
STAT5A[511,571]	Defective lobuloalveolar development in the mammary gland, a syndrome resulting from defective prolactin signaling. Defective IL-2-induced IL-2Rα expression and associated defects in IL-2-induced T-cell proliferation. Defective superantigen-induced expansion of Vβ8 T cells. Defective antigeninduced recruitment of eosinophils into the lung as well as antigen-induced IgG1 production.
STAT5B[512,572]	Defective growth analogous to Laron dwarfism, a disease of defective growth hormone signaling. Defective IL-2-induced IL-2Rα expression. More severe defects in IL-2-induced T-cell proliferation and NK-cell

	proliferation. Defective antigen-induced recruitment of eosinophils into the lung as well as antigen-induced IgG1 production. Defective NK cytolytic activity.
Partial STAT5A/STAT5B513,514	Defective signaling in response to prolactin and growth hormone. Absent NK-cell development. Major defect in T-cell proliferation and TCR signaling. Anemia.
Complete STAT5A/STAT5B573	Fetal lethality; absent T-cell development.
STAT6568,569,570	Defective Th2 development. Essentially, the same phenotype as IL-4-deficient mice. Defective B-cell proliferation.
JAK1463	Perinatal lethality, with defective signaling by gp130-dependent cytokines (IL-6, IL-11, CNTF, OSM, LIF, CT-1, and NNT-1/BSF-3). Defective signaling by γ_C-dependent cytokines (IL-2, IL-4, IL-7, IL-9, IL-15, IL-21; of these, IL-2 and IL-7 were formally evaluated).
JAK2733,734	Fetal lethality with profound anemia due to defective signaling in response to Epo.
JAK3470,471,472	Very similar and possibly identical to γ_C-deficient mice. Defective signaling in response to γ_C-dependent cytokines (IL-2, IL-4, IL-7, IL-9, IL-15, IL-21). Greatly diminished T cells in thymus and spleen, but then age-dependent peripheral expansion of CD4+ T cells. Unlike humans with JAK3 mutations, Jak3-deficient mice have greatly diminished B-cell numbers as well.
TYK2735,736,737	Mice lacking TYK2 exhibit diminished signaling in response to IFNα/β and IL-12, but it is not abrogated. Primarily STAT3 activation is diminished, even though STAT1/STAT2 and STAT4, respectively, are the STAT proteins that are primarily activated by IFNα/β and IL-12. Additionally, there are diminished responses to IFNγ and IL-18.

BFU, burst forming unit; BSF-3, B cell-stimulating factor-3; CD, cluster of differentiation; CFU, colony forming unit; CNTF, ciliary neurotrophic factor; CT-1, cardiotrophin-1; CTL, cytotoxic T lymphocyte; DC, dendritic cell; DKO, double

knockout; DTH, delayed type hypersensitivity; EAE, experimental autoimmune encephalomyelitis; Epo, erythropoietin; G-CSF, granulocytecolony stimulating factor; GM-CSF, granulocyte macrophage-colony stimulating factor; IFN, interferon; Ig, immunoglobulin; IL, interleukin; KO, knockout; LIF, leukemia inhibitory factor; M-CSF, macrophage-colony stimulating factor; NK, natural killer; NNT-1, novel neurotrophin-1; OSM, oncostatin M; STAT, signal transducer and activator of transcription; TCR, T-cell receptor; Th, T helper; Tpo, thrombopoietin; XSCID, X-linked severe combined immunodeficiency.

The previous discussion assumes that transphosphorylation of JAK kinases is a mechanism for the amplification of catalytic activity. Unless other kinases are involved, however, implicit to this idea is that the JAK kinases themselves must exhibit some basal activity that is amplified to a higher level by autophosphorylation or transphosphorylation. It is reasonable to speculate that both models may be operative, depending on the system. Consistent with JAK kinases being activated by phosphorylation, mutagenesis of a critical tyrosine in TYK2[492] or JAK2[493] (eg, tyrosine 1007 in the case of JAK2) in the activation loop of the kinase domain inhibits activity. It is also conceivable that phosphorylation of other tyrosines on the JAKs may create appropriate motifs for the recruitment of additional signaling molecules.

The function of the pseudokinase domain remains unclear. No other metazoan protein tyrosine kinases contain such a domain. The JH2 lacks the third glycine in the critical Gly-X-Gly-X-X-Gly motif, is missing an aspartic acid that serves as the proton acceptor that is typically conserved in the catalytic loop of both tyrosine and serine kinases, and is missing the conserved phenylalanine in the Asp-Phe-Glu motif that binds adenosine triphosphate[355] together, pre

sumably explaining the lack of catalytic function of the JH2 pseudokinase domain.[452] Despite the lack of catalytic activity, there are data in support of vital functions for this region. While the kinase domain alone can act as an active kinase, it is interesting that a mutation in the JAK kinase JH2 domain can hyperactivate the Drosophila (*hop*$^{Tum\text{-}l}$/DSTAT) JAK-STAT pathway, and that the corresponding Glu695 to Lys mutation in mouse JAK2 also resulted in increased autophosphorylation of JAK2 and phosphorylation of STAT5 in transfected cells.[494] Moreover, the JH2 domain may play an important role in mediating the interaction of JAKs with STAT proteins.[495]

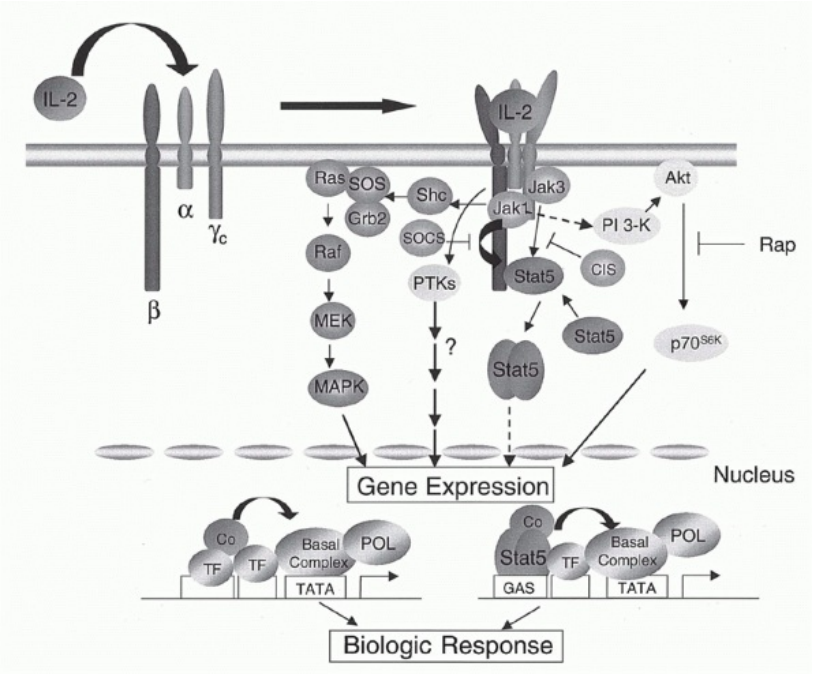

FIG. 25.7. Schematic of Cytokine Signaling Showing Multiple Signaling Pathways Activated by Interleukin (IL)-2. Shown is the association of JAK1 and JAK3 with different chains of the receptor. Activation of JAK kinases results in tyrosine phosphorylation of IL-2Rβ. This allows the docking of STAT5 proteins via their SH2 domain. The STATs themselves are tyrosine phosphorylated, dimerize, and translocate to the nucleus where they modulate expression of target genes. The schematic also indicates that another phosphotyrosine mediates recruitment of SHC, which then can couple to the Ras/Raf/MEK/mitogen-activated protein kinase pathway. Also shown is the important phosphatidyl inositol 3-kinase pathway. These and other pathways are activated by many type I cytokines.

Given that JAK kinases are associated with a wide range of IFN and cytokine receptors, it was predicted that JAKs would mediate signals involved in multiple processes. These include important roles in development (as demonstrated by the lack of T-cell and NK-cell development associated with JAK3 deficiency, a defect at least partially due to defective signaling in response to IL-7 and IL-15), signaling in response to cytokines that are mitogenic growth factors (eg, IL-2, IL-3, etc.), and in the antiviral response (IFNs). Studies in zebrafish revealed not only a role for JAK1 in early vertebrate development but also revealed that during early development JAK1 kinase was exclusively of maternal origin.[478] These developmental roles for JAK1 in zebrafish are consistent with the importance of a JAK kinase in early Drosophila development as well.[496]

SIGNAL TRANSDUCER AND ACTIVATOR OF TRANSCRIPTION PROTEINS ARE SUBSTRATES FOR JAKS THAT AT LEAST IN PART HELP DETERMINE SPECIFICITY

Given that there are only four JAK kinases but scores of cytokines, it is clear that JAKs by themselves cannot fully determine specificity. Indeed, different cytokines with different actions activate the same JAKs. One level of specificity comes from the same JAKs having different substrates, depending

on the receptor. The best characterized substrates for JAKs are the STAT

proteins,[355,447,448] and these appear to provide some, but not all of the specificity, particularly given that there are only seven STAT proteins. Among the mutant cell lines with defects in IFN signaling, in addition to the ones with defects in JAKs noted previously, others were defective in STAT proteins, providing perhaps the earliest data proving a vital role for STAT proteins in signaling in response to IFNs.

STAT proteins are classically considered to be latent transcription factors that initially exist in the cytosol but then must be activated by phosphorylation, with subsequent translocation to the nucleus. STATs were first discovered as factors that bound to the promoters of interferon-inducible genes. The seven mammalian STAT proteins are STAT1,[497] STAT2,[498] STAT3,[499,500] STAT4,[501,502] STAT5A,[503,504,505,506,507] STAT5B,[505,507,508] and STAT6.[509] Table 25.15 summarizes the cytokines that activate each of the STATs. Additionally, some STATs (eg, STAT3) are known to have more than one isoform with distinct functions.[510] Although the STATs conserve a reasonable level of homology, STAT5A and STAT5B are unusually closely related, being 91% identical at the amino acid level.[505,506,507,508] It is interesting that mouse and human STAT5A are more related than STAT5A and STAT5B within a single species. The same is true for mouse and human STAT5B, suggesting that there has been evolutionary pressure to maintain the difference between STAT5A and STAT5B and that these two proteins might have certain distinctive functions. In this regard, STAT5A and STAT5B knockout mice exhibit both similarities as well as some differences in their phenotypes[511,512,513,514]; however, given different levels of each STAT5 protein in certain tissues, it remains to be determined if the different phenotypes result from different intrinsic actions of STAT5A and STAT5B versus differences in the total level of STAT5.

TABLE 25.15 Cytokines and the Signal Transducer and Activator of Transcriptions They Activate

Cytokine	STATs Activated
IFNα/β	STAT1, STAT2, STAT4
IFNγ	STAT1
Growth hormone	STAT5A, STAT5B
Prolactin	STAT5A, STAT5B
Erythopoietin	STAT5A, STAT5B
Thrombopoietin	STAT5A, STAT5B
IL-10	STAT3
IL-12	STAT4, STAT3
G-CSF	STAT3

γ_c family	
IL-2, IL-7, IL-9, IL-15, IL-21	STAT5A, STAT5B, STAT3, STAT1
IL-4	STAT6, STAT5A, STAT5B
IL-13	STAT6
TSLP	STAT5A, STAT5B
β_c family	
IL-3, IL-5, GM-CSF	STAT5A, STAT5B
gp130 family	
IL-6, IL-11, CNTF, LIF, OSM, CT-1	STAT3
Leptin	STAT3

CNTF, ciliary neurotrophic factor; CT-1, cardiotrophin-1; G-CSF, granulocyte-colony stimulating factor; GM-CSF, granulocyte macrophage-colony stimulating factor; IFN, interferon; IL, interleukin; LIF, leukemia inhibitory factor; STAT, signal transducer and activator of transcription; TSLP, thymic stromal lymphopoietin.

Note that for IL-2, IL-7, IL-9, and IL-15, STAT5A and STAT5B appear to be the major STATs that are activated, although STAT3 in particular and STAT1 to a lesser degree can also be activated. For IL-21, STAT3 is the dominant STAT protein activated, followed by STAT1 and STAT5A/STAT5B.44,585

As active STAT proteins exist as dimers, the ability of at least some STATs to form heterodimers (eg, STAT1 with STAT2 or STAT3[448]) increases the number of different complexes that can form. In addition, further complexity can be generated by the ability of at least some of the STATs to exist in alternatively spliced forms,[508,515] some of which are inactive.

A schematic of STAT proteins is shown in Figure 25.8. The STATs can be divided into two basic groups: those that are longer (STAT2 and STAT6, approximately 850 amino acids) and those that are shorter (STAT1, STAT3, STAT4, STAT5A, and STAT5B, between 750 and 800 amino acids). The STAT genes cluster in three locations. Mouse STAT2 and STAT6 are both located on chromosome 10; STAT1 and STAT4 are located on chromosome 1; and STAT3, STAT5A, and STAT5B are located on chromosome 11.[516] Correspondingly, human STAT5A and STAT5B are closely positioned on chromosome 17q.[508]

The classic model is that in order for STATs to be “activated” and to be able to function as transcriptional activators, a number of cellular events must occur. They first bind to phosphorylated tyrosines on cytokine receptors, are tyrosine phosphorylated, dissociate, dimerize, translocate from the cytosol to the nucleus, bind to target DNA sequences, and activate gene expression. A number of conserved structural features common to all STATs help to explain these functions. These include an SH2 domain, a conserved tyrosine residue,

a DNA-binding domain, and a C-terminal transactivation domain, and an N-terminal STAT tetramerization region (Fig. 25.8). In addition, there is now evidence for the biologic function of nuclear STATs that are not phosphorylated, as discussed subsequently.

Docking of Signal Transducer and Activator of Transcription on Receptors or Other Molecules, their Tyrosine Phosphorylation, and Dimerization

Each STAT protein has an SH2 domain that plays two important roles: 1) for receptor docking, as for example, has been shown for STAT1 docking on IFNGR-1,[517] STAT2 docking on IFNAR-1,[518] STAT3 docking on gp130,[519] STAT5A and STAT5B docking on IL-2Rβ and IL-7Rα,[356,520] and STAT6 docking on IL-4Rα[521]; and 2) for STAT dimerization that is mediated by the SH2 of one STAT interacting with the conserved phosphorylated tyrosine of another STAT protein. In the case of the IFNα receptor, no STAT1 docking site on IFNAR-1 or IFNAR-2 has been identified, and it is believed that STAT1 may interact with STAT2 after STAT2 is itself tyrosine phosphorylated.[355] It is also possible that STATs can dock on JAKs, given the ability to directly coprecipitate JAKs and STATs.[480,495] After

docking has occurred, a conserved tyrosine (tyrosine 701 in STAT1, tyrosine 694 in STAT5A, etc.) can be phosphorylated. This phosphorylation is required for SH2 domain-mediated STAT dimerization, and the phosphorylation likely occurs while the STAT is docked on the receptor in physical proximity to receptor-associated JAK kinases. Following STAT phosphorylation, the STAT protein dissociates from the receptor, and its dimerization with itself or another STAT is presumably then favored over its reassociation with the cytokine receptor chain given that STAT dimerization involves two reciprocal phosphotyrosine-SH2 interactions, whereas docking on a receptor involves only one interaction. Thus, efficient activation of STATs requires the presence in STATs of a conserved SH2 domain and a critical tyrosine.

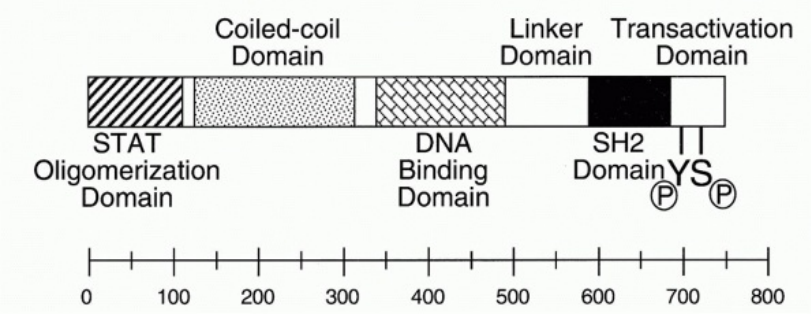

FIG. 25.8. Architecture of a Typical Signal Transducer and Activator of Transcription (STAT) Protein. Shown are the locations of the following important regions: 1) The N-terminal region has been shown to mediate the interaction of STAT dimers bound to adjacent gamma activated sites (known to be important for STAT1 but presumably true for all STATs), 2) the DNA-binding domain, 3) the SH2 domain that mediates STAT docking on receptors and STAT homodimerization/heterodimerization following tyrosine phosphorylation, and 4) the location of the conserved tyrosine whose phosphorylation allows the SH2-mediated dimerization. At least in STAT1 and STAT3, Serine 727, which is C-terminal to the conserved tyrosine, is an important site for phosphorylation. In the case of STAT1, p48 interacts downstream of the STAT dimerization domain. CBP/p300 interacts with two sites at both the N-terminus and C-terminus. Although it has been suggested that the region between the DNA-binding domains and the SH2 domain is an SH3 domain, this remains unproven, and no

interactions with proline-rich regions have been reported; as a result, the labeling of this region as an SH3 domain has been omitted. Note that this structure is typical of that for STAT1, STAT3, STAT4, STAT5A, and STAT5B. The main features are conserved in STAT2 and STAT6, but these are approximately 50 to 100 amino acids longer.

Whereas some receptor proteins such as IFNGR-1[517] and IL-7Rα[356] have a single STAT docking site (for STAT1 and STAT5, respectively), a number of receptor molecules, including IL-2Rβ,[356,520] IL-4Rα,[521] gp130,[519] Epo receptor (EpoR),[522] and IL-10R1,[523] have more than one docking site for their respective STATs. The presence of more than one site not only provides functional redundancy but also potentially could allow the simultaneous activation of two STAT molecules, providing a high local concentration of phosphorylated STATs to facilitate their dimerization.

Signal Transducer and Activator of Transcription Nuclear Translocation and Deoxyribonucleic Acid Binding

Following dimerization, the STATs translocate into the nucleus where they can bind to DNA as transcription factors. The mechanism for nuclear translocation was originally mysterious given the absence of an obvious nuclear localization signal.[524] However, it was shown that tyrosine-phosphorylated STAT1 dimers can directly interact with importin-α5, allowing internalization. This suggested that there indeed was a nuclear localization signal that is normally masked, and mutation of Leu407 does not interfere with tyrosine phosphorylation, dimerization, or DNA binding but prevents nuclear localization.[524] Following its dephosphorylation, nuclear STAT1 is exported to the cytosol by a process that is dependent on the chromosome region maintenance 1 (CRM1) export reporter.[525] Thus, both import and export of STAT1 appear to be regulated processes.[526]

Whereas most STAT dimers directly bind to DNA, in the case of IFN-α/β, STAT1-STAT2 heterodimers are formed, and these bind DNA in conjunction with a 48 kDa DNA-binding protein known as IRF9; the STAT1-STAT2-IRF9 complex is known as IFN-stimulated gene factor 3 (ISGF3).[448] In the case of other STAT dimers, accessory proteins are not required for DNA binding. The motif recognized by ISGF3 complexes is AGTTTNCNTTTCC (known as an ISRE, for IFN-stimulated response element), whereas the other STAT complexes bind more semipalindromic TTCNmGAA motifs that are generally denoted as gamma-activated site (GAS) motifs for IFNγ-activated sequences, reflecting their original discovery in the context of IFNγ.[355,397,447]

A series of chimeric STAT proteins were used to delineate a DNA-binding domain of approximately 180 amino acids, with two conserved subdomains. Although multiple STATs bind to the same motifs, their relative efficiencies vary, indicating fine specificities conferred by the different

DNA-binding domains. For example, whereas STAT1 homodimers favor a TTCN3GAA motif, STAT6 prefers a TTCN4GAA motif.[521] These differences partially explain why different STATs modulate the expression of nonidentical sets of target genes. The structures of STAT1 and STAT3β bound to DNA[527,528] (Fig. 25.9) almost resembles that of a vertebral column, wherein the DNA represents the spinal cord. The N-terminal and coiled-coil domains are spatially the furthest from the DNA, whereas the DNA-binding domain, linker, and SH2 domain surround the DNA, with the stability apparently being provided by the SH2-phosphotyrosine interaction between the STAT monomers and each STAT monomer-DNA interaction with the DNA, presumably via a “half GAS site,”[529] as discussed under STAT

tetramerization.

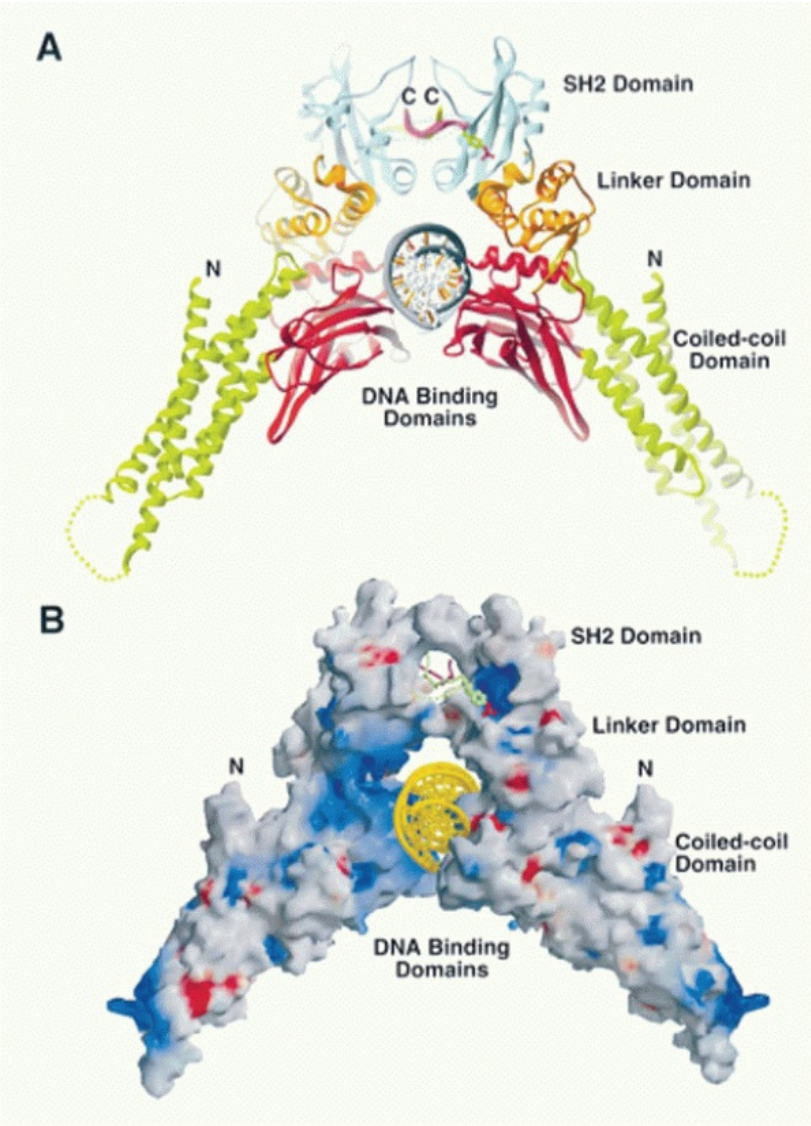

FIG. 25.9. Three-Dimensional Structure of a Signal Transducer and Activator of Transcription 1 Dimer Bound to Deoxyribonucleic Acid. Reproduced from Chen et al.[527] and Becker et al.,[528] with permission of Dr. Kuryian and Cell Press.

N-terminal regions mediate cooperative DNA binding of STAT proteins when multiple STAT-binding sites occur in close proximity,[530,531] for example, in the IFNγ gene.[530] In the IL-2Rα gene, IL-2 response elements have been described in both the 5′ regulatory region and the first intron, each of which has tandem GAS motifs that functionally cooperate to mediate IL-2-induced IL-2Rα transcription.[532,533,534,535]

STAT proteins were the first transcription factors that were identified as targets for tyrosine phosphorylation. Previously, tyrosine phosphorylation was primarily associated with membrane proximal events, but the tyrosine phosphorylation of STATs is associated with a membrane proximal event, as the STATs dock on cell surface receptors. This phosphorylation then allows the rapid dimerization that facilitates nuclear localization and DNA binding. STATs can interact directly with JAK kinases (first shown for STAT5 and JAK3),[480] suggesting that STATs may at times dock on JAKs rather than on receptors.

Nonphosphorylated Signal Transducer and Activator of Transcription Proteins Can Be Nuclear

In addition to the classical tyrosine phosphorylation-mediated dimerization and nuclear translocation, it is now clear that STAT proteins can exist in the nucleus even without being tyrosine phosphorylated and in that context can modulate gene expression.[536,537,538] Moreover, nonphosphorylaed STATs (eg, STAT4) can form N-domain-mediated dimers.[539]

Optimal Binding Sites for Signal Transducer and Activator of Transcription Proteins

The optimal binding motifs for several STAT proteins have been determined. For STAT1, STAT3, and STAT4, a TTCCSGGAA motif was defined,[448,530] while STAT5A and STAT5B optimally bind a TTCYNRGAA motif[529] and STAT6 binds a TTCNTNGGAA motif (where Y is C or T and R is G or A).[521,529] Whereas dimeric STAT protein binding strongly preferred canonical motifs, the range of sequences recognized by STAT5 tetramers is broader, often occurring to two imperfect motifs or with one canonical motif with an associated "TTC" or "GAA" half GAS motif. The optimal inter-GAS motif spacing is 11-12 bp, with relative secondary peaks of 6-7 bp and 16 bp as well.[529a] The presence of suboptimal GAS motifs spaced at appropriate distances to allow tetrameric binding may allow greater specificity via cooperative binding of STAT oligomers. A subset of genes bind STAT5 tetramers and STAT5 tetramers are critical for cytokine responses and normal immune function.

Transcriptional Activation by Signal Transducer and Activator of Transcription

In addition to tyrosine phosphorylation, some STATs can be phosphorylated on serine, and STAT1 and STAT3 phosphorylation at Serine 727 in the C-terminal transactivation domain is required for full activity.[540,541,542] The Serine 727 region resembles a MAP kinase recognition site, and one study indicated that MAP kinase activity is required for IFNα/β-induced gene expression.[543] Serine 727 mediates the interaction of STAT1 with MCM5, a member of the minichromosome maintenance family of proteins; this interaction presumably is important for maximal transcriptional activation.[544] In contrast, STAT2 is not serine phosphorylated.[448] STAT5A and STAT5B are serine phosphorylated,[545] and this phosphorylation may be important in cellular transformation.[546,547]

In addition to this regulated modification of the STAT proteins, STATs can also interact with other factors. For

example, as noted previously, STAT1-STAT2 heterodimers bind DNA only after interacting with IRF9 to form ISGF3.[448] STAT1 interacts with and synergizes with Sp1 for transcriptional activation in the ICAM-1 gene[548] and with TRADD to influence IFNγ signaling.[549] An alternatively spliced shorter form of STAT3, denoted STAT3β, associates with c-Jun to enhance transcriptional activity,[550] and full-length STAT3 can also associate with c-Jun.[551] Moreover, certain STATs can interact with the potent transcriptional coactivators CBP/p300.[552,553,554] In the case of STAT1, this is mediated by interactions involving both the N- and C-terminal regions of STAT1 and the CREB and E1A binding regions of CBP, respectively.[553] STAT5A has been shown to associate with the glucocorticoid receptor.[555] Additionally, the IL-2-response element in the IL-2Rα gene requires not only STAT5 binding but also the binding of Elf-1, an Ets family transcription factor, to a nearby site.[532] Thus, active STAT complexes appear to involve the coordination of STAT proteins with other

factors. The corepressor silencing mediator for retinoic acid receptor and thyroid hormone receptor was identified as a potential STAT5-binding partner that binds to both STAT5A and STAT5B and potentially plays a negative regulatory role.[556]

Specificity of Signal Transducer and Activator of Transcription Proteins

Analogous to the JAKs, the same STATs are activated by multiple cytokines. The phenotypes of mice lacking expression of each of the seven STAT proteins are known, and these knockout models have helped to clarify which cytokines critically depend on a given STAT protein. STAT1 knockout mice exhibit defects that are very selective for the actions of type I and type II IFNs,[557,558] suggesting that STAT1 is only vital for the actions of IFNs, even though a variety of other cytokines have been reported to activate STAT1. Although it is possible that STAT1 plays an important but redundant role for at least some of these other cytokines, the phenotype of STAT1-deficient mice indicates a need for caution in the interpretation of in vitro experiments that use high concentrations of cytokines or cell lines. STAT2-deficient mice exhibit defects consistent with selective inactivation of IFNα/β signaling.[559] STAT3-deficient mice exhibit fetal lethality; the embryos implant, but they exhibit defective development and growth.[560] Deletion of STAT3 within specific lineages has revealed that mice lacking STAT3 in T cells[561] have normal lymphoid development but exhibit a defect in IL-2-induced IL-2Rα expression, somewhat analogous to what is seen in STAT5A- and STAT5B-deficient mice (see the following discussion). They also exhibit defective Th17 differentiation due to defective signaling by IL-6 and IL-21.[169] Neutrophils and macrophages lacking STAT3 exhibit defective signaling to IL-10, and it is known that STAT3 is important for the normal involution of the mammary epithelium, for wound healing, and for normal hair cycle.[562,563] DCs lacking STAT3 exhibit a defect in Flt3L-dependent differentiation,[564] and antigen-presenting cells that are deficient in STAT3 exhibit disruption of priming of antigen-specific CD4+ T cells.[565] STAT4-deficient mice exhibit a phenotype similar to that of IL-12-deficient mice (ie, defective Th1 development), consistent with the observation that STAT4 is activated by IL-12.[566,567] Analogously, STAT6-deficient mice exhibit a phenotype similar to that of IL-4-deficient mice (ie, defective Th2 development),[568,569,570] in keeping with the observation that STAT6 is only activated by IL-4 and the closely related cytokine, IL-13. Interestingly, mice lacking STAT5A exhibit a defect in prolactin-mediated effects, including defective lobuloalveloar proliferation,[571] whereas mice lacking STAT5B have defective growth similar to that found in Laron dwarfism.[572] Thus, although STAT5A and STAT5B appear to always be coordinately induced, each of these STATs is important in vivo. In addition to these defects, both STAT5A- and STAT5B-deficient mice have defects in T-cell development and signaling.[511,512] STAT5A-deficient mice have diminished numbers of splenocytes and exhibit a defect in IL-2-induced IL-2Rα expression.[511] STAT5B-deficient mice have similar defects but also have diminished thymocytes.[512] Most dramatically, these mice have a major defect in the proliferation of freshly isolated splenocytes[512] and defective NK-cell development.[512] Mice lacking both STAT5A and STAT5B in lymphoid cells exhibit a dramatic defect in T-cell development,[573] and even hypomorphic expression of both STAT5A and STAT5B is sufficient to result in a lack of NK-cell development.[513] Presumably, the lack of T-cell development relates to defective IL-7 signaling, whereas the lack of NK-cell development relates to defective IL-15-dependent STAT5 activation. STAT5A/STAT5B double knockout mice exhibit lethality that is associated with severe anemia that develops in these mice.[574]

Signal Transducer and Activator of Transcription Proteins are Evolutionarily Old

Just as Drosophila has a JAK kinase, there is a Drosophila STAT, denoted as either DSTAT or STAT92E.[575,576] The existence of JAK kinases and STAT proteins in lower organisms suggest that the system is evolutionarily old. A STAT has been identified in *Dictyostelium* that recognizes the sequence TTGA,[577] has highest sequence similarity to STAT5B, and can bind mammalian IFN-stimulated response elements.[577] Interestingly, *Saccharomyces cerevisiae* do not appear to have STATs as no SH2 domains have been identified in the entire *S. cerevisiae* genome.

What Types of Functions Are Mediated by Signal Transducer and Activator of Transcriptions?

First and foremost, STAT proteins can translocate to the nucleus and bind to regulatory regions of target genes and influence transcription. Although STATs are generally activators of transcription, they can repress. For example, STAT1 can function as a transcriptional repressor of the c-myc gene.[578]

STAT proteins were discovered based on the study of IFN-inducible genes as part of studies intended to understand the cellular differentiation events that lead to development of the antiviral state. In addition to roles in differentiation, STAT proteins can contribute, directly or indirectly, to survival and/or mitogenic/proliferative responses that typify hematopoietic

and immunologic cytokines, such as IL-3, IL-5, GM-CSF, IL-2, and IL-4.[355] First, a number of in vitro systems have demonstrated that viruses or viral oncogenes are associated with activated JAK-STAT pathways, suggesting a role for STATs in cellular transformation. Indeed, STAT3 and STAT5 have been implicated as oncogenes, with compelling data for transformation capability of STAT3 in cell lines, persistently tyrosine-phosphorylated STATs in several types of leukemia and lymphoma, and the development of T-lymphoblastic lymphomas in STAT5 transgenic mice.[579] The role of STAT3 in the tumor microenvironment makes it an attractive target for cancer immunotherapy.[580] Second, there is diminished proliferation in a number of the STAT knockout mice that have been analyzed. For example, STAT4-deficient cells exhibit diminished cellular proliferation to IL-12566,567; STAT6-deficient cells exhibit diminished proliferation to IL-4[568,569]; and STAT5-deficient mice have diminished T-cell proliferation to IL-2.[511,512] Some of these effects are indirect, based on modulation of receptor expression. For example, STAT6-deficient mice exhibit decreased IL-4Rα expression. Similarly, the absence of STAT5 results in decreased IL-2-induced IL-2Rα expression as well as decreased proliferation.[511,512] Thus, in at least some cases, decreased proliferation results at least in part from decreased expression of receptor components. STAT5A and STAT5B regulate BCL-XL induction, indicating their ability to affect cell survival.[574] Finally, STAT1 has been linked to cell growth arrest and induction of the cdk inhibitor $p21^{WAF1/CIP1}$,[581] and activation of STAT1 occurs in thanatophoric dysplasia type II dwarfism as the result of a mutant fibroblast growth factor receptor.[582] In this chondrodysplasia, the mutant fibroblast growth factor receptor induces nuclear translocation of STAT1, expression of $p21^{WAF1/CIP1}$, and growth arrest, suggesting a possible relationship to the disease. Thus, different STATs may potentially mediate either growth expansion or growth arrest. Moreover, STATs may potentially play other types of roles, as well. For example, STAT3 has been reported to serve as an adapter to couple PI 3-kinase to the IFNAR-1 component of type I IFN receptors.[583]

A more complete understanding of the actions of the different STAT proteins may be

facilitated with a compilation of the genes that are regulated by each STAT. Progress in this area has been made for a number of cytokines by microarray or RNA-Seq analysis (eg, for the IFNs[399]). It is also important to recognize that not all cytokine signals are dependent on STATs, as illustrated, for example, by STAT1-independent IFN signals,[584] STAT5-independent IL-2 signals, 520 and STAT1/STAT3-independent IL-21 signals.[585]

Do Other Proteins Bind to GAS Motifs?

At least one non-STAT protein can bind to GAS motifs. The *BCL6* gene is often mutated or has undergone translocations in diffuse large cell B-cell lymphomas. Interestingly, BCL6 binds to GAS motifs capable of binding STAT6 and specifically can inhibit IL-4 action.[586] Mice lacking BCL6 expression exhibit defective germinal center formation, suggesting that formation of germinal centers may be at least partially dependent on BCL6 regulated (presumably negative) control of certain STAT-responsive genes.[586]

OTHER LATENT TRANSCRIPTION FACTORS AS EXAMPLES OF CYTOPLASMIC TO NUCLEAR SIGNALING (NF-κB, NFAT, AND SMADS)

An exciting feature of STAT proteins is that they exist in an inactive form in the cytosol and then are rapidly translocated to the nucleus. The rapid activation within minutes of signals from cell membrane to nuclear DNA binding makes the STAT acronym apt, analogous to the urgency associated with "STAT" emergency physician orders in clinical medicine. The rapid activation of STAT proteins is somewhat analogous to several other transcription factors.[587] NF-κB also undergoes rapid nuclear translocation but by a completely different mechanism from STATs. In contrast to STAT proteins where the tyrosine phosphorylation of the STATs is an initiator of nuclear translocation, for NF-κB, it is the serine phosphorylation and/or uquitination of IκB that results in its dissociation and/or destruction, allowing the release and translocation of NF-κB. There is the classical NF-κB pathway used by many cytokines, which involves the IKKα/IKKβ/IKKγ-dependent phosphorylation of IκB, resulting in the activation of NFκB1 (p50)/Rel-A (p65) heterodimers as well as the alternative pathway in which a homodimer of IKKα mediates the activation of NFκB2 (p52)/Rel-B heterodimers.[588,589,590,591,592,593,594] A third example of cytosolic to nuclear translocation occurs with nuclear factor of activated T-cell (NFAT) family proteins,[595,596,597] which are vital for regulating transcription of a number of cytokines, including for example IL-2, IL-4, and GM-CSF. NFAT is translocated to the nucleus where it associates with activator protein 1 (AP-1) family proteins to form a functional complex. It is the activation of calcineurin and dephosphorylation of NFAT that allows its nuclear translocation. A fourth example of cytosolic to nuclear translocation occurs with the SMAD proteins that mediate TGF-β signaling, which contributes to Th17 differentiation (discussed subsequently). For SMADs, the phosphorylation is on serine and the kinase is intrinsic to the receptor, but like STATs, activation of these latent transcription factors is rapid and initiated by the binding of a growth factor. Thus, several mechanisms, each involving phosphorylation or dephosphorylation, have evolved to allow cytoplasmic to nuclear translocation of latent transcription factors.

OTHER SUBSTRATES FOR JAKS

As JAKs are potent cytosolic tyrosine kinases, it is evident that the JAKs may do more than just phosphorylate tyrosine residues on receptors where STAT proteins dock as well as phosphorylating the STATs. In vitro data indicate that JAK kinases also can phosphorylate receptor tyrosines other than the docking sites for STATs. For example, in the case of IL-2Rβ, JAK1 can phosphorylate not only tyrosines 392 and 510, which are STAT docking sites, but also tyrosine 338, which is a docking site for SHC,[520] all of which are required for maximal

proliferation. JAK kinases are known to autophosphorylate themselves or transphosphorylate other JAKs. Other molecules are potentially phosphorylated by JAK kinases, including the STAM adapter molecule[598] and the p85 subunit of PI 3-kinase.[599]

Interferon Regulatory Factor Family Proteins

IRFs form a family of nine proteins that are regulated by type I IFNs.[395,600,601] They each have a well-conserved N-terminal DNA-binding domain that forms a helix-loop-helix structure as well as a C-terminal interaction domain. IRFs are critical for a number of actions, including type I IFN-dependent gene transcription.[395] Select IRFs play critical roles in TLR-mediated IFN induction. IRFs can have negative as well as positive effects. For example, IFNγ-mediated repression of IL-4 is mediated by IRF protein(s).[602]

OTHER SIGNALING MOLECULES IMPORTANT FOR CYTOKINES

Other Tyrosine Kinases besides JAKS

In addition to their activation of JAK kinases, a number of cytokines can activate Src family kinases. For example, IL-2 can activate p56lck[603,604] in T cells and p59fyn and p53/p56 lyn in B-cell lines.[605,606] The activation of some of these kinases has been reported to be mediated by associating with the "A" region of IL-2Rβ. Another tyrosine kinase, Syk, has been reported to associate with the S region of IL-2Rβ.[607] However, the significance of these interactions is less clear than that for JAK kinases. First, cells lacking Lck can vigorously proliferate in response to IL-2.[608,609] Second, when the A region is deleted, proliferation still occurs, albeit at a lower level than seen with wild-type IL-2Rβ.[610] However, Y338, which is required for the recruitment of SHC, is in the A region and is required for normal proliferation.[520] Thus, it is possible that the decrease in proliferation associated with deletion of the A region relates more to the loss of Y338 than it does to the loss of association of Lck. Moreover, in *Il2rb*-/- mice reconstituted with an IL-2Rβ A-region mutant, proliferation is increased rather than decreased.[611] Additional investigation is required to clarify the role of activation of Src family kinases by IL-2 and other cytokines as well as the significance of the Syk interaction with IL-2Rβ. As Syk and JAK1 both associate with the S region of IL-2Rβ, mutations that delete the S region simultaneous prevent both associations, making it hard to determine the specific role of Syk. Syk-deficient mice exhibit normal IL-2 proliferation,[612] further suggesting that Syk may not play an important role in IL-2-induced proliferation. The G-CSF receptor also can form a complex with Lyn and Syk,[613] but again Syk-deficient mice do not exhibit a defect in G-CSF signaling.[612] β_C has also been reported to interact with Src family kinases[614]; gp130 has been reported to associate with a number of other kinases, including Btk, Tec, and Fes[615,616,617]; and IL-4Rα has been shown to interact with Fes.[618] However, relatively little is known about the significance of tyrosine kinases besides JAKs in cytokine signaling. Additionally, PI 3-kinase, p38, ERK, and JNK can each become activated, leading to activation of many downstream transcription factors, including NF-κB, AP1, PU.1, IRF1, IRF4, and IRF8, to mediate a program of gene expression.

IRS Proteins

IRS-1 was discovered as a tyrosine phosphorylated substrate of the insulin receptor.[619] IRS proteins have a large number of phosphotyrosine docking sites, particularly for the p85 subunit of PI 3-kinase, and they presumably serve to recruit important accessory molecules.

Interestingly, both insulin and IL-4 could induce tyrosine phosphorylation of an IRS-1-like molecule in hematopoietic cells. The 32D myeloid progenitor cells lack IRS-1 and could only signal in response to insulin or IL-4 when they were transfected with IRS-1.[620] Both the insulin receptor and IL-4Rα proteins contain NPXY sequences that are important for IRS-1 or IRS-2 binding; in IL-4Rα, this is contained within a sequence denoted as the I4R motif.[621]

Other cytokines have subsequently been shown to activate IRS-1 and/or IRS-2. For example, growth hormone can induce phosphorylation of IRS-1[622] and IRS-2[623]; IFNγ and LIF induce phosphorylation of IRS-2[623]; and the γ_c-dependent cytokines IL-2, IL-7, and IL-15 can induce tyrosine phosphorylation of IRS-1 and IRS-2 in T cells.[624] The significance of these findings remain unclear, as 32D cells reconstituted with a complete IL-2 receptor can proliferative vigorously in response to IL-2,[608] whereas as noted previously, in these same cells, IL-4 responsiveness requires coexpression of both IL-4Rα and IRS-1, indicative of differing roles for IRS proteins for different cytokines.

Phosphatidylinositol 3-Kinase

PI 3-kinase is a lipid kinase that consists of an 85 kDa regulatory subunit and a 110 kDa catalytic subunit.[625] PI 3-kinase phosphorylation and activation can be induced by a number of cytokines,[626,627,628,629] and the use of inhibitors, such a wortmannin or LY294002, have demonstrated its importance in signaling for at least certain cytokines. IRS-1 has multiple docking sites for PI 3-kinase (YXXM motifs) and thus for some cytokines, such as IL-4, the association of IRS-1 might be the mechanism by which PI 3-kinase can be recruited.

The Ras/Mitogen-Activated Protein Kinase Pathway

Another major signaling pathway for a number of cytokines is the Ras/MAP kinase pathway.[630] This pathway presumably is used by cytokines whose receptors recruit the SHC adaptor molecule, which in turn mediates the recruitment of Grb2 and Sos, eventually leading to the activation of Ras. In turn, Ras couples to the MAP kinase pathway through a welldefined signaling cascade. Certain cytokines, such as IL-2 and IL-3, appear to use this pathway, whereas others, such as IL-4, do not, indicating that this pathway is differentially important depending on the cytokine that is being used.

DOWNMODULATION OF CYTOKINE SIGNALS

Much of the previous discussion has centered on the mechanisms by which cytokines induce signals. However, the mechanisms by which cytokine signals can be terminated are also extremely important. There are multiple levels at which negative regulation can occur. These include 1) regulating a balance between the production (transcriptional and translational control) of the cytokine, its receptor, and/or downstream signaling molecules and the degradation

of these same molecules; and 2) regulation of the activation state of the receptor and downstream signaling molecules. For example, these can be mediated by transcriptional repressors or molecules that either inhibit cytokine signaling (eg, SOCS proteins) or reverse activated states (eg, phosphatases).

Transcriptional control of cytokine production is a widely used mechanism. Many T-cell-derived cytokines such as IL-2, IL-3, and IL-4 are only produced by activated T cells, and their production is lost with the loss of activation. IL-15 provides an example where translation of the protein is carefully regulated, in part by the existence of multiple upstream antithymocyte globulins.[147] Most cytokine receptor chains are constitutively expressed, but some like IL-21R and IL-2Rβ are regulated in part by signals that act through the TCR. The

most regulated receptor chain may be IL-2Rα, whose expression is absent on resting lymphocytes but strongly induced following stimulation with antigens, mitogens, and certain cytokines, but the transcriptional/translational control of most cytokine receptors is poorly studied.

Because phosphorylation events are vital for the creation of phosphotyrosine docking sites, dephosphorylation is an obvious mechanism of control. Indeed, two tyrosine phosphatases, Shp-1 (formerly also known as SHP, HCP, SH-PTP1, and PTP1C) and Shp-2 (formerly also known as Syp and PTP1D) have been shown to play roles related to cytokine signaling.[631,632] Shp-1 mutations cause the motheaten (*me*) and viable motheaten (*me*v) phenotypes in mice.[633,634] The viable motheaten mouse had a less severe phenotype that is associated with increased numbers of erythroid progenitor cells and hyperresponsiveness to Epo,[635] suggesting that Shp-1 might normally diminish responsiveness to Epo. Indeed, it was demonstrated that Shp-1 binds directly to the EpoR when Y429 is phosphorylated.[636] This tyrosine is located in a "negative" regulatory region of the EpoR, and when mutated, Epo-responsive cells can grow in lower concentrations of Epo. Following Shp-1 binding to Y429, dephosphorylation and inactivation of JAK2 is facilitated.[636] Thus, the negative regulation of Epo signaling appears to be at the level of a receptor-dependent inactivation of a JAK kinase. Shp-1 has also been shown to interact with β_C and to mediate diminished IL-3-induced signaling[637] and to be able to associate with both TYK2[638] and JAK2.[639]

Shp-2 has generally been considered primarily an "activating" phosphatase; it is therefore interesting that it can also interact with JAK1, JAK2, and TYK2.[640] In addition to the presumed dephosphorylation of JAK kinases by phosphatases, STAT proteins also appear to be regulated at the level of tyrosine dephosphorylation,[641] and interestingly, it has been shown that dephosphorylation of phosphotyrosine on STAT1 dimers requires extensive spatial reorientation of the two monomers within the dimer, something that is facilitated by the N-terminal domain that is involved in tetramerization.[642] Finally, another type of phosphatase, namely the lipid phosphatases, known as SHIP and SHIP2, can act as negative regulators of cytokine signals.[643] In addition to Shp-1 and Shp-2, CD45, PTP1B, and T-cell PTP (TCPTP) have been reported to regulate JAK kinases. CD45 appears to play roles related to Epo and IFN signaling. PTP1B has been reported to dephosphorylate JAK2 and TYK2, and TCPTP has been reported to dephosphorylate JAK1 and JAK3.[449] In the cytosol, Shp-2 and PTP1B have also been reported to dephosphorylate cytosolic STAT5 and nuclear STAT1 and STAT3, whereas TCPTP has been reported to dephosphorylate STAT1 and STAT3 in both cytosol and nucleus, but additional work is needed to determine whether these events are occurring physiologically in vivo.[449]

In addition to dephosphorylation, another mode of negative regulation is by degradation. In addition to the degradation of receptor molecules, STAT1 itself is a target of the ubiquitin-proteasome pathway.[644] Finally, it is possible that regulation also can occur at the level of alternative splicing. In this regard, alternatively spliced versions of some of the STATs[448,508,515] have been reported.

THE CIS/SOCS/JAB/SSI FAMILY OF INHIBITORY ADAPTER PROTEINS

In 1995, the protoype molecule for an interesting class of proteins was discovered. The prototype molecule was named CIS, for cytokine inducible, SH2-containing protein, and it was shown to negatively regulate the actions of a set of cytokines.[645,646] CIS is rapidly induced by a variety of cytokines, including IL-2, IL-3, GM-CSF, and Epo, to physically associate with both the β_C and Epo receptors.[645,646] Subsequently, a related protein,

variably denoted SOCS-1, JAB (JAK-binding protein), and SSI-1 (STAT-induced STAT inhibitor-1) was identified that could negatively regulate the activity of other cytokines, including IL-6[647,648,649] and IL-2, among others. Interestingly, this protein could associate with JAK family kinases, whereas this function has not been reported for CIS. A total of eight CIS/SOCS/JAB/SSI family members have been identified that collectively regulate signals in response to multiple cytokines.[650,651,652,653,654] These proteins are now generally known as SOCS proteins and share a central SH2 domain and a region known as a C-terminal region known as a SOCS box. Additional SOCS box-containing proteins lack SH2 domains and include proteins known as ASBs (ankyrin repeat-containing proteins with a SOCS box), SSBs (SPRY domain-containing proteins with a SOCS box), and WSBs (WD40 repeat-containing proteins with a SOCS box). SOCS proteins tend to be expressed at very low levels in nonactivated cells and to be induced by cytokines and pathogens. Following their induction, they negatively influence cytokine signaling, serving as negative feedback regulators. Their actions can extend beyond type I cytokines, for example, SOCS-1 can negatively regulate LPS responses.[655]

Knockout mice for a number of the SOCS proteins have been prepared, alone and in combination. CIS knockout mice are relatively normal, but CIS transgenic mice exhibit low body weight, failure of lactation, and diminished numbers of NK and NKT cells as well as altered TCR-mediated responses, presumably related to its ability to inhibit STAT5-dependent responses including those related to growth hormone, prolactin, IL-15, and IL-2, as well as others. SOCS-1 knockout exhibit multiorgan inflammation and neonatal lethality as the result of augmented responsiveness

to IFNγ, and this lethality can be prevented if the mice are crossed to IFNγ-deficient mice. Interestingly, SOCS-1-/- mice also indicate an essential role for SOCS-1 in thymocyte differentiation, and there are diminished numbers of maturing B cells. Deletion of SOCS-1 within thymocytes/T cells/NKT cells results in multiple lymphoid abnormalites with increased CD8+ T cells due to increased sensitivity to γ_C-dependent cytokines, including IL-7.[656] SOCS-2 knockout mice exhibit gigantism, ostensible due to dysregulated growth hormone signaling. SOCS-2 knockout T cells exhibit enhanced Th2 differentiation, and knockout mice exhibit elevated Th2 responses after helminth infection.[657] SOCS-3 knockout mice exhibit embryonic lethality due to placental insufficiency and dysregulated responses to LIF and IL-6 as well as hematopoietic defects. Conditional SOCS-3 knockout mice have revealed a physiologic role for SOCS-3 in regulating G-CSF signaling in myeloid cells and for "emergency" granulopoiesis[658] as well as for IL-6/gp130 signaling.[659,660] SOCS-6 knockout have mild growth retardation.[449,652,661] Additional SOCS knockout mice and various combinations continue to be generated, adding additional information to this important area of negative regulation of STAT-dependent signaling.

PROTEIN INHIBITORS OF ACTIVATED SIGNAL TRANSDUCER AND ACTIVATOR OF TRANSCRIPTION PROTEINS

Protein inhibitors of activated STAT (PIAS) proteins are other negative regulators of cytokine actions,[449,662,663,664,665,666] with PIAS-1 being an inhibitor of STAT1-binding activity and PIAS-3 being a similar inhibitor of STAT3-binding activity. These PIAS proteins block the DNA-binding activity of STAT dimers. Two other members, PIASx (which has both α and β splice variants) and PIASy, have also been described, with PIASx inhibiting STAT4 and PIASY inhibiting STAT1. They appear to act at least in part as transcriptional corepressors by recruiting other proteins such as histone deacetylase. In addition, PIASx and PIASy have added actions not restricted to the context of STAT inhibition. For example, PIASy is a nuclear matrix-associated SUMO E3 ligase (a ubiquitin-related protein) that can repress the activitity

of the Wnt-responsive transcription factor, LEF1.[665] PIASy coexpression results in the covalent modification of LEF1 by SUMO. Thus, as a class, PIAS proteins have more than one type of action.[449,667]

DISEASES OF CYTOKINE RECEPTORS AND RELATED MOLECULES

A Range of Cytokine-Related Causes of Severe Combined Immunodeficiency

As detailed previously, mutations in the γ_C cause X-linked SCID, and mutations in JAK3 cause a similar T-B+NK-SCID. Given that γ_C-dependent cytokines activate primarily STAT5A and STAT5B as signaling molecules downstream of the JAKs, it remains an open question as to whether mutations in these STAT proteins also cause human disease. Although one could hypothesize that mutations in either STAT5A or STAT5B alone might not cause a phenotype due to potential redundancy, mice lacking STAT5A or STAT5B exhibit defects in T- and NK-cell numbers as well as T-cell proliferation and NK cytolytic activity,[511,512] and mice lacking both STAT5A and STAT5B have an even more profound defect, with absent T-cell[573] and NK-cell development.[513] Moreover, STATB mutations have been found and cause growth hormone insensitivity, IGF-1 deficiency, and immune dysfunction.[573a,573b]

It can be predicted that human immunodeficiencies might also result from mutations in some of the cytokines whose receptors contain γ_C or from mutations in other components of the receptors for these cytokines. Indeed, as noted previously, patients with IL-2 deficiency exhibit a SCID-like syndrome, due to inadequate function of their T cells, and recently, an unusual immunodeficiency has been found to result from a mutation in IL-2Rα.[369] One patient with defective IL-2Rβ expression also had an immunodeficiency syndrome characterized by autoimmunity,[668] somewhat analogous to IL-2Rβ-deficient mice. Given that mutations in IL-7Rα in humans cause T-B+NK+ SCID,[206] mutations in IL-7 might be predicted to cause a similar syndrome. The one major difference might be that IL-7-deficient humans might not be capable of receiving a successful bone marrow transplant if stromal IL-7 is required for the graft. Such patients have not yet been identified. Given the defective NK-cell development and CD8+ memory T-cell development in IL-15- and IL-15Rα-deficient mice, it is likely that these types of defects would also occur in humans lacking either of these proteins. However, again, such patients have not yet been identified. Although IL-9 transgenic mice develop lymphomas,[669] IL-9-deficient mice exhibit defects related to mast cells and mucous production rather than lymphoid defects. Thus, defects related to the IL-9 system seem unlikely as causes of SCID. At present, defective expression of IL-2, IL-2Rα, IL-2Rβ, IL-7Rα, γ_C, and JAK3 are the only cytokinerelated mutations that have been found to cause SCID, with TYK2 being implicated in another form of immunodeficiency. More time will be required to determine whether mutations in other cytokines, cytokine receptors, JAKs, or STATs can also cause SCID.

Defects in the Ability to Clear Mycobacterial Infections and Chronic Mucocutaneous Candidiasis

A number of immunodeficiencies have been characterized where affected individuals cannot properly clear mycobacterial infections. These have also turned out to be diseases of defective cytokine signaling. Mutations have been found in the components of either IL-12 itself or in the IFN or IL-12/IL-23 receptors, with mutations having been found in either the gene encoding the p40 subunit of IL-12 (which as noted previously is also a component of IL-23),[670] in IL-12Rβ1 (a component of both the IL-12 and IL-23 receptors),[671] or in either the IFNGR-1 or IFNGR-2 components of IFNγ receptors.[672,673] The critical role of IL-12 for Th1 cell-mediated differentiation and production of IFNγ provides the explanation for finding

similar clinical syndromes in humans lacking the p40, IL-12Rβ1, IFNGR1, or IFNGR-2. Moreover,

one patient with a mutation in the STAT1 gene was also identified with a similar clinical syndrome,[674] indicating that as anticipated, STAT1 is a critical mediator of IFNγ signaling. Interestingly, this patient had a mutation on only one STAT1 allele, but the mutation was a dominant negative mutations that selectively inhibits the formation of STAT1 dimers (hence abrogating IFNγ signaling) but yet had at most only a modest effect on the ability to form ISGF3, hence leaving signaling in response to IFNα/β relatively intact. Chronic mucocutaneous candidiasis can be caused by autosomal dominant IL-17F or autosomal recessive IL-17RA deficiency or by gain-of-function heterozygous STAT1 mutant alleles that impair IL-17 immunity.[675]

Somatic mutations that activate STAT3 occur in benign liver adenomas, suggesting a role for IL-6-STAT3 pathway in human hepatocellular tumorigenesis.[676]

Mutations in the WSX-1/TCCR Type I Receptor

Interestingly, there is a type I cytokine receptor denoted as TCCR or WSX-1 that is related to IL-12β2 and its mutations results in defective Th1-related responses and diminished IFNγ production, resulting in susceptible to *Leishmania major* and *Listeria monocytogenes*.[254,677,678] TCCR/WSX-1 is an essential component of the receptor for IL-27[300] and also has been found to be required for resistance to *Trypanosoma cruzi*.[679,680]

Other Diseases Associated with Cytokine Receptors

A number of other diseases have been reported that related to cytokine receptors. First, mutations in the growth hormone receptor have been found in a form of dwarfism (Laron dwarfism)[681] in which target cells cannot respond to growth hormone. Interestingly, some aspects of STAT5B deficiency are related to this syndrome. Second, a single patient with a form of congenital neutropenia (Kostmann syndrome) has been found to have a mutation in one of his G-CSF receptor alleles.[682] Third, a kindred of patients with familial erythrocytosis has truncation in the erythropoietin receptor, resulting in hypersensitivity to Epo.[683] Fourth, an altered virally encoded form (v-mpl) of the thrombopoietin receptor (c-mpl) was originally identified as the oncogene of the myeloproliferative leukemia virus.[684] Finally, gain-of-function mutations in *IL7R*[685] and genomic aberrations of *TSLPR* (also known as *CRLF2*)[686,687,688] have been found in childhood acute lymphoblastic leukemias, sometimes associated with mutations in JAK2 or JAK1 or TLSPR itself.

Modulation of Cytokines and the Clinic

Certain diseases are associated with increased levels of cytokines or other situations where treatment with an anticytokine receptor antibody is a rationale therapy. One major example is Castleman disease, which is associated with overproduction of IL-6 by lymph node cells, leading to the successful treatment of this disease with IL-6 receptor blockade.[257,689] Anti-IL-6R-based therapy also has utility for rheumatoid arthritis and possibly for Crohn disase.[257,690] Blocking the IL-2 receptor has been used in the treatment of patients with adult T-cell leukemia and other neoplasias, and the use of humanized and conjugated antibodies have produced responses in a number of individuals. Humanized anti-Tac monoclonal antibody, marketed under the name daclizumab, has shown very strong efficacy in the treatment of allograft rejection as well as in T-cell-mediated autoimmune disorders, including multiple sclerosis, uveitis, and tropical spastic paraparesis. Conjugated antibodies

to both IL-2Rα and IL-2Rβ are also being tested for use in a variety of malignant disorders, wherein the malignant cells express these proteins. Thus, there is the possibility of therapy, either based on blocking the cytokine or based on eliminating the responding cells.[691]

CONCLUSION

Type I cytokines and IFNs are involved in the regulation of an enormous number of immunologic and nonimmunologic processes. There has been a progressive transition from viewing these as discrete molecules with special actions to sets of molecules that can be grouped according to shared receptor components and common signaling pathways. Signaling is one area where our understanding has greatly expanded; the pathways that are activated are similar for many cytokines, even when the biologic functions they induce are dramatically different. Although some of the differences can be explained by "compartmentalization" according to which cells produce the cytokine and which cells express receptors that allow them to respond to the cytokine, a tremendous amount still needs to be learned about how distinctive signals are triggered as well as more regarding the sets of genes that are induced by each cytokine. These will provide vital information important to the quest to completely understand the mechanisms by which type I cytokines and IFNs can effect their actions. At the same time, the generation of knockout mice for most cytokines and their receptors, as well as many signaling molecules, has provided in vivo clues as to vital functions served by these cytokines. Caution is clearly needed, however, in generalizing from these findings to human biology, given some apparently major differences in roles served, such as the essential role played by IL-7 in both humans and mice for T-cell development, whereas IL-7 is also essential for B-cell development in mice but not in humans. The identification of so many humans disorders associated with cytokines and cytokine receptors has tremendously helped to teach us more about normal human biology as well.

Chapter 26

The Interleukin-1 Family

Charles A. Dinarello

Mihai G. Netea

INTRODUCTION

More than any other cytokine family, the interleukin (IL)-1 family of ligands and receptors is primarily associated with acute and chronic inflammation. Also, more than any other cytokine family, the IL-1 family plays a fundamental role in the nonspecific innate response to infection that facilitates specific immunologic responses such as antibodies and cytotoxic T-lymphocytes. This nonspecific response to infection is now termed the “innate immune response.” The cytosolic segment of each member of the IL-1 receptor family contains the toll-IL-1-receptor (TIR) domain. This domain is also present in each toll-like receptor (TLR), receptors that respond to microbial products, viruses, and nucleic acids. TIR is the functional domain for both the TLR and IL-1 receptor families, as mutations in this domain result in loss of response to IL-1 and TLR agonists. The biologic properties of both IL-1 family ligands and TLR agonists characteristically are proinflammatory and act as adjuvants for specific immune responses to antigen. Thus, the IL-1 family of ligands and receptors is fundamental to innate immunity. Of the 11 members of the IL-1 family, IL-1β has emerged as a therapeutic target for an expanding number of systemic and local inflammatory conditions termed “autoinflammatory” diseases. These diseases are distinct from autoimmune diseases and include rare hereditary conditions. But autoinflammatory diseases are also common diseases such as heart failure, gouty arthritis, and type 2 diabetes. For these, neutralization of IL-1β results in a rapid and sustained reduction in disease severity. Another member of the IL-1 family, IL-1α, is also a mediator of inflammation but is classified as an “alarmin” because the cytokine is present in most cells and readily released upon cell death. Whereas treatment for autoimmune diseases often includes immunosuppressive drugs, neutralization of IL-1β or blocking the IL-1 receptor is mostly anti-inflammatory.

With one exception, all members of the IL-1 family are initially translated as precursors lacking a signal peptide for secretion via the Golgi. The precursors are found in the cytosol and exit the cell following death by necrosis, not apoptosis. For example, once released, IL-1α, IL-33, and IL-36 can be processed extracellularly by neutrophil proteases into active cytokines. Although IL-1β is primarily processed intracellularly by the cysteine protease caspase-1, the IL-1β precursor can also be cleaved extracellularly into an active cytokine by similar serine proteases of neutrophils. The one member of the IL-1 family that is readily secreted is the IL-1 receptor antagonist (IL-1Ra). IL-1Ra is translated with a signal peptide (Fig. 26.1), although an intracellular form also exists.[1] IL-1Ra is produced in health and is

found circulating in mice and humans where the antagonist serves as a brake on inflammation driven by endogenous IL-1α or IL-1β. IL-1Ra binds to the IL-1RI and blocks the receptor from binding to either IL-1α or IL-1β (see Fig. 26.1C). Mice as well as humans born with a deficiency in functional IL-1Ra exhibit increased systemic and local inflammation; in humans, a deficiency in IL-1Ra is lethal. The IL-36 receptor antagonist (IL-36Ra), another member of the IL-1 family, inhibits the activity of endogenous IL-36α, β, and γ. Although IL-36Ra is not readily secreted, individuals with a mutation in IL-36Ra develop a severe form of psoriasis. One may conclude that most members of the IL-1 family primarily promote inflammation and enhance specific acquired immune responses. But there are also members that provide a brake on inflammation. The primary characteristics of the each member of the IL-1 family are depicted in Table 26.1.

INTERLEUKIN-1 FAMILY AND INNATE RESPONSES

Independent of the type of organism or its products, the innate response is one of inflammation in which the host musters its defenses to increase the production and infiltration of phagocytic cells to the area of the invading microbe in an attempt limit infection and kill-off the invader. Systemically, the liver increases the synthesis of acute phase proteins, include antiproteases. Even in humans, in most cases this process protects the subject without the use of antibiotics. For example, a break in the skin allows bacteria to gain access to the dermis and subsequent inflammation provides activation of complement, the release of preformed cytokines from keratinocytes, an increase in vascular wall adhesions molecules, and the extravasation of neutrophils. This response has functioned to battle against invaders for millions of years and can be traced back to fruit flies.

The skin, lung, and intestinal tract each provide a first line of defense against microbial invasion and the lining cells, whether keratinocytes of the skin, the alveolar epithelial cells of the pulmonary tree, or the epithelial cells of the entire gastrointestinal tract, each contain preformed IL-1α, IL-18, and IL-33 as well as the members of the IL-36 subfamily. Because these members of the IL-1 family are each preformed in these cells, their release is a consequence of injury and is immediate. Therefore, they are termed “alarmins” as they alert the host to initiate the response. There are other “alarmins” from the lining cells that participate in defense, for example, defensins, which are directly antimicrobial.

Each of the constitutively present IL-1 family members in lining cells is present as a precursor. In the case of IL-1α, the precursor is fully active; in the case of the other members, the precursors are weakly active at first but are converted to more active cytokines upon the infiltration of neutrophils and processing by extracellular neutrophil proteases. In the end, the infection is contained, the invading microorganism is eliminated, and skin begins its process of repair.

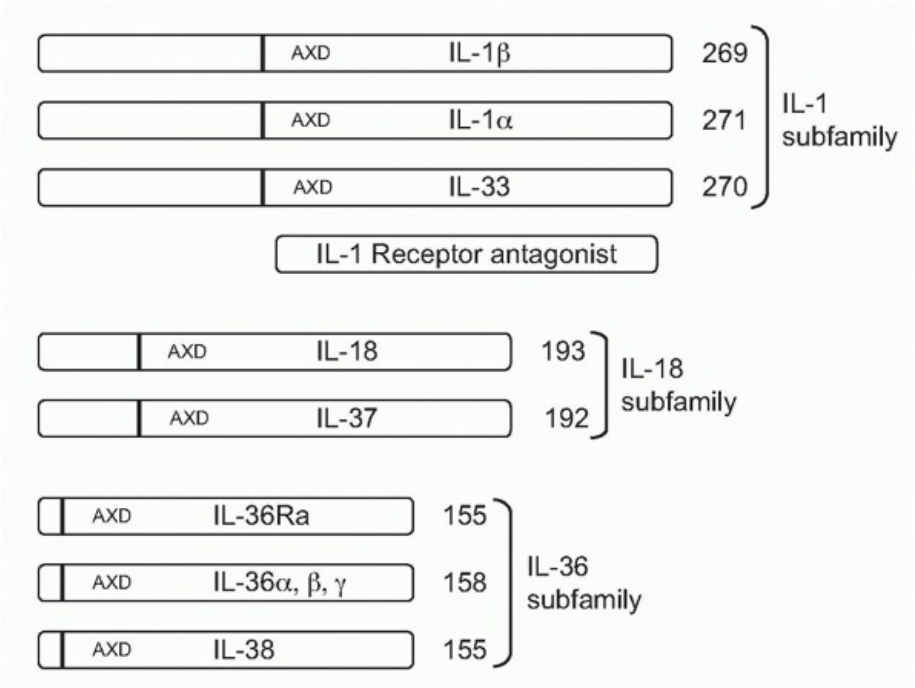

FIG. 26.1. Organization of the Interleukin (IL)-1 Family into Three Subfamilies. The number of amino acids of the fulllength of each member is shown at the C-terminal end. The consensus sequence (A-X-D) is common to all IL-1 family members and serves to locate the N-terminus nine amino acids forward from this site, as shown by the *dark vertical bar*. The N-terminus results in propieces of various lengths. The IL-1Ra has a bonafide signal peptide and is shown by comparison.

Following the cloning of the mouse IL-1 receptor,[2] the cytosolic domain of the IL-1 receptor was found to be homologous to toll of the fruit fly.[3] Moreover, at the same time, the TIR domain for IL-1 signaling (Fig. 26.2A) was shown by Heguy to be required for IL-1 signaling.[4] Toll had been initially studied since its discovery in 1985 because of its central role in establishing dorsal ventral polarity in *Drosophila*. Only since 1996 was toll linked to survival in fruit flies infected with fungi.[5] However, it had already been reported, back in 1988, that a member of the IL-1/TLR family, human IL-1β, protected mice from lethal *Pseudomonas* infection.[6] As noted previously, the TIR domain is essential for both IL-1 receptor family and TLR family signaling; a mutation in the TIR domain severely impairs responses to IL-1 family ligands as well to a large number of microbial products.[7]

TABLE 26.1 Interleukin-1 Family Members

Family Name	Name	Property
IL-1F1	IL-1α	Agonist

IL-1F2	IL-1β	Agonist
IL-1F3	IL-1Ra	Receptor antagonist
IL-1F4	IL-18	Agonist
IL-1F5	IL-36Ra	Receptor antagonist
IL-1F6	IL-36α	Agonist
IL-1F7	IL-37	Anti-inflammatory
IL-1F8	IL-36α	Agonist
IL-1F9	IL-36γ	Agonist
IL-1F10	IL-38	Receptor antagonist
IL-1F11	IL-33	Agonist

IL, interleukin.

The TIR domain binds MyD88 (see Fig. 26.2A and E), itself a TIR domain-containing protein, through TIR/TIR interactions triggering a cascade of kinases that propagate the IL-1 signal and result in transcription of a large number of genes, the majority of which code for other cytokines, chemokines, and a host of inflammatory mediators. Of these is IL-1 and other members of the IL-1 family such as IL-36 and IL-18.

The “innate immune response” regulates to the “acquired immune response.” The late Charles Janeway proposed that the innate response assists the host in mounting an acquired immune response. This relationship between a nonspecific cytokine providing help for a specific response to a microbial antigen is simply the adjuvant property of some cytokines. The adjuvant property of some cytokines functions by upregulating lymphocyte growth factors such as IL-2, IL-4, and IL-6, or lymphocyte receptors resulting in expansion of lymphocyte clones, which will either rid the host of the invading microorganism with neutralizing antibodies or in generation of cytotoxic T cells to eliminate viral infections. In 1979, purified human IL-1β, a nonspecific macrophage product, was shown to augment the T-cell response to specific antigen.[8] It was nearly 20 years later that TLR were identified as inducing IL-1β from monocytes.

ORGANIZATION OF THE INTERLEUKIN-1 FAMILY OF LIGANDS AND THE CONSENSUS SEQUENCE

As depicted in Figure 26.1, the IL-1 family can be divided into subfamilies according to the length of the precursor and the length of the propiece for each precursor. The IL-1 subfamily

is comprised of IL-1α, IL-1β, and IL-33. This subfamily has the longest proteins with the longest propieces. In the case of IL-1β, the propiece is cleaved intracellularly by caspase-1 and then the mature cytokine is secreted. In the case of IL-1α, cleavage appears to be by the membrane protease calpain, but

extracellular neutrophil proteases can also cleave the IL-1α precursor. Extracellular neutrophil proteases account for the cleavage of the propiece of IL-33. The exception in the IL-1 subfamily is IL-1Ra, which contains a signal peptide.

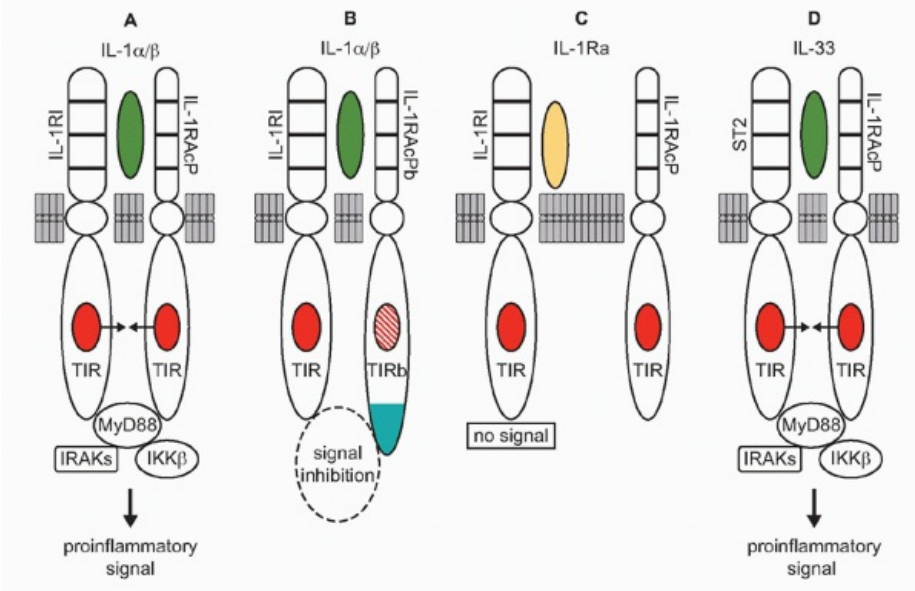

FIG. 26.2. Interleukin (IL)-1 Subfamily. A: IL-1α or IL-1β binds to the IL-1RI and recruits the coreceptor IL-1RAcP. The heterodimeric IL-1 receptor complex results in a close approximation of the toll-IL-1-receptor (TIR) domains on each receptor chain (*arrows*), resulting in the binding of intracellular MyD88 to the complex followed by phosphorylation of MyD88. Subsequent phosphorylations of IRAKs and IKKβ, increased NF-κB, and IL-1R AcP-1 translocation to the nucleus take place followed by expression of proinflammatory genes. **B:** In the central nervous system, IL-1α or IL-1β bind IL-1RI recruiting IL-1RAcP but can also recruit the coreceptor IL-1RAcPb. IL-1RAcPb contains an altered TIR domain, which results in a reduced signal. **C:** IL-1Ra binds to IL-1RI. There is no recruitment of the co-receptor IL-1RAcP, no approximation of the TIR domains, and no signal. **D:** IL-33 binds to its specific receptor, ST2, and recruits the coreceptor IL-1RAcP, the TIR domains approximate, and signal transduction is initiated resulting in the induction of proinflammatory gene profile.

The IL-18 subfamily is comprised of IL-18 and IL-37. By comparison, this subfamily has a smaller propiece. IL-18 requires the cleavage of its propiece by caspase-1 in order to be active. IL-37 is part of the IL-18 subfamily because the cytokine binds to the IL-18Rα chain. It is unclear how the propiece of IL-37 is removed. The IL-36 subfamily comprised of IL-36α, β, and γ, as well as IL-36Ra. In addition, IL-38 likely belongs to this family due to its binding to the IL-36R. The IL-36 subfamily has the shortest propiece.

A consensus sequence in all members of the IL-1 family is A-X-D, where A is an aliphatic amino acid such as isoleucine, methionine, or leucine; X is any amino acid; and D is aspartic acid. The aspartic acid of the consensus sequence is not the aspartic acid of the caspase-1 cleavage recognition site. The A-X-D motif is conserved in the IL-1 family where it plays a role in three-dimensional structure of the active cytokine. The actual N-terminus is often located nine amino acids before the A-X-D site. By eliminating the amino acids before the N-terminus, the first beta-sheet structure common to all members of the IL-1 family can form. For example, with the tenth amino acid before A-X-D consensus site as the N-terminus, the specific activity of the IL-36 subfamily (IL-36α, IL-36β, IL-36γ and the IL-36Ra) is low. However, with the ninth amino acid as the N-terminus, there was a marked increased in the activity.[9] In the case of IL-1β, the ninth amino acid before the A-X-D site coincides exactly with the N-terminal alanine generated by the caspase-1 site.

THE INFLUENCE OF INTERLEUKIN-1 FAMILY ON TH17 RESPONSES

The IL-1 family plays a significant role in interferon (IFN)γ production, which is essential for the defense against intracellular pathogens. On the other hand, Th2 cells are characterized by the production of IL-4 and are important in the host defense against parasitic infections. For more than one decade, the dichotomy between Th1 and Th2 has been the focus of studies on differentiation of cluster of differentiation (CD)4+ T-lymphocytes. More recently, Th17 helper cells have been described and are characterized by their production of IL-17. IL-17 plays a major role in neutrophil recruitment and host defense against extracellular bacteria and fungi. Th17 cells produce a distinct cytokine profile, namely IL-17A, IL-17F, IL-21, and IL-22. The cytokines produced

by Th17 cells, in addition to activating neutrophils, are also crucial for nonimmune cells, for example, induction of defensins by IL-22 in epithelial cells and keratinocytes, which are part of mucosal and skin defenses. It has become apparent that Th17 responses are associated with chronic inflammation and autoimmune diseases such as multiple sclerosis, type 1 diabetes, Crohn disease, and psoriasis. Furthermore, Th17 responses are fundamental for host defense against many microorganisms, although they also contribute to the inflammation during infection.

Whereas IL-4 and IL-12 were the first cytokines described as influencing Th-cell differentiation, cytokines of the IL-1 family also influence cytokine differentiation. IL-18 was initially described as IFNγ-inducing factor due to its strong stimulatory effect on Th1/IFNγ responses.[10] It is now known that IL-18 is, in fact, a crucial cytokine directing the development of Th1 cells, and one role of IL-12 is the induction of the expression of IL-18 receptors. In contrast, binding of IL-33, another member of the IL-1 family, to its ST2 receptor plays a role in inducing Th2 responses,[11] and it thus appeared as if distinct members of the IL-1 family of cytokines directed Th1 versus Th2 differentiation. Considering these effects of IL-18 and IL-33, it came as no surprise that IL-1, the most well-known member of the family, participates in the function of Th cells.

Known for over 30 years that IL-1 enhances T-cell activation and recognition of antigen, one of the early names of IL-1 was lymphocyte activation factor. The specificity of this response was, however, not known. Although initially only IL-23, IL-6, IL-21, and transforming growth factor-β were suggested to play a role in the development of Th17 responses in mice, there

is no dearth of data that a more complex picture exists. Thus, IL-1β, IL-6, and transforming growth factor-β have been reported to induce the development of Th17 cells, whereas IL-23 has been reported to be important for the maintenance of Th17 cells. The combination of IL-23 and IL-1β induce the development of human Th17 cells expressing IL-17A, IL-17F, IL-22, IL-26, the chemokine CCL20, and transcription factor RORγt.[12] Interestingly, these cells also released IFNγ, displaying a phenotype common to both Th17 and Th1 cells.[12] The strong capacity of IL-1 to induce Th17 differentiation has been also linked to its well-known capacity to induce the release of prostaglandins, as reviewed in Dinarello.[13] PGE2 induced by COX-2 is a stimulator of Th17 induction, and inhibitors of cyclooxygenase decrease IL-17 production.[14] On the other hand, engagement of the aryl hydrocarbon receptor, a pathway demonstrated to be crucial for the generation of Th17 cells, has been shown to strongly induce IL-1β.[15] In addition to inducing IL-17 production from the Th17 subset of lymphocytes, IL-1β is required for the production of IL-17 by natural killer (NK) T cells[16] and of IL-22 from NK cells.[17]

Thus, cytokines of the IL-1 family have an important role in the differentiation of the Th subsets, with IL-1β strongly inducing Th17 responses, IL-18 being crucial for the generation of Th1 cells, and IL-33 being important in Th2 responses. Interestingly, reciprocal regulation has been demonstrated between the various Th subsets, with cytokines released by Th2 cells inhibiting Th1 responses, whereas IFNγ release from Th1 cells impairing both Th2 and Th17 responses.

INTERLEUKIN-1α

From an evolutionary viewpoint, IL-1α is the oldest member of the IL-1 family and its primary amino acid sequence is closely related to that of the fibroblast growth factor family. Like fibroblast growth factor, IL-1α does not have signal peptide, binds to nuclear deoxyribonucleic acid (DNA), exits the cell upon death, and binds to its receptor as an unprocessed precursor. As shown in Figure 26.2A, IL-1α binds to the IL-1RI and recruits the IL-1R accessory protein (IL-1RIAcP) to form a heterodimeric complex, which signals to induce inflammation. In health, primary cells contain constitutive levels of the IL-1α precursor but not IL-1β.[18] The IL-1α precursor is present in keratinocytes, thymic epithelium, hepatocytes, endothelial cells, the epithelial cells of mucus membranes, including the entire gastrointestinal tract, and fibroblasts, regardless of their location. The propiece of IL-1α precursor can be cleaved extracellularly by neutrophil proteases, a step that increases its biologic activity. However, IL-1α can also be active as a membrane-associated cytokine. Most cell lines, including tumor cell lines, contain constitutive levels of IL-1α.[19,20,21] Using an epithelial cell line, what was considered to be intrinsic IFNγ activities depended largely on constitutively expressed IL-1α. IFNγ activities were inhibited by antibodies to IL-1α, but not to IL-1β.[20] The concept that IL-1α acts as an autocrine growth factor assumes that the intracellular IL-1α precursor regulates normal cellular differentiation, particularly in epithelial and ectodermal cells. In support of the concept, an antisense oligonucleotide to IL-1α reduces senescence in endothelial cells.[22] In fibroblasts, the constitutive IL-1α precursor binds to HAX-1, a nonreceptor substrate for tyrosine kinases in hematopoietic cells. In fibroblasts, the IL-1α HAX-1 complex translocates to the nucleus.[23] Although the concept is that IL-1α acts as an autocrine growth factor in

fibroblasts or endothelial cells in vitro, the data should be interpreted carefully as mice deficient in IL-1α show no demonstrable defects in growth and development, including skin, fur, epithelium, and gastrointestinal function.[24] However, mice deficient in IL-1α still retain the N-terminal propiece, which functions as nuclear factor.21 In fact, in another study, the N-terminal propiece of IL-1α was shown to bind HAX-1.[25]

Is there is a role for intracellular precursor IL-1α in normal cell function? The IL-1α precursor is present in cells that also contain large amounts of the intracellular form of the IL-1Ra (icIL-1Ra), as reviewed in Arend.[1] This form of the IL-1Ra also binds to the IL-1 receptor and prevents signal transduction. In fact, icIL-1Ra is thought to compete with the intracellular pool of precursor IL-1α for nuclear binding sites.

Membrane-Associated Interleukin-1α

Precursor IL-1α can be found on the surface of several cells, particularly on monocytes and B-lymphocytes, where it is referred to as membrane IL-1α.[26] Membrane IL-1α is biologically active[27]; its biologic activities are neutralized by antibodies to IL-1α but to IL-1β. Endothelial cells undergoing stress-induced apoptosis release membrane apoptotic bodylike particles containing nuclear fragments and histones as well as full-length IL-1α precursor and the processed mature

form.[28] When injected into mice, apoptotic body-like particles containing the IL-1α precursor induce neutrophilic infiltration that was prevented by neutralization of IL-1α but not IL-1β.[28]

Processing and Secretion of Interleukin-1 α

Although the IL-1α precursor is biologically active, the processed form is more active. Furthermore, the binding of IL-1α to the IL-1RI has been modeled using recombinant IL-1α with an N-terminus at 113. The processing of the IL-1α precursor is accomplished by calpain II, a membrane-associated, calcium-dependent cysteine protease.[29] In macrophages treated with hydroquinone, calpain II levels fall and are associated with inhibition of IL-1α precursor processing.[29] Not surprisingly, calcium influx induced IL-1α secretion of the processed form.[30] The secretion of IL-1α requires the presence of IL-1β, as IL-1β-deficient mice do not secrete IL-1α.[31] IL-1α binding to IL-1β has been reported in which IL-1β acts as a chaperone for the secretion mechanism via caspase-1.[31] In another study, IL-1β was shown to bind to, and enhance the activity of, high-mobility group protein B1 (HMGB1).[32] It is thus possible that both IL-1α exits the cell bound to IL-1β and HMGB1.

Biologic Functions of Constitutive Interleukin-1 α: Interleukin-1α and Sterile Inflammation

Large numbers of reports use bacterial and fungal products to induce cytokines as models of inflammatory disease; however, most inflammatory diseases are sterile. For example, the inflammation associated with atherosclerosis, myocardial infarction, stroke, cancer, and renal and liver failure is sterile. The hypoxic insult that takes place in ischemia results in local necrosis and release of cellular contents, including nucleic acids. Members of the IL-1 family contribute to sterile inflammation, and IL-1α plays a significant role in this regard. Upon cell

death by necrosis, the IL-1α precursor is released[33,34] and binds to the IL-1 receptor on nearby tissue macrophages and epithelial cells, triggering a response.[35,36] For example, infiltration of neutrophils occurs first and followed by influx of monocytes.[35] Extracts of tumor cells induce neutrophilic inflammation, which does not occur in mice deficient in IL-1RI and is prevented by neutralization of IL-1α, not neutralization of IL-1β.[37] Sterile inflammation is independent on TLR2 and TLR4.[37]

Thus, IL-1α, either the unprocessed precursor or the calpain cleavage form, is classified as an "alarmin" because the cytokine is preformed and triggers an inflammatory response rapidly. Endothelial cells subjected to nutritional stress release inflammatory apoptotic bodies, which contain both the precursor and processed forms of IL-1α.[28] Inflammatory apoptotic bodies induce chemokine and neutrophilic infiltration into the peritoneal cavity, both of which are IL-1α dependent.[28] Platelets also contain IL-1α as well as IL-1β.[38] Platelet-derived IL-1 induces chemokines such as IL-8 from endothelial cells[39] and monocyte chemotactic protein (MCP-1) from monocytes.[40] Platelet-derived IL-1α is important in brain injury in stroke models[41] and in atherosclerosis.[42]

Studies in Interleukin-1α-Deficient Mice

Mice deficient in IL-1α are born healthy and develop normally. In some models of local inflammatory responses, wild-type and IL-1α-deficient mice develop fever and acutephase proteins, whereas IL-1B-deficient mice do not.[24] In addition, although the inflammation-associated induction of glucocorticoids was suppressed in IL-1β-deficient mice, this suppression was not observed in IL-1α-deficient mice. However, expression of IL-1β messenger ribonucleic acid (mRNA) in the brain decreased 1.5-fold in IL-1α-deficient mice, whereas expression of IL-1α mRNA decreased more than 30-fold in IL-1β-deficient mice. These data suggest that IL-1β exerts greater control over production of IL-1α than does IL-1α over the production of IL-1β. In caspase-1-deficient mice, IL-1α production is also reduced,[43] further suggesting that production of IL-1α is under the control of IL-1β. It is important that caspase-1-deficient mice are also deficient in caspase-11.[44]

In mice fed a high-fat diet, serum amyloid A protein, a marker of inflammation in atherogenesis, was markedly lower in IL-1α-deficient mice compared to wild-type or IL-1β-deficient mice.[45] IL-1α-deficient mice had significantly higher levels of non-high-density lipoprotein cholesterol. The beneficial effect of IL-1α deficiency was due to hematopoietic cells transferred from the bone marrow of IL-1α-deficient mice, resulting in a reduction in aortic lesion size twice that observed in mice transplanted with IL-1β-deficient bone marrow cells. Therefore, IL-1α appears to play a greater role in the pathogenesis of lipid-mediated atherogenesis than IL-1β, and this may be due to an effect of membrane IL-1α.

INTERLEUKIN-1β

Interleukin-1β: The Master Cytokine in the Interleukin-1 Family

More than any other member of the IL-1 family, IL-1β has been the focus of most studies. IL-1β is a highly inflammatory cytokine, particularly in humans, as reviewed in Dinarello.[46] As

shown in Figure 26.2A, IL-1β and IL-1α bind to the same IL-1RI and trigger a proinflammatory signal. The interest in IL-1β is also due, in part, to it being a secreted cytokine from macrophages and to the importance of the macrophage in antigen presentation before the era of dendritic cells. The inactive IL-1β precursor is converted into an active cytokine by the intracellular cysteine protease caspase-1. In particular, persons with activating mutations in one of the key genes that control the activation of caspase-1 can develop life-threatening systemic inflammation, which is reversed by either blocking the IL-1 receptor or through the use of a neutralizing antibody to IL-1β. Other chronic inflammatory diseases are mediated by IL-1β, as neutralizing antibodies have been used to treat a broad spectrum of diseases.

The IL-1β-mediated illnesses fall into the category of "autoinflammatory" diseases, which are to be distinguished from the classic "autoimmune" diseases. Although inflammation is common to both autoinflammatory and autoimmune diseases, in the case of IL-1-mediated disease, there is no evidence for role of adaptive immunity in its induction.

Interleukin-1β is an Inducible Cytokine

Unlike IL-1α, the IL-1β precursor is not present in health. Also unlike IL-1α, IL-1β is primarily a product of monocytes, macrophages, and dendritic cells, as well as B-lymphocytes and NK cells. In health, circulating human blood monocytes or bone marrow cells do not constitutively express mRNA for IL-1β. Endothelial cells, skin keratinocytes, fibroblasts, and epithelial cells contain constitutive IL-1α and constitutive IL-33 as precursors as well as mRNA, but these cells do not express IL-1β mRNA even upon stimulation with TLR ligands. Melanoma cells do express IL-1β as a precursor, and the more aggressive and metastatic the melanoma, the greater the likelihood of active caspase-1 and IL-1β secretion.[47] In the bone marrow neutrophil precursors, IL-1β gene expression is inducible but mature neutrophils in the circulation no longer produce IL-1β. Neutrophil IL-1β plays a pathologic role in the severe inflammation of mice with a mutant form of the phosphatase SHP1.[48] Several malignant tumors do express IL-1β as part of their neoplastic nature, particularly acute myelogenous leukemia, melanoma, multiple myeloma, and juvenile myelogenous leukemia, each of which exhibit constitutive expression of IL-1β. Unlike most cytokine promoters, IL-1β regulatory regions are distributed over several thousand base pairs upstream from the transcriptional start site. In addition to a cAMP response element, there are NF-κB-like and activating protein-1 sites. IL-1β gene regulation has been reviewed in detail.[49] Although steady-state mRNA levels for IL-1β may be present, there is distinct dissociation between transcription and translation of the IL-1β precursor. Non-TLR ligands such as the complement component C5a, hypoxia, adherence to surfaces, or clotting of blood induce the synthesis of large amounts of IL-1β mRNA in monocytic cells without significant translation into the IL-1β protein. In these cells, the IL-1β mRNA assembles into large polyribosomes, but there is no significant elongation of the peptide.[50] This failure to complete the translation into IL-1β protein may be due to the instability element present in the coding region. This instability region is also found in IL-18 and IL-37, and appears to limit the mRNA of these cytokines.[51] However, completion of translation of the mRNA into the respective cytokines can be accomplished by adding low concentrations of TLR ligands or IL-1 itself to the "primed" monocytes.[52]

Processing and Secretion of Interleukin-1 β via the Caspase-1

Nearly all microbial products induce IL-1β via TLR activation; in addition, IL-1 (either IL-1α or IL-1β) induces itself both in vivo and in monocytes in vitro.[53] Other studies supporting this concept of IL-1-induced IL-1 have been reported.[54,55,56,57] Regardless of the stimulus, processing and secretion of IL-1β requires conversion of procaspase-1 to active caspase-1, although in some studies processing of the IL-1β precursor is caspase-1 independent.[58] The activation to active caspase-1 is dependent on a complex of intracellular proteins termed the "inflammasome" by the late Juerg Tschopp.[59,60] The critical component of the inflammasome is NACHT, LRR, and PYD domains containing protein 3 (NLRP3). NLRP3 is also termed cryopyrin as the gene was initially discovered in patients with "familial cold autoin-flammatory syndrome," a genetic disease characterized by constitutional symptoms, fevers, and elevated acute-phase proteins following exposure to cold.[61]

As monocytes exit the bone marrow, they circulate in the bloodstream for approximately 3 days. In the absence of disease, it is likely that these cells do not enter tissues but are destroyed in the spleen or undergo apoptosis. There is no dearth of reports that circulating human blood monocytes release processed IL-1β upon stimulation starting 4 hours after stimulation with TLR agonists and continue to release the cytokine during the following 20 to 40 hours. Following lipopolysaccharide (LPS), IL-1β mRNA levels rise rapidly within 15 minutes but begin to decline after 4 hours due to the short half-life of their mRNA or the action of micro RNA. In contrast, using IL-1 itself as a stimulant, IL-1β mRNA levels are sustained for over 24 hours.[52] Raising intracellular cAMP levels with histamine enhances IL-1-induced IL-1 gene expression and protein synthesis. Monocytes of patients with autoinflammatory diseases such as cryopyrinassociated periodic syndrome (CAPS) and hyper IgΔ syndrome (HIDS) release IL-1β even without TLR stimulation during a 24-hour incubation.[62,63]

When obtained from the venous blood of healthy subjects, human blood monocytes contain active caspase-1. Active caspase-1, as determined by its cleavage into the active dimer, is present even in the absence of stimulation.[64] Active caspase-1 present in freshly obtained monocytes is nevertheless dependent on the presence of the key components of the inflammasome, namely ASC and NLRP3.[64] However, during subsequent incubation, extracellular levels of adenosine triphosphate (ATP) increase in the supernatant as IL-1β also increases and inhibition of ATP by oxidized ATP reduces the secretion of IL-1β.[64] The inhibition of IL-1β secretion by oxidized ATP is consistent with the role of the P2X7 receptor, which binds ATP and opens the potassium channel for release of intracellular potassium. The presence of active caspase-1 in circulating blood monocytes suggests that the rate limiting step in the processing and release of IL-1β is at the level of gene expression.

However, upon differentiation of the same blood monocytes into macrophages in vitro, TLR-induced IL-1β release requires activation of caspase-1 by exogenous ATP.[64] The assembly of the inflammasome components with inactive pro-caspase-1 takes place following a fall in intracellular potassium triggered by ATP binding to the P2X7 receptor. ATP activation of the P2X7 receptor opens the potassium channel, and simultaneously, as potassium levels fall, caspase-1 is activated by the inflammasome.[65,66,67,68,69] Without exogenous ATP, there is little or no processing of the IL-1β precursor in differentiated monocyte-derived macrophages.

Alveolar macrophages obtained from the lungs of healthy human also do not release IL-1β with LPS stimulation unless exogenous ATP is added.[64] In addition to ATP activation of P2X7, activation of IL-1β processing can also take place with a cathelicidin-derived peptide termed LL37, which is released from neutrophils.[69]

The cleavage of the IL-1β precursor by active caspase-1 can take place in the specialized secretory lysosomes or in the cytoplasm. However, more than one pathway seems available for processed IL-1β to exit the cell. These include by exocytosis of the secretory lysosomes,[65,66] shedding of plasma membrane microvesicles, and direct release via transporters or multivesicular bodies containing exosomes.[70] In general, the release of processed IL-1β takes place before there is significant release of lactate dehydrogenase,[71] although in vitro cell death eventually takes place. Pyroptosis is a caspase-1-dependent form of cell death and is induced by certain bacteria using Ipaf, a member of the Nod-like receptor (NLR) family of intracellular receptors.[72] An increase in intracellular calcium is also required for the mature IL-1β to exit the cell and is phospholipase C dependent.[66]

Gain of Function Mutation in Cryopyrin

Diseases associated with single amino acid activating mutations in cryopyrin are termed CAPS. In monocytes from patients with CAPS, activation of caspase-1 occurs without a requirement for a rapid fall in the level of intracellular potassium.[57] Therefore, mutated cryopyrin allows for the assembly of the complex of interacting proteins in the presence of normal intracellular levels of potassium. Although often studied using LPS-induced synthesis of the IL-1β precursor,[73] it is unlikely that LPS plays a role in autoinflammatory diseases. On the other hand, spontaneous secretion of IL-1β from monocytes of patients is due to endogenous IL-1β stimulation. In patients with CAPS, there is a decrease in steady state levels of pro-caspase-1 mRNA with IL-1Ra treatment,[54] suggesting that IL-1β stimulates its own production and processing. Thus, in any disease process that includes an increase in the steady state levels of pro-caspase-1 mRNA, components of the inflammasome or the IL-1β precursor explain the “autoinflammatory” nature of the disease. Type 2 diabetes appears to be an example of an autoinflammatory disease where glucose induces IL-1β production from the insulin-producing beta cell and IL-1β induces the beta cell to produce its own IL-1β .[74]

Polymorphisms in P2X7 and the Activation of the Inflammasome

Patients with classic autoinflammatory diseases such as Familial Mediterranean Fever (FMF) or CAPS have nearly identical clinical parameters, secrete more IL-1β, and respond dramatically to IL-1 receptor blockade yet have no mutation in NALP3. It is therefore possible that mutations in P2X7 itself or regulation of the other genes controlling potassium channels[75] may account for dysfunctional secretion of IL-1β. For example, monocytes from patients with rheumatoid arthritis are more sensitive to release of IL-1β following ATP activation of the P2X7 receptor compared to monocytes from healthy controls.[76] However, monocytes from subjects with a P2X7 Glu496Ala loss-offunction polymorphism secrete

significantly less IL-1β.[77] Monocytes from subjects homozygous for this polymorphism also released significantly less IL-18.[78] Another P2X7 receptor polymorphism is associated with increased mortality in patients undergoing allogenic stem cell transplantation.[79] Bacteremia was documented in 68% of patients with this polymorphism compared to 18% in wild-type control patients.[79]

In mice deficient in P2X7 receptors, inflammation, pain, and IL-1β-mediated IL-6 production are markedly reduced.[80] In addition to a fall in intracellular potassium, ATP triggers formation of peroxynitrite, which is required for caspase-1 activation because peroxynitrite scavengers prevent IL-1β secretion.[81] Pannexin-1, a mammalian protein that functions as a hemichannel for the uptake of dyes, is required for caspase-1 processing and release of IL-1β via the P2X7 receptor.[82] Pannexin-1 can also function for LPS-induced IL-1β synthesis in the absence of TLR4.[83] P2X7 receptor activity is also regulated by "regeneration and tolerance factor."[84]

Non-Caspase-1 Processing of Interleukin-1β

Non-caspase-1 mechanisms also exist to generate active forms of IL-1β. For example, sterile inflammation induces fever, elevated IL-6, and increased production of hepatic acute-phase proteins. These responses are absent in mice deficient in IL-1β but present in mice deficient in caspase-1.[85,86] Sterile inflammation is often associated with neutrophilic infiltration and neutrophils produce IL-1β. Because neutrophils are short-lived cells dying within hours upon emigration, release of the IL-1β precursor from intracellular stores is not unexpected. Processing of the IL-1β precursor extracellularly into an active cytokine has been reported for the common neutrophil protease, proteinase-3.[86,87] Proteinase-3 also contributes to the processing of IL-18.[88] Other proteases such as elastase, matrix metalloprotease 9, and granzyme A process the IL-1β precursor extracellularly. In addition, a mast cell chymase generates active IL-1β.

Mice with a targeted IKKβ deletion in myeloid cells are more susceptible to LPS-induced shock than control mice,[55] and markedly elevated levels of IL-1β are found in the circulation associated with a prominent neutrophilia.[55] The elevated levels of IL-1β are lethal as blockade with IL-1Ra protects these mice from death. The source of the IL-1β in these mice is the neutrophil. When incubated with proteinase-3, cleavage of the IL-1β precursor is observed yielding molecular weights of 25,000 and 15,000 Daltons.[55] Because the cleavage of the IL-1β precursor by proteinase-3, elastase, and cathepsin G are within three amino acids of the caspase-1 cleavage site, the products of the non-caspase-1 cleavage are biologically active.[86,87] Therefore, in inflammatory conditions such as urate crystal arthritis, which is characterized by a prominent neutrophilic infiltration, proteinase-3 cleavage of extracellular IL-1β precursor likely takes place.[89] Mice deficient in caspase-1 are not protected against urate-induced inflammation. Although IL-1Ra is effective in treating gout, IL-1Ra would be equally effective in any disease with extracellular processing of the precursor.[90,91,92] The importance of extracellular processing of the IL-1β precursor by serine proteases may explain, in part, the anti-inflammatory properties of alpha-1-

antitrypsin.[93]

Reactive Oxygen Species and Interleukin-1β Processing

Is there a role for reactive oxygen species (ROS) in the activation of the IL-1β inflammasome? It was reported that uric acid crystals added to human monocytes result in the generation of ROS, which bind to and activate NLRP3 with subsequent secretion of IL-1β.[94] However, mice deficient in ROS production exhibit a proinflammatory phenotype.[95] Humans with chronic granulomatous disease (CGD) due to mutations in p47-phox cannot generate ROS and are severely affected by inflammatory granuloma. Uric acid crystal activation of primary monocytes from persons with CGD produced fourfold higher levels of IL-1β compared to monocytes from unaffected persons.[96] In contrast to previous studies,[94] the small molecule ROS inhibitor diphenyleneiodonium, which reduces the production of IL-1β, does so due to inhibition of IL-1β gene expression rather than decreased caspase-1 activation.[96] Another study identified phagocyte oxidase-defective monocytes from CGD patients as a source of elevated IL-1β.[97] These findings support the concept that ROS likely dampens inflammasome activation and may explain the presence of an inflammatory phenotype characterized by granulomas and inflammatory bowel disease occurring in patients with CGD. In fact, patients with CGD-related inflammatory bowel disease improve upon IL-1 receptor blocking therapy.[98]

Effects in Mice Deficient in Interleukin-1β

After 10 years of continuous breeding, mice deficient in IL-1β exhibit no spontaneous disease. However, upon challenge, IL-1β-deficient mice exhibit specific differences from their wild-type controls. The most dramatic is the response to local inflammation induced by a subcutaneous injection of an irritant. Within the first 24 hours, IL-1β-deficient mice do not manifest an acute-phase response, do not develop anorexia, have no circulating IL-6, and have no fever.[85,99] These findings are consistent with those reported in the same model using anti-IL-1R type I antibodies in wild-type mice.[85,99] IL-1β-deficient mice also have reduced inflammation due to zymosan-induced peritonitis.[85,100] In contrast, IL-1β-deficient mice have elevated febrile responses to LPS, IL-1β, or IL-1α compared to wild-type mice.[101] Nevertheless, IL-1β-deficient mice injected with LPS have little or no expression of leptin mRNA or protein.[102]

Mice deficient in IL-1β were compared to mice deficient in IL-1α after exposure to chemical carcinogens.[103] In IL-1β-deficient mice, tumors developed slower or did not develop in some mice. A deficiency in IL-1α, on the other hand, did not impair tumor development compared to wild-type mice injected with the same carcinogen. In IL-1Ra-deficient mice, tumor development was the most rapid. A leukocyte infiltrate was found at the site of carcinogen injection. The neutrophilic infiltrate was almost absent in IL-1β-deficient mice, whereas in IL-1Ra-deficient mice, a dense neutrophilic infiltrate was observed. In wild-type mice, the leukocytic infiltrate was sparse and the infiltrate that was observed in IL-1α-deficient mice was similar to that of control mice. These findings may reflect the fact that IL-1β is secreted into the microenvironment resulting in the emigration of monocytes and neutrophils, whereas

IL-1α remaining cell-associated is less likely to affect the microenvironment.

Interleukin-1α and Autophagy

Autophagy is an ancient process of recycling cellular components, such as cytosolic organelles and protein aggregates, through degradation mediated by lysosomes. Autophagy is activated in conditions of cell stress, hypoxia, starvation, or growth factor deprivation; it promotes cell survival by generating free metabolites and energy through degradation of the endogenous cellular components.[104] However, in addition to its role in the pathophysiology of cancer, neurodegenerative diseases, or aging, autophagy is also a modulator of inflammation.[105] A role for autophagy in production of proinflammatory cytokines, particularly of IL-1β, has emerged with deletion of ATG16-L1. For example, macrophages from *ATG16L1* -deficient mice produce higher levels of IL-1β and IL-18 after stimulation with TLR4 ligands.[106] The data suggest that higher activation of caspase-1 in the *ATG16L1*-deficient mice accounts for the higher production level.[106] This observation was related to the specific degradation of the IL-1β precursor in autophagosomes in mouse macrophages.[107] Additional studies in the *ATG16L1*-deficient mice point toward a regulatory effect of autophagy on caspase-1 activation through modulation of the NLRP3 inflammasome.[94,108,109]

This role of autophagy in the secretion of IL-1β was also observed in human primary monocytes, in which specific inhibition of autophagy leads to increased production of IL-1β .[110] However, in the same cells, tumor necrosis factor (TNF)α production was decreased by autophagy inhibition. These data suggest divergent effects of autophagy on the production of these two important proinflammatory cytokines. In mice, the increase in IL-1β production is ascribed to increased activation of the inflammasome, but in human cells, it is IL-1β mRNA transcription that is elevated when autophagy was inhibited, whereas no effects were observed on caspase-1 activation.[106,107,110] Despite these differences between mouse and human cells, the inhibition of autophagy increases the production of IL-1β but not TNFα.

The modulation of inflammation by autophagy in humans has been studied in Crohn disease. Genome-wide association studies in large cohorts of patients with Crohn disease have revealed that genetic variants in two autophagy genes, *ATG16L1* and *IRGM*, result in increased susceptibility to the disease. A nonsynonymous polymorphism in *ATG16L1* on chromosome 2q37.1 and two polymorphisms in *IRGM* on chromosome 5q33.1 were significantly associated with Crohn disease risk.[111,112] Another study revealed a significant association of Crohn disease susceptibility with an intronic polymorphism in the autophagy gene *ULK1*.[113] Moreover, autophagy defects have been reported in individuals bearing nucleotide oligomerization domain (*NOD)2* mutations and are consistent with the concept that impaired bacterial clearance and increased bacterial persistence are part of the pathogenesis of Crohn disease.[114]

The mechanism through which polymorphisms in autophagy genes influence susceptibility to Crohn disease appears to involve IL-1β production. The *ATG16L1* 300Ala risk allele was associated with elevated production of IL-1β and IL-6; however, this finding was only observed in cells stimulated with the NOD2 ligand muramyl dipeptide. In contrast, the

expected levels of IL-1β and IL-6 were produced upon stimulation with TLR2 and TLR4 ligands.[115] The increased production of IL-1β was associated with an increase in the steady state levels of IL-1β mRNA rather than increased activation of the inflammasome.[115] Studying the same polymorphism (*ATG16L1* Thr300Ala) in human dendritic cells, Cooney et al. reported defective NOD2-induced, but not TLR-induced, autophagy and antigen presentation.[116] Furthermore, effects of this polymorphism on antibacterial autophagy in epithelial cells have been observed.[117] The specific effect of the *ATG16L1* polymorphism on the NOD2 pathway, and not on TLR-induced stimulation, is likely related to the fact NOD2 and ATG16L1 form a protein complex that is essential for NOD2-induced autophagosome formation.[118] Because the *ATG16L1* Thr300Ala polymorphism affects protein stability,[119] defective induction of autophagy and therefore enhanced IL-1β mRNA transcription upon triggering of NOD2 may be due to the presence of defective complex.

INTERLEUKIN-33

Interleukin-33 as a Member of the Interleukin-1 Subfamily

Formerly termed IL-1F11, IL-33 belongs to the IL-1 subfamily and has been studied for its role in the Th2 paradigm of immune responses. IL-1β is also linked to the Th2 response. The existence of IL-33 was predicted in 1994 following the discovery of a novel member of the IL-1 receptor family termed ST2.[120] ST2 is the ligand binding chain for IL-33 (Table 26.2) and is structurally similar to the ligand binding chain of IL-1α and IL-1β. In addition, the coreceptor for IL-33 is the IL-1RAcP, which is also the coreceptor for IL-1α and IL-1β. It was not until 2005 that IL-33 was reported as the ligand for ST2.[11] ST2 is regulated by the estrogen inducible transcription factor Fos,[120] and this property of estrogens may be related to the large number of studies on the effect of estrogens to regulate IL-1 and inflammation.

TABLE 26.2 Interleukin-1 Receptor Family

Name	Designation	Ligands	Coreceptor
IL-1RI	IL-1R1	IL-1α, IL-1β, IL-1Ra	IL-1RAcP (IL-1R3)
IL-1RII	IL-1R2	IL-1β, IL-1β precursor	IL-1RAcP (IL-1R3)
IL-1RAcP	IL-1R3	IL-1α, IL-1β, IL-33, IL-36	Not applicable
ST2/IL-33Rα	IL-1 R4	IL-33	IL-1RAcP (IL-1R3)

IL-18Rα	IL-1R5	IL-18, IL-37	IL-18Rβ (IL-1R7)
IL-1Rrp-2	IL-1R6	IL-36α,β,γ	IL-1RAcP (IL-1R3)
IL-18Rβ	IL-1R7	IL-18	Not applicable
TIGIRR-2/IL-1RAPL	IL-1R8	Unknown	Unknown
TIGIRR-1	IL-1R9	Unknown	Unknown
SIGIRR	TIR8	Unknown	Unknown

IL, interleukin; SIGIRR, single immunoglobulin IL-1-related receptor; TIGIRR, three immunoglobulin IL-1-related receptor.

Similar to most members of the IL-1 receptor family, ST2 is comprised of three extracellular immunoglobulin domains and an intracellular TIR domain. Although the name ST2 is still used, the correct term is the IL-33 receptor α chain (IL-33Rα). As shown in Figure 26.2D, the IL-33Rα chain similar to the IL-1R1 in that it is the ligand binding chain for IL-33 but requires the IL-1RAcP to signal.[121,122]

Before the discovery of IL-33, several studies suggested that the putative ligand (IL-33) for the ST2 orphan receptor was playing a role in allergic type diseases. It became clear that activation of ST2 was uniquely driving Th2 responses. Structurally, IL-33 is closer to IL-18 than IL-1β. Biologically, IL-33 is closest to IL-1α, as the precursors for IL-1α and IL-33 are constitutively present in all endothelial cells. As discussed in the following, like IL-1α, IL-33 functions as a DNA-binding molecule. The dominant property of IL-33 is the induction of IL-4, IL-5, and IL-13, as well as other properties anticipated for a Th2 type cytokine. Diseases thought to be due to increased immunoglobulin production may also be related to IL-33. IL-33 induces the production of IL-6, IL-1β, and PGE2 from mast cells.

Interleukin-33 and Th2 Responses

The properties of recombinant IL-33 recapitulate much of the existing data that ST2 promotes Th2-type responses. For example, before its discovery, a role for IL-33 in the Th2 response was observed using soluble extracellular forms of ST2.[11] However, IL-33 has properties that go beyond its role in the Th2 paradigm because, similar to IL-1α, IL-1β and IL-36, IL-33 forms a heterodimeric complex with IL-1RAcP for signal transduction.[121,122] Although the IL-1RAcP is expressed on most nucleated cells, ST2 is somewhat restricted to low expression on most cells with the notable exception of mast cells.

There are several mechanisms by which IL-33 favors the Th2 response. Similar to IL-1β, IL-33 induces IL-6, an adjuvant for antibody production. IL-33 induction of IL-6 is prevented by a blocking antibody to IL-1RAcP.[122] IL-33 initiates signal transduction via activation of NF-κB,

is typical of IL-1α, IL-1β and IL-18,[11] but other studies have shown that antibody cross-linking of ST2 does not result in activation of NF-κB but rather activating protein-1. IL-33 treatment also increased serum immunoglobulin A and immunoglobulin E, an expected response for a switch from Th1 to Th2.

Processing of the Interleukin-33 Precursor

Initially, IL-33 was considered closely related to IL-1β and IL-18 because the IL-33 precursor contains a caspase-1 site, which upon activation would cleave the IL-33 precursor and release the active cytokine,[11] similar to that for IL-1β and IL-18. Indeed, the first recombinant forms of IL-33 were produced with an N-terminus at the caspase-1 site.[11] Although recombinant IL-33 was active, the concentrations required for activity were considerably higher than those of other members of the IL-1 family. Indeed, subsequent studies revealed that caspase-1 actually results in loss of IL-33 activity and that the full-length IL-33 precursor binds to ST2 and is active,[123] similar to the ability of the IL-1α precursor to bind to IL-1RI. In addition, it was reported that the caspase-1 cleavage site at 178 is similar to the consensus sequence for caspase-3 and that intracellular IL-33 precursor is a substrate for caspase-3.[123]

Using immobilized IL-33 precursor, neutrophil proteinase 3 (PR3) was isolated from human urinary proteins.[124] Neutrophil PR3 is known to process the IL-1β precursor into an active cytokine.[86] PR3 converted human and mouse precursor IL-33 proteins to biologic active forms; however, increasing the incubation time of PR3 abrogated IL-33 activities.[124] Using the consensus amino acid sequence sites for PR3, six human and mouse recombinant IL-33 proteins were produced and assessed for biologic activities; varying levels of activity were reported.[124] Another study also demonstrated cleavage of the IL-33 precursor by neutrophil proteases such as PR3, neutrophil elastase, and cathepsin G,[125] resulting in the generation of IL-33 with different N-termini and varying levels of activity. These studies support the concept that extracellular IL-33 is released as a precursor, is rapidly processed by neutrophil enzymes, and generates active forms with varying levels of activity. The implications for generation of active IL-33 by neutrophil enzymes for Th2 polarization remain unclear. It may be more relevant to study the effect of proteases from eosinophils in the processing of the IL-33 precursor. Nevertheless, the IL-33 precursor binds to ST2 and recruits the accessory chain for signal transduction, but compared to IL-33 generated by neutrophil proteases, the activity of IL-33 precursor is weak.[124,125]

There was no dearth of studies on ST2 tissue-specific localization, regulation of its expression, effects in transgenic mice overexpressing ST2, as well as deletion, neutralization, and antibody cross-linking of ST2. Elevated levels of the soluble form of ST2 were present in the circulation of patients with a various inflammatory diseases and that exogenous administration of pharmacologic doses of soluble ST2 neutralized endogenous levels of the then putative ligand IL-33 and reduced inflammation.[126] IL-33 activates Th2 lymphocytes, mast cells, basophils, and eosinophils, as well as NK T cells and blood monocytes. One of the most studied properties of IL-33 is the induction of IL-5 and IL-13 and their respective

roles in lung inflammation such as allergic type asthma. For example, instillation of IL-33 into the airways triggers an immediate allergic response in the lung of naïve mice and worsens the response in mice sensitized to antigen peripherally but challenged by exposure of antigen in the lung.[127]

Mice deficient in ST2 do not develop a Th2 response to *Schistosoma* egg antigen. Indeed, several studies have focused on the role of IL-33 in the pathogenesis of helminth worm infections. The Th2 response by the host contributes to the elimination of these worm infestations, which are worldwide and afflict hundreds of millions. The role of IL-33 in the induction of IL-4, IL-5, and IL-13 is of paramount importance in terms of pulmonary and intestinal complications that reduce lifespan. Using mice deficient in IL-33, a crucial role was demonstrated in mice to rid an infection with *Strongyloides venezuelensis*.[128] The infection induces a unique class of cells called natural helper cells or nuocytes, which upon activation by IL-33 produce IL-5 and IL-13, resulting in eosinophilic infiltration into the lungs. In this model, pulmonary inflammation causes damage via eosinophilic infiltration, which is IL-33 and IL-5 dependent.[128]

Mice injected with human IL-33 exhibit impressive pathologic changes in the arterial walls, lungs, and intestinal tissues.[11] Of particular relevance to the concept that IL-33 drives a Th2 response, eosinophilic infiltration was a prominent finding in the lung and in allergic rhinitis as well as allergic conjunctivitis.[129] These initial observations have been confirmed by other reports.[130] Although the interpretation of in vivo effects following the administration of an exogenous cytokine should be conservative, the findings are clearly consistent with IL-33 being a proinflammatory ligand of the IL-1 receptor family. Even before the ability to test IL-33-mediated activation, others had reported that neutralization of the putative ST2 ligand using soluble ST2 markedly reduced joint inflammation, synovial hyperplasia, and joint erosion when given in the therapeutic phase of collagen-induced arthritis in mice.[126]

Interleukin-33 as an Anti-inflammatory Cytokine

Members of the IL-1 family of ligands bind to their specific cell surface receptors and recruit an accessory chain. The IL-1RIAcP is used by IL-1α and IL-1β but also by IL-36 and IL-33. The accessory chain for IL-18 is related to the IL-1RIAcP but is encoded by a distinct gene. We now recognize that other members of the IL-1 receptor family will bind more than one cytokine. The best example is IL-1α and IL-1β. Both bind with similar affinities to IL-1RI, but the three-dimensional structure of IL-1α and IL-1β are hardy identical.[131] The IL-1β precursor binds to IL-1RII as well as a processed form with the first 112 amino acids cleaved from the precursor. IL-37 binds to the IL-18 receptor alpha chain,[132] and both IL-36 and IL-38 bind to the IL-36 receptor.[133]

IL-33 forms a complex with ST2 IL-1RIAcP but also with single immunoglobulin IL-1-related receptor (SIGIRR).[134]

This complex plays a role in the Th2 response by reducing IL-33 signaling,[134] and consistent with these observations, Th2 responses are increased in mice deficient in SIGIRR. Furthermore, there is high expression of SIGIRR in Th2 polarized cells and in models of Th2

antigen sensitization; SIGIRR-deficient mice exhibit a greater Th2 response.[134] The complex with SIGIRR and IL-33 may explain the antiinflammatory properties of IL-33. ST2 can sequester TLR adaptor molecules such as MyD88 and Mal.[135]

In mice deficient in ST2, there is myocardial hypertrophy, ventricle dilation, and fibrosis upon pressure overload, suggesting that IL-33 plays a protective role in the heart.[136] Furthermore, elevated levels of the extracellular domain of ST2 predict outcomes in patients with systolic heart failure or following a myocardial infarction.[136] In a model of cardiomyocyte hypertrophy induced by chronic administration of phenylephrine, administration of recombinant IL-33 inhibited the phosphorylation of IκB and reduced the hypertrophy and fibrosis.[136] One of the more challenging aspects of the properties of IL-33 to act as a Th2 cytokine is its role as an antagonist in the ApoE-deficient mouse model of atherosclerosis. In this model, arterial wall plaques of mice on a high-fat diet contain IL-33 and ST2. In mice treated with IL-33, the atherosclerotic plaques were markedly reduced.[137] In mice treated with soluble ST2 to neutralize IL-33, the disease worsened.[137]

Interleukin-33 as a Transcription Factor

Similar to IL-1α, there is another side to IL-33. Although IL-33 binds to its specific surface receptor, IL-33 is identical to a nuclear factor dominantly expressed in high endothelial venules.[138] This nuclear factor is termed NF-HEV. In addition to endothelial cells, constitutive nuclear localization of IL-33 has been reported in several cell types such as type II lung epithelial cells,[128] epithelial cells,[139] and pancreatic stellate cells.[140] In fact, IL-33 binding to DNA and acting as a nuclear factor is similar to IL-1α binding to chromatin and functioning as a nuclear factor.[21,33,141] A short IL-33 peptide similar to a sequence in Kaposi sarcoma virus binds chromatin.[142] The full-length IL-33 precursor, but not mature IL-33, binds to the N-terminal Rel homology domain of NF-κB p65.[143] In cells overexpressing the IL-33 precursor, there was a reduction in IL-1β-induced TNFα.[143] These data are consistent with other data that IL-33 possesses antiinflammatory properties (see previous discussion) and the mechanism for this property of IL-33 appears to be nuclear sequestration similar to that of IL-1α.[33]

INTERLEUKIN-18 AND INTERLEUKIN-37 SUBFAMILY

Interleukin-18

Background

IL-18 was first described in 1989 as "IFNγ-inducing factor" isolated in the serum of mice following an injection of endotoxin. The mice had been pretreated with *Proprionibacterium acnes*, which stimulates the reticuloendothelial system, particularly the Kupffer cells of the liver. Many investigators concluded that the serum factor was IL-12. With molecular cloning of "IFNγ-inducing factor" in 1995,[144] the name was changed to IL-18. Surprisingly, the new cytokine was related to IL-1 and particularly to IL-1β. Similar to IL-1β, IL-18 lacks a signal peptide, is first synthesized as an inactive precursor, and remains as an intracellular cytokine.

The tertiary structure of the mature form of IL-18 closely resembles that of IL-1β,[144] although the IL-18 precursor is closely related to the IL-37 precursor. Since 1995, many studies have used neutralization of endogenous IL-18 or IL-18-deficient mice to demonstrate the role for this cytokine in promoting inflammation and immune responses.[145] However, the biology of IL-18 is hardly the recapitulation of IL-1β. There are several unique and specific differences between IL-18 and IL-1β. For example, in healthy human subjects and also in healthy mice, gene expression for IL-1β in blood mononuclear cells and hematopoietic cells is absent, and there is no evidence that the IL-1β precursor is constitutively present in epithelial cells.[146] In contrast, in the same blood cells, large amounts of the IL-18 precursor are present. Peritoneal macrophages and mouse spleen contain the IL-18 precursor in the absence of disease.[146] The IL-18 precursor is also present in keratinocytes and nearly all epithelial cells. In this regard, IL-18 is similar to IL-1α and IL-33.

Processing of the Interleukin-18 Precursor

The IL-18 precursor has a molecular weight of 24,000 and is processed by caspase 1 cleavage into a mature molecule of 18,000. Compared to wild-type mice, following an injection of endotoxin into caspase-1-deficient mice, circulating IFNγ is absent. IL-12-induced IFNγ is also absent in caspase-1-deficient mice.[147] Importantly, any phenotypic characteristic of capsase-1-deficient mice must be studied as to whether the deficiency is due to reduced IL-1β or IL-18 activity. For example, the caspase-1-deficient mouse is resistant to colitis,[148] but the IL-1β-deficient mouse is susceptible in the same disease. Because neutralizing antibodies to IL-18 are protective in the colitis model, caspase-1 deficiency appears to prevent processing of IL-18.[148,149] On the other hand, there are examples where caspase-1 processing of IL-18 is not required. For example, Fas ligand stimulation results in release of biologically active IL-18 in caspase-1-deficient murine macrophages.[150] Similar to IL-1β processing, proteinase-3 appears to activate processing to mature IL-18.[88]

Similar to IL-1α and IL-33, the IL-18 precursor is constitutively expressed in endothelial cells, keratinocytes, and intestinal epithelial cells throughout the gastrointestinal tract. Macrophages and dendritic cells are the primary sources for the release of active IL-18, whereas the inactive precursor remains in the intracellular compartment of mesenchymal cells. Also, similar to IL-1α and IL-33, the IL-18 precursor is released from dying cells and processed extracellularly, most likely by neutrophil proteases such as proteinase-3.

The IL-1 family consensus sequence (A-X-D) in IL-18 is I-N-D at amino acid 50, but the N-terminus generated by caspase-1 is 14 amino acids before the consensus sequence rather than 9 amino acids (see Fig. 26.1). Although the IL-18 as well as the IL-1β precursor can be cleaved extracellularly by proteianse-3, there is an additional enzyme that cleaves the IL-18 precursor into an active cytokine. Merprin β is a

member of the merpin family of zinc metalloproteinases, which are expressed on the membrane surface of epithelial cells of the intestine and kidney but also on myeloid cells.[151,152] Merprin α will cut the IL-1β precursor into an active cytokine, and inhibitors of merprin α markedly reduce serum levels of IL-1β in mice subjected to cecal ligation and puncture.[151] Merprin β will cleave the IL-18 precursor and generate an active cytokine on

cells bearing the IL-18R.[153] In a model of dextran sulfate sodium (DSS) colitis, serum IL-18 is elevated on days 3 and 5, during which time the mice develop inflammatory colitis. However, in merprin β-deficient mice, there is a statistically significant reduction in serum IL-18.[153] The role of IL-18 and caspase-1 in DSS colitis is discussed in the following.

Signal Transduction by Interleukin-18

As shown in Figure 26.3A, IL-18 forms a signaling complex by binding to the IL-18 alpha chain (IL-18Rα), which is the ligand binding chain for mature IL-18; however, this binding is of low affinity. In cells that express the coreceptor, termed IL-18 receptor beta chain (IL-18Rβ), a high-affinity complex is formed, which then signals. The complex of IL-18 with the IL-18Rα and IL-18Rβ chains is similar to that formed by other members of the IL-1 family with the coreceptor, the IL-1R accessory chain IL-1RAcP. Following the formation of the heterodimer, the TIR domains approximate, and it appears that the cascade of sequential recruitment of MyD88, the four IRAKs, and TRAF-6 followed by the degradation of IκB and release of NFκB are nearly identical as that for IL-1.[154] There are differences between IL-1 and IL-18 signaling that remains unexplained. With few exceptions, IL-1α or IL-1β are active on cells in the low nanogram/mL range and often in the picogram/mL range. In contrast, IL-18 activation of cells expressing the two IL-18 receptor chains requires 10 to 20 ng/mL and sometimes higher levels.[155,156]

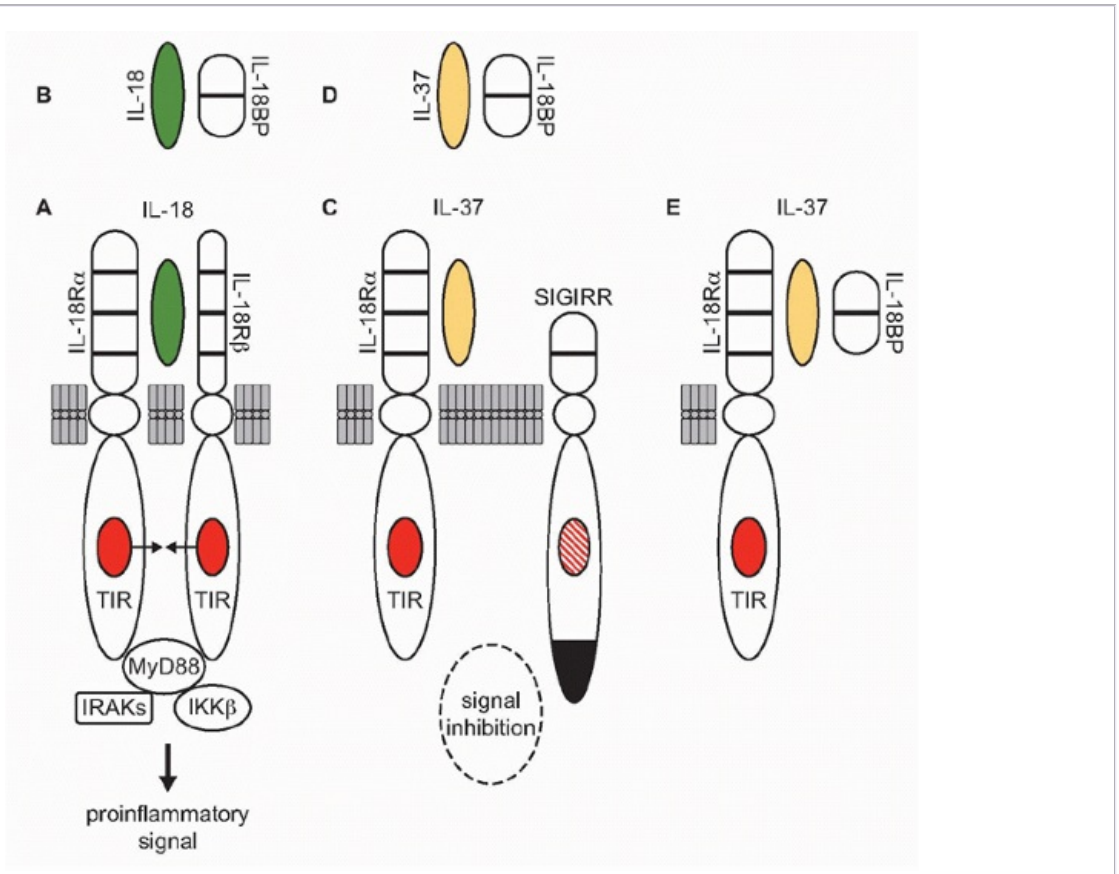

FIG. 26.3. Interleukin (IL)-18 Subfamily. A: IL-18 binds to the IL-18Rα chain and recruits the coreceptor IL-18Rβ. The signaling cascade of the IL-18 receptor complex is nearly the same as that of IL-1α and IL-1β, resulting in the expression of proinflammatory

genes. **B:** The natural occurring IL-18BP binds IL-18, thus neutralizing the activity of the cytokine. **C:** IL-37 also binds to the IL-18Rα but with an affinity lower than that of IL-18 binding to the same receptor. Furthermore, the binding of IL-37 to IL-18Rα does not recruit the coreceptor IL-18Rβ and therefore there is no proinflammatory signal. The anti-inflammatory properties of IL-37 require single immunoglobulin IL-1-related receptor, which may act as a "decoy" for MyD88. **D:** IL-18BP also binds to IL-37, thus preventing binding of IL-37 to the IL-18Rα. **E:** IL-37 binds to IL-18BP forming a complex, which then binds to the IL-18Rα, enhancing the anti-inflammatory property of IL-18BP.

Although nearly all cells express the IL-1RI, not all cells express IL-1RAcP. Similarly, most cells express the IL-18Rα but not all cell express the IL-18Rβ. IL-18Rβ is expressed on T cells and dendritic cells but not commonly expressed in mesenchymal cells. The best example is the A549 cell. This cell line, derived from a lung carcinoma epithelial cell, does not express IL-18Rβ,[157] and there is no signal unless IL-12 is added to induce IL-18Rβ.[10] In the absence of IL-18Rβ, IL-18 binds to IL-18Rα without a proinflammatory signal. In A549 cells transfected with IL-18Rβ, IL-18 induces IL-8 and a large number of genes. One of these genes is the former IL-2-induced gene termed NK4,[158] now termed IL-32.[157] IL-32 is not a member of the IL-1 family but plays an important role in the regulation of cytokines such as IL-1β and TNFα.

Interleukin-18 as an Immunoregulatory Cytokine

Together with IL-12, IL-18 participates in the Th1 paradigm. This property of IL-18 is due to its ability to induce IFNγ either with IL-12 or IL-15. Without IL-12 or IL-15, IL-18 does not induce IFNγ. IL-12 or IL-15 increases the IL-18Rβ, which is essential for IL-18 signal transduction. Without IL-12 or IL-15, IL-18 plays a role in Th2 diseases.[159] The importance of IL-18 as an immunoregulatory cytokine

is derived from its prominent biologic property of inducing IFNγ from NK cells. Macrophage-colony stimulating factor induces human blood monocytes to develop into a subset of macrophages; these cells express a membrane-bound form of IL-18.[160] Membrane IL-18 is expressed in 30% to 40% of macrophage-colony stimulating factor-primed macrophages. In contrast, monocytes, dendritic cells, and monocytes differentiated into M1 macrophages did not express membrane IL-18. Although the expression of membrane IL-18 is caspase-1 dependent,[160] LPS treatment was necessary for the release of membrane IL-18.[160] A major immunoregulating role for IL-18 is on the NK cell. Upon shedding of membrane IL-18 into a soluble form, NK cells expressed CCR7 and produced high levels of IFNγ. As expected, IFNγ production was prevented by neutralization of IL-18. This mechanism may account for the role of IL-18 as major IFNγ-inducing factor from NK cells and the role of NK cells in the pathogenesis of autoimmune diseases.

The induction of FFNγ by IL-18 has been studied with coinducer IL-12. For example, mice injected with the combination of IL-18 plus IL-12 develop high levels of IFNγ and die with hypoglycemia, intestinal inflammation, and inanition.[161] In leptin-deficient mice, IL-18 plus IL-12 induce acute pancreatitis.[162] Several human autoimmune diseases are associated with elevated production of IFNγ and IL-18. Diseases such as systemic lupus erythematosus, rheumatoid arthritis, type 1 diabetes, Crohn disease, psoriasis, and graft-versus-host disease

are thought to be mediated, in part, by IL-18.

Proinflammatory Properties of Interleukin-18

IL-18 exhibits characteristics of other proinflammatory cytokines, such as increases in cell adhesion molecules, nitric oxide synthesis, and chemokine production. Blocking IL-18 activity reduces metastasis in a mouse model of melanoma; this is due to a reduction in IL-18-induced expression of vascular call adhesion molecule-1.[163] A unique property of IL-18 is the induction of Fas ligand (FasL), which may account for the hepatic damage that takes place in macrophage activation syndrome.[150,164] The induction of fever, a well-studied property of IL-1α and IL-1β as well as TNFα and IL-6, is not a property of IL-18. Injection of IL-18 into mice, rabbits, or humans does not produce fever.[165,166] Unlike IL-1 and TNFα, IL-18 does not induce cyclooxygenase-2 and hence there is no production of prostaglandin E2.[156,167] IL-18 has been administered to humans for the treatment of cancer in order to increase the activity and expansion of cytotoxic T cells. Not unexpectedly and similar to several cytokines, the therapeutic focus on IL-18 has shifted from its use as an immune stimulant to inhibition of its activity.[145,168]

Because IL-18 can increase IFNγ production, blocking IL-18 activity in autoimmune diseases is an attractive therapeutic target as anti-IL-12/23 reduces the severity of Crohn disease as well as psoriasis. As discussed subsequently, there appears to be a role for blocking IL-18 in Crohn disease. However, there are several activities of IL-18 that are independent of IFNγ. For example, IL-18 inhibits proteoglycan synthesis in chondrocytes,[169] and proteoglycan synthesis is essential for maintaining healthy cartilage. IL-18 also increases vascular call adhesion molecule-1 expression in endothelial cells independently of IFNγ. Vascular call adhesion molecule-1 plays a major role in multiple sclerosis, other autoimmune diseases, as well as in the metastatic process.[170]

Role of Interleukin-18 in Models of Inflammatory Bowel Disease

Inflammatory bowel disease such as Crohn disease is a complex autoimmune disease. Treatment is initially based on immunosuppressive drugs. Not surprisingly, anticytokines such as neutralizing monoclonal antibodies to TNFα[171] or to IL-12/23 provide effective treatment for many patients.[172,173] The reduction of IFNγ in Crohn disease is linked to the clinical response to these agents.[173] IL-18 is found in affected intestinal lesions from patients with Crohn disease as a mature protein, but the IL-18 precursor form is present in uninvolved intestinal tissues.[174] This observation was confirmed in a similar assessment of mucosal biopsies from patients with Crohn disease.[175] Antisense RNA to IL-18 decreased IFNγ production in lamina propria mononuclear cells.[175]

A commonly used mouse model for colitis is DSS, which is added to the drinking water and which damages the intestinal wall. Thus in DSS-induced colitis, the epithelial barrier defenses against luminal bacterial products are breeched. In this model, reducing IL-18 with a neutralizing antibody is protective and linked to a reduction in IFNγ.[149] Blocking IL-18 with the IL-18 binding protein (IL-18BP) also reduces colitis induced by antigen sensitization.[176] Because generation of active IL-18 requires caspase-1, studies have also been performed in

mice deficient in caspase-1 and subjected to DSS colitis. Nevertheless, despite many studies, the role of caspase-1 in DSS colitis remains unclear. The first study showed that mice deficient in caspase-1 were protected.[148,177] In addition, treatment of mice with a specific caspase-1 inhibitor was also effective in protecting against the colitis.[178,179,180] In both studies, the effect of caspase-1 deficiency was linked to reduced IL-18 activity, whereas reducing IL-1 activity with the IL-1Ra was ineffective.[148] In support of the role of IL-18 in DSS colitis, inhibition of endogenous merprin β to reduce the generation of active IL-18 was protective in DSS colitis.[153]

However, a conundrum has developed whether caspase-1 deficiency is protective or detrimental in DSS colitis. DSS colitis is not the optimal model for Crohn disease, as the model is one of rapid loss of the protective barrier of the intestinal epithelium exposing the lamina propria mononuclear cells to a large amount and variety of bacterial products. Using the same DSS model, mice deficient in the adapter protein inflammasome component ASC experienced increased disease, morbidity, and precancerous lesions compared to wild-type mice exposed to DSS.[181] Similarly, mice deficient in caspase-1 died rapidly from DSS compared to wild-type mice,[182] whereas mice deficient in caspase-12, in which caspase-1 is enhanced, were protected.[182] Administration of exogenous IL-18 restored mucosal healing in caspase-1-deficient mice.[182] Also, mice deficient in NLRP3 were more susceptible to either DSS or 2,4,6-trinitrobenzene sulfonic acid (TNBS)-induced colitis and exhibited decreased IL-1β as well as decreased beta-defensins.[183] Macrophages from NLRP3-deficient mice failed to respond

to muramyl dipeptide.[183] Mice deficient in NLRP6 are also more vulnerable to DSS,[37,184] and the susceptibility appears to be due to lack of sufficient IL-18.

How to reconcile these data in mouse models of colitis was addressed by Siegmund[185]? It is likely that IL-18 being constitutive in the intestinal epithelium has a protective role in that the cytokine contributes to maintaining the intestinal barrier. With loss of the barrier, the microbial products stimulate macrophages in the lamina propria and caspase-1-dependent processing of IL-18 results in inflammation. In this model, inhibition of IL-18 production in caspase-1-deficient mice or treatment of wild-type mice with anti-IL-18 antibodies or caspase-1 inhibitors is protective. Worsening of disease in mice deficient in caspase-1 or NLRP3 or NLRP6 may lower the levels of active endogenous IL-18 needed to protect the epithelial barrier. Similarly, active endogenous IL-1β may be needed to protect to maintain the epithelial barrier by inducing growth factors.

Although it remains unclear why caspase-1 deficiency worsens DSS colitis, in humans with Crohn disease, natalizumab, the antibody that blocks the very late antigen-4, is highly effective in treating the disease. Very late antigen-4 is the α4 subunit of the β-1 integrin. Anti-very late antigen-4 binds to the surface of macrophages and other myeloid cells, and prevents the binding of these cells to the very late antigen-4 receptor on endothelial cells known as vascular cell adhesion molecule-1. Thus, the antibody disables the function of vascular cell adhesion molecule-1 and prevents the passage of macrophages and other myeloid cells into tissues such as the intestine in Crohn disease and the brain in multiple sclerosis. Because IL-18 induces vascular cell adhesion molecule-1, blocking IL-18 would

also reduce the passage of cells through the endothelium into to intestine.

Interleukin-18, Hyperphagia, and the Metabolic Syndrome

Whereas there is no constitutive gene expression for IL-1β in freshly obtained human peripheral blood mononuclear cells (PBMC), the same cells express constitutive mRNA for IL-18.[146] In western blot analysis from the same cells, the IL-18 precursor was present but not the IL-1β precursor. Similar observations were also made in mice.[146] These findings suggest that IL-18 may act as regulator of homeostasis. Starting at age 16 weeks of age, IL-18-deficient mice start to overeat, become obese, and exhibit lipid abnormalities; there is increased atherosclerosis, insulin resistance, and diabetes mellitus reminiscent of the metabolic syndrome.[186] IL-18Rα-deficient mice also develop a similar phenotype. The higher body weight is attributed to enhanced food intake, in which the IL-18-deficient mice begin to diverge from wild-type animals at a relatively early age, and to reach values 30% to 40% higher than that of wild-type mice. Others have observed similar findings.[187] A striking finding was an increase of more than 100% in the percent of adipose tissue in the IL-18-deficient animals that was accompanied by fat deposition in the arterial walls. The insulin resistance in these mice is corrected by exogenous recombinant IL-18. Mice deficient in IL-18 respond normally to a challenge with exogenous leptin, suggesting that expression of the leptin receptor is unaffected. The unexpected and unique mechanism is responsible for the higher food intake in the IL-18-deficient animals appears to be due to a central nervous system loss of appetite control. IL-18-deficient mice eat throughout the day, whereas wild-type mice eat once, nocturnally.

Interleukin-18 as a Protected Cytokine

As stated previously, mice deficient in caspase-1 experience increased disease severity when subjected to DSS colitis and that administration of exogenous IL-18 restored mucosal healing in these mice.[182] In addition, mice deficient in NLRP3 were more susceptible to DSS colitis, which is thought to be due to decreased IL-18.[183] Mice deficient in NLRP6 are also more vulnerable to DSS,[37,184] and the susceptibility appears to be due to lack of sufficient IL-18. Thus, there are a growing number of studies that support a protective role for IL-18. The fact that mice deficient in IL-18 develop a metabolic syndrome-like phenotype is consistent with a role for IL-18 in homeostasis. A study in age-related macular degeneration is also consistent with a protective role for IL-18. In that study, drusen, which is mixture of complement-derived and apolipoproteins and lipids, was shown to activate NLRP3 and induce the production of mature IL-1β and IL-18.[188] In a mouse model of “wet” age-related macular degeneration, the disease was worse in mice deficient in NLRP3 but not in IL-1RI-deficient mice.[188] Therefore, IL-18 rather than IL-1α or IL-1β were protective; upon administration of IL-IL-18, the disease severity improved. Taken together, there is a case for IL-18 being a protective rather than inflammatory cytokine.

Interleukin-18 Binding Protein

The discovery of the IL-18BP took place during the search for the soluble receptors for IL-18.[189] IL-18BP is a constitutively secreted protein with an exceptionally high affinity for IL-18

(400 pM) (see Fig. 26.3B). Present in the serum of healthy humans at a 20-fold molar excess compared to IL-18,[190] IL-18BP may contribute to a default mechanism by which a Th1 response to foreign organisms is blunted in order to reduce triggering an autoimmune responses to a routine infection. Although IL-18BP is readily secreted, it falls into the functional category of being a shed soluble receptor. As shown in Figure 26.3B, IL-18BP contains only one immunoglobulin G domain, whereas the type II IL-1 receptor contains three domains. In this regard, the single immunoglobulin G domain of IL-18BP is similar to SIGIRR, which also has a single immunoglobulin G domain and also functions as a decoy receptor. The salient property of IL-18BP in immune responses is in downregulating Th1 responses by binding to IL-18 and thus reducing the induction of IFNγ.[159] Because IL-18 also affects Th2 responses, IL-18BP also has properties controlling a Th2 cytokine response.[159] IL-18BP has a classic signal peptide and therefore is readily secreted. Serum levels in healthy subjects are in the range of 2,000 to 3,000 pg/mL compared to the levels of IL-18 in the same sera of 80 to 120 pg/mL/mL. Moreover, IL-18BP binds IL-18 with an affinity of 3 to 5 nM,[189] an affinity significantly higher than that of IL-18Rα. Because a single IL-18BP molecule binds a single IL-18 molecule, one can calculate bound versus free IL-18 in a mixture of both molecules.[190]

If one examines immunologically mediated diseases where IFNγ plays a pathologic role such as Wegener granulomatosis

and systemic lupus erythematosus, one must consider the level of free IL-18 compared to IL-18 bound to IL-18BP. In fact, in these diseases both IL-18BP and IL-18 are high,[191,192] but the level of IL-18BP is not sufficiently high enough to neutralize IL-18 and therefore, the level of free IL-18 is higher than in healthy subjects. In macrophage activation syndrome where IFNγ plays a pathologic role, both IL-18BP and IL-18 are also high but the clinical and hematologic abnormalities correlate with elevated free IL-18.[164]

A unique property of IL-18BP is that the molecule also binds IL-37[193] and in doing so, enhances the ability of IL-18BP to inhibit the induction of IFNγ by IL-18. IL-37 binds to the IL-18Rα with a very low affinity but in mice expressing human IL-37, a profound anti-inflammatory effect is observed,[194] particularly of LPS-induced cytokines and dendritic cell maturation.[194] Human IL-37-expressing mice are also resistant to colitis.[195] Thus, the anti-inflammatory property of IL-37 can be affected by the concentration of IL-18BP. As the concentration of IL-18BP increases and binds IL-37, there is the possibility that IL-37 becomes less available as an anti-inflammatory cytokine. Indeed, this has been observed in mice injected with IL-18BP. At low dosing of IL-18BP, there is reduced inflammation in a model of rheumatoid arthritis but as the doing of IL-18BP increases, the anti-inflammatory properties of IL-18BP are lost.[196]

IL-18BP is highly regulated at the level of gene expression and unexpectedly, IFNγ increases gene expression and synthesis of IL-18BP.[197,198] Therefore, IFNγ driving an increase in the natural and potent inhibitor of IL-18 falls into the category of a negative feedback loop. The concept is supported by clinical data showing that patients being treated with IFNα for hepatitis have elevated levels of IL-18BP.[199,200] IL-27, like IFNγ, functions as both a pro- as

well as an anti-inflammatory cytokine and both may accomplish their roles as anti-inflammatory cytokines at the level of increased production of IL-18BP. In the skin, IL-27 also acts through a negative feedback loop for inflammation. IL-27 is acting, as is IFNγ, by induction of IL-18BP gene expression and synthesis.[201]

Viral Interleukin-18 Binding Protein

Natural neutralization of human IL-18 by IL-18BP takes place during a common viral infection. In *Molluscum contagiosum* infection, characterized by raised but bland eruptions, there are large numbers of viral particles in the epithelial cells of the skin, but histologically there are few inflammatory or immunologically active cells in or near the lesions. Clearly, the virus fails to elicit an inflammatory or immunologic response. Amino acid similarity exists between human IL-18BP and a gene found in various members of the poxviruses; the greatest degree of homology is found to be expressed by *Molluscum contagiosum* gene.[202] The ability of viral IL-18BP to reduce the activity of mammalian IL-18 likely explains the lack of inflammatory and immune cells in the infected tissues and provides further evidence for the natural ability of IL-18BP to interfere with IL-18 activity.

Interleukin-37

IL-37 was formerly termed IL-1F7. IL-37 lacks a signal peptide and has a caspase-1 site, but the secretion of IL-37 has not been documented with any certainty. It is likely, however, that similar to IL-1α and IL-33, with loss of membrane integrity upon cell death, the IL-37 precursor exits from the cell. The recombinant form of the IL-37 precursor suppresses LPS-induced IL-1β, IL-6, and TNFα. However, this is observed primarily in macrophages that have been differentiated into the M1 phenotype by 5 days in the presence of granulocyte macrophage-colony stimulating factor. There are two consensus sequences (A-X-D) in N-terminal domain of IL-37: IHD and LED. A recombinant form of IL-37 with an N-terminus nine amino acids from the IHD site is active in suppressing LPS-induced TNFα and IL-6. Whether this short form of recombinant IL-37 exists in nature is unclear.

Interleukin-37 Reduces Interleukin-1β and Lipopolysaccharide-Induced Inflammation in Vivo

A mouse homologue for human IL-37 has not been identified. Therefore, to define the in vivo functional role of IL-37, a strain of transgenic mice was generated.[194] The full-length IL-37 complementary DNA was inserted into a vector using the standard cytomegalovirus (CMV) promoter for constitutive expression of the transgene in all cells. Both heterozygous and homozygous IL-37 transgenic mice (IL-37 tg) mice breed normally and exhibit no obvious phenotype. Despite the presence of the CMV promoter, the IL-37 transcript is not constitutively expressed in the tissues of the IL-37 transgenic mice. The failure to express IL-37 is likely due to a functional instability sequence found in IL-37, which limits the half-life of IL-37 mRNA.[51] Nevertheless, upon stimulation with LPS or IL-1β, levels of IL-37 increase after 4 to 24 hours. Once the transcript is present, the IL-37 precursor can be found in peripheral blood cells taken from the transgenic mice.[203]

IL-37 transgenic mice are protected against LPS challenge compared to similarly challenged wild-type mice. IL-37 transgenic mice exhibit significantly less hypothermia, acidosis,

hyperkalemia, hepatitis, and dehydration.[194] In addition, circulating cytokines are significantly reduced as well as cytokines induced in whole blood cultures and in lung and spleen cell homogenates. In addition to LPS-induced cytokines, whole blood cultures from IL-37 transgenic mice produce significantly less IL-6 and TNFα when stimulated by IL-1β or the combination of IL-12 plus IL-18. The antiinflammatory activity of IL-37 was not limited to a reduction of the cytokines and chemokines of innate immunity. Dendritic cells isolated from the spleen of IL-37 transgenic mice upon LPS stimulation revealed a marked reduction (75% and 89%) in expression of CD86 and MHC II, respectively.[194] The total numbers of dendritic cells, macrophages, NK cells, and CD4+ T cells were similar in all strains and experimental conditions.

A Role for Interleukin-37 During Experimental Colitis

IL-37 transgenic mice have been subjected to DSS-induced colitis. Despite the presence of a CMV promoter to drive expression of IL-37, mRNA transcripts were not present in colons in the resting state.[195] Expression was observed only upon disruption of the epithelial barrier, with a six- to sevenfold increase on days 3 and 5 after continuous exposure to DSS. During the development of colitis, clinical disease

scores were reduced by 50% and histologic indices of colitis were one-third less in IL-37 transgenic mice compared with wild-type counterparts. Reduced inflammation was associated with decreased leukocyte recruitment into the colonic lamina propria. In addition, release of IL-1β and TNFα from ex vivo colonic explant tissue was decreased 5- and 13-fold, respectively, compared with wild-type mice, whereas IL-10 was increased 6-fold. However, IL-10 was not required for the anti-inflammatory effects of IL-37 because IL-10 receptor antibody blockade did not reverse IL-37-mediated protection. Mechanistically, IL-37 originating from hematopoietic cells was sufficient to exert anti-inflammatory effects because wild-type mice reconstituted with bone marrow from IL-37 transgenic mice were protected from colitis.

A Nuclear Role for Interleukin-37

In stable transfectants of human IL-37 in RAW macrophages stimulated with LPS, levels of TNFα, IL-1α, IL-6, as well as the chemokine MIP-2 were substantially reduced (72% to 98%) compared with LPS-stimulated cells transfected with the empty plasmid.[204] Similar to IL-1α and IL-33, IL-37 translocates to the nucleus following stimulation.[204] In mouse RAW macrophages stably expressing IL-37, the mature carboxyl-terminal was detected in the nucleus. Furthermore, a specific caspase-1 inhibitor markedly reduced nuclear entry of IL-37.[204] The data demonstrate that IL-37 translocates to the nucleus after caspase-1 processing and may act as a transcriptional modulator reducing the production of LPS-stimulated proinflammatory cytokines, consistent with IL-37 being an anti-inflammatory member of the IL-1 family.

IL-37 was identified in a proteomics-based search for proteins that interacted with Smad3.[205] To test for a functional interaction of Smad3 with IL-37, IL-37 was transfected into A549 cells. IL-37 colocalized with phospho-Smad3 and was found in perinuclear and cytosolic regions, and a IL-37-Smad3 complex was observed.[194] A specific inhibitor of Smad3 reversed the inhibition of IL-6 and IL-1β expression in RAW cells stably transfected with IL-37. In stable

human macrophage lines expressing IL-37, depletion of Smad3 by lentiviral introduction of short hairpin RNA that inhibits Smad3 expression prevented the ability of IL-37 to reduce IL-1β- or LPS-induced production of IL-8, IL-6, and TNF. These in vitro findings were confirmed in vivo. IL-37 transgenic mice were pretreated intranasally with a Smad3 specific small interfering RNA and then challenged with intranasal LPS. The reduction of lung cytokines in IL-37 transgenic mice was reversed in transgenic mice with a lung knockdown of Smad3.[194]

Role of Interleukin-18Rα for Interleukin-37

From the first reports on IL-37, it was observed that the recombinant forms bound to the IL-18Rα.[132,206] This is shown in Figure 26.3C and E. The binding of IL-37 to IL-18Rα has also been observed in cells from IL-37 transgenic mice using immunofluoresence, immunoprecipitation, and fluorescence resonance energy transfer analysis.[207] IL-37 specifically binds to the third domain of the IL-18Rα.[193] Despite these studies showing binding of IL-37 to the IL-18Rα chain, IL-37 does not act as a classical receptor antagonist for IL-18 in that the ability of recombinant IL-18 to induce IFNγ is not inhibited by high concentrations of IL-37. However, in the presence of low concentrations of IL-18BP, recombinant IL-37 modestly reduces IL-18-induced IFNγ.[193] The concept that IL-37 binds to the IL-18Rα and reduces cytokine production is supported, in part, with the finding embryonic fibroblasts from mice deficient in IL-18Rα produce 10-fold more IL-6 in response to IL1β than do wild-type embryonic fibroblasts.[208] In addition, silencing of IL-18Rα in primary human blood monocytes results in a fourfold increase in the secretion of LPS-induced IL-1β, IL-6, IFNγ, and CD40 ligand.[208] Thus, the seemingly paradoxical hyperresponsive state in cells deficient in IL-18Rα supports the concept that IL-18Rα participates in both pro- and anti-inflammatory responses and that the endogenous ligand IL-37 engages the IL-18Rα to deliver an inhibitory signal.

Role of Single Immunoglobulin Interleukin-1-Related Receptor in the Anti-inflammatory Property of Interleukin-37

The mechanism by which an IL-1β or an LPS signal is suppressed by IL-37 requires an understanding of SIGIRR (Fig. 26.4G). The IL-1RAcP serves as the coreceptor for IL-1α, IL-1β, IL-36α, IL-36β, IL-36γ, and IL-33, each a proinflammatory cytokine. However, in the IL-1 family of receptors, three coreceptors contain unusually long intracellular domains. These are SIGIRR (Fig. 26.4G), a variant of the IL-1RAcP termed IL-1RAcPb (Fig. 26.4F) and receptors termed “three immunoglobulin IL-1-related receptors” (TIGIRRs). As shown in Figure 26.4H, there are two TIGIRRs: TIGIRR-1 and TIGIRR-2. IL-1RacPb is expressed only in the brain, and TIGIRR has limited expression. However, SIGIRR is expressed in most cells. The TIR domain of the three coreceptors is also different from that of other members of the IL-1 coreceptor family in that the TIR domain contains an amino acid sequence different from that of wild-type TIR.[209] As shown in Figure 26.2B, IL-1RAcPb forms the expected complex with IL-1 and IL-1R1 but does not recruit MyD88 or phosphorylate IRAK4.[209] Therefore, most IL-1 signaling is arrested. But as some genes are increased in response to the formation of the IL-1RI/IL-1RAcPb complex, partial IL-1 signaling must take place. Nevertheless, IL-1RAcPb functions as an inhibitory receptor chain but only in the brain. Mice deficient in IL-1RAcPb exhibit a normal inflammatory response in the periphery but greater neurodegeneration in the

brain. As such, IL-1RAcPb could play a role in chronic inflammatory responses in the brain by "buffering" IL-1-mediated neurodegeneration.

Like IL-1RAcPb, SIGIRR contains the same amino acids differences in its TIR domain, termed TIRb. Compared to wild-type TIR, TIRb likely has reduced binding of MyD88.[209] In addition to an altered TIR domain, SIGIRR has a carboxyl extension of 140 amino acids. Carboxyl extensions are also present in IL-1RAcPb as well as the two TIGIRRs. TIGIRR-2, which is associated with an X-linked cognitive deficiency, is apparently independent of IL-1 function. Little is known whether these C-terminal segments contribute to the inhibitory properties of these receptors. Nevertheless,

it seems likely that the alternative sequence in the TIRb domain of SIGIRR may act as a partial decoy for MyD88. MyD88 is phosphorylated upon TLR4 as well as IL-1β and IL-18 signaling, and results in downstream phosphorylation of IRAK-4. In cells expressing SIGIRR and activated by IL-37 binding to the IL-18Rα, the signal from either IL-1 or LPS initiates phosphorylation of MyD88. However, the decoy effect by the mutated TIRb of SIGIRR reduces the degree of phosphorylation of MyD88 and thus the phosphorylation of IRAK-4. The reduction, however, is partial. Indeed, the suppression by IL-37 added to blood macrophages is in the range of 20% to 50% and unlike the total loss of activation by a deficiency in MyD88.

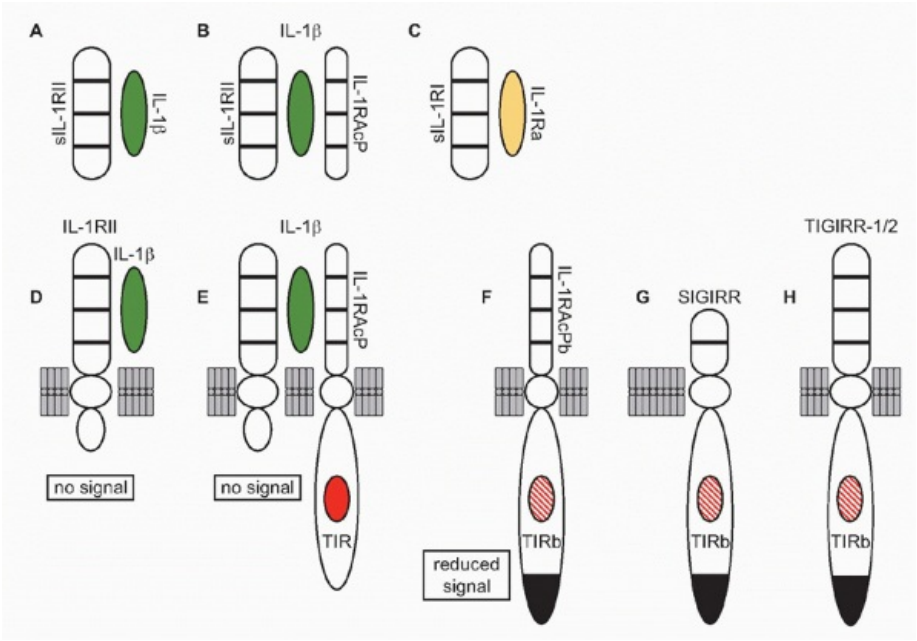

FIG. 26.4. Anti-Inflammatory Receptors of the Interleukin (IL)-1 Receptor Family. **A:** Soluble (extracellular) IL-1RII (sIL-1RII) binds and neutralizes either the precursor or mature form of IL-1β. **B:** A complex of IL-1β, sIL-1RII, and sIL-1RAcP neutralizes IL-1β activity. **C:** Soluble (extracellular) IL-1RI (sIL-1RI) binds IL-1Ra and prevents IL-1Ra from its function as a receptor antagonist. Similarly, IL-1α can bind to the sIL-1RI (not shown). **D:** IL-1RII expressed on the membrane binds mature IL-1β acting as a decoy receptor, preventing IL-1β from binding to its signaling receptor. **E:** A complex of membrane IL-1RII, IL-1β, and membrane IL-1RAcP also prevents IL-1β from signaling. **F:** The IL-1RAcPb is expressed in brain tissue (see Fig. 26.2B). **G:** Single immunoglobulin IL-1-related

receptor is expressed in myeloid cells and epithelial cells and function in damped inflammation due to the TIRb domain. **H:** Three immunoglobulin IL-1-related receptor is also an anti-inflammatory member of the IL-1 due to the toll-IL-1-receptor b domain.

Upon binding to the IL-18Rα, the IL-37 precursor may activate SIGIRR and provide a negative signal (see Fig. 26.3C). An inhibitory signal from IL-37 is enhanced by a low concentration of IL-18BP.[193] As shown in Figure 26.3D, IL-18BP binds IL-37[193] and likely presents the complex of the cytokine with the binding protein to the IL-18Rα (see Fig. 26.3E). Because A549 cells express SIGIRR, it is likely that the inhibitory signal from IL-37 activates SIGIRR or alternatively IL-37 recruits SIGIRR as the accessory chain. The inhibitory signal of SIGIRR is established in several mouse models of inflammation in which SIGIRR-deficient mice exhibit more inflammation compared to wild-type control mice.[210] In differentiated human blood M1 macrophages, recombinant IL-37 suppresses LPS-induced TNFα and IL-6 production 50% to 70%. A source of IL-18BP in this culture may be fetal calf serum. During the differentiation of macrophages into the M1 subset by granulocyte macrophage-colony stimulating factor, it is possible that SIGIRR expression increases whereas the level of IL-18Rβ decreases (see Fig. 26.3A). In the absence of IL-18Rβ, a proinflammatory complex is not formed with IL-18Rα and thus IL-37 binding to IL-18Rα may recruit or activate SIGIRR. Thus, expression of SIGIRR and the absence of IL-18Rβ would best explain the inhibitory properties of recombinant IL-37 reducing the response to LPS induction of IL-6 and TNFα.

INTERLEUKIN-36 SUBFAMILY

The IL-1 family members IL-1F5, IL-1F6, IL-1F8, and IL-1F9 are now termed IL-36Ra, IL-36α, IL-36β, and IL-36γ, respectively.[211] As shown in Figure 26.5A, each member of the IL-36

subfamily binds to the IL-1Rpr2, now termed IL-36R.[212] Because IL-38 also binds to the IL-36R (Fig. 26.5C),[133] IL-38 is included in the IL-36R subfamily. The IL-36 subfamily is closely related to the IL-1 subfamily because, similar to the IL-1α and IL-1β and IL-33, the IL-36R forms a signaling complex with the IL-1RAcP (Fig. 26.5A).[122,212] Thus of the 11 members of the entire IL-1 family,[6] members use IL-1RAcP as the coreceptor for signal transduction.

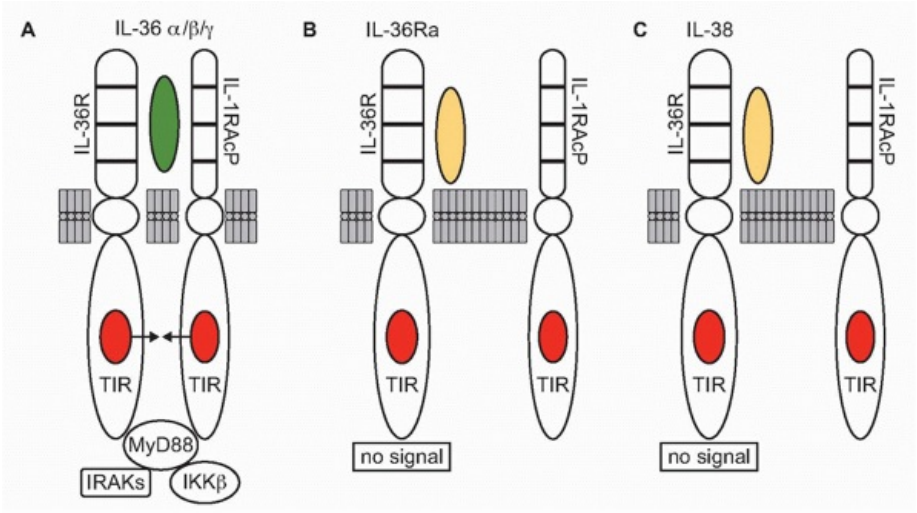

FIG. 26.5. Interleukin (IL)-36 Subfamily. A: IL-36α, IL-36β, or IL-36γ bind to the IL-36R and recruit the coreceptor IL-1RAcP. The heterodimeric IL-36 receptor complex results in a close approximation of the toll-IL-1-receptor (TIR) domains on each receptor chain (*arrows*), resulting in the binding of intracellular MyD88 to the complex with phosphorylation of MyD88. Subsequent phosphorylations of IRAKs and IKKβ, increased NF-κB, and activating protein-1 translocation to the nucleus take place, followed by expression of proinflammatory genes. **B:** IL-36Ra binds to IL-36R. There is no recruitment of the coreceptor IL-1RAcP, no approximation of the TIR domains, and no signal. **C:** IL-38 binds to IL-36R but there is no signal and acts similar to IL-36Ra.

Interleukin-36

The IL-36R is the ligand binding chain and therefore is comparable to the ligand binding IL-1R1 and the IL-18Rα. However, two members of the IL-36 subfamily bind to the IL-36R but do not signal, the IL-36 receptor antagonist (IL-36Ra) and IL-38 (see Fig. 26.5B and C). As such, these function as receptor antagonists.[9,133] An unusual property of IL-38 is that low concentrations (1 to 10 ng/mL) are able to reduce the activity of endogenous IL-36,[133] whereas in the case of IL-1Ra, higher concentrations are required to prevent the activating of endogenous IL-1α or IL-1β.

None of the members of the IL-36 subfamily have a signal peptide, indicating the generation of the N-terminus and secretion via the Golgi. In addition, each member of the IL-36 subfamily has an unusually short propiece compared to those of the IL-1α, IL-1β and IL-33 (see Fig. 26.1). Like IL-1β and IL-18, there is no true caspase-1 cleavage site for generation of an N-terminus in the IL-36 subfamily. It remains unknown which specific proteases generate the various N-termini of the IL-36 subfamily; nevertheless, each member has a unique N-terminus with a different levels of biologic activity.[9] What determines the N-terminus with optimal biologic activity in the IL-36 subfamily? Each member of the IL-36 subfamily contains the IL-1 family consensus sequence of A-X-D. The aspartic acid is not the recognition amino acid for caspase-1 or caspase-3, but rather participates in the stabilization of the first beta sheet of the three-dimensional structure that characterizes the entire IL-1 family.

The “A” of the consensus sequence is for any aliphatic amino acid, for example, leucine or isoleucine. Nine amino acids before the “A” of the consensus sequence is the N-terminal site, which results in the cytokine with the greatest activity.[9] For example, the biologic activity of IL-36γ increases by a factor of 1,000 when the N-terminus is at the site nine amino acids before the consensus sequence and in the case of the IL-36β, there is a 10,000-fold increase.[9] The nine amino acid forward site from the consensus sequence is not only the N-terminus for the agonist members of the IL-36 family but also the IL-36 receptor antagonist (IL-36Ra),[9] which increases from a low level of blocking of IL-36 family ligands to a high degree of blockade. It is unclear what specific protease cleaves at this site as the amino acid is different for each member of the IL-36 subfamily. Moreover, the site for the N-terminus of the IL-36Ra (valine) is but one amino acid from the N-terminal precursor methionine and yet IL-36Ra with an N-terminus at the valine site is 10,000-fold more potent that the IL-36 precursor. It is also an unusual situation that proteases that usually

are inflammatory in processing members of the IL-1 family in that case of IL-36Ra generate an anti-inflammatory molecule.

Interleukin-36α, β, and γ, Proinflammatory Members of the Interleukin-36 Subfamily

IL-36α was highly expressed in the murine model of glomerulonephritis 213 where the cytokine was localized to the kidney epithelium and also in CD3 T cells surrounding the tubules. IL-36α is also found in the kidneys of the MRL/lupus, nephritic syndrome, and streptozotocin-induced diabetic models.[213] IL-36γ increases IL-8, CXCL3, and the Th17 chemokine CCL20 in human lung fibroblasts,[214] and thus may account for acute neutrophilic lung inflammation. In addition to CD4+ T cells, human articular chondrocytes and synovial fibroblasts express the IL-36R.[215] In chondrocytes, there is also constitutive gene expression of IL-36β. Following stimulation with IL-1β or TNFα, levels of the IL-36β precursor rise intracellularly but the cytokine is not secreted. Although IL-36β levels were detected in the joint fluids of patients with rheumatoid arthritis as well as in serum samples, there was no correlation with disease severity.[215] It is likely that IL-36 ligands are functional only when released from dying cells and can be processed extracellularly by enzymes present in inflammatory conditions such as the joints of patients with rheumatoid arthritis. It unclear to what extent IL-36β plays a role in joint disease, although constitutive expression in primary chondrocytes may indicate a role for the cytokine in osteoarthritis.[215]

High levels of this cytokine are found in mouse embryonic tissues rich in epithelial cells.[216] In humans, IL-36α is observed in keratinocytes, not fibroblasts, and is thought to contribute to the inflammation of psoriasis. Upon forming the heterodimer with IL-36R and IL-1RAcP, IL-36α activates NF-κB similar to that of IL-1β.[212] In addition to NF-κB activation, IL-36α also activates MAPK, JNK, and ERK1/2.[212] In the mouse, bone marrow-derived dendritic cells and CD4+ T cells express IL-36 receptors in health. In a comparison with IL-1 as a stimulant, the three IL-36 ligands are more active in inducing IL-1β, IL-6, IL-12, TNFα, and IL-23.[217] In addition, IL-36 ligands induced the production of IFNγ, IL-4, and IL-17 from CD4+ T cells. Not unexpectedly, cytokines induced by IL-36 lands were prevented by 100- to 1,000-fold excess IL-36Ra.[217]

Interleukin-36 in Psoriasis

Several studies implicate IL-36 ligands in the pathogenesis of psoriasis.[218,219,220] IL-36γ is highly expressed in keratinocytes from healthy human skin and increases upon stimulation with TLR polyI:C.[221] Furthermore, polyI:C induced caspase-3, which resulted in cell death and the release of IL-36γ. Unexpectedly, stimulation of IL-36γ gene expression was dependent on caspase-1.[221] The caspase-1 dependency may be due to IL-18 as this cytokine is constitutively present in keratinocytes as is IL-1α. With the release of IL-36γ by polyI:C and the subsequent death of the cell, IL-36γ falls into the category of being an alarmin in the skin, particularly due to infection.[221] There is also a role for IL-36 in the production of IL-17: studies suggest that each of the IL-36 ligands is expressed in the skin

and dependent on IL-22.[222] Furthermore, the expression of IL-36 ligands in the psoriatic skin correlated with IL-17.[222] Similar to other models in the IL-1 family, auto- and coinduction accounts for a role in a pathologic process.

Overexpression of IL-36 in mice results in inflammatory skin lesions that resemble psoriasis in humans, as reviewed in Towne and Sims.[223] Likewise, mice deficient in endogenous IL-36Ra results in a severe lesion similar to that of humans with pustular psoriasis. The role of IL-36 in pustular psoriasis may include IL-1α, as humans with pustular psoriasis responds to an antibody that neutralizes IL-1α. Both IL-36 and IL-1α are found in the keratinocytes in healthy skin.

A Role for Interleukin-36R in Metabolic Regulation

Obesity is characterized by chronic low-grade inflammation originating from expanding adipose tissue. Human adipogenic tissue levels of IL-36α is primarily present in adipose tissue resident macrophages and induced by inflammation; however, IL-36β is absent.[224] IL-36α, but not IL-36β, reduces adipocyte differentiation, as shown by a significant decrease in PPARγ gene expression. Both IL-36α and IL-36β induce inflammatory gene expression in mature adipocytes.[224] Therefore, IL-36α and IL-36β are present in adipose tissue and are involved in the regulation of adipose tissue gene expression. Importantly, IL-36α inhibits PPARγ expression, which may lead to reduced adipocyte differentiation suggesting metabolic effects of this cytokine.

Although IL-36Ra is known to occupy the IL-36R and act as a receptor antagonist, earlier studies revealed that IL-36Ra inhibited the induction of IL-1β by LPS. The role of IL-36Ra was also examined in the brain. IL-36Ra injected into the rat brain induced IL-4 and also in glial cells in vitro.[225] Moreover, the reduction in LPS-induced IL-1β was not observed in cells deficient in IL-4 and also not observed in cell deficient in SIGIRR.[225] However, these unique properties of IL-36Ra were not observed in peripheral monocytes or dendritic cells but only in the brain.

Role of Interleukin-36 in Human Disease

The importance of any cytokine in human biology can be found in mutations that result in a profound clinical picture. In the case IL-1, a mutation in the naturally IL-1Ra (see Fig. 26.5B) results in severe systemic inflammation with erosive bone lesions, sterile meningitis, and death; the syndrome is called deficiency of IL-1Ra.[226,227] In case of the IL-36 family, persons with a mutation in the naturally occurring IL-36Ra suffer with a severe form of pustular psoriasis.[228,229] These human studies are consistent with the data from transgenic mice overexpressing IL-36α in the skin and with the ability of IL-36Ra to suppress the

severity of the inflammation.[218] In mice overexpressing IL-36a in the skin, crossing the mice to generate a strain of mice heterozygous for natural IL-36Ra knockout results in worsening of the skin lesions.[218]

Interleukin-38

IL-38 is the name for the IL-1 family member 10. During the nomenclature revision of the IL-1

family in 2010,[211] the term IL-38 was assigned to IL-1F10 without any known biologic function. Since then, IL-38 has been shown to bind to the IL-36 receptor (formerly IL-1Rrp2) (see Fig. 26.5C).[133] In order to find the receptor for IL-38, each member of the IL-1 receptor family was immobilized and recombinant IL-38 precursor containing 152 amino acids was added and binding assessed using an antibody to the ligand. IL-38 bound only to the IL-36 receptor, as did IL-36Ra.[133] To assess the biologic function of IL-38, heat-killed *Candida albicans* was used to stimulate memory T-lymphocyte cytokine production in freshly obtained human peripheral blood mononuclear cells from healthy subjects. The addition of recombinant IL-38 inhibited the production of T-cell cytokines IL-22 and IL-17. The dose-response suppression of IL-38 as well as that of IL-36Ra of *Candida*-induced IL-22 and IL-17 was not that of the classic IL-1 receptor antagonist, because low concentrations were optimal for inhibiting IL-22 production.[133] These data provide evidence that IL-38 binds to the IL-36R, as does IL-36Ra, and that IL-38 and IL-36Ra have similar biologic effects on immune cells by engaging the IL-36 receptor.

CONCLUSION

In conclusion, IL-1 family of cytokines is one of the most important families of proinflammatory mediators, that have profound local and systemic effects. The importance of these molecules has been demonstrated in homeostasis, as well as in autoinflammatory diseases, and treatment strategies based on modulation of IL-1 cytokines have begun to be employed successfully. Furthermore, important and novel biologic roles are currently being described for the members of IL-1 family of cytokines, and it is to be expected that this will represent one of the most dynamic areas of research in immunology in the coming years.

Chapter 27

Tumor Necrosis Factor-Related Cytokines in Immunity

Carl F. Ware

INTRODUCTION

Lymphocytes are highly mobile, transiting the vascular and lymphatic circulatory systems with limited stopovers in organized lymphoid tissues (lymph nodes, spleen, and Peyer's patches) in which they commune to initiate immune responses. Cytokines, both secreted and membrane-anchored proteins, serve as the communication media of the immune system. Cytokines in the tumor necrosis factor (TNF) superfamily (TNFSF) help orchestrate the development, homeostasis, and effector actions of cells in the immune system. The diversification of the TNFSF is evidenced by its roles in regulating cells of neuronal, skeletal, and ectodermal origin. This chapter's focus is on members in the TNFSF that are primarily involved in regulating immunity.

The ligands belonging to the TNFSF initiate intercellular communication by binding specific receptors on the surface of the receiving cell. The TNF-related ligands are membrane-bound and require cell-cell contact to initiate signaling, although some ligands may be secreted in soluble form influencing cellular responses at locations distant from the source of production. The TNF receptors (TNFRs) form a corresponding superfamily of cognate membrane proteins that initiate intracellular signaling pathways that influence cellular growth, differentiation, and survival. Each ligandreceptor pair forms a “system” with over 40 distinct ligandreceptor systems. Many of the ligands and receptors engage more than one cognate, thereby forming “circuits” of signaling systems, which often function together as coordinated or integrated networks with other cytokines to regulate a specific cellular process. The signals delivered to the cytosol activate transcription factors such as NF-κB and AP1, which in turn initiate the expression of hundreds of genes that alter cellular differentiation. Additionally, some TNFRs activate cell death pathways, both apoptotic and necrotic, terminating cellular life. Genetic mutations have revealed the importance of individual TNFSF members in human immune responses and development. Moreover, the beneficial effect of TNF antagonists in patients with certain autoimmune diseases brings the need to understand the complexities of the TNFSF into sharp focus.

The nomenclature of the TNFSF is a bit of a morass for students new to the field, although introduction of a numerical system standardizing gene names (www.genenames.org/) helps in accessing genomic databases. However, the use of more common, often colorful, acronyms continues. The name, rank, and genomic identification of each ligand (Table 27.1) and receptor (Table 27.2) is tabulated along with additional pertinent information for human and mouse genes.

TUMOR NECROSIS FACTOR LIGAND FAMILY

The TNF-related cytokines are type II transmembrane proteins (intracellular N-terminus) with a short cytoplasmic tail (15 to 25 residues in length) and a larger extracellular region (˜150 amino acids) containing the signature TNF homology domain where the receptor binding sites are located (Fig. 27.1). The TNF homology domain assembles into trimers, the functional unit of the ligand. Atomic analysis of several members of the family[1,2,3,4,5] revealed the ligands have a highly conserved tertiary structure folding into a β sheet sandwich, yet amino acid sequence conservation is limited to < 35% among the family members. The conserved residues defining this superfamily are primarily located within the internal β strands that form the molecular scaffold, which promote assembly into trimers. The residues in the loops between the external β-strands are variable and in specific loops make contact with the receptor. Although most of the TNF ligands self-assemble into homotrimers, heterotrimers can also form between LTα and LTβ[6] and APRIL and BAFF.[7] The stoichiometry of the LT heterotrimer is 1:2 (LTαβ2), which imparts its distinct receptor specificity from the LTα homotrimer. Interestingly, complement component C1q and several related proteins are structurally related to the TNF family, containing a TNF homology domain, a rather surprising finding given the apparent functional divergence between the complement and TNF systems.[8] Alternate splicing can also generate distinct ligands, such as the splice form joining TWEAK and APRIL (TWE-PRIL),[9] the alternate ligands for ectodysplasin receptor,[10] and a cytosolic form of LIGHT.[11]

The genetic organization of TNF ligands is highly conserved and typically encoded in three or four exons, with the fourth exon encoding most of the extracellular TNF homology domain. The genes encoding TNF, LTβ, and LTα reside adjacent to each other in a compact loci in the class III region of the major histocompatibility complex (MHC) (in humans at chromosome 6p21) sandwiched between the antigenic-peptide presenting MHC proteins encoded by MHC class I and II genes.[6,12] Three other genetic clusters of TNF-related cytokines are found within the corresponding MHC paralogous regions, located on chromosomes 1, 9, and 19. These genetic clusters share a remarkably conserved gene structure and transcriptional orientation, and a similar function linked to regulating cellular immune responses.[11] The evolutionary pressures retaining this genetic configuration of the MHC in general is encompassed in the paralogy theory of genome

evolution.[13] Conservation of gene structure of the TNF ligands outside these MHC paralogs is limited. An evolutionarily conserved pathway in *Drosophila melanogaster*, Eiger-Wengen system, is structurally and functionally related to the TNFSF-related signaling pathway, although this system is predominantly expressed in the nervous system in invertebrates.[14,15,16]

TABLE 27.1 Tumor Necrosis Factor Superfamily Chromosomal Locations

	Chromosomal Location

Gene Name/Alias	Human	Mouse	Ligand Symbol
TNF	6p21.3	ch17 (19.06 cm)	TNFSF1A
LTα	6p21.3	ch17 (19.06 cm)	TNFSF1B
LTβ	6p21.3	ch17 (19.06 cm)	TNFSF3
OX40-L	1q25	ch1 (84.90 cM)	TNFSF4
CD40-L, CD154	Xq26	chX (18.0 cM)	TNFSF5

TUMOR NECROSIS FACTOR RECEPTOR FAMILY

Members of the TNF receptor superfamily (TNFRSF) include proteins of vertebrate and viral origin. Most of the signaling receptors in the TNFRSF are type I transmembrane glycoproteins (N-terminus exterior to the cell). However, several TNFRSF members lack a membrane-anchor domain, are proteolytically cleaved from the surface, or are anchored via glycolipid linkage (eg, TNF-related apoptosis inducing ligand [TRAIL]R3). These soluble receptors, termed “decoy receptors,” retain their ligand-binding properties and compete with cellular receptors for the specific ligands, thus earning the title of decoy. The structural motifs in the cytoplasmic domains further categorize the TNFR into two groups based on their signaling properties: those contain a death domain (DD) and others that engage TNFR-associated factors (TRAFs).

TABLE 27.2 Tumor Necrosis Factor Receptor Superfamily

	Chromosomal Location		
Gene Name/Aliases	**Human**	**Mouse**	**Gene Symbol**
TNFR-1, p55-60	12p13.2	ch6 (60.55 cM)	TNFRSF1A

From Ware CF. The TNF superfamily-2008. *Cytokine Growth Factor Rev* . 2008;19:183-186.

The cysteine-rich domain (CRD) in the extracellular, ligand-binding region defines membership in the TNFRSF (see Fig. 27.1). Each CRD typically contains six cysteine residues forming three disulfide bonds. The CRD is pseudorepeated in different members ranging from one to six. Based upon the crystal structures solved for several TNFRSF members, the CRD confers an elongated shape and sidedness to the ectodomain.[17,18] The crystal structure of the complex between TNFR1 and one of its ligands, the LTα homotrimer, revealed

that residues in CRD2 and 3 of TNFR1 contact the ligand. Variation in binding interactions has been identified; for example, the receptors for BAFF have one functional CRD.[2,19]

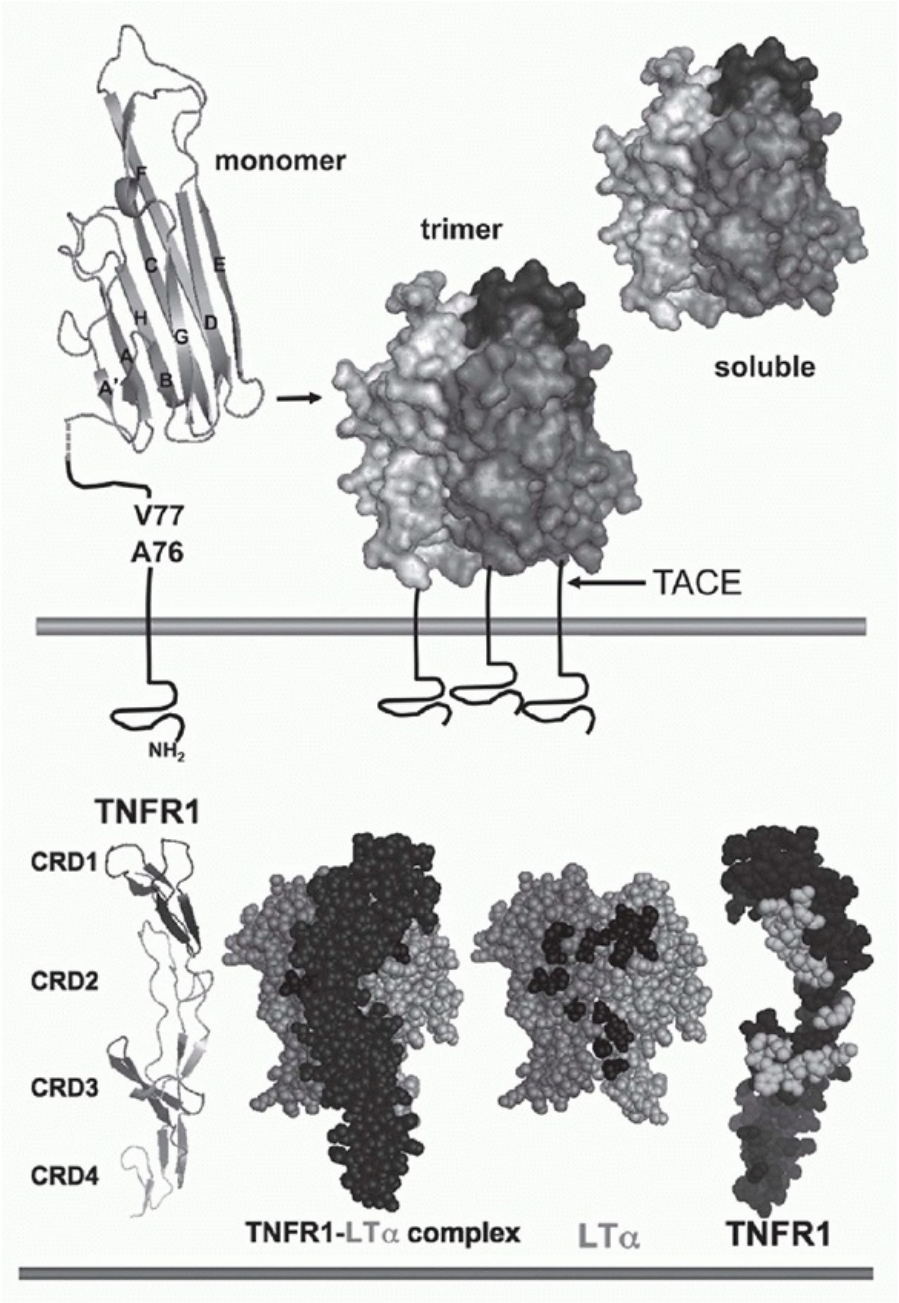

FIG. 27.1. Structure of Tumor Necrosis Factor (TNF) and TNF Receptors (TNFRs). **Top:** TNF. The β-sandwich of the TNF monomer (1A8M.pdf) (shown as a *ribbon diagram*) contains two stacked β-pleated sheets each formed by five antiparallel β strands (*wide ribbons given letter designations, A-G*) that fold into a Greek key or "jelly-roll" topology.[219] The inner β-sheet (strands A, A′, H, C, and F) is involved in contacts between adjacent subunits, which promotes assembly into a trimer. The trimer is formed such that one edge of each subunit is packed against the inner sheet of its neighbor. The outer β sheet (strands B, B′, D, E, and G) is surface exposed. The trimeric structure is characteristic of all TNF-related ligands. The type II configuration of TNF (N-terminus inside the cell) anchors TNF to the membrane. The TNF trimer is ˜60 Å in height with a relatively flat base residing close to the membrane, resembling a bell-shape (shown as surface representation with *different shades of gray* used for each subunit of the trimer). The surface exposed loops between A-A′ and D-E strands are involved in receptor

binding. TNF is cleaved by TNFα-converting enzyme (TACE), a member of the ADAM family of metalloproteinases (ADAM17) involved in processing of many cell surface proteins. TACE is a type 1 transmembrane protein that cleaves TNF between residues Val77 and Ala76, when all three sites in the trimer are cleaved TNF is released from the membrane. **Bottom:** TNFR and ligand complex. The ectodomain of TNFR1 forms an elongated molecule with CRD1 proximal to the N-terminus (*ribbon diagram*). The face of TNFR1 on the left engages LTα. In the ligand-receptor complex, the elongated receptor (*dark*) lies along the cleft formed between adjacent subunits. Shown (space-filling) is a single TNFR1 in complex with two subunits of LTα (*lighter shades*); the receptor N-terminus points upward, closest to the base of the ligand (transorientation). In the exploded view, TNFR1 is removed from in front of the ligand revealing the contact residues in the ligand, which are primarily located in the D-E and the A-A″ β-strands (*dark shade*). TNFR1 is rotated 180 degrees, exposing the contact residues in the receptor (*light shade*). Structures from 1TRN.pdf[17] as visualized with MacPyMOL (www.pymol.org).

RECEPTOR-LIGAND COMPLEX

The binding specificity of the various members of the TNF ligand and receptor superfamilies show monotypic interaction, yet several members interact with multiple partners[20] (Figs. 27.2 and 27.3). The binding interactions between TNF-related ligands and TNFR are typically high affinity, with equilibrium binding constants measured in the high pM to low nM range. The membrane position of the ligands further enhances the binding interaction with their receptors. In the membrane anchored position, the ligands and receptors must be in trans to form a complex. In the LTα-TNFR1 complex, the surface loops between A-A″ and D-E β strands contain many of the amino acid residues that make contact with the receptor, with the receptor binding site formed as a composite of adjoining subunits in the trimeric ligand[17] (see Fig. 27.1).

The trimeric architecture of the TNF ligands, containing three equivalent receptor-binding sites, provides the basis for initiating signaling through aggregation or clustering of receptors. This concept is supported by the finding that receptor-specific bivalent antibodies can act as agonists mimicking the signaling activity of the natural ligand.[21] Indeed, antibodies or peptide mimetic to TNFR can function as antagonists, blocking the ability of the natural ligand to bind the receptor while simultaneously activating the receptor as an agonist.[22] Some ligands such as FasL, TRAIL, and BAFF form higher ordered oligomers of the basic trimer. These higher ordered oligomers promote supraaggregation of receptors, enhancing or sustaining signaling pathways in the receptor-bearing cell.[23,24] Overexpression of TNFR in cells can also lead to ligand-independent signaling, a

feature bestowed in part by the propensity of the cytosolic tails to self-associate.[25] In the physiologic setting, the expression level and compartmentalization of these receptors are tightly controlled. A subregion in the first CRD of TNFR1 known as the preligand assembly domain may restrict the orientation of the unligated receptor to prevent spontaneous activation.[26] It is not known if this mechanism applies to all TNFRSF. Interestingly, some

patients with periodic fever syndrome have mutant TNFR1 that form abnormal disulfide-linked oligomers that are retained intracellullarly and provoke misfolded protein response.[27]

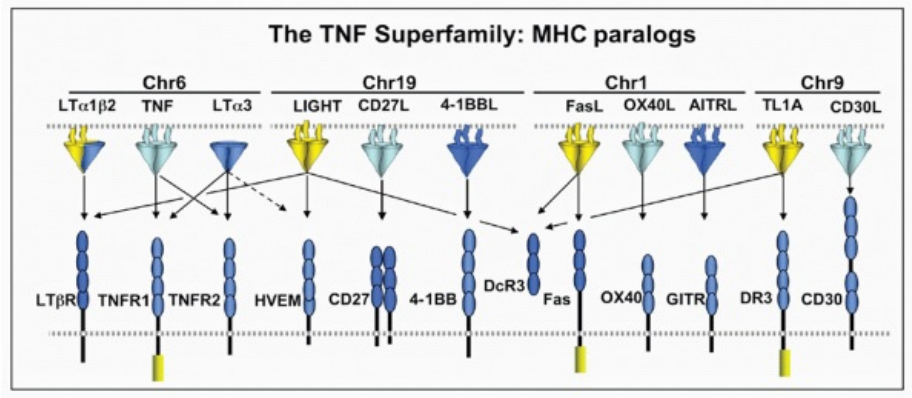

FIG. 27.2. The Tumor Necrosis Factor (TNF) Superfamily-Major Histocompatibility Complex (MHC) Paralogs. Members of the TNF ligand superfamily (*above*) and their corresponding receptors (*below*) are identified by connecting *arrows*. The ligands are grouped according to their chromosomal locations in the MHC paralogous regions. The number of cysteine-rich domains are depicted for each TNF receptor, and TNF receptors containing a death domain are identified by cylinder in the cytoplasmic tail. (Modified from Ware[336]).

Alternate Ligands

There is significant divergence in the ligands and the mechanisms of ligand binding by the TNFR family. A major branch point is exemplified by the ligands for p75 neurotrophin receptor (nerve growth factor and the other neurotrophins), which are structurally unrelated to TNF ligand family. Molecular contacts between NGF and p75NTR occur through two spatially separated binding regions located at the first and second CRD and the junction between the CRD3 and CRD4.[28] The p75NTR functions in complex with two other proteins, Nogo66 and LINGO, to engage myelin-associated inhibitory factors. Taj/TROY can supplant p75NTR in this complex.[29] Like p75 NTR, DR6, ILGF1R, and TROY/Taj do not bind any of the known TNF ligands but do engage other ligands. The pathways activated by p75NTR and TROY/Taj systems show both positive and inhibitory regulation of axonal regeneration.[29,30]

The herpesvirus entry mediator (HVEM; TNFRSF14) provides an example of a TNFR system that binds alternate ligands. Although HVEM engages two TNF-related ligands, LIGHT and LTα, it also engages two members of immunoglobulin (Ig) superfamily, B- and T-lymphocyte attenuator (BTLA)[31] and cluster of differentiation (CD)160.[32] BTLA binding to HVEM occurs in CRD1, on the opposite face of where LIGHT/LTα bind in CRD2 and 3. The BTLA binding site in CRD1 of HVEM is a region also targeted by herpesviruses.[33,34,35] Recent evidence indicates the neurotrophin and chondrocyte growth factor-like protein progranulin interacts with TNFR1 and TNFR2 and competes with TNF for binding.[36]

An insulin growth factor-like protein was recently identified as a ligand for a TNFR-like type 1

transmembrane protein (insulin growth factor-like R, formerly TMEM149).[37] Insulin growth factor-like R has conserved positioning of cysteines delineating a CRD1, but atypical CRD2/3. Insulin growth factor-like messenger ribonucleic acid (mRNA) is expressed in psoriatic skin lesions and the receptor is detected in T cells suggesting a possible role in skin inflammation.

Death receptor-6 (DR6) engages the growth factor-like domain in β-amyloid precursor protein[38,39] and thus may function as a negative regulator more like p75 neurotrophin receptor.[40] Emerging evidence suggests DR6 has a role in neuroimmune function. In a mouse experimental autoimmune encephalomyelitis (EAE) model, DR6-deficiency was shown to protect against central nervous system demyelination and leukocyte infiltration, but also enhanced overall CD4+ T-cell proliferation and T_H2 differentiation, underscoring a role for DR6 in mediating T_H1-specific immune responses in EAE progression.[41] Taj/TROY and RELT also do not bind any of the known TNFSF ligands; however, recent evidence indicates that Taj/TROY functions more like p75NTR, capable of binding myelin inhibitory factors.[29,30] A role for Taj/TROY and RELT in immune function is presently unclear.

The engagement of ligands distinct from TNFSF members implicates a higher level of integration with other signaling pathways.

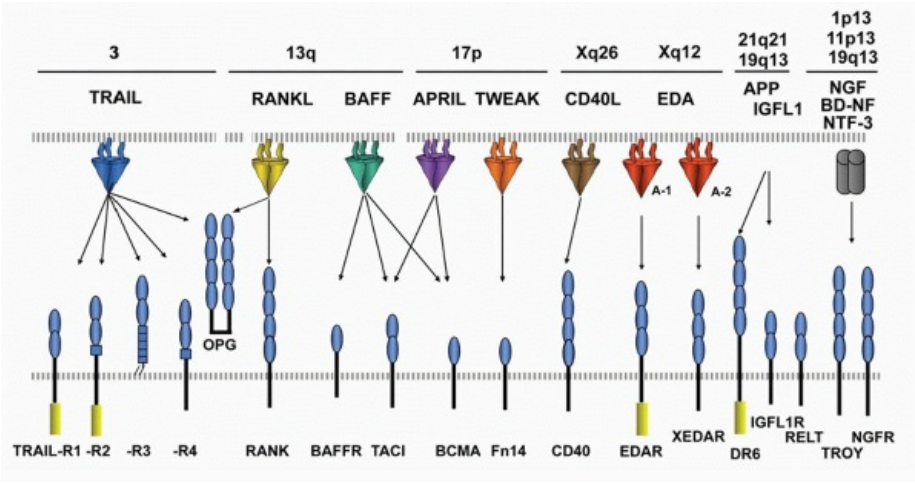

FIG. 27.3. The Tumor Necrosis Factor (TNF) Superfamily—Part 2. Members of the TNF ligand superfamily (*above*) and their corresponding receptors (*below*) are identified by connecting *arrows*. The ligands are grouped according to their chromosomal locations. The number of cysteine-rich domains are depicted for each TNF receptor, and TNF receptors containing a death domain are identified by cylinder in the cytoplasmic tail. (Modified from Ware[336]).

Viral Orthologs

TNFR-like proteins are found in the genomes of several viral pathogens representing captured cellular genes that have evolved as part of that pathogen's immune evasion

strategy (Table 27.3). Poxviruses were the first pathogens identified harboring a version of a cellular TNFR.[43] Poxvirus TNFR displays significant sequence homology to TNFR2 and binds TNF and LTα. The rabbit poxvirus protein T2 is secreted by virally infected cells and contributes to the virulence of infection.[44,45] Smallpox virus, the former scourge of mankind, also harbored viral versions of TNFR2.[46]

TABLE 27.3 Viral Orthologs and Modulators of the Tumor Necrosis Factor Superfamily

Virus	Name/ORF	Ortholog[a]	Mechanism
Poxvirus			
Myxoma	T2	Soluble TNFR2	TNF and LTα decoy
Variola	crm B (G2R)	Soluble TNFR2	TNF and LTα decoy
Cowpox	vCD30	Soluble CD30	CD30 ligand inhibitor
Herpesvirus			
HSV1&2	Glycoprotein D	BTLA	Entry; HVEM blockade
HCMV	UL144	HVEM	BTLA activation
EBV	LMP1	CD40 intracellular	TRAF activation
γHV	vFLIP	FLIP	Caspase 8 blockade
Adenovirus	E3-10.4, 14.5, 6.7	?	Fas and TRAILR downmodulation
Retrovirus			
EIAV	Envelope gp90	?	HVEM entry factor
FIV	Envelope gp95	?	Ox40 entry factor
ASLV	Envelope gp85	?	TRAILR entry factor

Rabies virus	Envelope RVG	?	NTRp75 entry factor

ASLV, avian sarcosis and leukosis virus; BTLA, B- and T-lymphocyte attenuator; CD, cluster of differentiation; EBV, Epstein-Barr virus; HCMV, human cytomegalovirus; HSV, herpes simplex virus; γHV, equine gamma herpesvirus; EIAV, equine infectious anemia virus; FIV, feline immunodeficiency virus; TNFR, tumor necrosis factor receptor; TRAF, TNFR-associated factor; TRAIL, TMF-related apoptosis inducing ligand;?, no homology recognized.

[a] Relationship determined by sequence or structural homology to the indicated TNF superfamily member.

SIGNALING PATHWAYS AND CELLULAR RESPONSES

Regulation

The cellular response activated by a TNF-related cytokine depends on several factors including the temporal patterns of expression of the ligands and receptors on the interacting cells, and the cellular context (the state of differentiation of the responding cell). Regulation is achieved at the level of transcriptional and translational controls, and by modulating the availability of the ligand or receptors (Fig. 27.4). For some ligands, transcriptional activation is a critical feature controlling the duration of mRNA expression. Some ligands exhibit inducible, transient expression of mRNA following signals from antigen receptors or innate receptor recognition systems. The half-life of mRNA

for TNF is short, controlled by an adenylate-uridylate-rich element in the 3′ untranslated region.[47] Deletion of the adenylate-uridylate-rich element in TNF mRNA in mice leads to a profound inflammatory disease.[47,48] TNF mRNA is inducible in macrophages by multiple pathways, particularly innate activation pathways such as toll-like receptor signaling, whereas other ligands like 41BBL and OX40L are constitutively expressed in differentiated antigen-presenting dendritic cells (DCs). T- and B-lymphocytes require activation prior to expression of TNF. In these cells, signals via the antigen receptor utilizing nuclear factor of activated T cells (NFAT) transcription factors are needed for the induction of TNF transcription. The inducible or constitutive patterns of expression are also observed with some receptors as well.

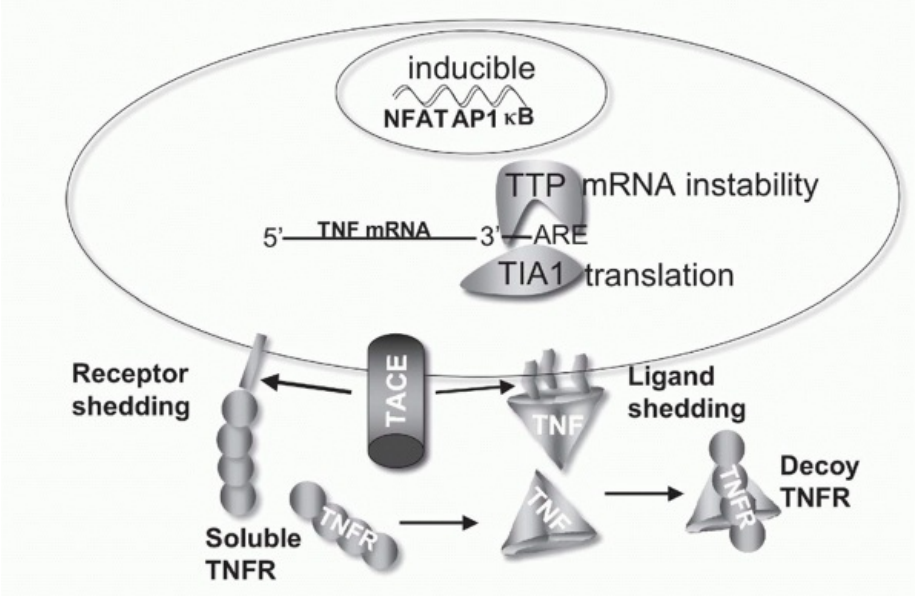

FIG. 27.4. Regulation of Tumor Necrosis Factor (TNF) Bioavailability. The expression of TNF is regulated at the transcriptional and translational levels, and bioavailability by altering its physical location and cellular receptors. TNF transcription is regulated by the action of multiple transcription factors including nuclear factors of activated T cells (NFAT), activated protein-1 (AP1), and NF-κB. NFAT is a predominant acting transcription factor regulating TNF transcription in T- and B-lymphocytes, and NF-κB and AP1 are important in myeloid lineage cells following activation via innate pattern recognition receptors, such as the toll-like receptors. TNF messenger ribonucleic acid (mRNA) stability is controlled by an adenylate-uridylate-rich element (ARE) in the 3′ untranslated region present in many transiently expressed inflammatory genes.[337] Stability of TNF mRNA is decreased by the action of tristetraprolin, and T-cell intracellular antigen silences translation of TNF mRNA through the ARE.[338] TACE proteolytically controls TNF at the membrane, generating the soluble form of TNF. TACE also cleaves TNFR1 and 2,[339] downregulating cell surface receptors and releasing soluble receptors that retain TNF binding activity. Soluble TNFR can stabilize the TNF trimer at sub saturating concentrations, and at higher, saturating concentrations act as decoys competing for TNF binding to cellular receptors.[340]

Posttranslational regulation of signaling is achieved by proteolytic cleavage of the ligand or receptor from the cell's surface, which places the protein into the soluble phase, where its half-life may be dramatically shortened. TNF and Fas ligand, for example, are shed from the surface by membrane proteases. ADAM17 (also known as TNFα-converting enzyme [TACE]), the enzyme that processes TNF into a soluble form, is involved in cleaving multiple cell surface proteins including transforming growth factor α, L-selectin, and TNFR1 and 2. Production of soluble TNFR1 and 2 may be important in regulating TNF bioavailability (see Fig. 27.4).

Most of the TNF-related ligands are expressed by DCs, activated lymphocytes, and myeloid cells, particularly macrophages, but can also be produced by nonlymphoid cells. TNF is an

example of a ligand expressed by many cell types depending on the stimulus. Expression of TNFR is widespread. TNFR1 is expressed on most cells, while TNFR2 is limited to cells of hematopoietic origin and is expressed following activation of B or T cells. Macrophages are a primary source of TNF in response to toll-like receptor signaling, and T cells produce TNF when activated by antigenic stimuli. Fibroblasts also produce TNF in response to virus infection, and nonlymphoid tumor cells may ectopically express TNF. FasL is another example of a ligand with a varied cellular expression pattern. FasL is expressed by effector T cells and natural killer (NK) cells as a component of their cell lytic activity, yet FasL mRNA is also detected in reproductive organs and epithelium of the eye, which may use this TNFSF member to kill organ infiltrating inflammatory cells as a mechanism to dampen inflammation.

Signal Transduction Pathways

TNF receptors initiate signaling pathways that alter gene expression patterns, changing the differentiation status of a cell, as well as apoptotic pathways that terminate cellular life. The propagation of signals from receptor to enzymatically active proteins is mediated by two distinct types of signaling motifs in the cytosolic domain of the TNFR: DDs and TRAF-binding motifs. TNFR that contain a DD include Fas, TNFR1, DR3, and TRAILR1 and 2. Other TNFRs have TRAF recruitment motifs. Three basic schemes are used by TNF receptors to connect to enzymatically-driven signaling pathways (Fig. 27.5A). Adaptor molecules are required to establish the signaling connections between the receptor and signaling enzymes. The DD connects TNFR to cytosolic proteins containing a Death Effector Domain (DED), which in turn link to caspases (cysteine based, aspartic acid specific proteinases). Alternately, the TRAF proteins connect to the cytosolic domain of the TNFR, altering ubiquitin-dependent pathways that regulate key serine kinases that activate NFκB and AP1 transcription factors. The third scheme involves an indirect link between the death domain and TRAFs via the adaptor TNFR-associated death domain (TRADD).

The apoptotic and NF-κB pathways activated by the TNFR family help regulate cellular homeostasis by controlling cell death and survival. In the immune system, apoptosis is essential for homeostasis and for eliminating antigen-bearing cells from the host. Many TNFR can induce activation of survival or death pathways depending in part on the differentiated state of that cell. In all nucleated cells, apoptosis is the default pathway; that is to say, all of the constituents of the pathway are expressed and ready to be activated (Fig. 27.6), whereas cellular survival requires transcriptional control of genes that encode regulatory proteins that suppress the progression of the apoptotic pathway.

Apoptosis

Ligation of TNFR promotes assemble of the death-inducing signaling complex (DISC) that promotes dimerization of procaspase 8 forming an active enzyme complex.[49] Activated caspase 8 acts directly to cleave procaspase 3 and 7, which are known as the executioner caspases as they directly cleave critical cellular substrates leading to apoptotic death. Caspase 8 also cleaves BID, a crucial connector to the mitochondria-associated death mechanism, which greatly amplifies the apoptotic process.[50] A cell must be capable of actively transcribing and translating genes to resist apoptosis signaling. A variety of genes can inhibit apoptosis and cell death pathways. For example, the cellular inhibitor of apoptosis (XIAP) is a direct caspase inhibitor that is regulated at the level of gene expression by

transcription factor NF-κB. Another regulator, FLIP (FLICE inhibitory protein), is also an NF-κB-regulated gene that contains a DED and a pseudocaspase domain that attenuates the apoptotic pathway by blocking conversion of procaspase 8 to the active form.[51] Many viral pathogens parasitize the transcriptional capabilities of the cell and prevent the cell from making new survival proteins, allowing apoptosis to proceed. As expected, viruses have evolved many different strategies to alter proapoptotic pathways (eg, viral orthologs of XIAP and FLIP prevent premature death of the cell) (see Fig. 27.6).

Cell Survival Signaling

Activation of transcription factors by TNFR utilizes the TRAF adaptors. There are seven members of the TRAF family (given numerical designations) that play key roles in regulating TNFR signaling and activation of host defenses. Each TRAF appears to play different roles in modulating signaling. Each TRAF protein contains a TRAF homology domain that binds TNFR and a RING and/or zinc finger domain characteristic of E3 ubiquitin ligases.[52,53,54] Ubiquitination plays an essential role in regulating signal transduction by TNFR[55,56] and in the pathogen recognition receptors as part of innate host defenses.[57]

Clustering of the TNFR promotes the recruitment of TRAFs into a complex with the receptor through two different mechanisms. TRAF2, 3, and 5 bind directly to the receptor's cytosolic domain recognizing a consensus PXQS/T motif,[58] whereas TNFR1 uses TRADD to couple to TRAF2. TRAF3 and TRAF6 are preassociated with different proteins, including protein kinases involved in multiple signaling pathways including the pathogen recognition and interferon (IFN) pathways.[53,59] TRAF adaptors link TNFR directly to protein kinase cascades, which in turn lead to activation of transcription factors including NF-κB and AP1.

The NF-κB family of transcription factors control expression of genes critical for cell survival, inflammatory, and immune responses. In mammalian cells, the NF-κB family consists of five members: RelA, RelB, c-Rel, p50/NFκB B1, and p52/NFκB B2 (proteolytic processing of p105 and p100 yields the active forms p50 and p52, respectively).[60,61] Activation of NF-κB releases inhibitors that restrict nuclear translocation.[62] Homo- and heterodimers of NF-κB family members are held inactive in the cytosol by inhibitors of κB (IκB), such as IκBα, that mask nuclear localization motifs on the NF-κB dimers. A complex consisting of the kinase catalytic subunits IKKα and IKKβ and the regulatory/scaffold subunit IKKγ form the IKK complex that mediates phosphorylation and ubiquitination of IκB, leading to its degradation and release of the active transcription factor. IκB is the common target of a variety of signals that control the activation of the RelA NF-κB transcription factor, which in turn regulates expression of many proinflammatory genes within a signal responsive cell.[63]

A distinct pathway regulates the activation of RelB NF-κB through the NF-κB-inducing kinase (NIK) and IKKα kinases. In unstimulated cells, NIK levels are maintained at vanishing low levels by ubiquitination and proteosome degradation through an E3 ligase complex comprised of TRAF3, TRAF2, and CIAP1/2.[52] Receptor ligation releases the active form of NIK by competitively displacing TRAF3, preventing further ubiquitination and allowing NIK to accumulate.[64] NIK phosphorylates IKKα, which induces the proteosome dependent processing of p100 to p52, degrading the inhibitory domain of p100 and allowing the

RelB/p52 complex to activate gene transcription.

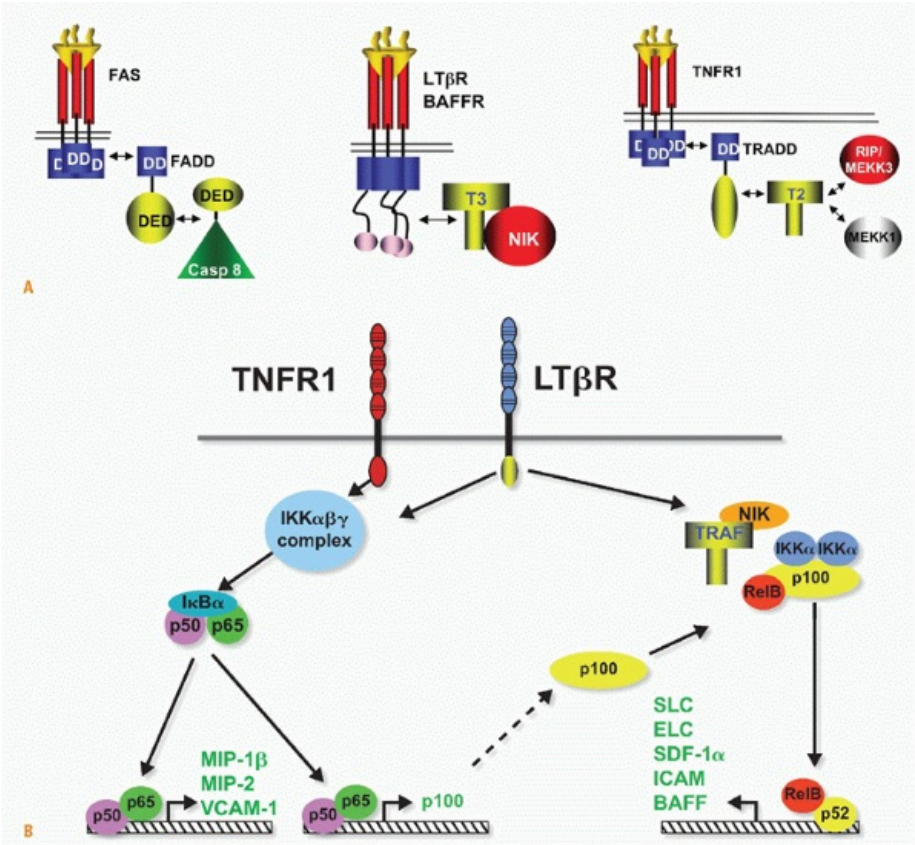

FIG. 27.5. Signaling Pathways and NF-κB. A: Adaptors link tumor necrosis factor receptors (TNFRs) to proteinases and kinases (*upper panel*). Three basic schemes link activated TNFRs to signaling pathways: the death inducing signaling complex formed with Fas is initiated by ligand clustering of Fas, promoting death domain (DD) interactions, which recruits Fas-associated death domain (FADD) (heterotypic interaction). The death effector domain of FADD links to the death effector domain of procaspase 8. The proximity of multiple procaspase 8 domains forms an active enzyme that can process other caspase 8 molecules. By contrast, TNFRs bind TNF-associated factor (TRAF) adaptors via short peptide motifs that release TRAF from associated kinases, such as NF-κB-inducing kinase (NIK). The third scheme is a combination of DD and TRAF recruitment. TNFR1 uses the DD protein TRADD to recruit RIP and TRAF2, promoting the activation of NF-κB. There are currently seven TRAF members with distinct interaction patterns with the TNFR family. TRAF proteins may function as regulators of key kinases. TRAF2, 3, and 6 function as modulators of several different kinases involved in toll-like receptor signaling, induction of type 1 interferon responses, and signaling by some TNFR family members. TRAF proteins contain an N-terminal RING finger motif, a coiled coil domain (isoleucine zipper), and the receptor association domain (TRAF) domain. The TRAF are trimers formed through their TRAF and coiled domains. The TRAF domain can bind to several different TNFR through a relatively short proline-anchored sequence that is responsible for binding directly to the mushroom head of various TRAF molecules.[341] The zinc RING of TRAF6 functions together with Ubc13

and Uev1A as ubiquitin E3 ligase targeting proteins for proteosome degradation. TRAF2, 3 and cIAP form the ubiquitin E3 ligase that targets NIK. Modified with permission from Ware CF. Tumor necrosis factors. In: Bertino JR, ed. *Encyclopedia of Cancer* . San Diego, CA: Academic Press, Inc.: 2002;475-489. **B:** NF-κB activation. TNFR1 and LTβR induce distinct forms of the NF-κB family of transcription factors. TNFR1 signaling is a potent activator of RelA/p50 but does not activate the RelB pathway, whereas lymphotoxin βR can activate both. The RelA and RelB forms of the κB family control transcription of distinct sets of genes; however, the two pathways are interrelated through the control of p100 expression by the RelA/p50 complex. Modified from Dejardin et al.[66]

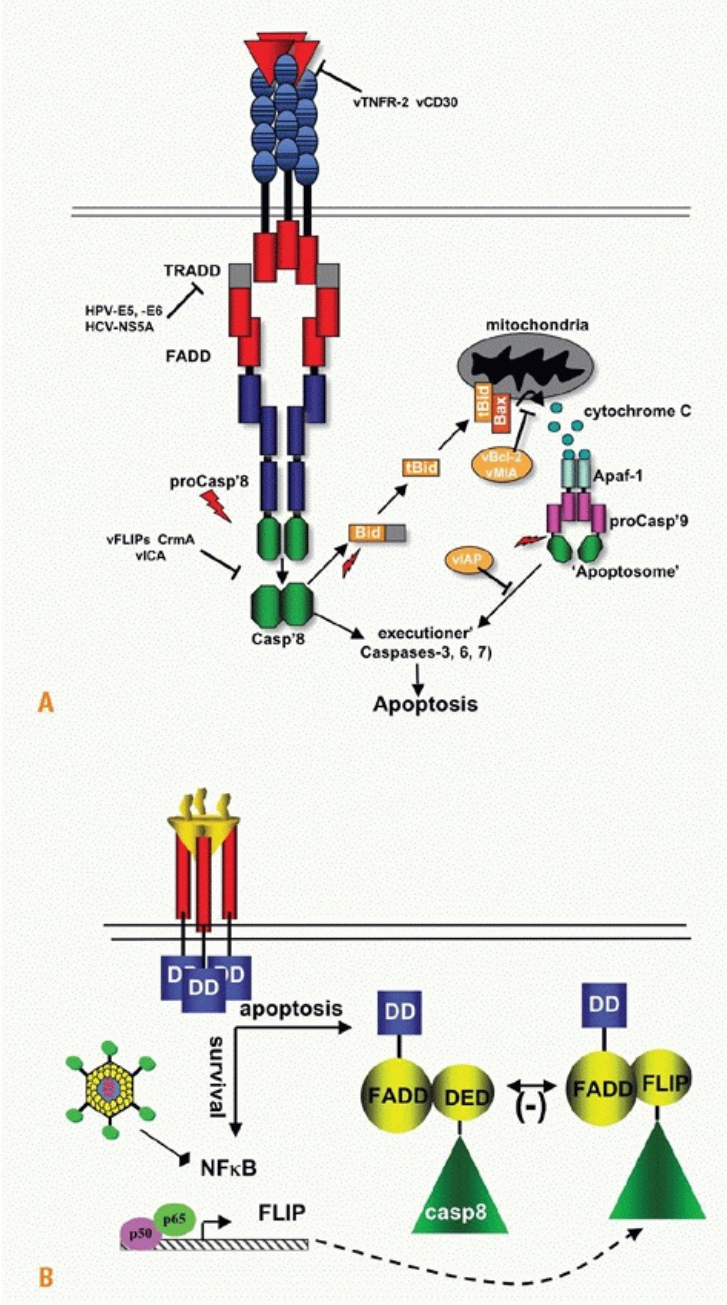

FIG. 27.6. Apoptosis and Survival Signaling. A: Ligation of tumor necrosis factor (TNF) receptor 1, Fas, or TNF-related apoptosis inducing ligand 1 and 2 activates apoptosis pathways. The nascent death-inducing signaling complex can directly cleave the executioner caspases 3, 6, and 7. Caspase 8 also cleaves BID to tBID, activating the mitochondrial regulated apoptotic pathway, dramatically accelerating cellular death. A number of viral proteins interfere with apoptosis induced through TNF pathway including human papilloma virus, hepatitis C virus, herpesvirus vFLIP, and virus orthologs of BCL2 and vMIA act on the mitochrondria. Adapted with permission.111 **B:** The components of the apoptotic pathway are preformed in the cytosol enabling the cell to respond rapidly to death signaling. In contrast, the key regulators of the apoptotic pathway, including Bcl2 and inhibitor of apoptosis, require new gene expression controlled by NF-κB. An important NF-κB-induced gene is cellular FLIP, which contains a pseudocaspase domain. The cFLIP protein interferes with caspase 8 activation, blocking the prodeath pathway. If the cell is transcriptionally inactive or unable to activate NF-κB, which often occurs in a pathogen-infected cell, then the proapoptotic pathway dominates the signals emanating from the TNF receptor 1 signaling complex leading to apoptosis and curtailing parasitism of the cell.

As examples, TNFR1 and LTβR activate separate yet related pathways that lead to distinct forms of NF-κB, the RelA/p50, and RelB/p52 complexes.[65] Each form of NF-κB activates a large number of genes with distinct roles in physiology (see Fig. 27.5B). TNFR1 signaling rapidly mobilizes (within minutes) the RelA/p50 complex, which controls expression of many proinflammatory and survival genes. By contrast, the processing of p100 and accumulation of nuclear RelB/p52 takes several hours after the initial stimulus. RelB-dependent genes are often involved in lymphoid tissue organogenesis and homeostasis. NIK is also required for NF-κB RelB and RelA activation by CD27, CD40, and BAFF-R, but not by TNFRI, which is restricted to activating RelA/p50 complex.[66,67] Components of the NF-κB pathway, including TRAF3, cIAP, NIK, and A20, are frequently mutated in cancer, leading to constitutive expression of survival factors such as the BCL2 family.[68]

THE IMMEDIATE LYMPHOTOXIN AND TUMOR NECROSIS FACTOR FAMILY

TNF (formerly TNFα or TNFSF2) and lymphotoxin (LT)α (formerly TNFβ (or TNFSF1) were originally pursued and characterized as inducers of tumor cell death, holding promise as antitumor therapeutics. However, the potent inflammatory action of TNF, particularly in the cardiovasculature, was quickly realized by the response of cancer patients injected with recombinant protein. We now recognize that TNF and LTα are two components of an interconnected network of “signaling circuits” that include LT-β, LIGHT (TNFSF14), and their specific receptors and regulatory proteins (Fig. 27.7). Each individual pathway has unique and cooperative signaling activities with other members of this immediate family. The immunologic processes controlled by this cytokine network are extensive, ranging from the development and homeostasis of lymphoid organs to the mobilization of innate defense systems to cosignaling activity promoting adaptive immune responses.[69,70,71]

TNF, LTα, LTβ, and LIGHT define the immediate group of TNF-related ligands that bind four cognate cell surface receptors with distinct but shared specificities. TNF and LTα both bind

two distinct receptors, TNFR1 (p55-60, *TNFR1A*) and TNFR2 (p75-80, *TNFR1B*). The heteromeric LTαβ2 complex binds the LTβR, which also binds LIGHT (TNFSF14). LIGHT also engages the HVEM (TNFRSF14), which acts as a ligand for BTLA and CD160,[31] an Ig superfamily member. Two distinct human herpesviruses, herpes simplex virus and cytomegalovirus, target the HVEM-BTLA pathway using different mechanisms[35,72] (see Fig. 27.7).

TNF mediates a diverse range of cellular and physiologic responses linked to acute and chronic inflammatory processes. The diversity of responses is due in part to the broad expression of TNFR1 and the release of TNF as a soluble mediator where it can act in a systemic fashion. TNF production is triggered by many of the innate recognition systems, such as the toll-like receptors and by T and B cells. In chronic inflammation, TNF production can lead to tissue damage and organ failure. Genes expressed in response to TNF signaling

coordinate the physiologic responses during inflammation (Table 27.4). The responses will reflect the characteristic of the inflamed organ, the local or systemic source of TNF, and the duration of TNF signaling. Acute inflammatory responses involve rapid changes in hemodynamics (plasma leakage and edema) and leukocyte adherence, extravasation, and organ infiltration induced by TNF. TNF production during chronic inflammation may contribute to systemic metabolic derangements and wasting (cachexia) or loss of organ structure and function (bone erosion in joints of patients with rheumatoid arthritis [RA]). In some models, TNF can promote an inflammatory environment that promotes tumor formation.[73,74,75]

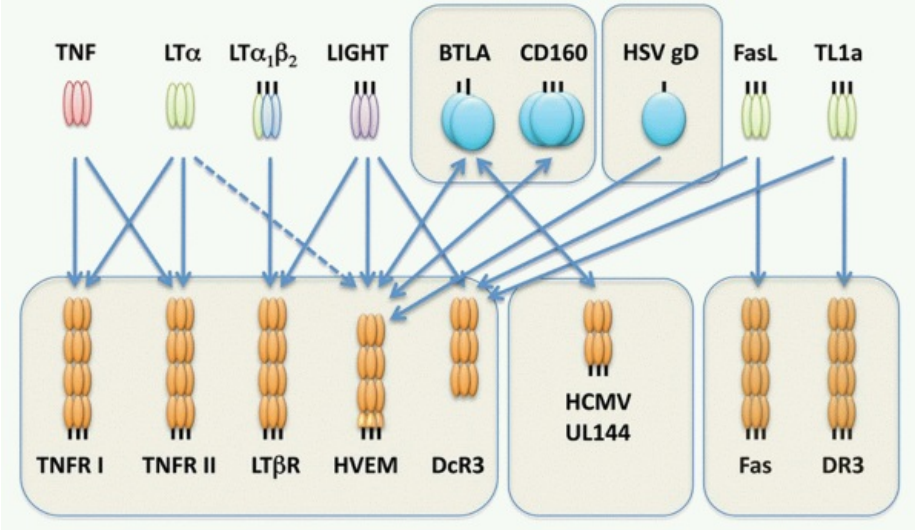

FIG. 27.7. The Immediate Tumor Necrosis Factor (TNF) Lymphotoxin (LT) Network. The cartoon depicts the signaling network formed between TNF, LTα, LTβ, and LIGHT, and their receptors. Each *arrow* indicates a ligand-receptor interaction. The network is defined by the extensive cross-utilization of ligand and receptors. Herpesvirus entry mediator (HVEM) forms a switch between positive cosignaling through LIGHT-HVEM interaction and inhibitory signaling through B- and T-lymphocyte attenuator (BTLA). LIGHT bound to HVEM activates TNF receptor-associated factor-dependent activation of NF-κB, whereas HVEM-BTLA acts through an immunoreceptor tyrosine-based inhibitory motif of BTLA to recruit the phosphatase SHP2, attenuating kinases

activated by T-cell receptor signaling. The herpes simplex viron envelope protein gD attaches to HVEM acting as an entry step for infection. UL144 gene of human cytomegalovirus binds BTLA, but not LIGHT, selectively mimicking the inhibitory pathway of HVEM-BTLA. Fas Ligand and TL1A are included in this network through their interaction with decoy receptor-3.

Elucidation of the functions associated with this TNF/LT signaling network has been aided by studies with genetically modified mice engineered with null or transgene expression of the cytokine or receptor (Table 27.5). Deficiency in TNF or TNFR1, but not TNFR2, have similar phenotypes with alterations in host defense to intracellular bacterial pathogens, like *Listeria monocytogenes* and *Mycobacterium tuberculosis*, but surprisingly modest susceptibility to some viral pathogens. These results demonstrated a role for TNF in acute-phase response of the host defense system. In contrast, LTα-deficient mice showed a failure in formation of peripheral lymphoid organs, a phenotype not observed in mice deficient in either TNFR or TNF, which implicated the LTαβ complex signaling through the LTβR as a key developmental pathway for lymphoid organogenesis.

Lymphotoxinαβ-LymphotoxinβR, A Mammalian Organ Development Pathway

Gene-deficient mice sharing a common phenotype of no lymph nodes revealed the framework of a signaling pathway involved in mammalian organ development. LTα-, LTβ-, or LTβR-deficient mice fail to develop secondary lymphoid tissues.[76,77] Several other knockout mice, including the transcriptional regulators Ikaros, ID2, and RORγt, also lack lymph nodes,[78,79,80,81,82] as do mice deficient in components of the NF-κB

activation pathway, including TRAF6, NIK, IKKα, and Rel B, and their gene targets. Target genes including CXCR5, the receptor for CXCL13, show defective lymphoid organ structure, as do CCR7-/- mice (receptor for CCL19/CCL21). The developmental program of secondary lymphoid organ formation initiates at 9 days post coitus progressing in organized fashion from dorsal to lateral movement, with intestinal Peyer's patches forming during the first postnatal week.[83] The defect is irreversible in that transferring LTαβ-sufficient bone marrow into an adult LT-mutant mouse failed to induce lymph node formation. Accumulating studies indicate that the formation of lymphoid organs involves two distinct cell types, an embryonic LTβR-expressing mesenchymal stromal cell that responds to LTαβ expressed in a cell of hematopoietically derived lineage, termed the lymphoid tissue inducer cell. The lymphoid tissue inducer cell develops separately from lymphocytes and myeloid cells in a pathway dependent on ID2 and RORγt and different cytokines including interleukin (IL)7, RANK ligand (TRANCE, TNFSF11), and TNF. These cytokines induce surface LTαβ in lymphoid tissue inducer cells that differentially engenders formation of lymph nodes and Peyer's patches.[84] Cells of the lymphoid tissue inducer lineage are maintained in the adult tissues at low levels (0.5%), presumably aiding in the homeostasis of lymphoid organs.[85,86]

TABLE 27.4 Physiologic Correlates of Tumor Necrosis Factor-Mediated Gene Induction

Induced Gene	Response
iNOS	Vasodilation, edema
VCAM-1	Leukocyte margination and extravasation
IL-8	Leukocyte chemotaxis
MHC-1	Antigen presentation
Caspase 8 activation	Apoptosis
LPL	Cachexia

Caspase 8, cysteine-dependent aspartic acid specific proteinase-8; IL-8, interleukin-8 (CXC chemokine); iNOS, inducible nitric oxide synthetase; LPL, lipoprotein lipase; MHC-1, major histocompatibility complex-1; VCAM-1, vascular cell adhesion molecule-1.

TABLE 27.5 Phenotypes in Mice Deficient in Lymphotoxin and Tumor Necrosis Factor Immediate Family

	Phenotypes					
Gene Deletion	**LN**[a]	**PP**[b]	**Architecture**[c]	**NK**[d]	**NKT**[e]	**DC**[f]
LTα	-	-	Disrupted	Impaired	Impaired	CD8-DC

[c] Architecture of the splenic white pulp includes T- and B-zone segregation, MZ, germinal center and follicular DC network.

[d] NK-cell deficiency includes reduced cell numbers and enhanced tumor susceptibility.346

[e] NKT cells Vα14 subset.347

[f] CD8- DC subsets in spleen are diminished from failure to proliferate.95

[g] LTβ conditionally deleted in B cells or T cells.348 LTβ-B cells showed partial disruption in architecture; normal for LTβ-T, but combined knockout in both B and T cells was worse than LTβ-B.

[h] Normal architecture observed in TNF point mutant344; abnormal architecture in TNFR1-/- mice.345

Modified with permission from Ware.70

The microarchitecture of the white pulp in the spleen[87] is disrupted in LT- and TNF-deficient mice.[88] Multiple abnormal features of the architecture are observed in LT- and TNF-deficient mice, including missing macrophages in the marginal sinus and the loss of positional segregation of T and B cells into discrete zones. The segregation of T and B cells into discrete compartments depends on expression of the tissue organizing chemokines CCL19 and CCL21, which attract T cells, and CXCL13, which attracts B cells. CCL19 and CCL21 act through the chemokine receptor CCR7 expressed on T cells, and CXCL13 binds CXCR5 on B cells to promote localization in the follicles. An LT-chemokine circuit is formed by migration

of B cells to LTβR+ stromal cells expressing CXCL13, which in turn induces expression of LTαβ on B cells.[89,90,91] Circulating B cells lack surface LTαβ, but expression is regained upon reentry into the CXCL13 rich microenvironment.[91] The formation of the splenic microarchitecture depends on B-cell expression of LTαβ, which induces differentiation of specialized stromal cells (eg, secretion CCL20 and CXCL13 chemokines) in the spleen during postnatal maturation. Remodeling of the microarchitecture of the secondary lymphoid organs occurs during immune responses, which requires both TNF and LT pathways signaling on fibroblastic reticular cells.[92] A viral pathogen, cytomegalovirus, can induce specific changes in the splenic microenvironment through modulation of CCL21 expression.[93]

The LTβR and TNFR pathways facilitate lymphocyte entry into lymphoid tissues in part by modulating expression of adhesion molecules, such as peripheral node and mucosal addressins on high endothelial venules.[94] LTβR signaling is necessary to maintain networks of follicular DCs involved in capturing antigen and immune complexes that aid in activating B cells. These cellular interactions are further enhanced by LTβR signals that provide growth signals for some conventional myeloid DC (CD8- subsets) within the lymphoid organ, whereas TNF plays a role in differentiation of DC progenitors in bone marrow.[95]

T and B cells can communicate with stromal and myeloid cells via the LTαβ-LTβR pathway and thus modify their immediate microenvironment during the course of an immune response. Nonlymphoid tissues suffering from chronic inflammation associated with autoimmune disease, graft

rejection, or microbial infection often contain organized accumulations of lymphocytes reminiscent of secondary lymphoid organs, called tertiary lymphoid organs. Activated T and B cells provide the source of LTαβ that helps drive the process of forming these structures, but as antigen is cleared, immune responsiveness subsides and these structures resolve. A gradation of features may be found in the tertiary lymphoid organs including presence of DCs, expression of chemokines, high endothelial venules, segregated regions of T and B cells, and germinal centers, but these structures typically lack the permanence of a lymph node. TNF also contributes to formation of granuloma that assists in walling off bacteria.[96] Thus, the LTαβ and TNF pathways operative in embryonic life also play critical roles in the adult in the formation of tertiary lymphoid structures.

Influence of the Lymphotoxinαβ Pathway on Lymphocyte Development

Mounting evidence indicates the LTαβ-LTβR pathway contributes to the ontogeny of unconventional T cells, including γδ T cells and invariant NK T cells, whereas conventional T cell subsets are normal in mice deficient in the TNF and LTβR pathways. The LTβR pathway seems to operate at distinct levels during thymic development.[97] Double positive thymocytes regulate the differentiation of early thymocyte progenitors and γδ T cells via the LTβR pathway,[98] yet the LTβR is not expressed in thymocytes, suggesting an indirect mechanism. In this regard, LTβR signaling is required for the proper formation and function of the thymic stroma, which influences T-cell development.[99] The thymic medulla appears to control the export of invariant NK T cells from the thymus.[100,101] In addition, LTβR signaling in thymic stroma affects central tolerance to peripherally restricted antigens, which may be either

dependent or independent upon the autoimmune regulator *Aire*.[102] Thymic differentiation depends on the LTβR pathway to mediate the cellular communication between lymphoid and stromal compartments.

Autoimmunity

Dysregulated expression of several members of the TNFSF leads to autoimmune-like diseases in humans and animal models. For example, enforced expression of TNF or LIGHT, which overrides the normal transient expression, causes severe autoimmune and inflammatory processes in mice.[103,104,105] LTα or LTαβ transgenic expression in the pancreas leads to insulitis and formation of tertiary lymphoid structures.[106] These types of results have implicated members of the TNF superfamily as immune regulators and support the notion that LTαβ and LIGHT pathways contribute to inflammation and tissue destructive processes.

Infectious Diseases

TNF is a major inflammatory cytokine required for the acutephase response to bacterial infection. For instance, lipopolysaccharide in gram-negative bacteria is a potent inducer of TNF secretion through the TLR4 innate recognition system. In mice, lipopolysaccharide induces a shock syndrome that is rapidly lethal owing to profound changes in blood circulation. However, mice survive lipopolysaccharide in the genetic absence of TNFR1 or if treated with an TNF-neutralizing antibody, indicating that host-derived TNF mediates pathogenesis.[107,108,109] On the other hand, TNFR1 is essential for resistance to infection with a live organism, such as *Listeria monocytogenes*, through multiple processes including enhancement of phagocytosis and bacteriocidal destruction by macrophages. By contrast, T-cell immunity is not overtly impaired in TNFR1-/- mice. Humans treated with TNF inhibitors show some increase in susceptibility to selective pathogens, particularly *Mycobacterium tuberculosis*, reinforcing the role of TNF as a critical host defense system.[110]

In contrast, LT-deficient mice showed significant variability in susceptibility to individual pathogens (Table 27.6). Increased susceptibility resulted from either developmentally controlled aspects of lymphoid organ structure (eg, lymphocytic choriomeningitis virus, *Leishmania*) or a requirement for LTαβ-LTβR pathway as an effector system in innate and adaptive immune systems (eg, murine cytomegalovirus). Viewed from an evolutionary perspective, this variation in the requirement for LT signaling may reflect specific contributions from the pathogen used to evade the broader TNF- and LT-dependent pathways.[35,111]

TUMOR NECROSIS FACTOR SUPERFAMILY AND T-CELL COSIGNALING

Antigen recognition together with cooperating signaling “cosignaling” systems determine the quality of the adaptive immune responses. Lymphocyte responses to antigen are dynamic processes that start with the activation of naïve cells and transition through effector and memory phases. Cosignaling systems assist these phases by promoting more efficient engagement of antigen-binding TCR molecules to enhance initial cell activation and cell division (clonal expansion), augment cell survival (clonal contraction or memory cell differentiation), or induce effector functions such as cytokine secretion or killer function.

Negative signals (inhibitory cosignaling) may also be delivered to T cells depending upon the particular system, which may prevent initial cellular activation or eliminate excess activated cells to dampen inflammation. Cosignaling can be quantitative, modifying thresholds of common signaling intermediates, or qualitative, involving signals distinct from other cosignaling systems or the TCR. Cosignaling receptors and ligands can be up- or downregulated at the transcriptional and protein levels depending on the stage of the T-cell response and the inflammatory milieu. In the absence of cosignaling, T cells may become unresponsive (anergic) or die.

The TNFRSR is one of two major families of cosignaling regulators that modulate T cells. The other cosignaling systems belong to the Ig superfamily, such as CD28,[112] cytotoxic T-lymphocyte (CTL)A-4,[113] ICOS,[114] PD1,[115] and BTLA.[116,117] TNFRSF members involved in T-cell cosignaling include OX40, 41BB, DR3, CD27, CD30, and HVEM,[118,119,120,121,122] whereas CD40 and BAFFR are more involved in cosignaling in B lymphocytes.[123,124] However, considerable crossover of activities in both lymphocyte populations can be demonstrated. Death

receptors such as Fas and TNFR1 are thought to be involved in clonal contraction through apoptosis of activated effector cells, although TNF via TNFR2 also shows costimulatory action in naïve T cells. In tissue culture models, several of the TNF-related signaling pathways show costimulatory activities for T cells, which probably reflects the common induction of NF-κB-dependent survival genes, a common trait of TNFRSF members. However, analyses of physiologic models using genetically deficient mice reveal distinct roles for these molecules in the life cycle of T cells. Cosignaling systems are emerging as important targets to enhance immune responses to tumors or attenuate autoimmune diseases.[114,125,126,127,128,129]

TABLE 27.6 Lymphotoxins in Host Defense: Mouse Models

Pathogen[a]	Mouse Model[b]	Susceptibility	Mechanism	Reference
Herpesvirus

Expression and Function of Tumor Necrosis Factor Receptor Superfamily Cosignaling Molecules During Primary T-Cell Responses

The TNFRs encoded on Chr 1p36 share a common function as cosignaling systems for T cells.[120,122] This region (human 1p36.33-1p36.21; syntenic with mouse 4E2-D3) contains the genes encoding GITR, OX40, HVEM, DR3, 41BB, CD30, and TNFR2, and is paralogous to the region on Chr 12p13 where genes for TNFR1, LTβR, and CD27 reside. The TNF-related ligands for these receptors are linked in the MHC paralogs on Chr 1, 6, 9, and 19, reflecting a common functional link as costimulatory molecules modulating T-cell differentiation (see Fig. 27.2).

Expression of TNFRSF members by T cells follows several distinct patterns during T-cell activation: expression on naïve T cells in peripheral lymphoid tissues (eg, CD27 and HVEM) that are upregulated or downregulated, respectively, following activation. OX40, 4-1BB, TNFR2, and CD30 are only expressed by T cells after initial activation[120]; TNFR2 is rapidly downmodulated following cleavage by TACE-generating soluble receptors that modulate TNF availability. The differing time course of expression of these molecules determines the phase of when they act in T-cell differentiation.

Experimental activation of TNFRSF members can be achieved with agonist monoclonal antibodies. Antibodies specific to OX40, 4-1BB, CD30, or CD27 all augment T-cell clonal expansion and TCR-induced cytokine expression in tissue culture and mouse models. For example, CD27, which is expressed at very early stages of T-cell activation, mediates initial cytokine production, cell division, and/or survival,[130,131] whereas OX40 and 4-1BB, which are expressed after cellular activation, promote T-cell survival and proliferation during the later stages of the primary response.[132,133,134] CD30-CD30L interactions promote primary CD8+ T-cell expansion and with OX40 act to promote CD4+ T-cell memory,[135,136] suggesting functional parallels with other TNFRSF molecules. Cowpox virus encodes a specific CD30 mimic to block the action of CD30L as part of its immune evasion strategy (see

Table 27.6).

Death receptor-3 (DR3) engages TL1A, promoting IFNγ expression by proinflammatory TH1 cells in mouse[137] and humans,[138] especially in intestinal tissues.[139] Polymorphisms in TL1A are associated with inflammatory bowel disease.[140,141] The LIGHT-HVEM-LTβR pathway is also associated with T-cell inflammatory processes in mucosal tissues.[104,142] Similar cosignaling activities are reported for GITR,[143] with the potential of these systems to affect different subsets of T cells, such as GITR expression on T-regulatory subsets. The role of TNFRSF in regulating different T-cell subsets is an active area of research.

HVEM appears to play a role as an inhibitor of naïve T-cell activation through engagement of the Ig superfamily members BTLA and CD160.[144,145] In this situation, HVEM acts as a ligand for BTLA, which limits signaling by antigen receptor-associated tyrosine kinases through a phosphatase recruitment domain (immunoreceptor tyrosine-based inhibitory motif) in its cytosolic tail.[146,147] Naïve T cells coexpress HVEM and BTLA, forming an intrinsic complex that limits HVEM activation by its ligands expressed in the surrounding microenvironment. The BTLA binding site on HVEM is distinct from the position occupied by LIGHT, yet membrane LIGHT can disrupt the HVEM-BTLA complex, suggesting that HVEM acts as a regulatory switch between inhibitory and stimulatory cosignaling. Interestingly, like LIGHT, BTLA and CD160 can activate HVEM in trans, promoting cell survival gene expression in cells expressing HVEM.[148] This pathway appears particularly effective in controlling CD4 T-cell activation,[144,149] but it is also important in regulating differentiating memory CD8 T cells.[150]

T-Cell Memory

Cosignaling through several TNFRSF members promotes the differentiation of memory T cells. Mice deficient in OX40-OX40L, CD27-CD70, CD30-CD30L, or HVEM pathways all display defective memory responses to antigen.[131,135,151,152,153,154] The OX40 system is illustrative of the costimulatory signals provided to T cells by these TNFR. Pharmacologic stimulation of OX40 with an agonist antibody or ligand during a primary antigen-specific response in mice enhances the generation of memory CD4 T cells.[155] The enhanced response of T cells includes increased accumulation of antigen-specific effector T cells producing effector cytokines such as IFNγ at the site of inflammation.[156] Moreover, blockade of OX40-OX40L interactions during recall responses with monoclonal antibody specific to Ox40L ameliorates inflammation in models of collagen-induced arthritis[157] and experimental allergic lung inflammation.[158] In OX40-deficient mice, CD8 T cells expand normally, but their accumulation and survival at later times in the primary response was significantly impaired. T cells from OX40-deficient mice also failed to fully differentiate as measured by loss of expression of effector cell surface markers and decreases in synthesis of cytokines and cytotoxic activity. By contrast, the formation of extrafollicular plasma cells, germinal centers, and antibody responses was independent of OX40. OX40 signaling induces transcription of survival genes such as BCL2 and survivin in T cells, which may serve as the key targets that allow memory cell differentiation.[159,160]

The discovery that HVEM can elicit inhibitory signaling in T cells through engagement with the Ig family member BTLA highlights the possibility that, in certain situations, TNFRSF molecules can counter regulate the stimulatory actions during T-cell responses. Indeed, 4-1BB-deficient CD4+ T cells in some models are hyperresponsive,[161] and stimulation of 4-1BB can suppress immune responses in several models of autoimmune disease.[162,163,164,165] Although activation of 4-1BB enhances the expansion of human antiviral memory CD8+ T cells in vitro,[166] several studies demonstrate that the absence of 41BB in mice leads to enhanced T-cell responses,[161,167] reminiscent of the phenotype associated with HVEM-deficient mice.[168,169] Moreover, CD30 signals can, in some circumstances, suppress cytotoxic T-lymphocyte activity.[170] The expression of TNFRSF molecules such as GITR or OX40 on T-regulatory cells suggests that costimulatory pathways may enhance the suppressive function of these cells during immune responses.

Mouse models of autoimmune diseases such as EAE and diabetes uncover critical roles for OX40-Ox40L.[171,172] Blockade of the CD27-CD70 pathway also ameliorates EAE through the suppression of TNF induction, but not T-cell priming.[173] Furthermore, blockade of OX40, 4-1BB, CD27, or CD30 costimulation can all reduce transplant rejection and/or graft-versus-host disease.[174,175,176,177]

Stimulation of these pathways may also be applicable for the treatment of diseases such as cancer and infectious diseases where antigen-specific T-cell responses are ineffective. Stimulation of OX40, 4-1BB, CD30, and CD27 with agonist antibodies augments T-cell-mediated killing of a variety of tumors. The critical roles of the cosignaling TNF-TNFRSF members are discerned in immune responses to infectious pathogens. Similar to the immediate TNF family, the role of a specific cosignaling pathway in mediating protective T-cell responses during infection depends on the pathogen (Table 27.7).

CD40L AND BAFF SYSTEMS

The CD40 and BAFF systems play a major role in coordinating a range of costimulatory signals important to B-cell function, such as affinity maturation, isotype switching, Ig production, and clonal expansion.[123,178,179,180,181] In common with other TNFSF members, the CD40 system (see Fig. 27.3) is a key communication mechanism in host defense, autoimmunity, and cancer. Often, these pathogenic processes are centered on the function of B cells. CD40 ligand maps to the X chromosome and is regulated at the transcriptional level by NFAT, resulting in inducible CD40 ligand expression by T helper cells that promotes humoral immunity. CD40 ligand is also expressed in a variety of other cells including activated B cells, endothelial cells, basophils, mast cells, and platelets. CD40 is expressed on many cells, prominently on B cells, and utilizes both TRAF3 and 6 to activate NF-κB and AP1 transcription factors, among other signaling pathways.[182,183] Epstein-Barr virus, a B-cell-transforming herpesvirus, mimics the CD40 pathway though its LMP1 protein, driving naïve B cells into a memory state.[184,185,186]

Adapted from Croft.120

CD40 signaling is necessary for induction of activationinduced cytidine deaminase, a key enzyme in class switching and somatic mutation of Ig genes. This process occurs in B cells in contact with T helper cells, which express CD40 ligand. The importance of CD40 system in the activity of B cells was revealed in patients with hyper-IgM syndrome. Several mutated genes underlie this syndrome including CD40 ligand and CD40,[187,188] the RelA NF-κB activating kinase subunit, IKKγ (NEMO), and activation-induced cytidine deaminase, among

others.[189] Patients with hyper-IgM syndrome with mutated CD40L have elevated levels of IgM, often with no serum IgG, IgE, or IgA, and display increased susceptibility to bacterial and opportunistic infections. Treatment of these patients with passive transfer of human immune IgG corrects infection by bacteria, but not opportunistic pathogens, such as *Pneumocystis carinii*. This latter result reflects the importance of CD40 system in T-cell-mediated macrophage activation, which controls these opportunistic pathogens. In some patients with hyper-IgM syndrome, significant amounts of IgA and IgE are present in serum, even in the complete absence of CD40L, a result indicating that another mechanism(s) can induce Ig class switching. Evidence has emerged that the BAFF/APRIL system can induce Ig class switch independent of CD40 system.[190]

Since the discovery of B-cell-activating factor of the TNFSF (BAFF, TNFSF13B; BLyS) and a proliferation-inducing ligand (APRIL, TNFSF13), much has been elucidated with regard to CD40L-independent isotype switching and B-cell development and survival in the periphery, as well as the implications of BAFF-APRIL dysregulation in autoimmune disease and lymphomas.[124,191] Although human *BAFF* maps to Chr 13q34 and APRIL to 17p13.1, the proteins are strikingly more conserved (˜50% homology) than other TNF ligands. TWEAK (TNF-related ligand with weak apoptosis activity) maps adjacent to APRIL, part of a clade of genetically similar members that also includes ectodermal dysplasin (EDA1/EDA2). BAFF and APRIL form homo- and heterotrimers that interact with multiple receptors to form a complex signaling circuit (see Fig. 27.3). Membrane BAFF is shed via a furin protease at the cell surface, while APRIL is processed in the Golgi and secreted only in soluble form,[192] although the receptor binding domain of APRIL can be membrane-anchored via an unusual splice variant with the TWEAK cytosolic and transmembrane domain (TWE-PRIL).[193] The significance of membrane-restricted local BAFF expression to systemic availability of soluble BAFF and APRIL remains to be established, although BAFF-APRIL heterotrimers are detected in serum from patients with systemic rheumatic diseases.[7] BAFF and APRIL are inducibly expressed in monocytes, macrophages, DCs, and T cells in the spleen and lymph nodes in response to certain cytokines in different cell types, such as type I and II IFN, IL-10, and other TNF family members like CD40 and LTβR signaling. BAFF can be expressed in some B-cell-derived chronic lymphocytic leukemia cells, and some epithelial-derived cancer cell lines and primary tumor tissues express APRIL. Stromal cell expression of BAFF maintains the major mature B-cell pool, whereas inducible BAFF expression in myeloid cells aids in local B-cell survival at sites of inflammation.

Three cognate receptors mediate the biological actions of BAFF. BAFFR (TNFRSF13C), transmembrane activator and calcium signal modulating cyclophilin ligand interactor (TACI; TNFRSF13B), and B-cell maturation antigen (BCMA; TNFRSF17) are expressed on B cells and on other cell types. APRIL also engages matrix proteoglycans with weak binding, which may serve to enhance access to TACI and BCMA or function as a distinct receptor-ligand interaction.[194] Signaling through BAFFR and BCMA are required for B-cell survival and differentiation at different stages of B-cell-mediated humoral response. BAFFR-/- mice display an almost complete loss of mature and marginal zone B cells beginning from the late transitional phase of B-cell maturation, whereas BCMA deficiency impairs the survival of long-lived bone marrow plasma cells.[195,196]

By contrast, APRIL-/- mice develop normally but have altered class switching to IgA.[197,198] TACI signaling may antagonize BAFFR and BCMA, as TACI-/- mice have elevated numbers of mature B cells.[199] Both classical and alternative NF-κB pathways have been implicated BAFFR and BCMA survival signals, with BCL2 expression rescuing the B-cell defect in BAFFR-/- mice. BAFFR and TACI engagement

has also been shown to provide the necessary signals for CD40L-independent class switch recombination, to IgG and IgE for BAFFR, and IgG, IgE, and IgA for TACI, though IgA production seems specifically dependent upon APRIL-TACI interaction.[200] BAFFR is also connected to promoting the B-cell coreceptor complex CD19/CD21/CD81, which binds to C3b-opsonized antigens to enhance rapid T-independent antibody responses. Overall impairment of T-independent antibody responses appears to be greatest in TACI-/- mice, and is dependent upon APRIL-TACI interactions in B1 B cells. BAFFR, and not TACI, has also been proven to be important in T cell costimulation in in vitro and in vivo mouse models of allograft rejection response, where BAFFR-/- and BAFF-/-, but not TACI-/- nor BCMA-/-, mouse recipients prolong graft survival due to weakened alloproliferative response.[201]

Elevated levels of BAFF and APRIL have been detected in the serum, and especially the synovial fluid, of patients suffering from inflammatory autoimmune disorders such as systemic lupus erythematosus, RA, Sjörgen syndrome, and multiple sclerosis.[202] These levels tend to correlate with increasing amounts of autoreactive antibodies in serum, and in mouse models of lupus and collagen-induced arthritis, soluble TACI-Ig treatment can lessen the severity of disease symptoms and progression.[203] It is hypothesized that these excess quantities of BAFF and APRIL may contribute to the formation of autoreactive B-lymphocytes and loss of tolerance during development and perpetuating their survival as plasmablasts. Emerging evidence connects the BAFF and APRIL system to the pathology of B-cell-derived cancers like B-cell chronic lymphocytic leukemia, non-Hodgkin lymphoma, and multiple myeloma. Malignant myeloma cells express high levels of BAFF and APRIL and receive ligand-induced survival signals, with upregulation of antiapoptotic Bcl-2 and Mcl-1 molecules.[204] Therefore, BAFF and APRIL may bolster tumor survival via autocrine and paracrine signaling mechanisms.

TWEAK-FN14 SYSTEM

The TWEAK-Fn14 system is emerging as an important signaling system between the immune system and epithelial and stromal tissues.[205] TWEAK is limited to a monogamous interaction with Fn14, its cognate receptor, which is a fibroblast growth factor-2-inducible gene (see Fig. 27.3). Fn14 has one CRD and binds TWEAK homotrimers in a manner similar to BAFF, APRIL, and their receptors.[206,207] TWEAK, like BAFF and APRIL, is cleaved by furin protease to produce an active soluble form.[206] Human and mouse TWEAK share > 90% sequence identity in the receptor binding domain and manifest high affinity cross-species interaction to respective Fn14 homologues.[192] The biologic functions of TWEAK-Fn14 system are broad and perhaps paradoxical, promoting both cell survival and death. TWEAK/Fn14 signaling induces apoptosis in some cancer lines (HT29, HSC3) and primary neurons.[208,209,210] TWEAK is produced primarily by leukocytes, whereas Fn14 expression

is induced during inflammatory and tissue destructive processes. TWEAK-Fn14 system may provide important homeostatic functions to promote regenerative processes that conclude inflammatory responses. These homeostasis-promoting functions include induction of survival and growth in endothelial cells, migration and wound closure in endothelial cells, and angiogenesis.[206,207] Fn14 contributes to the activation of progenitor cell types including liver, skeletal muscle, and mesenchymal lineage progenitors such as osteoblast, chondrocyte and adipocyte, and neuronal progenitors.

TWEAK regulates the shift from innate to adaptive immune responsiveness by repressing innate inflammatory cytokines (IL-12, IFNγ) important in promoting TH1 immunity—a potential counterbalance to the proinflammatory actions of TNF.[208] TWEAK may also have a potentiating influence in chronic tissue inflammation when dysregulated, such as its role in excessive demyelination and ultimate progression to excessive autoimmune encephalomyelitis.[211] In a mouse collagen-induced arthritis model, elevated levels of TWEAK in serum correspond to severe disease progression and enhanced arthritogenic mediator molecules.[212] In obese patients with type 2 diabetes, TWEAK-Fn14 signaling augments proinflammatory cytokine release by adipocytes.[213] In rats, TWEAK may prevent excessive luteinization after gonadotrophin-induced ovulation by controlling progesterone production.[214] The seemingly contradictory functions of TWEAK/Fn14 are less puzzling when TWEAK/Fn14 is viewed as an important signaling system that aids in achieving homeostasis following inflammation, as cell death and survival are essential for homeostasis.

DEATH RECEPTORS AND LIGANDS

Fas Ligand and Fas System

The Fas (CD95, TNFRSF6)-Fas ligand (TNFSF6) system is an example of a direct signaling pathway to apoptotic cell death. The importance of the Fas-FasL system in immune regulation was revealed by the recognition that mice with the autoimmune-like disorders, *lymphoproliferative* (lpr) and *generalized lymphproliferative disorder* (gld) harbored mutations in Fas and Fas ligand and humans with the autoimmune lymphoproliferative syndrome have mutations in Fas.[215,216,217] Mice with *lpr* or *gld* mutations display autoimmune phenotypes with high accumulation of activated T cells in the periphery and CD4-CD8- T cells in the lymph nodes (lymphoadenopathy) and autoantibody production. The Fas-FasL system is involved in proinflammatory responses, tumor survival, and nonimmune tissue homeostasis in osteoclastogenesis and angiogenesis.[218] Activated lymphocytes are particularly sensitive to Fas-induced apoptosis, suggesting a role for Fas in the clonal contraction phase of the immune response. The epithelial cells in the eye express FasL, which may limit inflammation in organs sensitive to immune damage. FasL is thought to be one of several proapoptotic systems used as a killing mechanism by cytotoxic T cells and NK cells. In primates, Fas ligand binds Fas and decoy receptor-3, which also binds LIGHT and TL1A.[219]

FasL can undergo cleavage by matrix metalloproteases to produce soluble FasL, which may induce markedly different events when it engages Fas compared to the membrane-bound form, such as loss in cytotoxicity.[220]

Other findings suggest that soluble FasL may counteract the proinflammatory properties of membrane-associated FasL as an immunosuppressive, particularly in the eye and tumor environments.[221,222] Conversely, Fas has also been linked to lymphoproliferation and lymphocyte activation via NF-κB-signaling pathways.

Essential biologic roles FasL-Fas include regulating lymphocyte homeostasis (via contraction of clonally expanded effector T and NK cells), directing CTL-mediated apoptosis and lysis (immune surveillance), and establishing immune privileged organs and sites. Fas is expressed in a wide variety of tissues such as the thymus, spleen, heart, and liver, whereas FasL can be found on activated T cells, NK cells, tumor cells, immune privileged sites, lung, and other tissues.[218,223,224] In mature activated T and NK cells, Fas-FasL signaling plays a critical role in inducing apoptosis during the latter stages of inflammation, or activation-induced cell death, and shifts lymphocyte population numbers back to baseline.[225] In certain organs like the liver, lung, and small intestine, FasL on stromal cells can be upregulated to control the overabundance of activated T cells after an inflammatory response and ultimately reduce tissue damage. Alternately, dysregulation during hepatitis C infections can lead to death of hepatocytes and acute liver damage.[226] The Fas system has also been implicated in curtailing autoantibody production by damping T cell helper-induced B-cell activation and direct elimination of activated B cells, where CD40 stimulation also upregulates Fas expression.[218]

The Fas-FasL system, together with perforin and granzymes, is a mechanism vital to CTL-mediated destruction and clearance of tumor and virally infected cells. Viruses have evolved multiple mechanisms of suppressing Fas signaling, 111 including downmodulation of Fas[227] or blockade of caspase 8 activation.[228] Tumor genome instability may lead to mutations that aid in escaping or resisting death pathways, conducive to developing the metastatic phenotype.[229] Uterine and breast cancer patients may have elevated levels of soluble FasL and Fas, which may aid in neutralizing CTL- and NK cell-induced lysis or even killing Fas-expressing effector cells. Herpes simplex virus-1 infection in vitro of human neonatal neutrophils upregulates Fas and FasL surface expression, leading to apoptosis, exemplifying a theme of pathogenic modulation of apoptotic signaling events to evade or attenuate immune response.[230] FasL is constitutively expressed in the eye, central nervous system, testis, fetal trophoblast, and placenta, where any lymphocyte infiltration could lead to unrestricted, irreversible bystander damage to these tissues.[231] The implications of immune privilege have been applied to tissue transplantation rejection therapies; however, conflicting results as to whether FasL expression reduces likelihood of allograft rejection[232,233] or potentates effector responses[234,235] emphasize that induction of immune privilege by the Fas L system is complex. Fas-FasL interactions are at the core of graft-versus-host disease, where contaminating donor effector T cells in an allograft expand to damage the recipient's tissues. In a mouse model for acute graft-versus-host disease, p53-dependent upregulation of Fas on host stem cells leads to subsequent bone marrow depletion through FasL-mediated apoptosis.[236] With regard to tissue homeostasis, FasL has been reported to enhance RANKL-mediated osteoclastogenesis and differentiation in mouse bone marrow-

derived macrophages.[237] Fas is also implicated in pulmonary inflammatory diseases resulting in fibrosis after acute lung injury.[223]

TRAIL RECEPTOR SYSTEM

TRAIL (TNFSF10) is closely related to FasL and TNF based on sequence homology. Interest in TRAIL was spurred by its ability to selectively induce apoptosis in tumor cells.[238] TRAIL binds five different receptors: TRAILR1 (DR4, TNFRSF10A), TRAILR2 (DR5, TNFRSF10B), TRAILR3 (DcR1, TNFRSF10C), TRAILR4 (DcR2, TNFRSF10D), and osteoprotegerin (OPG, OCIF, TNFRSF11B) (see Fig. 27.3). TRAILR1, 2, and 4 are type I transmembrane proteins and are membrane associated, whereas the more distantly related OPG is a dimeric, soluble decoy receptor. TRAILR3 is a type III transmembrane protein.[239] TRAILR1 and 2 contain highly homologous DD in their cytoplasmic tails that form the death-inducing signaling complex[240,241] responsible for apoptosis. TRAILR3 is anchored to the membrane via a glycophosphatidyl inositol tail, whereas TRAILR4 has a truncated, nonfunctional DD.[219,242,243] The lack of a functional DD indicates TRAILR3 and 4 antagonize TRAIL-induced apoptosis. Alternative splicing is a common feature amongst TRAIL and its receptors, and is believed to regulate programmed cell death.[244,245,246] The genetic organization of the TRAIL receptor loci in the mouse differs from that of the human. The mouse genome has TRAILR2, 3, and 4 homologues, but the TRAILR4 homologue does not bind TRAIL.

TRAIL-TRAILR signaling system induces apoptosis and to a lesser degree NF-κB activation. For example, the apoptotic function of TRAIL system is necessary for regulating the response of memory CD8+ T cells to rechallenge with antigen. In the absence of CD4 T-cell help, CD8 T cells undergo apoptosis mediated by TRAIL.[247,248] In much the same way as Fas, TRAILR death domains are thought to recruit FADD and initiator caspases 8 and/or 10 into the DISC to activate downstream effector caspases in apoptosis. Caspase 8 contribution to this process is well defined, but caspase 10 involvement was less so until recent studies in patients with autoimmune lymphoproliferative syndrome II and some carcinoma cell lines found that mutant caspase 10 ablates TRAIL-induced apoptosis.[242] In some cell types, the extrinsic mitochondrial pathway is important in amplifying DISC signals in TRAIL-induced apoptosis, which is analogous to mechanisms for Fas-FasL signaling.[249] TRAIL is being intensely pursued as an anticancer therapeutic and has proved particularly potent in combination with chemotherapy, because TRAILR2 expression can be increased in response to deoxyribonucleic acid damage.[250]

TRAIL seems most involved in regulating immune homeostasis and immune surveillance, or clearing virally infected and cancerous cells. IFNγ treatment of tumor cells increases sensitization to TRAIL-induced death. This has been observed in melanoma and ovarian carcinoma cells,[242] and is analogous to Fas-FasL apoptotic signaling in the human colorectal carcinoma line, HT-29. IFNα possesses

powerful antiviral and antitumor properties as well, and have been shown to upregulate TRAIL via JAK-STAT pathways in stimulated human multiple myeloma in vitro. TRAIL is also upregulated on NK cells in response to IFNγ, enhancing antitumor effector function.[251]

TL1A-DR3 SYSTEM

The TL1A-DR3 system provides essential signals that promote the expansion of effector T cells at the sites of inflammation. 139 However, the broad tissue expression profile of DR3 indicates its involvement is a range of cellular responses beyond T cells. TL1A (TNFSF15) is a paralog of FasL, LIGHT, and LTβ, and its receptor, DR3, is a homolog of TNFR1. TL1A also binds decoy receptor-3, potentially limiting any TL1A signaling mediated by DR3. Gene deletion experiments of TL1A or DR3 in mice revealed poor T-cell responses, but no overt developmental abnormalities.[137,252,253,254] Specific mutations in the ligand-binding domain of DR3 are linked to RA and interestingly appear to parallel other TNFRSF members and associated autoimmune pathologies.[255]

RANK LIGAND, RANK, AND OSTEOPROTEGERIN SYSTEM

OPG (TNFRSF11B) was initially identified as key mechanism regulating bone density[256] (see Fig. 27.3). As a soluble receptor, OPG is a regulator of the RANK (receptor activator of NF-κB, TNFRSF11A) and RANK ligand (also known as TRANCE) signaling pathway involved in the differentiation of bone-resorptive osteoclasts from hematopoietic progenitors (osteoclastogenesis).[257,258,259] However, this system is also crucial for development of mammary glands,[260] lymph nodes, and DC-T-cell interactions.[261,262] Bone remodeling needed to sustain skeletal integrity and calcium homeostasis is regulated by a dynamic equilibrium between osteoblasts (bone forming) and osteoclasts (bone resorbing), which is regulated by RANKL-RANK-OPG system. Dysregulation of the RANKL-RANK-OPG system has consequences in inflammatory, osteologic, and cancer pathophysiology, such as bone loss in inflammatory autoimmune diseases, preferential breast and prostate tumor metastasis to the bone, and gender bias in osteoporosis.

OPG functions as a decoy receptor that binds RANKL with high affinity, and also binds TRAIL, albeit at low affinity in comparison to RANKL.[263,264] Despite such a weak binding, in vitro studies show that OPG can block TRAIL-mediated apoptosis, which suggests the OPG-TRAIL system contributes to osteoclastogenesis. RANK interacts with TRAF2, 5, and 6. The membrane-proximal TRAF site is highly specific for TRAF6, and several studies have shown TRAF6 to be essential in RANKL-RANK signaling in osteoclastogenesis and lymph node genesis.[265,266] Several “osteotropic” factors have been reported to regulate RANKL and OPG expression in osteoblast and osteoclast lineages, such as transforming growth factor β, IL-1, TNF, estrogen, prostaglandin E2, glucocorticoids, and vitamin D3.[265,267] In a few cases, OPG and RANKL are differentially modulated by the same factor; for example, parathyroid-related protein increases RANKL while decreasing OPG mRNA expression in osteoclast-like odontoclasts.[268] The components in the RANK signaling triad are widely expressed. RANK is upregulated on CD40L-stimulated maturing DCs, while RANKL is upregulated during T-cell activation and is constitutively expressed in some tumors and mammary gland epithelial cells.

RANK-/- and TRAF6-/- mice lack NF-κB activation in osteoclasts and exhibit abnormally high bone density (osteopetrosis).[269,270] Osteoblasts and stromal cells stimulate differentiation via direct cell contact with osteoclast precursors. Macrophage colony stimulating factor cooperates with RANKL-expressing osteoblasts to transmit positive signals through c-Fms

and RANK expressed on precursors promoting their differentiation,[259] whereas OPG negatively regulates by competitively binding RANKL, thus ablating all signals through RANK. RANK-/- and RANKL-/- mice phenocopy each other, displaying severe osteopetrosis due to the lack of osteoclasts.[271] Complementing the observations in RANKL and RANK deficiencies, OPG blocks osteoclast differentiation in a dose-dependent manner. OPG overexpression in transgenic mice causes acute osteopetrosis, while OPG-deficient mice suffer from osteoporosis due to excessive osteoclastogenesis. In humans, OPG and RANK mutations are linked to juvenile Paget disease, familial expansile osteolysis, and other osteolytic disorders.[258,265]

The RANKL-RANK system is proving to be an important enhancer of cell-mediated immune responses by promoting DC survival and naïve T-cell proliferation. RANKL stimulates DCs to produce proinflammatory cytokines like IL-12.[272,273] The RANK pathway may serve to bolster CD40-CD40L interaction between DC and T cells after T-cell receptor stimulation, or prolong survival of activated DCs to ensure the establishment of T-cell memory. For instance, in CD40L-/- mice, RANKL-RANK costimulation is protective against *Leishmania* infection by inducing IL-12 secretion and consequent T_H1 immune response.[274]

Bone loss in autoimmune and infectious models of inflammatory disease is mediated through slightly different mechanisms. In recent studies, activated, CD4+RANKL+ T cells have been shown to support osteoclastogenesis and mediate bone loss in humanized mouse models of *Actinobacillus*-specific periodontal disease, suggesting a role for T_H1 immunity in inflammatory bone destruction.[275,276] In patients with human immunodeficiency virus, the viron envelop gp120 induces disease-related osteoporosis via induction of RANKL on CD4+ T cells and augmentation of osteoclastogenesis.[277]

In mouse models of tumor metastasis, high OPG and RANK levels are risk factors for metastasis to the bone and subsequent osteolysis, especially in breast tumors.[278] OPG from human bone marrow stroma can protect prostate tumors from TRAIL-mediated apoptosis,[279] and treatment with anti-TRAIL neutralizing antibodies reduces osteoclastogenesis in mixed lymphocyte-bone marrow cultures from patients with multiple myeloma, presumably by interfering with OPG-TRAIL complexes formed by activated T cells expressing TRAIL, OPG, and RANKL.[280] The

RANKL-RANK-OPG system has also been implicated in diabetes-associated osteopenia, as serum levels of OPG are higher in patients with type I and II diabetes.[281] Interestingly, these patients are at greater risk for developing atherosclerotic plaques, which is perhaps reflected in the phenotype of OPG-deficient mice. These mice suffer from arterial calcification,[282] presumably from unrestricted bone resorption and calcium release. Although elevated endogenous OPG levels are considered a risk factor in certain disease manifestations, the complexity of the cytokine networks that regulate RANKL-RANK-OPG interactions and vice versa render the clinical data difficult to interpret.

TABLE 27.8 Human Genetic Diseases Associated with the Tumor Necrosis Factor

Superfamily

SYSTEM	Disease	Mutation
TNFR1	Familial periodic fever	Mutation in first cysteine-rich domain
CD40 Ligand	Hyper-IgM syndrome	Multiple mutations affecting receptor binding and processing
EDA	X-linked hypohidrotic ectodermal dysplasia	Multiple mutations affecting receptor binding, trimerization, and secretion
RANK	Familial expansile osteolysis	Mutation in the signal peptide
Fas	Autoimmune lymphoproliferative syndrome	Multiple mutations/deletion in Fas

CD, cluster of differentiation; EDA, ectodermal dysplasin A; Ig, immunoglobulin; TNFR, tumor necrosis factor receptor.

TABLE 27.9 Tumor Necrosis Factor Superfamily Therapeutics

TNFRSF Member	Drug	Therapeutic Designation	Indication	Status
TNF	Chimeric Ab	Remicade (infliximab)	RA, Ps, IBD	Approved
TNF LTα	TNFR-Fc	Enbrel (etanercept)	RA, Ps	Approved
TNF	Hu Fab-PEG	Cimzia (certolizumab)	RA, Ps, IBD	Approved
TNF	Hu mAb	Humira (adalimumab)	RA, Ps, IBD	Approved
TNF	Hu mAb	Simponi (golimumab)	RA, Ps, IBD	Approved

BAFF	Hu mAb	Benlysta (belimumab)	Lupus	Approved
CD40 L	chimeric mAb	ruplizumab	Lupus	Stopped
″	Hu Fab-PEG	CDP7657	Lupus	In trials
RANK L	Hu mAb	Prolia (denosumab)	Osteoporosis	Approved
″	Hu mAb	Xgeva (denosumab)	Bone metastasis	Approved
TRAIL	Recom cytokine		Cancer	In trials
TRAILR1	Hu mAb	mapatumumab	Cancer	In trials
TRAILR2	Hu mAb	conatumumab	Cancer	In trials
LTβR	LTβR-Fc	baminercept	Autoimmune diseases	In trials
LTα	Hu mAb	MLTA3698A	Autoimmune disease	In trials
OX40	chimeric mAb	9B12	Cancer	In trials
TWEAK	chimeric mAb	BIIB 023	Lupus nephritis	In trials

Fab-PEG, fragment of antibody polyethyleneglycoylated; IBD, inflammatory bowel diseases; LT, lymphotoxin; Ps, psoriasis; RA, rheumatoid arthritis; TNF, tumor necrosis factor; TNFR, tumor necrosis factor receptor; TNFRSF, tumor necrosis factor receptor superfamily.

TUMOR NECROSIS FACTOR SUPERFAMILY IN THE THERAPY OF HUMAN DISEASE

Tumor Necrosis Factor Inhibitors

The TNFSF is associated with a wide range of human diseases, evidenced by genetic deficiencies or mutations in individual components of the TNFSF and in the therapeutic efficacy of TNF inhibitors in autoimmune diseases (Table 27.8). Although cancer therapy was the original motivation in developing TNF, the success of TNF inhibitors in limiting symptoms in several autoimmune diseases provides significant motivation to explore therapeutics targeting other members of the TNFSF, currently an active area of research. Research into the function of TNFSF in human diseases is providing strong rationale for testing both inhibitors and agonists of these cytokines (Table 27.9).

TNF inhibitors are specific antibodies or soluble receptors and are classified as biologics (protein-based drugs). These biologic-based drugs provide specificity and desirable pharmacodynamic properties (Fig. 27.8). Both antibody- and receptor-based drugs function as competitive antagonists, sterically hindering the binding of ligand to receptor. The approved antibody-based drugs include a partially humanized mouse monoclonal antibody to human TNF (infliximab), two fully human antibodies (adalimumab and golimumab), and a monovalent Fab fragment of a TNF antibody (certolizumab pegol). Certolizumab is derivatized with polyethylene glycol to enhance half-life. To create a soluble “decoy” receptor, the extracellular domain of TNFR-2 was genetically linked to the Fc region of human IgG1, forming a bivalent molecule (etanercept) that has higher avidity for TNF than naturally occurring soluble receptors. Etanercept binds both TNF and LTα, whereas anti-TNF antibodies are specific for TNF and do not cross-react with LTα.

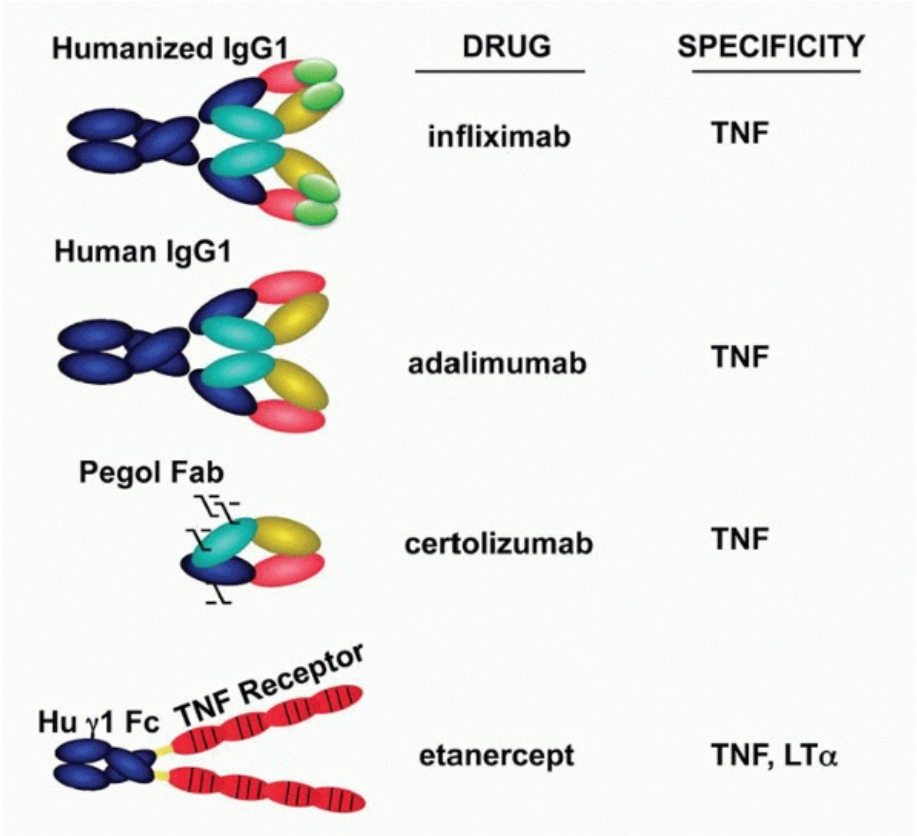

FIG. 27.8. Tumor Necrosis Factor (TNF) Inhibitors. The diagram depicts the structural features of the antibody- and receptor-based drugs targeted at TNF that are approved

for use in patients with autoimmune diseases. Monoclonal antibody specific for human TNF derived from mice and partially humanized (infliximab), a fully human antibody (adalimumab) containing both heavy and light immunoglobulin chains, and an antibody-binding fragment (Fab) of a human anti-TNF antibody (certolizumab). Certolizumab is monovalent and derivatized with polyethyleneglycol to extend half-life in vivo. TNF decoy receptor (etanercept) created as a genetic fusion protein of the ectodomain of TNF receptor 2 with the Fc region of human immunoglobulin G1 forms a disulfide-linked dimer. Both immunoglobulin and receptor-based inhibitors are approved for use in treating autoimmune diseases: rheumatoid arthritis, psoriasis, and inflammatory bowel diseases.

Bivalent antibodies directed to TNFRs can function as agonists, mimicking the ligand but specific for a single receptor, a feature that may distinguish an antibody from ligand such as TRAIL, which has multiple receptors. Moreover, antibodies are inherently more stable than the native ligand, providing better pharmacodynamics (serum half-life and bioavailability). Agonist receptor antibodies (eg, anti-TRAILR, anti-Ox40) are in preclinical studies and clinical trials.

Impact of Tumor Necrosis Factor Blockade in Inflammatory Diseases

TNF inhibitors are approved for use in the treatment of RA, psoriatic arthritis, ankylosing spondylitis, juvenile rheumatoid arthritis, Crohn disease, and ulcerative colitis. RA is a chronic autoimmune joint disease that occurs in genetically predisposed individuals. Treatment of RA is usually initiated with disease-modifying antirheumatic drugs such as methotrexate or corticosteroids to improve symptoms and reduce joint damage. The American College of Rheumatology uses clinical and laboratory measures to assess improvement in response to therapy in RA. A patient with a 70% or greater improvement according to these parameters is designated as having an ACR-70 response. TNF inhibitors in combination with methotrexate (the most widely used disease-modifying antirheumatic drugs) produce ACR-70 responses in 33% to 40% of patients with early RA and in 10% to 27% in established RA. In comparison to patients receiving methotrexate alone, the ACR-70 responses occurred in 19% to 21% of early RA patients and fewer than 5% of patients with established disease.[283] In RA, joint damage begins early in the disease course as articular erosions when visualized by radiographic techniques in 40% of patients in the first year of disease and 90% by the second year.[284] TNF inhibitors slow radiographic progression in RA.[285] Interestingly, in a randomized controlled trial of 428 patients with active RA, the combination of infliximab and methotrexate reduced the radiographic progression.[286]

The inflammatory bowel diseases, ulcerative colitis (limited to colon and bowel), and Crohn disease (entire intestine) are chronic inflammatory conditions where TNF is disproportionately expressed when the disease is active. Monocytes from patients with inflammatory bowel disease produce significantly higher levels of TNF after stimulation by lipopolysaccharide.[287] The formation of fistulating inflammatory granulomas is a pathologic feature of Crohn disease. Clinical trials demonstrated an initial response in 59% to 69% of patients, and a dose-dependent clinical remission that ranged between 28% to 38% in nonfistulating Crohn disease and 64% to 97% of patients with complete fistula disease, when categorized by

location.[288,289] In ulcerative colitis, controlled trials (800 patients with active ulcerative colitis) showed an initial response in 8 weeks with 65% response in patients treated with anti-TNF (infliximab) versus 35% in the placebo group, with remission achieved in 35% and 15% in patients treated with infliximab and placebo, respectively.[290] Anti-TNF (adalimumab) was efficacious in controlled trials in patients with moderate to severe Crohn disease.[288] By contrast, soluble TNFR2-Fc (etanercept) at doses known to be effective in RA failed to produce benefit in a controlled trial for Crohn disease.[291]

Erythrosquamous lesions containing infiltrating leukocytes and epidermal hypertrophy characterize psoriasis, a chronic inflammatory skin disease. Skin lesions of psoriatic patients contain elevated levels of TNF, and following treatment with TNF inhibitors, serum and skin levels of TNF decrease with remarkable clinical response.[292,293] A significant subset of patients with psoriasis develops inflammatory, erosive arthritis.[294] In clinical trials, both etanercept and infliximab significantly inhibited disease activity and improved the quality of life in patients with psoriatic arthritis.[295,296,297,298,299]

Serious Adverse Effects

TNF inhibitors are inherently safe because of their specificity. However, side effects occur with the use of TNF inhibitors and include lupus-like syndrome, aplastic anemia, hepatotoxicity, interstitial lung disease, optic neuritis, and exacerbations of quiescent multiple sclerosis. TNF inhibition is associated with diminished host defense, perhaps expected based on the role of TNF in innate and adaptive immune responses. The rate of serious skin and soft-tissue infections is higher in treated patients, and there is an increase risk of intracellular bacterial infections, primary tuberculosis and reactivation of latent

Mycobacterium tuberculosis among patients treated with TNF inhibitors.[300,301] Risk due to infection can be minimized and controlled (eg, a tuberculosis skin test prior to treatment in patients that have not been previously vaccinated for *Mycobacterium*). The contribution of anti-TNF therapy to the increase the risk of cancer is still unclear. A systematic review of randomized clinical trials using infliximab and adalimumab found a dose-related increase of malignancies in patients with RA patients.[302] Some of the increase risk of malignancy (ie, lymphoma) is difficult to dissect due to the increased association of lymphoma with RA.[301] TNF has been implicated in the pathogenesis of cardiac dysfunction, in part due to the negative ionotropic activities in vitro and in vivo; however, TNF blockade significantly increased the incidence of cardiac death. This observation led to the recommendation that TNF inhibitors be discontinued in patients with cardiac dysfunction.[303,304,305] Limiting adverse effects have been observed with biologics targeting other TNFSF members. Although interference with CD40L ameliorated autoimmune disease and allograft rejection in animal models,[306,307,308,309,310] anti-CD40L had an unacceptable impact on platelet function in transplantation and autoimmune diseases. The use of monovalent Fab of anti-CD40L may avoid these problems.[311,312,313] Another TNFRSF member, OPG, was dropped out of clinical investigation because the recombinant protein induced antibody responses that limited its therapeutic effects. Thus, dose- or mechanism-limiting toxicities can impact physiology in unanticipated ways, limiting successful clinical outcomes.

Anti-RANK Ligand

The central function of RANK-RANKL system in osteoclastogenesis has led to the development of anti-RANKL antibodies to treat bone-resorbing conditions. Human anti-RANKL monoclonal antibody (denosumab) to disrupt RANKL-RANK signaling has been approved for the treatment of osteoporosis in postmenopausal women and for treatment of skeletal changes from metastasis of solid tumors. Anti-RANKL therapy reduces osteoclastic bone resorption, thereby increasing bone mineral density at both the lumbar spine and the hip. Treatment with anti-RANKL for 36 months decreased the risk of vertebral, nonvertebral, and hip fractures.[314] There is no apparent increased risk of cancer or serious infection associated with anti-RANKL therapy in subjects with osteoporosis, although longer study periods are needed.

Treatment of patients with prostate cancer with androgen deprivation therapy and patients with breast cancer with aromatase inhibitors leads to increased bone loss and increased risk of fracture. Anti-RANKL is prescribed to increase bone mass both of these patient populations.[315,316] In a double-blind phase III clinical trial, women with nonmetastatic breast cancer who received anti-RANKL therapy had an increased lumbar spine bone mineral density of 7.6% after 24 months of treatment compared to placebo.[316] Similarly, patients with prostate cancer on androgen deprivation therapy that were treated with anti-RANKL in a phase III clinical trial had increased bone mineral density at all measured sites (hip, femoral neck, radius, and whole body) compared to placebo.[315] Anti-RANKL reduced the overall risk of bone fracture in the prostate cancer trial, while the phase III trial of patients with breast cancer treated with aromatase inhibitors was not designed to evaluate risk of fracture.[315,316]

In addition to patients with prostate and patients with breast cancer undergoing hormone deprivation therapy, anti-RANKL aids in prevention of skeletal-related events in patients with bone metastasis from solid tumors.[317,318,319] Three independent phase III clinical trials compared anti-RANKL with zoledronic acid, a drug prescribed to alleviate bone pain and reduce fracture risk in cancer patients with bone metastasis.[317,318,319] Anti-RANKL therapy delayed the time to the first skeletal changes in patients with metastatic breast cancer and metastatic, castration-resistant prostate cancer.[317,319] In a third phase III trial of patients with solid tumors (excluding breast and prostate) or multiple myeloma, anti-RANKL was equivalent to zoledronic acid in reducing fracture risk.[318]

Anti-BAFF

Systemic lupus erythematous is characterized by hyperreactive B cells, production of antideoxyribonucleic acid antibodies, and overproduction of BAFF.[320,321] The anti-BAFF antibody (belimumab) was approved in 2011 for the treatment of systemic lupus erythematosus, becoming the first new drug to gain approval for the condition in 56 years. In a phase III clinical trial, anti-BAFF decreased the rate of disease flares and increased the time between disease flares compared with placebo.[322] Anti-BAFF treatment increased systemic lupus erythematosus responder index (a reduction of SELENA-SLEDAI score of four or more points) compared to placebo.[322]

Tumor Necrosis Factor Superfamily in Cancer Therapy

Tumor angiogenesis, the formation of vessels to support cancer growth, is a process essential for tumor growth. The ability of TNF to induce apoptosis of tumor-associated endothelial cells can result in the impairment of the tumor vasculature leading to necrosis of the tumor. This mechanism involves perturbation of cell-cell adhesive junctions and inhibition of αvβ3-integrin signaling in tumor-associated vessels.[323] However, clinical phase I and II studies in cancer patients receiving recombinant TNF reported "septic shock-like syndrome," a dose-limiting toxicity in quantities 10 times lower than the calculated antitumor dose extrapolated from animal studies.[324,325] Animal studies also revealed the strong hemodynamic effects of TNF in the mediation of septic shock.[326] Although there are anecdotic reports of tumor regression following TNF administration,[327] due to the induction of vasoplegia, TNF use as an antitumor agent has been limited to treatment of locally advanced tumors by isolated limb perfusion, which limits systemic toxicity of TNF.[328]

A number of studies are in progress to determine whether TRAIL and its death receptors can be used in treatment of

cancer.[329] In phase 1/2 studies, TRAIL and agonist mAb to TRAILR1 or R2 showed no dose-limiting toxicities.[330,331,332,333]

Early clinical trials are in progress for other members of the TNFSF. For example, antibodies to LTα and LTβR-Fc decoy are in clinical trials for suppressing inflammation in autoimmune diseases. Agonist antibodies to OX40 appear promising for induction of tumor immunity.[334] Redirecting T cells using a retroviral-based vector incorporating 41BB can eliminate leukemic cells.[335] It is not surprising that several other TNFSF systems are being targeted to modify inflammatory, infectious, and malignant diseases.

Chapter 28

Chemokines

Philip M. Murphy

INTRODUCTION

Chemokines constitute a large specialized family of cytokines that regulate immune responses by activating specific G protein-coupled receptors (GPCRs) on leukocytes.[1,2,3,4,5,6,7,8,9,10,11,12,13,14] Chemokines may act at multiple levels, including immune system development,[15] leukocyte transendothelial migration,[15,16,17,18] leukocyte positioning within microenvironments,[19,20,21,22,23] and both phagocyte and lymphocyte activation.[24,25,26] They may function beneficially, for example in the setting of antimicrobial host defense and tissue repair, or harmfully, for example in the setting of cancer, chronic inflammation, autoimmunity, and infectious disease (Fig. 28.1). Many pathogens produce broad-spectrum chemokine blocking agents, attesting to the importance of chemokines in host defense,[27,28,29] and some pathogens, most notably human immunodeficiency virus (HIV) and *Plasmodium vivax*, exploit host chemokine receptors as essential cell entry factors.[30,31,32] Chemokines may also have nonimmunologic functions, including regulation of organ development.[33,34,35] Together, these attributes have suggested potential chemokine-based therapeutic opportunities, and there are now two drugs targeting chemokine receptors approved by the U.S. Food and Drug Administration (FDA), the CCR5 antagonist maraviroc (Pfizer) in HIV,[36,37] and the CXCR4 antagonist plerixafor (Sanofi-Aventis) in hematopoietic stem cell mobilization for transplantation in cancer.[38]

To date,[48] chemokines and 23 chemokine receptors have been discovered in man. The goal of this chapter is to delineate their molecular properties and provide an overview of current knowledge of how they coordinate innate and adaptive immune responses, focusing on mouse and human. In this regard, it is important to note that the chemokine system may differ substantially among species, even at the genomic level.[39,40,41] In addition, despite adopting a standard nomenclature in the year 2000,[42,43,44] competing nonstandard aliases continue to be used in the primary literature, confusing even experts in the field. To address these challenges to clear communication, three illustrations are provided. The first defines the chemokine system repertoire at the genomic level in mouse and human, allowing comprehensive and facile identification of orthologues and species-specific elements (Fig. 28.2); the second is a dendrogram depicting the evolutionary relationship of chemokine and chemokine receptor protein sequences in mouse and man (Fig. 28.3); and the third provides the standard nomenclatures approved by the International Union of Immunological Societies for chemokine proteins and by the International Union of Pharmacology for chemokine receptors, linked to nonstandard aliases and protein sequence accession numbers (Tables 28.1 and 28.2). The names assigned by the HUGO Gene Nomenclature Committee are used for the corresponding chemokine system genes (see Fig. 28.2). In most cases, but not all, the approved gene and protein names are the same.

MOLECULAR ORGANIZATION OF THE CHEMOKINE SYSTEM

Chemokine Structure and Classification

The word "chemokine" is a contraction of " *chemo*tactic cyto*kine*," which conveys the main function possessed by members of the family. Nevertheless, chemokines are defined by structure, not function, and may have other functions besides inducing cell movement. At the level of primary structure, chemokines occupy a common sector of sequence space bounded by ~20% identity for any pairwise comparison, and after processing most are 66 to 111 amino acids in length. At the level of tertiary structure, chemokines fold in a highly conserved manner constrained in part by conservatively spaced disulfide-bonded cysteines.[45] The family is subclassified based on the number and location of these cysteines. All chemokines have at least two cysteines, and all but two have at least four cysteines (Fig. 28.4A). In the four cysteine group, the first two are either adjacent (CC motif) or separated by either one (CXC motif) or three (CX3C motif) amino acids. C chemokines have only two cysteines, corresponding to the location of Cys-2 and Cys-4 in the other groups. Most chemokines are members of either the CC or CXC group; there is only one CX3C chemokine and one (mouse) or two (human) C chemokines. The group motifs are used as roots followed by the letter "L" (for "ligand") and a number to create standard chemokine names (see Tables 28.1 and 28.2, and Fig. 28.2).[44] In human names, all letters are capitalized; in the corresponding mouse name, only the first letter is capitalized. Amino acid sequence identity is < 30% between members of the four major chemokine groups, but ranges from ~30% to 99% among members of the same group, indicating separate evolutionary histories. Although chemokine genes are located on 10 different human chromosomes, most are found in two large clusters, one for CXC chemokine genes on chromosome 4q21 and one for CC chemokine genes on chromosome 17q12 (see Fig. 28.2). These two clusters contain most of the chemokines that mediate inflammatory immune responses, whereas other chemokines, scattered throughout the genome either alone or in

small clusters on chromosomes 1, 2, 5, 7, 9, 10, 16, 17, and 19, mainly subserve homeostatic immune functions. The strongest functional correlate of the four major chemokine groups is receptor specificity: that is, most chemokine receptors bind more than one chemokine but are restricted by group (Table 28.3). With regard to leukocyte specificity, most neutrophil-targeted chemokines are in the CXC group and most of the monocyte-/macrophage-targeted chemokines are in the CC group. Major T and B cell-targeted chemokines can be found in both groups. The leukocyte target specificity of a chemokine may be narrow or broad and is defined by the expression pattern of its cognate receptor(s) (Table 28.4).

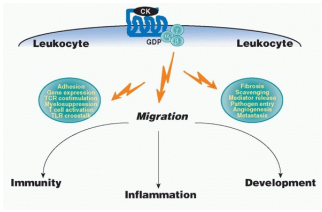

FIG. 28.1. Chemokines Coordinate Immune System Development and Immune Responses in Large Part by Inducing Leukocyte Migration Through Activation of G Protein-Coupled Receptors. Other functions induced by chemokines are listed in the *green spaces*. CK, chemokine.

CC and CXC chemokines can be further subclassified. The ELR subgroup of CXC chemokines is defined by the amino acid motif glu-leu-arg *N*-terminal to Cys-1 and is encoded by a cluster of genes on human chromosome 4q21 (see Fig. 28.2). A major species difference is the presence of the major neutrophil-targeted chemokine CXCL8 in human, but not in mouse. ELR is required for function of these chemokines, which are all > 40% identical at the amino acid level (see Fig. 28.3), attract neutrophils, bind the same receptor CXCR2, and are angiogenic.[46,47] Of the ELR-negative CXC chemokines, only CXCL12 is angiogenic and attracts neutrophils, but by activating CXCR4.[48] The so-called IP-10 subgroup, comprised of CXCL9-11, is encoded by a distinct cluster of related genes on human chromosome 4q21. Members share the receptor CXCR3, but are angiostatic, not angiogenic.[46,49]

The CC group is comprised of multiple subgroups. The two largest are the monocyte chemoattractant protein and macrophage inflammatory protein (MIP) clusters on human chromosome 17q12, which typically chemoattract monocytes/macrophages, plus other differential cell targets[50] (see Fig. 28.3). CC chemokines may also be subclassified by the presence or absence of additional cysteines (see Fig. 28.4). Although in separate groups as defined by cysteine motifs, CXCL16 and CX3CL1 also form a unique multimodular subgroup[51,52] (see Fig. 28.4). In addition to a typical chemokine domain, both these chemokines have a mucin-like stalk, a transmembrane domain, and a *C*-terminal cytoplasmic module, and can exist as a membrane-bound or shed form, mediating direct G protein-

independent cell-cell adhesion and chemotaxis, respectively.[53] The discovery of CXCL17 by sequence threading techniques, not by primary sequence homology, provides proof of principle that the boundaries of chemokine sequence space could expand substantially as protein structures are determined or modeled.[54]

All chemokines fold into a highly conserved and compact three-dimensional structure. Disulfide bonds link Cys-1 to Cys-3 and Cys-2 to Cys-4.[45,55] The core, which contains three β sheets arranged in the shape of a Greek key, is overlaid by a C-terminal α-helical domain and is flanked by an *N*-terminal domain that lacks order (see Fig. 28.4). Forced chemokine monomers are active,[56,57] but dimer and tetramer structures may occur, and complex quaternary structures bound to glycosaminoglycans (GAGs) on the surface of cells may be important for function in vivo.[4,58,59,60,61,62] Location of the GAG binding domains is variable and depends in part on the highly basic nature typical of most chemokines. Chemokine heterodimers have been described, both CC/CC and CC/CXC, and some may form preferentially over homodimers in a GAG-dependent manner; native heterodimers have also been identified.[63,64,65,66,67,68]

Chemokine Receptor Structure and Classification

Chemokine receptors are defined as mediators that activate cellular responses upon binding chemokines. All 23 known subtypes, together with receptors for the classical lipid and peptide chemoattractant receptors, are members of the rhodopsin-like seven-transmembrane (7TM) domain superfamily of GPCRs[8,42,43] (see Fig. 28.3; www.gpcr.org/7tm). The leukocyte chemoattractant receptors comprise the second largest subfamily of GPCRs (see Fig. 28.3). Chemokine binding, membrane anchoring, and signaling domains are formed from a single polypeptide chain ~340 to 370 aa long. CXCR4 is the only chemokine receptor, and one of only four 7TM receptors, whose structure has been determined. When bound to small molecule and cyclic

peptide antagonists, it is a dimer, in general agreement with previous biochemical data describing ligand-independent CXCR4 dimerization[69,70] (Fig. 28.5). Viral GPCRs have been proposed to hijack human receptors such as CXCR4 by heterodimerization.[71] Evidence for homo- and heterodimerization has been reported for other chemokine receptors, such as CCR2, CCR5, and CX3CR1, but the precise physiologic forms remain undefined.[72,73,74]

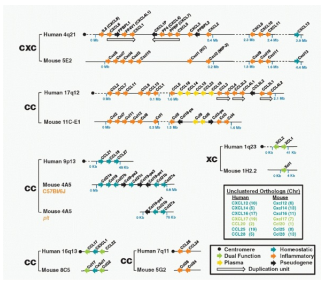

FIG. 28.2. Chemokine Gene Repertoires in Mouse and Human. Data are from www.ncbi.nlm.nih.gov/genome Builds 37.2 for *Homo sapiens* and *Mus musculus*. *Brackets* pair regions of conserved synteny between the indicated mouse and human chromosomes. *Bracket labels* denote chemokine groups (see text). Gene names are from the HUGO Gene Nomenclature Committee assignments. Protein names that differ from gene names are given in parentheses. *Arrows*, gene location and orientation relative to centromere; Mb, megabases; plasma, chemokines found at high concentrations constitutively in plasma. Other codes are in box at lower right. The figure layout is based on a previously published design and helpful advice from Hisayuki Nomiyama of Kumamoto University.

Standard receptor names are based on the property of chemokine group restriction, as follows: receptor name = ligand group root + R (for "receptor") + number, in order of discovery. An exception is the C chemokine receptor XCR1, where "X" distinguishes it from CR1, the previously assigned name for complement receptor 1. For consistency, the XCR1 ligands are named XCL1 and XCL2. All but six chemokines have had their receptors identified (see Table 28.3). Chemokines have unique receptor specificity profiles, and chemokine receptors have unique chemokine specificity profiles. Ligands that share a common receptor interact with the same receptor chain, in contrast to many other types of cytokines that share receptors via specialized subunits.[75] Pharmacologically, almost all chemokines are agonists, but a few are agonists at one receptor and antagonists at another (see Table 28.3).

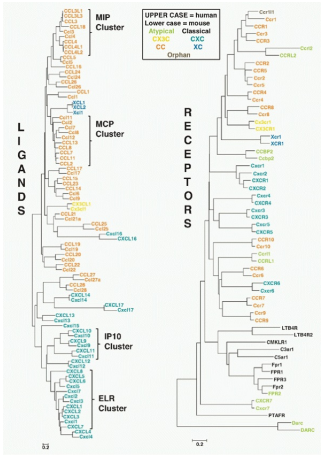

FIG. 28.3. Chemokine and Chemokine Receptor Family Trees in Mouse and Human. Branch distances are calibrated by the bar at the bottom of each tree. The dendrograms were created in collaboration with Steven Tsang, National Institute for Allergy and Infectious Diseases.

Atypical Chemokine System Components

There are at least six categories of atypical chemokine system components. The first includes the chemokines and 7TM chemokine receptors encoded by poxviruses and herpesviruses, the probable result of "molecular piracy" of their hosts.[29,71,76,77] This group includes chemokine scavengers and chemokine receptor antagonists thought to function in immune evasion; additional functions include modulation of host cell proliferation and movement. The second is a heterogeneous group of host 7TM chemokine-binding proteins that signal anomalously or not at all.[78,79,80,81] Included in this group are Duffy antigen receptor for chemokines (DARC), CXCR7, CCBP2 (also known as D6), CCRL1, and CCRL2. CXCR7, DARC, and CCBP2 are the best studied. CXCR7 has been included in the standard nomenclature system due to evidence of β-arrestin- but not G-protein-mediated signaling.[82] Its functions will be discussed in a later section with CXCR4, with which it shares a common ligand, CXCL12. DARC is nonsignaling and is expressed on red cells, lymphatic endothelium,

and cerebellar Purkinje cells, but not

P.685

P.686

P.687

P.688

P.689

leukocytes. It is an exception to the ligand rule as it binds many, but not all, CC and CXC chemokines.[83] DARC mediates transcytosis of chemokines across endothelial cells[84] and modulates inflammatory responses.[85] CCBP2 is expressed on leukocytes but at low levels. More prominently expressed on placental trophoblasts[86] and lymphatic endothelium,[87] CCBP2 scavenges inflammatory CC chemokines by a process of rapid internalization and recycling to plasma membrane,[88] and affects embryo survival, inflammatory responses, immune activation, and antimicrobial resistance in infection and cancer models.[89] One theory is that nonsignaling chemokine binding proteins function as antiinflammatory chemokine buffers, and accordingly they have been referred to as chemokine scavengers, interceptors, and silent or decoy receptors. A third category includes structurally unique broad-spectrum anti-inflammatory chemokine

P.690

binding proteins encoded by microbes, including several herpesviruses and poxviruses,[90] as well as *Schistosoma mansoni*[91] and ectoparasitic ticks.[92]

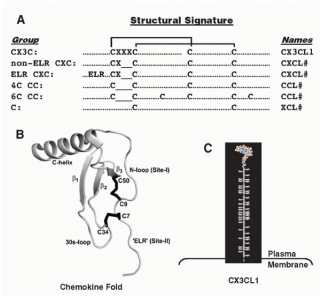

FIG. 28.4. Chemokine Classification, Nomenclature, and Structure. A: Chemokine groups are defined by the number and arrangement of conserved cysteines, as shown. *Brackets* link cysteines that form disulfide bonds. ELR, glu-leu-arg; X, an amino acid other than cysteine. The *underscore* is a spacer used to optimize the alignment. The *N-* and *C-* termini can vary considerably in length (not illustrated). For the molecules with four cysteines, there are approximately 24 amino acids between Cys-2 and Cys-3 and 15 amino acids between Cys-3 and Cys-4. At right is listed the nomenclature system. **B:** The chemokine fold illustrated by monomeric CXCL8. **C:** Model of transmembrane chemokine CX3CL1. See text for details.

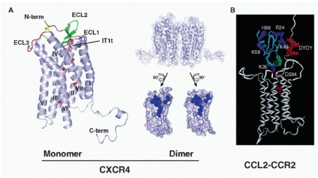

FIG. 28.5. Chemokine Receptor Structure. A: Structure of CXCR4 bound to ligand IT1t, at left[70]; CXCR4 dimer, at right, illustrating the dimer contact surface at the bottom right.[70] **B:** CCL2 monomer docking to model of CCR2.[135]

The fourth group of atypical components includes endogenous nonchemokine ligands that bind chemokine receptors. Examples include aminoacyl transfer ribonucleic acid synthetases, some of which function as autoantigens in autoimmune disorders[93,94]; the antimicrobial peptide β defensin 2, which activates CCR6 on immature dendritic cells (DCs), possibly linking innate to adaptive immunity[95]; and cluster of differentiation (CD)82 (KAI1), a tetraspanin expressed on leukocytes and cancer cells that binds to endothelial cell-expressed DARC, triggering senescence in tumor cells and suppression of metastasis.[96] The fifth group includes chemokines that bind scavenger receptor ligands, such as oxidized LDL, through their receptor binding domains.[97] The prototype is CXCL16, which was originally called scavenger receptor for phosphatidyl serine and oxidized LDL, or SR-PSOX. CXCL16 has also been shown to function as a transporter for CpG dinucleotides across the plasma membrane for action at toll-like receptor 9, as well as to mediate bacterial phagocytosis by antigen-presenting cells.[98]

In contrast, a truncated form of CCL23, unlike full-length CCL23, has not been shown to activate any chemokine receptors, yet is an agonist at FPR2, a member of the classical chemoattractant fMet-Leu-Phe receptor subfamily.[99] Perhaps the most surprising example of an alternative chemokine receptor agonist is the tripeptide Pro-Gly-Pro, a breakdown product of collagen from extracellular matrix that is found in bronchoalveolar lavage samples from patients with chronic obstructive pulmonary disease.[100] This peptide shares structural homology with a domain in CXC chemokines and has been shown to recruit neutrophils via CXCR2 activation in a mouse model of lung inflammation. It has been reported to be a chemotactic agonist at CXCR2, but this has not been confirmed.[101]

A final category of atypical components includes nonchemokine ligands for chemokine receptors (agonists or antagonists) produced by pathogens. For example, HIV Tat is an antagonist at CXCR4,[102] and CCR5 can be activated by viral (HIV gp120), bacterial (*Mycobacterium tuberculosis* Hsp70), and protozoan (*Toxoplasma gondii* immunophilin) factors.[103,104,105,106] *M. tuberculosis* Hsp70 activation of CCR5 induces DC aggregation, T-DC immune synapse formation, and effector immune responses.

Chemokine System Genes and Evolution

The chemokine system appears to have originated in teleost fish (for updates and phylogenies, see the Cytokine Family cDNA database at http://cytokine.medic.kumamoto-u.ac.jp). Comparative whole genome analysis has now shown that the chemokine repertoire differs dramatically in size throughout phylogeny with zebrafish having 63 chemokine genes compared to 48 in human.[40,41,107,108] Only human CXCL12 and CXCL14 have unambiguous orthologues in fish, and none of the other mammalian CXC chemokines has clear orthologues in any other vertebrate class, including birds. In addition, gene copy number may differ among closely related species (see Fig. 28.2 for human and mouse) and among individuals of the same species (eg, the triplicated MIP cluster in humans). A model of chemokine system evolution has been proposed involving lineage-specific en bloc and tandem duplications with expansion and functional specialization accompanying the origin of adaptive immunity.[107]

Chemokine genes typically are ˜4 kb long and usually have four exons in the case of CXC chemokines and three exons in the case of CC chemokines. The promoter is immediately upstream of exon 1, which encodes a leader sequence and a few amino acids of the mature peptide. Alternative

P.691

splicing has been reported for several chemokines, but the significance is not well defined. CCL14 and CCL15 are an exceptional example of neighboring genes that give rise to a family of mono- and bicistronic transcripts.[109]

The 23 chemokine receptor genes can be divided by chromosomal location into three groups: a large cluster on human chromosome 3p21-23 including multiple CCRs, CX3CR1, XCR1, and CXCR6, plus CCBP2 and CCRL1; CXCR1, CXCR2, and one receptor pseudogene clustered on 2q34-q35; and the rest unclustered. With the exception of CCR9, genes in the two clustered groups lack introns in the open reading frame (ORF) but have at least one and as many as 10 introns separating the promoter from the ORF. In contrast, an intron divides the *N*-terminus of the majority of unclustered receptor genes (CXCR3, 4, and 5; CCR6 and 10). Several of these undergo alternative splicing but the products appear to function similarly. CCR2 undergoes alternative splicing of a virtual intron in the *C*-terminal region of the ORF, but the two products have similar function and CCR2B appears to be the major expressed form.

With regard to horizontal evolution, variation in gene copy number among individuals has been observed for only a few chemokines. *CCL3* is an example of this in human,[110] and the *plt* locus (*p*aucity of *l*ymph node *T* cells), which will be discussed in a later section, is an immunologically important example in mouse[111] (see Fig. 28.2). In contrast, variation in gene sequence is common among individuals for most chemokine and chemokine receptors. However, the degree of polymorphism varies greatly among different genes. The most extreme and important example is the *CCR2-CCR5* locus in human, in which combinations of common dimorphic single nucleotide polymorphisms in the CCR5 promoter with a single nucleotide polymorphism in the ORF of *CCR2* named *CCR2 V64I* and a 32 base pair deletion in the ORF of *CCR5* named *CCR5Δ32* together form at least eight distinct haplotypes and in some cases affect HIV disease susceptibility.[112,113,114]

TABLE 28.5 Sources and Main Immunologic Functions of Human CXC, CX3C, and C Chemokines

Chemokine	Main Source	Main Immunologic Roles
CXCL1	Inducible in most hematopoietic and tissue cells	Neutrophil trafficking
CXCL2	Many tumors Neutrophil	trafficking
CXCL3		Neutrophil trafficking
CXCL4	Preformed in platelets	Procoagulant
CXCL4L1	Preformed in platelets	ND
CXCL5	Induced in epithelial cells of gut and lung; N, Mo, Plts, EC	Neutrophil trafficking
CXCL6	Induced in lung microvascular EC; Mo; alveolar epithelial cells, mesothelial cells, EC and MΦ	Neutrophil trafficking
CXCL7	Preformed in platelets	Neutrophil trafficking
CXCL8	Induced in most cell types	Neutrophil trafficking
CXCL9	Induced in PMN, MΦ, T cells, astrocytes, microglial cells, hepatocytes, EC, fibroblasts, keratinocytes, thymic stromal cells	Th1 response
CXCL10	Induced in ECs, Mo, keratinocytes, respiratory & intestinal epithelial cells, astrocytes, microglia, mesangial cells, smooth muscle cells	Th1 response
CXCL11	ECs, Mo	Th1 response
CXCL12	Constitutive in bone marrow stromal cells; most tissues	Myelopoiesis HPC, neutrophil homing to BM B lymphopoiesis
CXCL13	Constitutive in follicular HEV of secondary lymphoid tissue	Naïve B- and T-cell homing to follicles B1 cell homing to peritoneum Natural Ab production
CXCL14	Constitutive in most tissues, breast and kidney tumors	Macrophage migration
(CXCL15)	Constitutive in lung epithelial cells	Neutrophil trafficking
CXCL16	Constitutive in spleen; DCs of the T zone	T-cell, NK and DC trafficking
CX3CL1	EC, neurons, Mo, DC	NK, Monocyte, MΦ, and Th1 cell migration; neuroprotection
XCL1	γδ epidermal T cells, NK, NK-T, activated CD8+ and Th1 CD4+ T cells	Cross presentation of antigen by XCR1+ CD8+ DC to CD8+ T cells
XCL2		

Immunologic Classification of the Chemokine System

Chemokines and chemokine receptors have differential leukocyte specificity but together regulate all leukocyte subsets (Tables 28.5 and 28.6). As such, they can be loosely divided into two main functional systems, *homeostatic* and

P.692

P.693

inflammatory. Homeostatic chemokines are differentially and constitutively expressed primarily in specific microenvironments of primary and secondary immune organs, and coordinate migration of hematopoietic precursor cells, mature DCs, and naïve and central memory lymphocyte subsets via constitutively expressed receptors.[115,116,117,118,119] Inflammatory chemokines are induced by noxious stimuli in tissue cells and leukocytes. Inflammatory chemokine receptors tend to be constitutively expressed on myeloid cells, natural killer (NK) cells, and effector but not naïve lymphocytes.[120,121] Dynamic shifts in receptor expression occur during leukocyte differentiation, maturation, and activation.[115,122,123,124,125] This is not an absolute classification, because constitutive chemokines may be further induced, and chemokines that are highly inducible in some cell types may be constitutively expressed in others. In addition, there may be differences between mouse and human leukocyte subsets. Table 28.4 condenses a small portion of this vast subject available from the literature. Additional information can be obtained from the Immunologic Genome Project (www.immgen.org), which is a consortium systematically evaluating surface molecule expression in over 250 leukocyte subsets.

TABLE 28.6 Sources and Main Immunologic Functions of Human CC Chemokines

Chemokine	Sources	Main Immunologic Roles
CCL1	Inducible in Mo and CD4+ and CD8+ αβ and CD4-CD8- γδ T cells	Th2 response
CCL2	Inducible in Mo, fibroblasts, keratinocytes, EC, PMN, synoviocytes, mesangial cells, astrocytes, lung epithelial cells and MΦ Constitutively made in splenic arteriolar lymphatic sheath and medullary region of lymph node, many tumors, and arterial plaque EC Innate immunity	Th2 response CD4+ T cell differentiation
CCL3	Inducible in Mo/MΦ, CD8+ T cells, B cells, plts, PMN, Eo, Ba, DC, NK, mast cells, keratinocytes, fibroblasts, mesangial cells, astrocytes, microglial cells, epithelial cells	Innate immunity Th1 response CD4 T-cell differentiation
CCL3L1	Similar to CCL3	Probably similar to CCL3
CCL4	Similar to CCL3	Innate immunity Th1 response
CCL5	Inducible in EC, T cells, epithelial cells, Mo,	Innate

	fibroblasts, mesangial cells, NK cells Constitutively expressed and stored in plt and Eo granules	immunity Th1 and Th2 response
(Ccl6)	Inducible in bone marrow and peritoneal-derived MΦ	ND
CCL7	Inducible in Mo, plts, fibroblasts, EC, skin, bronchial epithelial cells, astrocytes	Th2 response
CCL8	Inducible in fibroblasts, PMN, astrocytes Constitutively expressed in colon, small intest, heart, lung, thymus, pancreas, spinal cord, ovary, placenta	Th2 response
(Ccl9/10)	Constitutively expressed in all mouse organs except brain; highest in lung, liver and thymus Induced in heart and lung	ND
CCL11	Epithelial cells, EC, smooth muscle, cardiac muscle, Eo, dermal fibroblasts, mast cells, MΦ, Reed-Sternberg cells	Th2 response Eosinophil trafficking Mast cell trafficking Basophil trafficking, degranulation
(Ccl12)	—Inducible in lung alveolar MΦ smooth muscle cells; spinal cord. Constitutive expression in lymph node and thymic stromal cells	Allergic inflammation
CCL13	Inducible in nasal and bronchial epithelial cells; dermal fibroblasts; PBMCs; atherosclerotic plaque EC and MΦ —Constitutively expressed in small intestine, colon, thymus, heart and placenta	Th2 response
CCL14a	Constitutively expressed in most organs; high plasma levels	ND
CCL14b	Same as CCL14b except absent from skeletal muscle and pancreas	ND
CCL15	Inducible in Mo and DC Constitutive RNA expression in liver, gut, heart and skeletal muscle, adrenal gland and lung leukocytes.	ND
CCL16	Constitutively expressed in liver, possibly many other organs. Also, Mo, T cells, and NK cells express mRNA.	DC maturation factor
CCL17	Constitutive in normal DC and Reed-Sternberg cells of Hodgkin's Disease	Th2 response
CCL18	Constitutive in Mo/MΦ, germinal center DC	DC attraction of naïve T cells Hematopoiesis
CCL19	Constitutive on interdigitating DC in secondary lymphoid tissue	Naïve and memory T cell & DC homing to lymph node
CCL20	Constitutive in follicle-associated epithelium overlying GALT inductive sites (Peyer's patches and isolated lymphoid follicles) Inducible in GALT	GALT development B and DC homing to GALT IgA humoral response in gut
CCL21	Constitutive in lymphatic EC, HEV, and interdigitating DC in T areas of 2° lymphoid tissue, thymic medullary epithelial cells and EC	Naïve and memory T cell and DC homing to lymph node
CCL22	Constitutive in DC and MΩ Inducible in Mo, T, and B cells	Th2 response
CCL23	Constitutive in pancreas and skeletal muscle	ND
CCL24	Inducible in Mo	Eosinophil migration
CCL25	Constitutive in thymic stromal cells and small intestine	Thymocyte migration Homing of memory T cells to gut
CCL26	Constitutive in heart and ovary Inducible on dermal fibroblastsand EC	Th2 response
CCL27	Constitutive in placenta, keratinocytes, testis, and brain	Homing of memory and effector T cells to skin
CCL28	Constitutive in epith cells of gut, airway	Homing of T cells to mucosal surfaces

The Issue of Chemokine Redundancy

Two chemokines that bind to the same receptor may still have highly specific biologic roles, due to differential expression in time and space,[126,127,128,129] activation of the same receptor via different signal transduction pathways or the same pathway with differential efficacy, or activation of additional differentially expressed receptors. A good example of differential expression is CXCL7 (neutrophil-activating protein-2) and CXCL8. Both are agonists for neutrophil CXCR2, but CXCL7 is stored in platelet α granules and released upon platelet activation,[130] whereas CXCL8 is made by many human cell types upon gene induction by proinflammatory stimuli. There are few inflammatory processes in which only one chemokine is involved. Instead, inflammatory chemokines typically act cooperatively, on the same or separate cell types, but in a hierarchical manner through promiscuous chemokine receptors sometimes in concert with classical chemoattractant receptors. The net result is that there may be enough functional redundancy in the whole system such that loss of a single inflammatory chemokine or chemokine receptor, for example in a knockout mouse, does not cause altered susceptibility to naturally acquired infections or other diseases, yet there may not be sufficient redundancy to handle a stronger stress when one particularly important component is missing. In contrast, homeostatic chemokines act much less redundantly, with typically only one or two ligands per receptor, and their loss has been associated with major defects in development and leukocyte trafficking and in some cases,

death.

Chemokine Presentation Mechanisms

Chemokines typically act locally and are thought to be concentrated for cell activation by tethering to endothelial cells via GAGs or transmembrane domains, or to matrix.[22,59] GAG-dependent oligomerization has been shown to be important for in vivo activity of CCL5 and CXCL10.[62,131] The tethering cell may have produced the chemokine or else imported it by transcytosis from neighbors.[132,133] The ligand binding site includes 1) the receptor *N*-terminus and one or more extracellular loops, depending on the specific chemokine, which allow docking of the chemokine *N*-loop domain, and 2) the 7TM domains, which then accept the chemokine's *N*-terminus and are critical for triggering[134,135] (see Fig. 28.5C). Tyrosine sulfation on the receptor *N*-terminus has been shown to facilitate chemokine receptor binding to both chemokine and nonchemokine ligands (eg, HIV gp120).[136,137]

LEUKOCYTE RESPONSES TO CHEMOKINES

Both homeostatic and inflammatory leukocyte trafficking requires transendothelial migration, a multistep process involving an endothelium- and leukocyte-specific molecular code, in which chemokines regulate at least two steps.[16,18] In an initial chemokine-independent step, leukocytes roll on inflamed endothelium in a selectin-dependent manner. Next, chemokines posted on endothelium stimulate rolling leukocytes to express activated β2 integrins, which mediate shear-resistant adhesion via endothelial intercellular adhesion molecules. Leukocytes respond to chemokine gradients by changing their shape to produce a front and a back and by crawling toward the front.[138,139] Motion involves sheardependent coordinated cytoskeletal remodeling, involving expansion of the front (lamellipodium), myosin-based contraction at the back (uropod), release of the uropod from substrate, and membrane lipid movement. Navigation through tissue may require relays of chemokines and adhesion molecules. Fine navigation within tissue microenvironments has also been shown to be directed by specific chemokines up to the point of immunologic synapse formation.[26,140,141,142] There is now evidence that CCR5 and CXCR4 may accumulate in the immunologic synapse formed by CD4+ T cells and DCs in vitro, and that this may provide chemokine-dependent costimulatory signals.[142,143]

Chemokines and their receptors have increasingly been implicated in other cell functions, including regulation of proliferation and apoptosis,[34,144,145,146,147,148,149,150,151,152,153,154] regulation of antigen sampling by immature DCs (eg, CCR7 and CX3CR1), maturation of DCs (CCR7), and inhibition of mature DC endocytosis (CCR7).[155,156] Inflammatory chemokines may induce mediator release (eg, defensins, proteases, perforins, histamine, eicosanoids) resulting in cytotoxic or vasomotor responses.[121,157] Some chemokines even have direct antibacterial activity,[158,159] which could explain why some of them can be found constitutively at high concentrations in body fluids such as blood and sweat.[109]

CHEMOKINE SIGNALING PATHWAYS

Gi-Dependent Effectors

Classically, ligand-bound chemokine receptors, possibly in the dimer state,[72] act as guanine nucleotide exchange factors, especially for G_{i2} (Fig. 28.6).[160] G protein activation presumably

involves a conformational change in the transmembrane domains of the receptor and binding of the G protein to multiple intracellular domains, including the C-tail, intracellular loop 3 and the DRY motif at the end of TMD2. The latter is highly conserved in classic chemokine receptors but mutated in atypical chemokine receptors, which do not couple to G protein-dependent signaling. Activation of G proteins involves exchange of GDP for GTP by the α subunit, leading to dissociation of the trimer into α and βγsubunits. The duration of G protein signaling is regulated in part by intrinsic GTPase activity possessed by the α subunit which can be markedly increased by GTPase activating proteins known as RGS proteins (*r*egulators of *G* protein signaling).[160,161] Signaling appears to be mainly mediated by βγ ,[162,163] which activates diverse effectors, including phospholipases A2, C (subtypes β2 and β3) and D, phosphatidylinositol-3-kinase γ (PI3Kγ), protein tyrosine kinases and phosphatases, low molecular weight GTPases, and mitogen-activated protein kinases. The requirements of these enzymes for chemotaxis are both chemoattractant- and celltype dependent, and the complex mechanistic details underlying specificity remain to be elucidated.

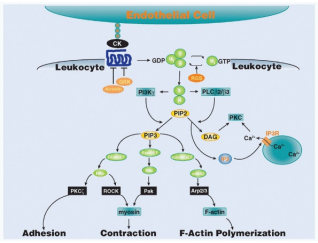

FIG. 28.6. Chemokine Signal Transduction in Chemotaxis. Depicted are key steps in two of the main pathways induced by most chemokines. The PI3Kγ pathway is particularly important for cell migration. Chemokines are able to activate other pathways as well, including non-Gitype G proteins, protein tyrosine kinases and MAP kinases, resulting in effects on cell proliferation and activation. Model is modified from the Alliance for Cell Signaling (www.signaling-gateway.org). CK, chemokine; DAG, diacylglycerol; GAG, glycosaminoglycan; GEF, guanine nucleotide exchange factor; GRK, G protein-coupled receptor kinase; IP3, inositol trisphosphate; PI3K, phosphatidylinositol-3-kinase; PIP, phosphatidylinsol phosphate; PKC, protein kinase C; PLC, phospholipase C; RGS, regulator of G protein signaling.

PLC hydrolyzes PI(4,5) bisphosphate (PIP_2) to form 1,2-diacylglycerol and inositol-1,4,5-trisphosphate.[164,165] Inositol-1,4,5-trisphosphate induces calcium release from intracellular stores, which acts with diacylglycerol to activate protein kinase C. PI3Kγ phosphorylates PIP_2 to form PIP_3, which recruits proteins containing pleckstrin homology or Phox domains to lamellipodium, thereby converting shallow extracellular chemokine gradients to steep intracellular effector gradients.[166,167] Four pleckstrin homology domain-containing targets —Akt, and guanine nucleotide exchange factors for Rac, Rho, and cdc42—modulate distinct phases of cell movement in various model systems. Rho regulates cell adhesion and chemotaxis, and myosin contraction. Rac and cdc42 control lamellipodia and filipodia formation, respectively. Downstream targets of Rac

include PAK1, which also regulates myosin contraction. In neutrophils, signal amplification, gradient sensing, and cell orientation have been shown to be further amplified and reinforced by ATP release at the leading edge, which provides autocrine feedback signaling through P2Y2 nucleotide receptors. This is further amplified by conversion of ATP to extracellular adenosine, which signals through A3 receptors mobilized to the leading edge.[168] Motility, phagocytosis, and immunologic synapse formation are all critically dependent on local polymerization of actin, coordinated by actinbinding proteins.

Gi-Independent Effectors

Many chemokine receptors couple to G proteins other than Gi in vitro; however, the role of these proteins in vivo is not well defined. There is in vitro evidence from studies of the fMet-Leu-Phe receptor that G12/13 through activation of Rho may be important in formation of the uropod.[169] Mice lacking both G12 and G13 selectively in B cells have reduced numbers of splenic marginal zone B cells, resulting in a delay of antibody production in response to thymus-independent antigens. However, responsiveness of these cells to chemokines is normal. Instead, the phenotype may be due to impaired sphingosine-1-phosphate signaling.[170]

Chemokines may activate effectors such as MAP kinases and nonreceptor protein tyrosine kinases by a variety of Gi-independent mechanisms. An example is CXCR4, which has been shown to physically associate with T-cell receptors (TCRs) in a CXCL12-dependent manner, resulting in activation of ZAP-70 and downstream effectors, including ERK, calcium flux, AP-1, and costimulation of cytokine secretion.[143] β-arrestin signaling has been reported for

chemokine receptors, including the atypical receptor CCBP2/D6.[88] Constitutive activity has also been reported, most notably for the HHV8 receptor encoded by ORF74.[171] Signaling through the Jak-Stat pathway has also been proposed and debated.[72,172]

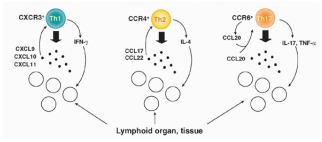

FIG. 28.7. Chemokine-Cytokine Feedback Loops in T Helper Cell Polarization. *Dots* denote gradients of the chemokines indicated to the left. *Thick arrows* denote the direction of T helper cell movement. *Afferent thin arrows*, release of the indicated factors from the indicated cell; *efferent thin arrows*, action of the indicated factor on the indicated cell. The figure was created and generously provided by Joshua Farber, National Institute for Allergy and Infectious Diseases.

REGULATION OF CHEMOKINE ACTION

Virtually all nucleated mouse and human cell types are able to produce chemokines, but in a differential and highly regulated manner (see Tables 28.5 and 28.6). Chemokine and chemokine receptor expression may be positively or negatively regulated at the transcriptional level by diverse factors, including proinflammatory cytokines, hypoxia, viruses, bacterial products, cell adhesion, shear stress, antigen uptake, T-cell costimulation, and diverse transcription factors. Proinflammatory cytokines such as interleukin (IL)-1, tumor necrosis factor, and IL-15 induce expression of many of the inflammatory chemokines involved in innate immunity such as CXCL8, whereas immunoregulatory cytokines such as interferon (IFN)γ, IL-4, and IL-17 are more tightly focused on Th1 (eg, CXCL9-11)-, Th2 (eg, CCL11)-, and Th17 (CCL20)-selective chemokines, respectively (Fig. 28.7). IFNs, glucocorticoids, and anti-inflammatory cytokines (eg, IL-10) may inhibit inflammatory chemokine gene expression. Chemokines may also be regulated at the level of messenger ribonucleic acid stability and cell type-specific polyubiquitinylation and proteasomal degradation.[173,174]

A chemokine gene may generate families of proteins varying dramatically in activity and potency by alternative splicing and posttranslational modification, especially *N*- and *C*-terminal proteolytic trimming. Proteases may target many chemokines (eg, CD26 [dipeptidyl peptidase IV] and matrix metalloproteinases),[175,176,177,178] or few or only one (eg, TACE [the tumor necrosis factor α converting enzyme],[179] plasmin, urokinase plasminogen activator, and cathepsin G), and the cleaved forms may be the dominant forms in biologic fluids, as shown for several CCR1 ligands.[180] Chemokine action may be blocked by receptor decoys (eg, DARC),[181] endogenous receptor antagonists, and autoantibodies. In addition, cytokines may convert a signaling receptor into a decoy (eg, IL-10 inactivates CCR2 and other receptors on monocytes/macrophages).[182] Also, a receptor may have different functions on different cell types.

P.696

In addition to RGS proteins, chemokine receptor signaling may be regulated by homologous and heterologous desensitization, which involves phosphorylation by G protein-coupled receptor kinases or protein kinase C and protein kinase A, respectively, and internalization by clathrin-dependent and -independent mechanisms.[183] Release mechanisms may vary dramatically for different chemokines. CXCL4 is stored in platelet α granules, whereas the highly related CXCL4L1 is continuously produced and released.[184] CCL5 is released from T-cell granules preassociated with GAGs.[185] CCL3 is released multidirectionally from activated T cells, presumably to create chemotactic gradients, unlike IL-2 and IFNγ which are secreted directly into the immunologic synapse.[186]

CHEMOKINE REGULATION OF HEMATOPOIESIS

For the next two sections, Figure 28.8 provides an overview of chemokine receptors that regulate movement of specific leukocyte subsets between compartments of the hematopoietic system during immune system development and during the immune response. Table 28.7 contains a list of major phenotypes observed in chemokine receptor knockout mice.

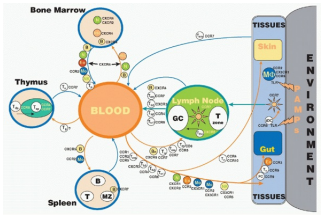

FIG. 28.8. Chemokine Control of Leukocyte Trafficking. Shown are routes among primary and secondary immune organs and the periphery, leukocyte subtypes trafficking on those routes and some of the chemokine receptors that appear to be most important in regulating each route. Eo, eosinophil; iDC, immature dendritic cells; GC, germinal center; HSC, hematopoietic stem cell; MΦ, macrophage; Mo, monocyte; MZ, marginal zone; N, neutrophil; NK, natural killer cell; PAMP, pathogen-associated molecular patterns; PC, plasma cell; Tcm, central memory T cells; Tem, effector memory T cells; T_{FH}, follicular help T cells; TLR, Toll-like receptor; Tm, memory T cells; Tn, naïve T cells; Tp, precursor T cells. Model is based primarily on studies in knockout mice.

CXCR2, CXCR4, and CXCR7

Originally identified as a stromal cell-derived pre-B cell stimulatory factor that also enhanced hematopoietic progenitor cell (HPC) colony formation ex vivo, the homeostatic chemokine CXCL12 is the most abundant chemokine produced in bone marrow. Its production is under the control of granulocyte-colony stimulating factor and adrenergic neurotransmission, among other factors.[34,187] CXCL12 is the only chemokine ligand known for CXCR4 but also binds to the atypical receptors DARC and CXCR7.[188,189,190,191,192,193,194,195,196,197,198,199,200] CXCL12, CXCR4, and CXCR7 are unusual among chemokine elements in being extremely highly conserved phylogenetically from fish to man, yet CXCR4 and CXCR7, despite binding the same ligand, are very distantly related (see Fig. 28.3). The three molecules also have the shared property of being essential for life in mice, the only chemokine system components tested to date for which this is true.[35,201] Yet their biologic roles are very different.

Loss of Cxcl12 or Cxcr4 in knockout mice results in the same dramatic and fatal multisystem developmental phenotype: ventricular septal defect, defective gastric vascularization, defective cerebellar development, and severe defects

P.697

P.698

in bone marrow myelopoiesis and B-cell lymphopoiesis. The phenotype is consistent with the widespread constitutive expression of both CXCL12 and CXCR4 on both hematopoietic and vascular cells. In bone marrow, CXCR4 activation by CXCL12 is thought to induce β2 integrin-mediated retention of neutrophils, hematopoietic stem cells, and probably other hematopoietic cell types, which normally regulate leukocyte distribution among hematopoietic compartments.[189,202,203] The balance of CXCR2 and CXCR4 signaling is thought to be particularly important in regulating neutrophil distribution between blood and bone marrow.[204,205] Immature neutrophils express high levels of CXCR4 and low levels of CXCR2. As they mature, there is a reciprocal switch in expression of these two receptors, and the cells leave the marrow in response in part to CXCR2 signaling. As the cells senesce in the periphery and undergo apoptosis, CXCR4 expression increases and the cells home back to marrow in response to CXCL12 activation for destruction by macrophages. The importance of CXCR4 in this process is dramatically illustrated by patients with WHIM syndrome (*w*arts, *h*ypogammaglobulinemia, *i*nfections, and *m*yelokathexis syndrome), a primary immunodeficiency that will be described in the section on disease.

TABLE 28.7 Some Phenotypes of Chemokine Receptor Knockout Mice

Receptor	Phenotype of Knockout Mouse
Cxcr2	• Increased susceptibility to *Toxoplasma gondii*, brain abscess, *Onchocerca volvulus*, *Escherichia coli* pyelonephritis • Reduced: wound healing, *Aspergillus fumigatus* AHR, urate crystal-induced synovitis • Expansion of neutrophils and B cells in blood, marrow, and lymphoid organs (not seen when derived in germ-free environment)
Cxcr3	• Increased susceptibility to MTb • Delayed cardiac allograft rejection
Cxcr4	• Perinatal lethality • Defective: ventricular septum, bone marrow myelopoiesis, B-cell lymphopoiesis, gastric vascularization, cerebellar granule cell migration
Cxcr5	• Few Peyer's patches, no inguinal LN; defective germinal centers and B-cell homing to LN
Cxcr7	• Defective cardiac valve development
Ccr1	• Increased susceptibility to *T. gondii*, Pneumonia virus of mice, *A. fumigatus* • Increased:Th1 response and glomerular injury in nephrotoxic nephritis model, Th2 response to SEA • Reduced: neutrophilic alveolitis in pancreatitis-acute respiratory distress syndrome model, airway remodeling and Th2 response in *A. fumigatus* model; Th1 response and resistance to EAE; Th1 response to PPD; delayed cardiac allograft rejection
Ccr2	• Monocytopenia; enhanced myeloid progenitor cell cycling and apoptosis • Increased susceptibility to *Cryptococcus neoformans*; mouse hepatitis virus; *Leishmania monocytogenes*; *Leishmania major*; *Mycobacterium tuberculosis* • Resistance to *Leishmania donovani*, influenza A • Decreased: EAE; DVT resolution; response to PPD; atherosclerosis; cardiac allograft rejection; AHR to CRA; dextran sulfate-mediated colitis; thioglycollate-induced peritonitis; FITC and bleomycin induced pulmonary fibrosis; MΦ recruited to injured nerve; DTH; ⁺-monocyte extravasation • Increased: AHR to OVA and to *A. fumigatus*; glomerulonephritis in antiglomerular basement membrane antibody model
Ccr3	• ip OVA sensitization → OVA challenge: increased AHR and airway mast cells; decreased airway eos, trapped between elastic lamina and endothelial cells • Epicutaneous OVA sensitization → OVA challenge: protection from allergic skin inflammation and AHR. Eos and mast cells not recruited to skin or lung. • Decreased IL-13-induced pulmonary eosinophilia and remodeling
Ccr4	• Increased susceptibility to Ips
Ccr5	• Increased susceptibility to *L. monocytogenes*; *C. neoformans*; *T. gondii*; influenza A; *L. major* • Resistance to *L. donovani* • Decreased: dextran sulfate-mediated colitis; Lps toxicity; mouse hepatitis virus-induced demyelination due to decreased MΦ recruitment to CNS; cardiac allograft rejection • Increased: DTH; humoral response to T-dependent Ag
Ccr6	• Defective CRA-induced allergic airway inflammation • Increased contact hypersensitivity to 2,4-dinitrofluorobenzene • Resistance to DTH to allogeneic splenocytes • Absent myeloid CD11b+ CD11c+ dendritic-cells in subepithelial dome of Peyer's patches • Increased T cells in intestinal mucosa • Impaired humoral immune response to orally administered antigen and to rotavirus • Protection from IL-22-induced psoriasoform lesions in skin
Ccr7	• Defective: humoral responses; contact sensitivity; DTH; renal fibrosis and fibrocyte accumulation in unilateral ureteral obstruction; lymphocyte and DC migration to LN • Undeveloped T-cell zones; impaired trafficking of T cells and DC to LN
Ccr8	• Defective SEA-induced granuloma formation; • Decreased OVA- and CRA-induced allergic airway inflammation
Ccr9	• Decreased: preproB cells, but nl T and B cells; ratio of gut intraepithelial T-cell-to-epithelial cell ratio due to decreased γδ T cells
Cx3cr1	• Increased susceptibility to *Salmonella* infection and to retinal degeneration • Resistance to atherosclerosis and cardiac allograft rejection in cyclosporin A treated animals
Darc	• Increased or decreased neutrophil mobilization, depending on the model
Ccbp2	• Increased CFA- or TPA-induced psoriasiform dermatitis • Reduced EAE

AHR, airway hyperreactivity; CRA, cockroach antigen; DC, dendritic cell; DTH, delayed type hypersensitivity; EAE, experimental allergic encephalitis; LN, lymph node; NR, not reported; OVA, ovalbumin; SEA, *Schistosoma mansoni* soluble egg antigen.

A developmental role for CXCR4 has also been found in zebrafish, where the orthologue *cxcr4b* mediates gonadal germ cell migration and self-organizing tissue migration in the lateral line during morphogenesis.[206] Consistent with a more general role in vascular biology, CXCR4 is expressed on vascular and cancer stem cells under the control of oxygen tension. These cells home to vascular niches under hypoxic conditions that occur during wound healing and in tumors. Hypoxia induces reduction of pVHL, which derepresses transcription factor HIF-1, a strong inducer of *CXCR4* expression.[207,208,209]

In contrast to CXCR4, CXCR7 is expressed in a more restricted manner, on marginal zone B cells, possibly on some T-cell subsets and on endothelial cells of all four cardiac valves.[35,188,195] It has been reported to couple to β-arrestin-but not G protein-dependent signaling, and to modulate cell survival, adhesion, and tumorigenesis.[195] It may function as a chemokine scavenger in vitro, and in zebrafish has been shown to modulate gonadal germ cell migration by shaping gradients of CXCL12 acting at CXCR4 as the signaling receptor.[21] In mice, it plays an essential role in development of all four cardiac valves, but the mechanism is not precisely defined.[35]

Myelosuppressive Chemokines

When added to bone marrow culture systems ex vivo, many chemokines are able to suppress

growth factor-dependent colony formation, apparently by acting directly on stem cells and early progenitors. The biologic significance of this remains unclear except for CXCR2. *Cxcr2*-/- mice develop massive neutrophilia, splenomegaly, myeloid hyperplasia, and expansion of HPCs.[210] CXCR2-dependent myelosuppression may be important for opposing overstimulation of hematopoiesis induced by environmental flora, as this phenotype is absent in mice derived in germ-free conditions. These mice also develop lymph node B-cell hyperplasia, which may occur by an indirect mechanism.

T Lymphopoiesis

During development, T cells must migrate from thymic cortex to medulla. CCR9 and its ligand CCL25 appear to be important as competitive transplantation of *Ccr9*-/- bone marrow is less efficient than normal marrow at repopulating the thymus of lethally irradiated *Rag-1*-/- mice.[211,212] CCL25 is expressed by medullary DCs and both cortical and medullary epithelial cells, and CCR9 is expressed on the majority of immature CD4+CD8+ thymocytes, but is downregulated during transition to the CD4+ or CD8+ single-positive stage.[213] Just before thymic egress, thymocytes become CCR9 negative and upregulate L-selectin. Transition from CD4+CD8+ thymocytes in the cortex to CD4 or CD8 single-positive thymocytes in the medulla is also associated with upregulation of CCR4 and CCR7, receptors for CCL22, and CCL19 and CCL21, respectively, which are expressed on endothelial cells of medullary venules. Studies with knockout mice have suggested that CCR7-dependent cortex to medulla migration of positively selected thymocytes may be essential for establishing central tolerance but not for maturation or export of thymocytes in vivo.[214]

Hematopoietic Cell Positioning in Peripheral Tissue

CXCL14 has been reported to have antitumor activity. It is a highly selective chemoattractant for monocytes and DCs, and may be important for their positioning in certain tumors.[215,216] CCL11 and its receptor CCR3 are important for migration of eosinophils to the gastrointestinal tract (and spleen).[23] CCL20 and its receptor CCR6 regulate positioning of immature myeloid CD11c+CD11b+ DC in the subepithelial dome of Peyer's patches, which may explain in part why humoral immune responses within the gut mucosa and defense against enteroinvasive pathogens are abnormal in *Ccr6*-/- mice.[217,218] CCR6 is also expressed on gut-homing B and T cells, which may become rapidly activated by CCR6+ DCs. CX3CR1 also regulates location of myeloid DCs in Peyer's patches and may promote dendrite protrusion into the lumen as a method of antigen sampling. Consistent with this, CX3CR1 is important for controlling *Salmonella* infection after oral challenge.[155] CCL25/CCR9 signaling regulates gut cryptopatch formation and subsequent positioning of intraepithelial lymphocytes.[218]

CHEMOKINE REGULATION OF THE IMMUNE RESPONSE

Innate Immunity

Platelet-Derived Chemokines

Made primarily during platelet development, stored in platelet α granules and rapidly released during platelet degranulation, CXCL4, CXCL4L1, and CXCL7 may be among the first chemokines to appear at sites of tissue injury

and infection, particularly when there is hemorrhage and vascular damage, and may reach high concentrations.[130,219] CXCL4 aggregates to form tetramers critical for binding to chondroitin sulfate proteoglycans. In contrast, CXCL7 is activated by sequential proteolysis of its *N*-terminus. The preproppeptide form, named platelet basic protein (92 aa), is trimmed during platelet maturation to produce the 85 aa major stored form, named connective tissue activating peptide-III, which is inactive on neutrophils. Connective tissue activating peptide-III is further processed during degranulation to 81 aa β-thromboglobulin, also inactive. This is then cleaved by a cell surface-bound, cathepsin G-like enzyme on neutrophils to form 70 aa CXCL7, which has high homology to CXCL4 (70% aa identity). Thus, CXCL7 may function as an immediate-early mediator of neutrophil recruitment released from platelets at sites of inflammation. Although it is not a prominent leukocyte chemoattractant and does not induce degranulation of neutrophil lysosomal enzymes, CXCL4 is able to induce secondary granule exocytosis and release matrix-degrading enzymes that may facilitate neutrophil penetration of infected or injured tissues. Both CXCL4 and CXCL4L1, the product of the highly homologous non-allelic variant gene of CXCL4, *PF4V1*, are strong angiostatic factors.[220,221] In contrast, another plateletderived chemokine, CXCL12, may be a major determinant of revascularization, as suggested by an ischemic hindlimb mouse model, where its release could be regulated by Kit ligand and thrombopoietin and it functioned to recruit CXCR4+ VEGFR+ hemangiocytes to the site of injury.[222] The ultimate response in inflammation and revascularization may depend on the relative concentration and activities of these counterregulatory chemokines.

Neutrophil-Targeted Chemokines

All seven ELR+ CXC chemokines preferentially recruit neutrophils in vitro by binding to CXCR2. One of these, CXCL8, is also a potent agonist at CXCR1, which is coexpressed at similar levels on neutrophils.[223] These seven chemokines are rapidly inducible but may differ biologically due to temporal and spatial differences in expression, which may provide a mechanism for graded navigation of neutrophils through tissue. Blocking studies in multiple animal models have demonstrated the importance of CXCL8 and CXCR2 in neutrophil accumulation in response to infectious and noninfectious stimuli.[224,225] The role of CXCR1 in vivo has not yet been defined and is difficult to analyze because its major human agonist, CXCL8, is not found in the mouse. In a human blister model, endogenous CXCL8 peaks at ~24 hours, whereas C5a and leukotriene B4, which also recruit neutrophils, appear earlier. Thus the primary role of CXCL8 may be to amplify recruitment of neutrophils initiated by other chemoattractants.

Intradermal injection of CXCL8 in man causes rapid (<30 minutes) and selective accumulation of large numbers of neutrophils in perivascular regions of the skin without causing edema. Tissue-specific transgenic overexpression of mouse CXCL8 paralogues Cxcl1 (KC) and Cxcl2 (MIP-2) results in a similar picture, suggesting that in vivo these factors may recruit cells but not independently activate cytotoxic mechanisms. In vitro, the ability of CXC chemokines to activate neutrophil cytotoxic responses is modest. Instead, they may prolong survival of neutrophils in the setting of bacterial infection and paradoxically provide an intracellular niche in which at least some bacterial species such as *Staphylococcus aureus* may persist.[226] Studies in mice have revealed that αβ CD4+ T cells are critical in providing CXC chemokines that foster abscess formation in several models of experimental *S. aureus* infection and that the absence of these cells results paradoxically in smaller/fewer abscesses with reduced bacterial burden. In addition, pathogens such as *Streptococci* may actively interfere with the action of CXC chemokines by degrading them with specific proteases.[227] Thus, while there is no question that neutrophils are critical in defense against bacterial and fungal pathogens and that CXCR2 agonists are critical for neutrophil trafficking in the setting of infectious disease, the ultimate outcome of infection may be determined by a balance between CXCR2-dependent neutrophil recruitment, niche development, and negative regulatory mechanisms.

CXCL1, 2, 3, 7, and 8 have also been reported to induce basophil chemotaxis and histamine release in vitro, which together with other factors such as complement-derived anaphylatoxins may promote vasodilatation during early stages of the innate immune response.[157] Some CC chemokines can also activate human neutrophils, but this typically requires prestimulation of the cells with IFNγ and other factors able to induce expression of appropriate receptors. Conversely, late apoptotic neutrophils can actively promote the resolution phase of acute inflammation by terminating chemokine signaling through scavenging by CCR5, which is expressed in a manner dependent on caspases and antiinflammatory lipid mediators.[228] In the mouse, CCR1 is an important neutrophil chemotactic receptor and has been demonstrated to function in a sequential manner with the LTB4 receptor for neutrophil recruitment in a model of rheumatoid arthritis.[229]

Monocyte/Macrophage-Targeted Chemokines

Circulating blood monocytes can be divided into two principal subsets with distinct migratory properties based on chemokine receptor expression.[230] *Inflammatory* monocytes are short-lived CX3CR1^{lo}CCR2+Ly6C^{hi} cells actively recruited to inflamed tissues in the mouse. These cells correspond to human CD14^{hi}CD16- monocytes. *Resident* monocytes are long-lived CX3CR1^{hi}CCR2-Ly6C^{lo} cells in the mouse, characterized by CX3CR1-dependent engraftment and recruitment to noninflamed tissues. These cells correspond to human CD14^{lo}CD16+ monocytes that are CX3CR1^{hi} but do not express inflammatory chemokine receptors. Both subsets can differentiate into DCs in vivo that stimulate naïve T cells. There are numerous examples of the functional importance of these receptors in the monocyte/macrophage lineage in vivo. Monocyte CCR2 is required for normal bone marrow egress of monocytes to blood under homeostatic conditions in mice, as well as after infection with pathogens such as *Listeria* or West Nile virus.[231,232,233] Both receptors have been linked to human disease, as will be detailed in the

disease section. Monocytes express additional inflammatory chemokine receptors including CCR1, CCR5, CXCR1, and CXCR2. Differentiation in vitro to macrophages is associated with downregulation of CCR2 and induction of CCR5 and CX3CR1. Polarized M1 and M2 subsets of macrophages have been described in keeping with the Th1/Th2 polarization paradigm for T cells. In this regard, the classic anti-inflammatory Th2 cytokine IL-10 is able to downregulate signaling by inflammatory chemokine receptors on macrophages.[234]

Natural Killer Cell-Targeted Chemokines

Human NK cell subsets express unique repertoires of chemokine receptors.[122] The $CD56^{dim}CD16+$ subset, which is associated with high cytotoxic capacity and low cytokine production, expresses primarily CXCR1 and CX3CR1, whereas the minor subset of $CD56^{bright}CD16^{dim}$ cells, which produce large amounts of cytokines but have low killing capacity, preferentially express CCR7.[120] The exact profile of chemokine receptor expression can be modulated by adherence and stimulation ex vivo with IL-2.[121] Cognate chemokines chemoattract NK cells and promote degranulation and killing. The importance of chemokines in NK cell function in vivo is well illustrated by mouse cytomegalovirus infection, a cause of hepatitis. Mouse cytomegalovirus induces CCL3 production in the liver, which is required for recruitment of NK cells. NK cells are the major source of IFNγ in this model, and IFNγ induces CXCL9, which is required for protection. Thus, a cytokine to chemokine to cytokine cascade is required for NK cell-mediated host defense against this pathogen.[235]

Dendritic Cells and Transition to the Adaptive Immune Response

Transition from innate to adaptive phases of the immune response involves antigen uptake by antigen-presenting cells, especially DCs, mediated by Fc and complement phagocytic receptors, as well as pattern recognition receptors, including DC-specific intercellular adhesion molecule and toll-like receptors.[236] Through specific pattern recognition receptor ligands, pathogens may shape the nature and magnitude of the immune response in a specific direction, in part by inducing production of specific sets of chemokines with distinct leukocyte specificities.[6,237]

Chemokine receptor expression and function depends not only on the nature of the inflammatory stimulus, but also on the type of DC. For example, blood-derived plasmacytoid and myeloid DCs express a similar repertoire of inflammatory chemoattractant receptors but they are functional only on myeloid DCs. CCL3, CCL4, and CCL5 may be particularly important for recruiting additional mononuclear phagocytes and DCs to sites of infection. This can amplify the late stage of the innate immune response, and in the extreme may devolve into endotoxic shock. Consistent with this idea, genetic disruption of the CCL3/CCL4/CCL5 receptor CCR5 renders mice relatively resistant to lipopolysaccharide-induced endotoxemia. CCR4-/- mice are also resistant to endotoxic shock; this is associated with reduced macrophage extravasation to the peritoneum and production of the CCR4 ligand CCL17, which can be produced by DCs.[238]

Adaptive Immunity

Afferent Trafficking to Secondary Lymphoid Tissue

The homeostatic receptors CXCR4, CXCR5, and CCR7 and their ligands are major regulators of lymphoid development and the adaptive immune response.[20,123,239,240,241,242] DC maturation in peripheral tissues is associated with downregulation of inflammatory receptors, which may be important for recruitment, migration, and retention in the periphery, and reciprocal upregulation of CCR7, which mediates mature DC migration via afferent lymphatics to draining lymph nodes in response to CCL21 expressed on lymphatic endothelial cells. Inflammatory receptors may also contribute as demonstrated for CCR2 on Langerhans cells in a mouse model of *Leishmania* infection.[243]

With regard to lymphocytes, CCR7, and to a lesser extent CXCR4, mediate both B- and T-cell entry from blood into lymph node. In lymph node and Peyer's patch T zones, CCL21 is produced by high endothelial venule (HEV) endothelial cells, whereas CCL19 (the second CCR7 ligand) and the CXCR4 ligand CXCL12 are produced by adjacent stromal cells. All three chemokines are displayed on the luminal and abluminal sides of the HEV appropriately positioned to mediate transendothelial migration from the blood of naïve B- and T-lymphocytes, which both coexpress CCR7 and CXCR4.[244,245] CCR7 plays a dominant role in mediating B- and T-cell adhesion, but CXCR4 also contributes. *Ccr7-/-* mice and the *plt* mouse, which is naturally deficient in Ccl19 and the Ccl21 isoforms expressed in secondary lymphoid organs (see Fig. 28.2 for *plt* locus description),[111] have similar phenotypes: atrophic T-cell zones populated by a paucity of naïve T cells. This plus the failure of activated DCs to migrate to lymph node from the skin of these mice, explains why contact sensitivity, delayed type hypersensitivity and antibody production are severely impaired.

CXCR5 is expressed on all peripheral blood and tonsillar B cells, but only on a fraction of bone marrow B cells. Its ligand CXCL13, produced selectively by HEV endothelial cells and follicular stromal cells, is constitutively displayed on follicular HEV. The CXCL13/CXCR5 axis supports ~50% of the signaling required for B cell entry from blood to Peyer's patch; CXCR4 may also contribute.[244,245] In *Cxcr5-/-* mice, B cells do not migrate to lymph node, Peyer's patches are abnormal, and inguinal lymph nodes are absent. CXCL13 is also required for B1 cell homing, natural antibody production, body cavity immunity, and lymphoneogenesis in the setting of autoimmunity.[246,247] *Cxcr5-/-* mice still can produce antibody, perhaps in part because B cells and follicular DCs, by an unknown mechanism, are able to form ectopic germinal centers within T zones of the periarteriolar lymphocyte sheath of spleen. In Peyer's patches, B-cell entry is also dependent on CCR7 and CXCR4.

CXCR5 and CCR7 are probably not the only chemokine receptors responsible for afferent trafficking of leukocytes to lymph node. CCL9 has been reported to mediate monocyte homing.[248] In addition, inflamed peripheral tissues

may exert "remote control" for monocyte homing to draining lymph nodes from the blood by "projecting" their local chemokine profile to HEVs of the draining lymph node.[249] Migration of T cells to splenic red pulp may involve local production of CXCL16.[52] NK-T cells and activated CD4+ and CD8+ T cells are found in this area and express the CXCL16 receptor CXCR6. CXCL16 is also made by DCs in the T zone, and CXCR6 is also found on intraepithelial lymphocytes. Thus, CXCL16 may function in T cell-DC interactions and in regulating movements of activated T cells in the splenic red pulp, and in peripheral tissues.

Migration within Lymph Node Microenvironments

CXCR5 and CCR7 also appear to be important for lymphocyte movement within the lymphoid microenvironment. So-called follicular help T cells, a CD57+ subset, lack CCR7 but express CXCR5, which appears to facilitate migration from the T zone following activation to the follicles in response to CXCL13, where they provide help for B-cell maturation and antibody production. Reciprocally, B cells activated by antigen in the follicles upregulate CCR7 and move toward the T zone in response to CCL21.[250] Thus B-T interaction may be facilitated by reciprocal movement of these cells, which may be determined in part by the balance of chemokines made in adjacent lymphoid zones.

CXCR4 signaling may also be important in naïve and memory B cell trafficking to germinal centers. An active chemokine-dependent process has also been identified for CD4+ T cell-dependent activation of rare antigen-specific naïve CD8+ T cells.[141] After immunization in a TCR-transgenic mouse model, but before antigen recognition, naïve CD8+ T cells in immunogen-draining lymph nodes upregulate CCR5, permitting the cells to home to sites of CD4+ T cell-DC interaction in lymph nodes, where CCL3 and CCL4 are produced. Interference with this process inhibits antigen-specific memory CD8+ T-cell generation. There is also evidence that T-cell zone chemokines such as CCL21 are bound to the surface of lymph node DCs in vivo and function to capture and prime naïve T cells for activation by peptide-MHC. Thus T cells are costimulated "in trans" and sequentially after initial engagement with their chemokine-rich environment.[251]

DCs appear to swarm to T-cell zones in lymph node by using immobilized CCL21 for adhesive random migration and soluble CCL21 for chemotactic steering, both acting through CCR7 activation.[252,253] CCL21 is produced by fibroblastic reticular cells in T-cell zones and is immobilized on the reticular network by GAG interaction with its extended C-terminal domain. The chemokine domain appears to be cleaved from the GAG binding domain by an undefined protease. CCL19, the other CCR7 ligand, lacks a C-terminal domain extension and may preferentially function chemotactically as a soluble ligand, not haptotactically bound to surface.

Efferent Trafficking

Critical determinants of lymphocyte egress from lymph node are sphingosine-1-phosphate and its receptor S1P.[19,20] Naïve lymphocytes that do not encounter antigen continue to recirculate between the blood and secondary lymphoid tissue without acquiring any tissue-specific homing properties. In contrast, most antigen-stimulated T cells die by apoptosis. The survivors may be divided into functionally distinct subsets that preferentially express certain chemokine receptors. Within the CD4+ subpopulation, at least three memory subsets and two primary effector subsets can be distinguished. The memory subsets include follicular help T

cells, described previously, and effector memory (T_{EM}) and central memory (T_{CM}) cells.[254] Memory cells classically express CD45RO. In addition to this, classic T_{CM} cells also express L-selectin (CD62L) and CCR7, which are thought to mediate homing of the cells from blood to secondary lymphoid organs across HEVs; these cells are not polarized and lack immediate effector function. Instead, they are thought to interact with DCs in lymph node and differentiate into T_{EM} upon secondary stimulation. T_{EM} cells lack L-selectin and CCR7, and were originally proposed to differentiate from T_{CM} and to traffic through peripheral tissues as immune surveillance cells, rapidly releasing cytokines in response to activation by recall antigens.

It is increasingly clear that the original T_{CM}/T_{EM} paradigm requires revision, in part because CCR7+ effector memory cells have been detected in inflamed tissues and CCR7 facilitates their exit into lymphatics.[255,256,257,258] Also, rather than a dualism with a single precursor-product relationship, analysis of freshly isolated human peripheral blood CD4+ T cells has suggested that memory cell differentiation may be a continuum with multiple branch points arising probabilistically, giving rise to many subpopulations that preferentially express certain chemokine receptors.[259]

Upon activation, the classic polarized effector subsets, Th1 and Th2, downregulate CXCR5 and CCR7 and upregulate inflammatory chemokine receptors.[260] This switch facilitates exit from lymph node via efferent lymphatics and homing to inflamed sites. In vivo, Th1 cells, which by the simplest definition secrete IFNγ but not IL-4 and control cellular and humoral immunity to intracellular pathogens, more frequently express CXCR3, CXCR6, CCR2, CCR5, and CX3CR1 than Th2 cells. In contrast, Th2 cells, which express IL-4 but not IFNγ and are associated with cellular and humoral immunity to extracellular pathogens and allergic inflammation, more frequently express CCR3, CCR4, and CCR8 than Th1 cells. CXCR3 expression is dependent on T-bet expression and has been most consistently associated with Th1 immune responses and Th1-associated disease. Consistent with this, its agonists CXCL9-11 are highly induced by IFNγ but not by IL-4. Thus, in Th1 immunity there is the potential for a positive feedback loop in which IFNγ induces production of CXCL9-11 that then recruits CXCR3+ Th1 cells that produce IFNγ (see Fig. 28.7). The "Th1 chemokines" may also help maintain Th1 dominance in part through their ability to block CCR3. Specific cytokines, microenvironments, and inflammatory stresses may differentially regulate CXCL9-11 expression, which may account for specialized biologic roles. For example, though all three chemokines are inducible by IFNγ, CXCL10 and CXCL11 but not CXCL9 are also inducible by type I IFN. There is evidence that Th1 and Th2 cell recruitment into tissue is

differentially regulated by Stat1 and Stat6, respectively, and that Stat1 controls recruitment of Th1 cells through the induction of CXCR3 ligands and CXCL16.[261]

Conversely, research on chemokine expression and targets has led to a model of Th2 immunity in which IL-4 and IL-13 made at inflamed sites in the periphery may induce production of CCL7, CCL11, and other CCR3 ligands, the CCR4 ligands CCL17 and CCL22, and the CCR8 ligand CCL1. CCR3 is expressed on a subset of Th2 T-lymphocytes as well as on eosinophils and basophils, the three major cell types associated with Th2-type allergic inflammation and Th2 cells are associated with CCR4 expression. Arrival of Th2 cells amplifies a positive feedback loop through secretion of additional IL-4. Moreover, CCL7 and CCL11 may block Th1 responses by antagonizing CCR2, CXCR3, and CCR5. Many chemokine receptors have been identified on CD4+ regulatory T cells, including CCR4, CCR5, and CCR8. CCR5 has been shown to play an important role in homing of these cells to skin during *Leishmania major* infection, favoring pathogen persistence.[262]

All Th17 cells express CCR6 controlled by the signature Th17 transcription factor Rorγt; CCR6 may also participate in a positive feedback loop with tissue cells and Th17 cells themselves expressing its ligand CCL20.[263,264] The CCR6+ subset of human CD4+ T cells is much larger, however, and includes IL-22-producing, IL-17-negative skinhoming memory T cells and IL-10-producing, autoreactive memory T cells with context-dependent regulatory function.[265,266]

Some chemokines appear to regulate not just trafficking but also T-cell polarization at least in certain contexts. CCL2 and its receptor CCR2 have been most extensively studied in this regard, but the results are complex and appear at first glance contradictory as in vivo CCR2 is strongly associated with Th1 immune responses and CCL2 is associated with Th2 responses.[126] CCL2 appears to promote Th2 polarization directly, by inhibiting IL-12 production in monocytes, and by enhancing IL-4 but not IFNγ production in memory and activated T cells. Thus, CCL2 influences both innate immunity, through effects on monocyte trafficking, and adaptive immunity, through control of T helper cell trafficking and potentially T-cell polarization. In the case of aerosol challenge with *M. tuberculosis* in *Ccr2-/-* mice, DC migration to draining lymph node is markedly impaired which preempts any direct effects of CCL2 on T cells. Why CCL2 and CCR2 have opposite effects on Th polarization is unclear but is most likely due to ligand-receptor promiscuity.

Tissue-Specific Lymphocyte Homing

CLA+ T-lymphocytes, which home to skin, preferentially express CCR4 and CCR10.[267] The CCR4 ligand CCL22 is made by resident dermal macrophages and DCs, whereas the CCR10 ligand CCL27 is made by keratinocytes. Blocking both of these pathways, but not either one alone, has been reported to inhibit lymphocyte recruitment to the skin in a DTH model, implying that in this model these two molecules act redundantly and independently of inflammatory chemokines.[268]

Homing to small intestine is determined in part by T-lymphocyte expression of the integrin $\alpha_4\beta_7$ and CCR9. The $\alpha_4\beta_7$ ligand MAdCAM-1 and the CCR9 ligand CCL25 colocalize on normal and inflamed small intestinal endothelium, and most T cells in the intraepithelial and lamina propria zones of the small intestine express CCR9. These cells, which are mainly γδ TCR(+) or CD8αβ(+)αβTCR(+), are reduced in number in small intestine from *Ccr9-/-* mice. CCL20 and its receptor CCR6 are also important in gut mucosal immune responses. CCL20 is constitutively expressed in follicle-associated epithelial cells overlying gutassociated lymphoid tissue (GALT) inductive sites (Peyer's patches and isolated lymphoid follicles), but can also be induced in GALT under inflammatory conditions. It is important for GALT development and for B and DC homing to GALT. CCR6+ DCs recruited to the dome region of Peyer's patches upon invasion of follicle-associated epithelial cells by an enteric pathogen have been shown to mediate rapid activation of pathogen-specific T cells.[269]

As B cells differentiate into plasma cells, they also downregulate CXCR5 and CCR7 and exit the lymph node. B immunoblasts expressing immunoglobulin (Ig)G coordinately upregulate CXCR4, which promotes homing to the bone marrow, whereas B immunoblasts expressing IgA specifically migrate to mucosal sites.[270] Like gut-homing T cells, gut homing IgA-secreting B immunoblasts express $\alpha_4\beta_7$ integrin and CCR9 and respond to CCL25. Intestinal DCs may help shape mucosal immunity by generating gut-homing IgA-secreting B cells through the synergistic action of several mediators, including retinoic acid, IL-5, and IL-6.[271,272]

CHEMOKINES AND DISEASE

There is a vast literature correlating the presence of chemokines with diverse human diseases and delineating diverse phenotypes of chemokine and chemokine receptor knockout mice (see Table 28.7). Due to space limitations, this section will address a small subset of these diseases, including ones with strong evidence in humans for prominent chemokine involvement (Table 28.8).

Human Immunodeficiency Virus

HIV infection requires fusion of the viral envelope to a target cell membrane, a process that is initiated by direct binding of the HIV envelope glycoprotein gp120 to both CD4 and a coreceptor on the target cell.[30,32,273] Although many chemokine receptors and related GPCRs can function as coreceptors in vitro, CCR5 and CXCR4 appear to be the most relevant on primary cells (Fig. 28.9). Their interaction with CD4 may be constitutive and stabilized by gp120. The usage of these receptors is so important that HIV strains are now functionally classified and named according to their specificity for CXCR4 (X4 strains), CCR5 (R5 strains), or both (R5X4 strains).

The importance of CCR5 in clinical HIV/acquired immunodeficiency syndrome (AIDS) was established at the population level by the seminal discovery that *CCR5Δ32*, a nonfunctional allele founded more than 5000 years ago in Caucasians and now present in ~20% of North American

Caucasians, is a strong AIDS restriction factor, protecting homozygotes from initial infection and slowing the rate of progression to AIDS in infected heterozygotes.[274,275,276] Additional genetic risk factors affecting the rate of HIV disease progression have been identified in the CCR5 signaling system, including single nucleotide polymorphisms in the promoters for *CCR5* and its ligand *CCL5*, and variation in the gene copy number of the CCR5 ligand CCL3L1.[110,114,277] The pattern of genetic variation at *CCR5Δ32* is most consistent with neutral evolution.[278] *CCR5Δ32* homozygotes appear healthy as do unstressed CCR5 knockout mice. These observations provided proof-of-principle for the central role of CCR5 in

HIV transmission and progression and for development of the FDA-approved CCR5 antagonist maraviroc in HIV/AIDS[36,37] (Fig. 28.10). In addition, a patient with HIV and leukemia was fortuitously transplanted after cytoreductive therapy with bone marrow from a *CCR5Δ32* homozygous donor in February 2007 and as of January 2012 had remained well off antiretroviral therapy with undetectable viral load.[279,280] This has fortified efforts to develop zinc finger nuclease and other genetic methods to block CCR5 in patients.

TABLE 28.8 Chemokines and Human Disease

Molecule	Disease	Mechanism	Mutation
CCR5	HIV/AIDS	Cell entry	*CCR5Δ32*
	West Nile virus infection	Immune control	
	Rheumatoid arthritis	Inflammation	
	Chronic renal allograft rejection	Inflammation	
CXCR4	HIV/AIDS	Cell entry	None
	WHIM syndrome	Myelokathexis	Autosomal Dominant
		HPV proliferation	C-terminal truncation
CX3CR1	Cardiovascular disease	Undefined	*CX3CR1-M280*
	Age-related macular degeneration	Microglial cell activation	
DARC	*Plasmodium vivax* malaria	Cell entry	*Fy*
CCL26	Eosinophilic esophagitis	Eosinophil trafficking	SNP
HHV8 ORF74	Kaposi's sarcoma	Angiogenesis	None defined
		Inflammation	
CXCL4	Heparin-induced thrombocytopenia	Autoantibody to CXCL4-heparin complex	Not defined

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; HPV, human papillomavirus; SNP, single nucleotide polymorphism.

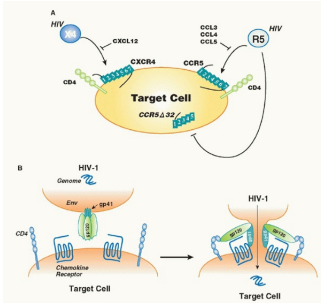

FIG. 28.9. Model of Human Immunodeficiency Virus (HIV) Coreceptor Activity. A: HIV cytotropism is explained by differential usage of CXCR4 and CCR5 as coreceptors. The mutant receptor CCR5Δ32 is not expressed on the cell surface and cannot be used for cell entry by HIV. **B:** Chemokine receptors in a proposed mechanism of HIV entry.

CCR5 is also important in the neuropathogenesis of West Nile virus infection, in both humans and in a mouse model of disease, but unlike HIV, it plays a protective role by facilitating antiviral leukocyte trafficking to the brain.[281,282,283] CCR5-blocking agents could theoretically increase the risk of symptomatic West Nile virus disease in infected patients, particularly in the setting of HIV/AIDS where the immune system is already compromised. Pathogenesis in the mouse model of West Nile virus is also regulated by neuronal CXCL10 through recruitment of CD8+ T cells to the brain.[284] CXCL10 also controls pathogenesis in a mouse model of the related flavivirus dengue virus, both by regulating T-cell recruitment through CXCR3 and by competitively inhibiting viral binding to cell surface heparan sulfate.[285]

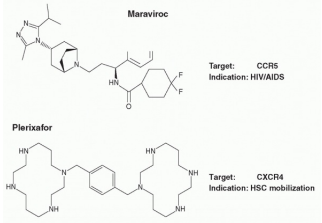

FIG. 28.10. U.S. Food and Drug Administration-Approved Chemokine Receptor Antagonists. Plerixafor was developed by Genzyme, Inc., and is now marketed by Sanofi-Aventis; maraviroc was developed and is marketed by Pfizer.

X4 HIV strains typically do not transmit disease, but instead appear to evolve from R5 quasispecies in a minority of patients late in infection during the transition to clinical disease. Consistent with this, these strains appear more virulent than R5 strains in vitro. The reason is not fully defined; however, it is important to note that the percentage of CD4+ T cells expressing CXCR4 exceeds that expressing CCR5 in vagina, blood, and rectum. Moreover, the X4 envelope protein expressed on CD4+ T cells has been shown to induce autophagic programmed cell death of uninfected bystander cells by binding to CXCR4 on the cell membrane, signaling in a non-Gi-, noncaspase 3-dependent manner.[286] An unresolved question is why X4 strains do not readily transmit disease, given the broad expression of CXCR4 on macrophages and CD4+ T cells.

Malaria

Analagous to CCR5 and HIV, DARC, the 7TM promiscuous chemokine binding protein and minor blood group antigen, is required for infection of erythrocytes by *P. vivax*, a major cause

of malaria. The parasite ligand, which is named the *P. vivax* Duffy binding protein, is expressed in micronemes of merozoites and binds to the *N*-terminal domain of Duffy via a cysteine-rich domain.[287] This interaction is required for junction formation during invasion but not for initial binding or parasite orientation. DARC deficiency, which is due mainly to an inherited single nucleotide substitution named -46C at an erythroid-specific GATA motif in the DARC promoter,[288] is fixed in sub-Saharan Africa but not in other malaria-endemic regions of the world. Accordingly, *P. vivax* malaria is rare in sub-Saharan Africa but common in Central and South America, India, and Southeast Asia. Fixation of the mutation in Africa presumably occurred because of positive selective pressure from malaria. Together with *CCR5Δ32*, DARC -46C is the strongest genetic resistance factor known

for any infectious disease in man. Chemokine control of *P. falciparum* malaria is less well studied although, in an intriguing development, endothelial cell CX3CL1 was reported to bind parasite-infected erythrocytes in vitro,[289] suggesting the parasite expresses a mimic for the CX3CL1 receptor CX3CR1. Conversely, the G glycoprotein of respiratory syncytial virus has been reported to function as a CX3CL1 mimic binding to CX3CR1 to induce chemotaxis and possibly to promote viral entry[290]; human cytomegalovirus encodes US28, a chemokine receptor able to bind CX3CL1, possibly to mediate viral attachment to target cells. Together, these examples show the rich dialogue between hosts and pathogens using the chemokine system as a preferred method of communication.

WHIM Syndrome

WHIM syndrome is a rare combined immunodeficiency disorder caused by autosomal dominant inheritance of gainof-function mutations truncating the C-tail of CXCR4.[291,292] Enhanced function appears to result from CXCR4 dimerization and β-arrestin signaling plus impaired receptor desensitization and internalization.[293,294] This causes exaggeration of CXCR4's normal neutrophil and hematopoietic stem cell retention function in the bone marrow resulting in myelokathexis (neutropenia without maturation arrest). Patients typically have panleukocytopenia but suffer mainly from recurrent sinopulmonary and skin infections caused by pyogenic organisms typically controlled by neutrophils. Hypogammaglobulinemia probably also contributes; however, pathogens typically associated with T-cell deficiency are not a problem. Neutrophils can be mobilized in the setting of infection by unknown mechanisms, so that the condition is debilitating but usually not acutely life-threatening. Patients also develop large numbers of warts due to human papillomavirus, the signature pathogen in the disease and the only problematic virus. This may be caused by virus-induced CXCR4 expression and signaling directly in keratinocytes.[295]

Administration of the drug plerixafor (Mozobil, AMD 3100) (see Fig. 28.10), a selective CXCR4 antagonist, results in mobilization of almost all leukocyte subpopulations, but not erythrocytes or platelets, to the blood in healthy human subjects as well as in patients with WHIM syndrome.[296,297] This provides proof-of-concept for development of CXCR4 inhibitors as mechanism-based therapy, with the goal of restoring signaling to normal, not blocking it entirely, which would heighten safety concerns. Plerixafor was originally developed in combination with granulocyte-colony stimulating factor for mobilization of hematopoietic stem cells for transplantation in patients with multiple myeloma or non-Hodgkins lymphoma receiving cytoreductive therapy, and is now FDA-approved for those indications.[38,298,299] Its use in chronic therapy, as would be necessary in WHIM syndrome, is limited by a very short half-life, parenteral administration, and high cost.

In G6PC3 deficiency, a recently described second rare primary immunodeficiency disorder characterized by neutropenia/myelokathexis and recurrent bacterial infections, the mechanism may also involve increased CXCR4 signaling.[300,301] In this case, however, CXCR4 is indirectly affected by metabolic stress caused by the total absence of glucose-6-phosphatase activity in neutrophils. This increases neutrophil apoptosis and induces high expression of wild-type CXCR4, which is thought to drive the cells back to the bone marrow for destruction, contributing to the neutropenia picture. Unlike WHIM syndrome, G6PC3 patients do not have deficiencies in other leukocyte lineages, due to expression of other glucose-6-phosphatase isoforms in those cells.

Kaposi's Sarcoma

A full discussion of the many virally encoded chemokines and chemokine receptors is beyond the scope of this chapter, but can be found in recent reviews.[76,77] HHV8 ORF74 deserves special mention however. HHV8 encodes three CC chemokines, vMIP-I, II, and III, as well as a constitutively active CC/CXC chemokine receptor named vGPCR encoded by ORF74.[171,302] All of these factors are angiogenic and may contribute to the pathogenesis of Kaposi's sarcoma, a highly vascular multicentric nonclonal tumor caused by HHV8 typically in the setting of immunosuppression such as in HIV/AIDS. Consistent with this, vGPCR induces Kaposi's sarcoma-like tumors when expressed constitutively or inducibly in transgenic mice on endothelial cells.[303] The mechanism may involve signaling through diverse pathways including the nonconventional G protein Gq and phosphorylation of tuberin, which promotes activation of mTOR (mammalian target of rapamycin) through direct and paracrine mechanisms.[304] The latter may include activation of NF-κB and induction of angiogenic factors such as vascular endothelial growth factor and proinflammatory chemokines and cytokines.[305] Thus, this virus appears to have converted a hijacked receptor, probably CXCR2, into a regulator of gene expression. The model identifies rapamycin as a candidate therapeutic in Kaposi's sarcoma.

Atherosclerosis

There is now compelling genetic evidence from knockout mice and human disease cohorts that CX3CR1 is a significant proatherogenic factor. The mechanism remains unclear but may involve induction of CX3CL1 on vascular smooth muscle cells, and recruitment and retention of CX3CR1-positive monocytes to plaque through the dual chemotactic and adhesive functions of this ligand-receptor pair.[306] The evidence in man is based in part on consistent association of a defective receptor variant named CX3CR1 M280 with reduced risk of cardiovascular disease endpoints in multiple cohort studies; mice lacking Cx3cr1 on the *ApoE-/-* background fed a Western diet are also at reduced risk of developing vascular lesions.[307,308,309,310,311] There is also extensive evidence for a proatherogenic role for CCL2 and its receptor CCR2.[312,313,314]

Adoptive transfer studies of bone marrow from knockout mice have also revealed a role for CCR5 and CXCR2 in mouse models of atherosclerosis. CXCR2 may work by promoting monocyte adhesion to early atherosclerotic endothelium, through interaction with its mouse ligand KC and activation of the VLA-4/vascular cell adhesion molecule-1 adhesion system.[315,316] Immunoneutralization experiments have revealed

a role for CCR7 on foam cells in a mouse model of atheroregression, and statins may be protective in part through this pathway.[317,318] Surprisingly, CCR1 and CXCL16 deficiency appeared to increase inflammation in atherosclerosis models.[319] CXCL10 has also been implicated in atherogenesis in a mouse model, possibly acting by recruitment of CXCR3+ Th1 cells.[320] Lack of CXCL10 was also associated with a relative increase of regulatory T cells in plaque. CCR6 has also been implicated as a proatherogenic factor possibly acting at the level of monocyte distribution and trafficking.[321]

Age-Related Macular Degeneration

CX3CR1 is particularly important in microglial cell migration and activation in the inflamed central nervous system.[3] Mice lacking Cx3cr1 develop retinal lesions similar to macular degeneration. Human age-related macular degeneration is associated with a loss-of-function mutant allele in *CX3CR1*,[322,323,324,325] The mechanism appears to involve dysregulated activation of microglial cells in the retina. CCR3 has also been detected in human age-related macular degeneration, and targeting Ccr3 was effective in a mouse model of age-related macular degeneration.[326]

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia is a human autoimmune disease directly linked mechanistically to chemokines.[327] An established risk factor for thromboembolic complications of heparin therapy, heparin-induced thrombocytopenia occurs in 1% to 5% of patients treated with heparin and is the result of autoantibodies that bind specifically to CXCL4-heparin complexes in plasma.

In general, T cell-dependent autoimmune diseases in man such as psoriasis, multiple sclerosis, rheumatoid arthritis, and type I diabetes mellitus are associated with inflammatory chemokines and tissue infiltration by T-lymphocytes and monocytes expressing inflammatory chemokine receptors. There is an extensive literature exploring chemokine mechanisms in mouse models of these diseases.[128,198,323,328,329,330,331,332,333,334,335,336] Rheumatoid arthritis has been consistently negatively associated with homozygous *CCR5Δ32*, suggesting that CCR5 is important in pathogenesis in humans.[337]

The eosinophil selective CCL26/CCR3 axis has been implicated in eosinophilic esophagitis, based on high expression of CCL26 in the esophagus from patients, association of a

polymorphism in *CCL26* with human disease, and resistance of *Ccr3*-/- mice to experimental eosinophilic esophagitis.[338,339]

Acute Neutrophil-mediated Inflammatory Disorders

Many neutrophil-mediated human diseases have been associated with the presence of CXCL8, including psoriasis, gout, acute glomerulonephritis, chronic obstructive pulmonary disease, actue respiratory distress syndrome, rheumatoid arthritis, and ischemia-reperfusion injury. Systemic administration of neutralizing anti-CXCL8 antibodies is protective in diverse models of neutrophil-mediated acute inflammation in the rabbit (skin, airway, pleura, glomeruli), providing proof-of-concept that CXCL8 is a nonredundant mediator of innate immunity and acute pathologic inflammation in these settings.[224,225] Moreover, CXCR2 knockout mice are less susceptible to acute urate crystal-induced gouty synovitis,[340] and SB-265610, a nonpeptide small molecule antagonist with exquisite selectivity for CXCR2, prevents neutrophil accumulation in the lungs of hyperoxia-exposed newborn rats.[341] Together, the results identify CXCL8 and its receptors as candidate drug targets for diseases mediated by acute neutrophilic inflammation. CXCR2 knockout mice also have delayed wound healing.[342]

Transplant Rejection

An advantage of transplant rejection over other animal models of human disease is that, in both the human and animal situation, the time of antigenic challenge is precisely known. The most extensive analysis of the role of chemokines in transplant rejection has been carried out in a major histocompatibility complex class I/II-mismatched cardiac allograft rejection model in the mouse, which is mediated by a Th1 immune response.[343] Similar sets of inflammatory chemokines are found in the mouse model as in the human disease. Analysis of knockout mice has demonstrated that while multiple chemokine receptors contribute to rejection in this model, there is a marked rank order: CXCR3 >> CCR5 > CCR1 = CX3CR1 = CCR2. Most impressively, rejection and graft arteriosclerosis do not occur if the recipient mouse, treated with a brief, subtherapeutic course of cyclosporin A, is *Cxcr3*-/- or if the donor heart is *Cxcl10*-/-, identifying this axis as a potential drug target.[344] Neutralization of Cxcl9, a Cxcr3 ligand that appears later than Cxcl10, can also prolong cardiac allograft survival and delay T-cell infiltration and acute rejection in class II major histocompatibility complex-disparate skin allografts.[345] In man, CCR5 may be important in chronic kidney allograft rejection, as individuals homozygous for *CCR5Δ32* are underrepresented among patients with this outcome in a large German kidney transplantation cohort.[346]

Allergic Airway Disease

Chemokine receptors associated with asthma include CXCR2, CXCR4, CCR3, CCR4, and CCR8.[347,348,349] CCR3 is present on eosinophils, basophils, mast cells, and some Th2 T cells, and CCR4 and CCR8 identify airway T cells of allergen-challenged atopic asthmatics. Ccr8 knockout mice have reduced allergic airway inflammation in response to three different Th2-polarizing antigens: *Schistosoma mansoni* soluble egg antigen, ovalbumin, and cockroach antigen.[350] A role for the CCR3 axis in asthma has been supported by Ccl11 neutralization in guinea pig and Ccr3 gene knockout in mouse. The net effect of *Ccr3* knockout was expected to be more profound; however, the exact phenotype depends dramatically on the specific method of sensitization and challenge due to complex and opposite effects on eosinophil and mast cell trafficking.[351,352] CCR3 and its ligands have also been clearly shown to play a critical role in an *Aspergillus*-induced chronic allergic airway disease mouse model, in part due to failure of eosinophils to traffic to the lung.[353] CCR6 also appears to play a role, as *Ccr6*-/- mice have decreased allergic airway inflammation in response to sensitization and challenge with cockroach antigen, which

is consistent with the induction of its ligand CCL20 in this model. The CXCL12/CXCR4 axis may be more than a homeostatic regulator since neutralization of either ligand or receptor resulted in decreased lung eosinophilia and airway hyperreactivity in a mouse model of allergic airway disease.[354]

Cancer

Many chemokines have been detected in situ in tumors, and cancer cells have been shown to produce chemokines and express chemokine receptors.[355] However, the exact role played by endogenous tumor-associated chemokines in recruiting tumor-infiltrating lymphocytes and tumorassociated macrophages and in promoting an antitumor immune response has not been delineated. On the contrary, there are data from mouse models suggesting that the overall effect may often be to promote tumorigenesis through additional effects on cell growth, angiogenesis, apoptosis, immune evasion, and metastasis.[234,356] Controlling the balance of angiogenic and angiostatic chemokines may be particularly important.[357] This has been shown in several instances, including human non-small cell lung carcinoma, in which the ratio of ELR to non-ELR CXC chemokine expression is high, and where in a *Scid* mouse model neutralization of endogenous tumor-derived CXCL8 (angiogenic) could inhibit tumor growth and metastasis by about 50% through a decrease in tumor-derived vessel density, without directly affecting tumor cell proliferation. Chemokine receptors on tumor cells have been shown to directly mediate chemokine-dependent proliferation, for example in the case of CXCL1 in melanoma, and metastasis, in the case of CXCR4 in a mouse model of breast cancer and glioblastoma, and CXCR4 in human breast cancer cells, responding to CXCL12 produced by carcinoma-associated fibroblasts.[358] Moreover, chemokines may function in cancer by reprogramming cancer-associated stromal fibroblasts to a senescent protumorigenic state, as shown in ovarian cancer for CXCL1.[359] It remains to be seen how general and important these effects are for human cancer.

THERAPEUTIC APPLICATIONS

Chemokines and Chemokine Receptors as Targets for Drug Development

The two FDA-approved drugs targeting the chemokine system, plerixafor (CXCR4) and maraviroc (CCR5), are both small molecules developed for surprising indications, hematopoietic stem cell mobilization from bone marrow in cancer and HIV/AIDS (see Fig. 28.10), respectively, as discussed previously.[36,37,38] Despite major investment, there has not been success in therapeutically targeting the chemokine system for expected indications, such as acute and chronic inflammation or cancer. For these areas, despite the ability of the pharmaceutical industry to develop many orally available high potency small molecule chemokine receptor antagonists and other chemokine-blocking agents, there are major obstacles to clinical application, including the issue of inflammatory chemokine redundancy, difficulties in optimizing bioavailability and timing in patients, and the unreliability of many preclinical disease models in predicting the best indications and targets.[360]

Chemokines as Biologic Response Modifiers

Both inflammatory and homeostatic chemokines are being evaluated for therapeutic potential as biological response modifiers, acting mainly as immunomodulators or as regulators of angiogenesis.[361,362,363,364,365,366,367,368,369] Studies to date have not revealed major problems with toxicity, and efficacy has been observed in animal models of cancer, inflammation, and infection. To date, clinical trials in cancer and stem cell protection have been disappointing. Chemokines are also being developed as vaccine adjuvants, delivered either as pure protein, immunomodulatory plasmid, or as recombinant protein within antigen-pulsed DCs. Chemokine gene administration has also been shown to induce neutralizing antibody against the encoded chemokine and has successfully blocked immune responses and improved experimental autoimmune encephalomyelitis and arthritis scores in rodent models.

Many chemokines, when delivered pharmacologically as recombinant proteins or by plasmid deoxyribonucleic acid or in transfected tumor cells, are able to induce immunologically mediated antitumor effects in mouse models and could be clinically useful. Mechanisms may differ depending on the model but may involve recruitment of monocytes, NK cells, and CD8+ cytotoxic T cells to tumor. Chemokines may also function as adjuvants in tumor antigen vaccines. Chemokine-tumor antigen fusion proteins represent a novel twist on this approach that facilitates uptake of tumor antigens by antigen-presenting cells via the normal process of ligand-receptor internalization. Non-ELR CXC chemokines such as CXCL4 also exert antitumor effects through angiostatic mechanisms.

CONCLUSION

The immune system is a system in motion, and the study of chemokines has provided major new insights into how order is maintained as cells enter a tissue, traffic to targets, and in some cases leave and recirculate. In addition, chemokines are increasingly appreciated as multifunctional cytokines, playing large roles in some cases such as CXCL12 in development, and perhaps smaller or less well-appreciated ones in immune activation processes. A major challenge for the future is to deepen basic knowledge of chemokine-mediated immunoregulation as a way to advance new therapeutics for immunologically mediated disease.

ACKNOWLEDGMENTS

This review was supported with funding from the Division of Intramural Research, National

Institute of Allergy and Infectious Disease. I am grateful to Hisayuki Nomiyama of Kumamoto University for advice regarding Figure 28.2; Steven Tsang of the National Institute for Allergy and Infectious Diseases for creating the dendrogram in Figure 28.3; and Joshua Farber of the National Institute for Allergy and Infectious Diseases for providing Figure 28.7.

Chapter 29

Helper T-Cell Differentiation and Plasticity

John J. O'Shea

INTRODUCTION

Cluster of differentiation (CD)4 T cells are critical for the elimination of microbial pathogens, but different types of microbes demand distinct responses. To effectively combat these microbes, CD4 T cells differentiate to form subsets of activated cells with specific characteristics. These discrete subsets of CD4 T cells in turn cause the recruitment of different types of inflammatory cells. Each type of inflammatory cell is adapted to eliminate particular types of microorganisms, and this cooperation of T-lymphocytes with other effector cells links adaptive and innate responses for optimal host defense.

In this respect, the action of CD4 T cells role is largely indirect in that they primarily exert their effect by acting on other cells. For this reason, CD4 T cells are referred to as “helper cells,” which can influence macrophages, B cells, CD8 T cells, natural killer (NK) cells, and other effector cells. The “help” provided by CD4 comes largely in the form of cytokines; however, the production of cytokines is a tightly controlled process: distinct subsets of CD4 T cells secrete characteristic repertoires of cytokines. That is, after activation, CD4 T cells divide, differentiate, and adopt restricted patterns of gene expression, which depend upon the nature of the offending microbial pathogen. Consequently, depending upon whether the pathogen is an intracellular microbe, a worm, or an extracellular bacteria or fungus, different types of activated CD4 T cells are generated. Sometimes though, helper cells are not so helpful insofar as CD4 T cells are also important drivers of autoimmunity.

In this chapter, the different fates available to CD4 T cells will be discussed, as will the molecular mechanisms underlying their specification. The degree to which T cells exhibit characteristics of terminal differentiation versus plasticity will also be considered, as will the mechanisms underlying commitment versus flexibility. Finally, the contribution of different helper T-cell subsets to immune-mediated disease will also be discussed.

FROM THE THYMUS TO THE PERIPHERY

Following maturation and selection in thymus, single positive CD4 T cells exit the thymus and migrate through blood to secondary lymphoid tissues including the spleen, lymph nodes, and mucosal-associated lymphoid tissues.[1,2] These tissues and organs are composed of zones that are enriched with T- or B-lymphocytes: in the lymph node, the paracortical region contains T cells and dendritic cells (DCs), whereas in the spleen, T cells and DCs reside within the white pulp in the periarteriolar lymphoid sheath.

The trafficking and retention of CD4 T cells in secondary lymphoid tissue is dependent upon selective expression of chemokine receptors and adhesion molecules.[3] In lymph nodes and Peyer patches, T cells enter the tissue via specialized blood vessels termed high endothelial venules (HEVs). HEVs express L-selectin and CCL21. Naive T cells, T cells that have yet to encounter foreign antigen, express ligands for L-selectin and CCL21, namely CD62L and CCR7. These ligands promote the entry of naïve T cells into these tissues.[4,5,6] Extravasation of naïve lymphocytes through HEVs is dependent upon intercellular adhesion molecules that bind the integrin lymphocyte function-associated antigen-1. Within secondary lymphoid organs, naïve T cells are retained in the T-cell-rich zones by the chemokines CCL21 and CCL19.

If no antigen is encountered, naïve T cells exit the lymph node through the efferent lymphatic vessels and then return to the bloodstream via the thoracic duct. Egress from lymph nodes (and the thymus) requires the seven transmembrane receptor sphingosine 1-phosphate receptor-1.[7,8] The concentration of sphingosine 1-phosphate is higher in blood, and this provides a concentration gradient for emerging lymphocytes to follow. The immunomodulatory drug fingolimod,[1] a partial agonist of S1P1, acts by blocking egress of T cells from the thymus and lymph nodes.[8] Expression of S1P1 is under the control of the transcription factor KLF2, a factor that promotes the naïve state.[7,9,10] The transcription factor Foxp1 and miR-125b are two additional factor that preserve T-cell naïveté.[11]

In the spleen, naïve T cells enter through terminal arterioles, not HEVs; as a result, expression of CD62L is not required. Migration to the splenic white pulp does require integrin and chemokine receptor signaling. Exit from the spleen is thought to occur by migration from white pulp to red pulp with subsequent entry into blood.

Naïve T cells spend relatively short times in the blood before finding a new secondary lymphoid organ to enter. In the absence of encountering cognate antigen, T cells repeat this

cycle many times over their lifespan. In this stage, they receive survival signals from low-level, or “tonic,” signaling through the T-cell receptor (TCR) provided by self-peptide/major histocompatibility complex (MHC) complexes and interleukin (IL)-7.

ENCOUNTERING ANTIGEN: NAÏVETÉ LOST

Free antigen can travel by blood to the spleen or by lymph via the afferent lymphatic vessels to lymph nodes. Alternatively, pathogen-associated inflammatory signals activate nonlymphoid resident tissue DCs, causing them to mature. Activated DCs express the receptor CCR7 and migrate to lymph nodes in a CCL21-dependent manner. B cells can also serve as antigen-presenting cells (APCs). Within the lymph nodes, APCs activate naïve T cells bearing the appropriate TCRs in a process that involves direct physical contact involving an array of receptor/ligand interactions including: specific foreign peptide/MHC complex recognized by the TCR; costimulatory molecules CD80, CD86 (ligands for CD28), and adhesion molecules such as CD2; and lymphocyte function-associated antigen-1. In this phase of activation, T cells have prolonged interactions with APCs that last up to several hours.[12,13] The ability of CD4 T cells to promote contacts with DCs appears to involve the chemokines CCL3 and CCL4, and ligation of CD40. The adapter molecule SAP (encoded by *SH2D1*), which regulates signaling by signaling lymphocytic activation molecule-family molecules, promotes stable interactions between T and cognate B cells in nascent germinal centers in the lymph node.[14]

Within the first 24 hours of encountering antigen, T cells secrete cytokines such as IL-2 and tumor necrosis factor (TNF)α. Transcription factors activated by TCR signals include NF-κB family members, NFAT proteins, and AP-1, which are critical for cytokine production. At approximately 25 to 30 hours after initial antigen presentation, T cells begin to divide and proliferate. This is followed by the hallmark of lymphocyte activation: clonal expansion of T cells expressing TCRs that recognize cognate peptide.

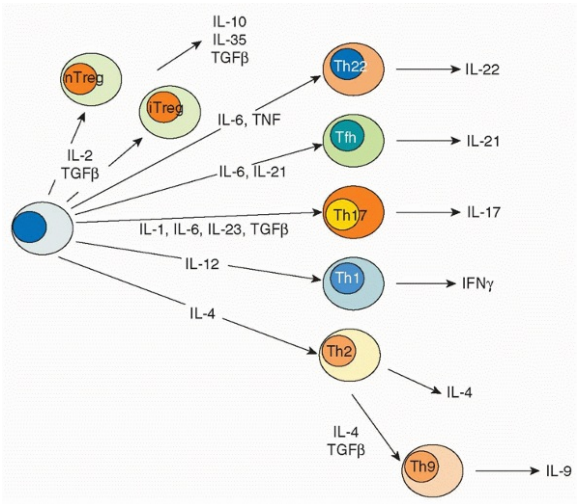

FIG. 29.1. Helper T Cell Fates. In response to the distinct cytokine milieux elicited by different microbial pathogens, naïve T cells become specified to produce selective cytokine repertoires. For instance, intracellular pathogens can induce production of interleukin (IL)-12, which acts via STAT4 to promote differentiation of Thelper (Th)1 cells that selectively produce interferon-γ and not other cytokines. Likewise, helminthes induce IL-4 production, which acts via STAT6 to drive cells toward a Th2 phenotype characterized by IL-4 secretion. Fungi and extracellular bacteria elicit secretion of IL-23 and IL-6, which activate STAT3 and produce CD4 cells that produce IL-17, so-called Th17 cells. Each of these effector cells express transcription factors that enforce commitment to these distinctive phenotypes. These transcription factors can be referred to as “master regulators.” Other cluster of differentiation (CD)4 T cells reside in germinal centers and provide help to B cells. This subset of CD4 T cells is termed follicular helper cells. Another subset of CD4 T cells arises in the thymus and expresses the transcription factor Foxp3. These cells are termed natural regulatory T cells. Foxp3 can also be induced in cells in the periphery and these cells are termed induced Treg cells. Foxp3+ regulatory T cells are critical for constraining immune responses.

Next, T cells must migrate to infected tissues to exert their effect. This occurs by the loss of homing receptors for the secondary lymphoid organs, CD62L and CCR7, and acquisition of new homing molecules such PSGL-1, CD44, CCR5, and CXCR3.[15] At this time, T cells transiently downregulate S1P1. Ligation of the TCR induces expression of the integrins, VLA-4 and VLA-5, which bind to fibronectin in extracellular matrices, Activated T cells also upregulate CD44, which binds to hyaluronan. Consequently, T cells that have encountered

antigen are retained at the extravascular site where the offending antigen is present.

MANY FATES FOR ACTIVATED CLUSTER OF DIFFERENTATION 4 T CELLS

After initial activation, CD4 T cells can differentiate further such that they begin to selectively produce certain cytokines and not others. A major driver of the selective differentiation of CD4 T cells to populations of cells with distinctive cytokine production is the cytokine milieu generated by DCs and other innate cells. The resultant T cells tend to preserve their phenotype and with time maintain their distinctive phenotypes in a cell-autonomous manner. In this respect, the acquisition of the distinct fates can be thought of as a process of lineage commitment, although the extent to which activated T cells are terminally differentiated or retain a flexible repertoire is the topic of intense ongoing research.

Classically, T cells were viewed as having two major fates: Thelper1 (Th1) cells, which selectively produce interferon (IFN)-γ, and Th2 cells, which produce IL-4[16,17,18,19,20] (Fig. 29.1 and Table 29.1). In addition to a stereotypic pattern of cytokine production, these lineages express a "master regulator"

P.710

P.711

transcription factor responsible for the distinctive pattern of gene expression.[21,22] Recently, though, newer fates for helper T cells have been recognized, and they are designated based on expression of their eponymous, signature cytokines: Th17, Th22, and Th9 cells.[23] These newly appreciated subsets can also express characteristic, lineage-defining transcription factors; however, as will be discussed, the expression of these master regulators is now recognized to be more promiscuous than previously appreciated. In addition to Th1, Th2, Th17, Th9, and Th22 cells subsets are T cells that reside in proximity to B cells in germinal centers, so-called follicular helper T (Tfh) cells. However, the distinction between Tfh cells and cytokine-secreting effector subsets is also a topic of intense investigation. Finally, there are various types of regulatory T cells. Each subset will be briefly discussed with respect to their characteristics features, inductive factors, key transcription factors, and negative regulators.

TABLE 29.1 Th Subsets

Subset	Inducing Cytokines	Sensors	Master Regulator Transcription Factor	Other Transcription Factors	Signature Cytokine	Other products	Inhibitors	Function	Host Defense Against:
Th1	IL-12, IFN-γ Also IL-18, IFNα/β, IL-2, IL-27	STAT4, STAT1	T-bet	Hlx Runx3 Ets family Eomes	IFN-γ	TNF IL-12Rβ1 IL-12Rβ2, IL-18R, CXCR3, CCR5	IL-4	Activation of macrophages, enhanced antigen presentation, B-cell class switching to IgG1, IgG3(human), IgG2α, IgG3 (mouse)	Intracellular microbial pathogens (eg, *Mycobacteria*, *Listeria monocytogenes*, *Toxoplasmosis gondii*, viruses
Th2	IL-4 Also IL-2, IL-25, IL-33, TSLP	STAT6, STAT5	GATA3	Maf STAT3, Notch, IRF-4, Gfi-1	IL-4	IL-5, IL-13, IL-24, IL-31, CCR3, CCR4, CCR8, ECM1	IFN-γ Mina	Activation and mobilization of mast cells, basophils, eosinophils, Alternative macrophage activation, barrier function, mucus production, B-cell class switching (IgE)	Helminths
Th17	IL-6, IL-23, TGFβ, IL-1, TLR2	STAT3	Rorγt	Ahr, Batf, IKBζ, IRF-4, Runx1, HIF1α,	IL-17a, IL-17f	IL-21, IL-22, CCR6, CCL20	IL-2, IFN-γ, IL-4, Foxp3, T-bet, Ets-1, Tcf-1	Induction of neutrophilia and recruitment of neutrophils, germinal	Extracellular bacteria: *Staphylococcus aureus*, *Klebsiella pneumoniae*

								center formation	Candida
Th22	IL-6, TNF	STAT3	?	Ahr, Rorgt, Notch	IL-22	CCR10, CCR6, CCR4	TGFβ	Induction of defensins	*Klebsiella pneumoniae*
Th9	IL-4, TGFβ IL-2 IL-25			Pu.1, IRF-4				Mucus production	
Tfh	IL-6, IL-21	STAT3 Also STAT4	Bcl6		PD-1, CXCR5, BTLA, PSGL-1, ICOS		IL-2 Blimp1	B-cell maturation, plasma cell differentiation, Ig class switching	
Treg	IL-2, TGFβ, retinoic acids	STAT5	Foxp3	Runx/CBF, Nrfa2, Foxo1, Foxo3, Eos, Helios	IL-10, TGFβ IL-35		IL-6 Roryt gamma, HIF1a		Maintenance of peripheral tolerance
Tr1	IL-27, IFNα/β, ICOS		?	Ahr					

IFN, interferon; Ig, immunoglobulin; IL, interleukin; TNF, tumor necrosis factor.

As indicated, activated CD4 T cells help eliminate pathogens by recruiting different types of effector cells (macrophages, neutrophils, eosinophils, NK cells, B cells, and CD8 T cells). However, activated, differentiated CD4 T cells are themselves referred to as *effector* cells. While this terminology may be confusing, it refers to the ability of activated CD4 T cells to rapidly produce maximal levels of their signature cytokines. The limitation of the terminology is that it does not refer to an exact, precisely defined step in maturation, but is rather used largely to distinguish them from naïve and "memory" cells. Unlike CD8 T cells, CD4 T cells are much more heterogeneous; not surprisingly, CD4 memory T cells are also more heterogeneous and our understanding of the transition of CD4 effector cells to memory cells is poorly understood. Memory CD4 cells can be broadly classified as effector memory (Tem) and central memory (Tcm).[24,25,26] Tcm express CCR7 and recirculate through lymphoid organs. Tem do not express CCR7 and home to nonlymphoid tissues. Tem rapidly produce cytokines following secondary stimulation, but have limited proliferative capacity. Tcm, by contrast, produce IL-2 and are able to proliferate.

Th1 Cells

Th1 cells are defined by the selective secretion of IFN-γ. IFN-γ activates macrophages to kill phagocytosed microbes. It enhances antigen presentation, by upregulating MHC and costimulatory molecules, amplifying T-cell-dependent immune responses. IFN-γ also further promotes the differentiation of CD4+ T cells to the T_H1 subset and activates NK and CD8 T cells, thereby further enhancing production of IFN-γ and inhibiting T_H2 and T_H17 cell differentiation. IFN-γ promotes B-cell class switching to immunoglobulin (Ig)G1 and IgG3 (IgG2a or IgG3 in mice) and inhibits switching to IL-4-dependent isotypes (eg, IgE). In this manner, Th1 cells effectively protect the host against intracellular pathogens including: *Mycobacteria*, *Toxoplasma*, *Listeria*, and viruses.

In addition to expressing their signature cytokine IFN-γ, T_H1 cells also express high levels of IL-12 receptor β1 and β2 subunits, IL-18 receptor, E-selectin, P-selectin, CXCR3, and CCR5.

T_H1 differentiation is stimulated by intracellular bacteria, viruses, and adjuvants that elicit production of IL-12, IL-18, and type I IFN. IL-12 and to some extent type I IFNs activate the transcription factor STAT4, which has thousands of targets in developing Th1 cells, including the genes encoding IFN-γ, and IL-12 and IL-18 receptors.[27] IFN-γ, acting via STAT1, reinforces Th1 differentiation. STAT4 and STAT1 induce expression of T-bet (encoded by the *Tbx21* gene), which has been termed the master regulator of Th1 cells.[28,29,30,31] Conversely, though, the transcriptional repressor Twist1 is also target of STAT4. Twist1 limits the expression of cytokines including IFN-γ, IL-2, and TNF.[32] Similarly, the protease Furin, which processes the anti-inflammatory cytokine transforming growth factor (TGF)-β, is also regulated by STAT4.[27,33] Thus, STAT4 simultaneously promotes and constrains T-cell activation and thereby limits Th1-mediated immunopathology.

T-bet regulates thousands of genes in Th1 cells.[34,35] It binds to the *Ifng* gene and promotes its expression.[36,37,38] T-bet also directly binds and inhibits expression of the *Socs1*, *Socs3*,

and *Tcf7* (which encodes TCF-1) genes. Interestingly, it can also associate with the repressor Bcl6 and inhibit IFN-γ expression. T-bet also inhibits expression of Rorγt, the master regulator of Th17 cells, by blocking the action of Runx1.[39] T-bet inhibits *Il4* gene expression in a Runx3-dependent manner.[36] T-bet is phosphorylated by Itk, and phosphorylated T-bet binds and inhibits the action of GATA3, the master regulator of Th2 cells.[40] T-bet is also important for T-cell trafficking and promotes the differentiation of T cells to an effector phenotype.[41] As will be discussed, T-bet antagonizes the Tfh characteristics.[42,43]

It is important to bear in mind that Th1 differentiation can occur in the absence of either T-bet or STAT4, indicating that there are alternative means of regulating IFN-γ. In CD8 cells, a related T-box family member, Eomes, is the major regulator of IFN-γ production. In addition, other transcription factors are preferentially expressed in Th1 cells including Hlx, Runx3, and Ets family members; they also promote IFN-γ production and repress IL-4 transcription. Another factor that influences Th1 specification is the "strength" of TCR signaling, with strong signaling favoring TCR signaling. The mechanisms underlying this are relatively poorly characterized. A downstream signaling molecule engaged following TCR ligation and cytokine receptor occupancy is mammalian target of rapamycin (mTor). Deficiency of mTor inhibits effector cell differentiation including generation of Th1 cells.[44] Its regulators include Tor complex (Torc)1 and Torc2. Inhibition of Torc1 signaling inhibits Th1 and Th17 differentiation.[45,46,47]

Th2 Cells

The signature cytokines for Th2 cells are IL-4, IL-13, and IL-5, which are important for barrier defense at mucosal and epithelial surfaces. IL-4 stimulates the development of T_H2 cells and functions as an autocrine growth factor for differentiated T_H2 cells. It also stimulates B-cell immunoglobulin class switching to IgG4 in humans (IgG1 in mice) and IgE in both species. Conversely, IL-4 inhibits switching to the IgG2a

and IgG3 isotypes in mice, both of which are stimulated by IFN-γ. IL-4, together with IL-13, promotes the formation of "alternatively activated" macrophages, suppresses IFN-γ-mediated classical macrophage activation and thus inhibits defense against intracellular microbes. IL-4, IL-13, and IL-5 mobilize eosinophils, basophils, and mast cells, and IL-13 increases mucus secretion from airway and gut epithelial cells. These actions contribute to elimination of microbes at epithelial surfaces. In this manner, Th2 cells are important for host defense against helminths and other parasites, but are also the major drivers of allergy and asthma.

T_H2 cells also produce IL-24 and IL-31, and express the chemokine receptors CCR3, CCR4, and CCR8.[48,49] Th2 cells also expression extracellular matrix protein-1, which regulates cell migration and expression of S1P1.[50]

For Th2 cells, a major driver of differentiation is IL-4 itself. IL-4 can be produced by an array of innate cells including: NK T cells, mast cells, and basophils.[51,52,53,54,55] More recently recognized are innate cells designated natural helper cells that reside in fat associated lymphoid clusters.[56,57,58] IL-25, an IL-17-related cytokine, IL-33, an IL-1-related cytokine, and thymic stromal lymphopoietin all promote Th2 responses, principally by driving IL-4 production in innate cells.[51,57,59,60,61,62]

IL-4 stimulates T_H2 development by activating STAT6, which together with TCR-dependent signals, induces expression of the Th2 master regulator, GATA-3. Like STAT4, STAT6 also regulates thousands of other genes in Th2 cells including pivotal transcription factors, cytokines and cytokine receptors, and chemokines and chemokine receptors.[27,63,64,65] IL-2 also contributes to Th2 differentiation by activating STAT5, which positively regulates expression of both IL-4 and the IL-4 receptor.[66,67,68,69] STAT5's targets in Th2 cells include both the *Il4* and the *Il4r* gene.[70] Additionally, STAT3 has been reported to be a contributor to Th2 differentiation.[71]

Gata-3 is a critical factor for lineage commitment of Th2 cells, although it also plays essential roles in thymic differentiation. Gata-3 binds to many key Th2 genes including the *Il4*, *Il5*, *Il13*, *Gata3*, and other genes. 72 GATA3 also actively represses RUNX3, which in turn leads to reduced IFN-γ production.[73] GATA3 also induces the transcription factor c-Maf, which can aid in Th2 differentiation; however, c-Maf deficiency does not abrogate production of Th2 cytokines.[74] GATA3 also has important roles in thymic development, regulating key factors such as Th-POK, Notch, and TCR subunits.[72]

The transcription factors Notch, IRF-4, and growth factor independent (Gfi)-1 also aid in Th2 differentiation. Notch has been reported to promote Gata3 expression and to do so in a Stat6-independent manner.[75] IRF-4 is a contributor to Th2 differentiation, but it is also important for other subsets.[76] Gfi is induced by IL-4 and regulates Th2-cell proliferation.[77,78,79] Whereas "strong" TCR signals favor Th1 differentiation, weak TCR signaling favors Th2 differentiation; again, the signaling intermediates responsible remain unclear. In addition, deletion of Torc2 inhibits Th2 differentiation.[45]

Finally, Mina, a member of the jumonji C (JmjC) protein family, binds and represses the *Il4* promoter. Conversely, reducing levels of Mina in T cells leads to *Il4* de-repression.[80] Eomesodermin (Eomes), a key regulator of IFN-γproduction in CD8 T cells, is important for limiting IL-5 production in Th2 memory cells.[48] Eomes acts by limiting GATA3 binding to the *Il5* promoter.

Th17 Cells

The appreciation that the Th1/Th2 paradigm failed to explain a good deal about immunity and autoimmunity,[81,82,83] and the recognition of the existence of a subset of T cells that preferentially produces IL-17 led to a small renaissance in CD4 T-cell biology. This newly appreciated subset, termed Th17 cells, was noted to produce IL-17A, IL-17F, IL-21, and IL-22.[84,85,86,87,88,89,90,91,92]

IL-17 enhances neutrophil generation by increasing granulocyte macrophage colony stimulating factor production and promotes neutrophil recruitment by production of chemokines.[93,94,95] Because neutrophils are a major defense mechanism against extracellular bacteria and fungi, T_H17 cells play an especially important role in defense in such infections including *Staphylococcus aureus*, *Klebsiella pneumoniae*, and *Candida albicans*.[49,96] The IL-23/IL-17 axis also contributes to host defense against *Mycobacteria tuberculosis*.[97] Additionally, IL-17 stimulates the production of antimicrobial substances, including defensins. IL-17 also contributes to germinal center formation, as well as lymphoid structures induced during inflammation.[98,99] As will be discussed, Th17 cells are also very important in the pathogenesis of a variety of autoimmune and immunemediated diseases.

Th17 cells typically express the chemokine receptor CCR6, along with its ligand, CCL20.[100] Cytokines that promote Th17 differentiation include IL-6, IL-23, IL-1, and TGF-β.[91,101,102,103,104,105,106,107,108,109,110,111,112] IL-6 and IL-23 activate Stat3, which directly regulates many genes that contribute to the phenotype of Th17 cells including *Il17a/f*, *Il23r*, and *Il21*.[113] Stat3 also regulates *Rorc*, which encodes Rorγt, the master regulator for Th17 cells and other transcription factors expressed by Th17 cells.[114,115] In the mouse, absence of *Stat3* in T cells blocks Th17 differentiation.[116,117] Th17 cells are abundant in the gut and are regulated by intestinal flora, but the precise mechanisms responsible for driving IL-17 production have not been elucidated.[114]

Rorγ is an orphan retinoid receptor that is ubiquitously expressed.[118] One splice variant, Rorγt, is selectively expressed in hematopoietic cells. In addition to serving as "master regulator" of a helper-cell subset, like GATA3, Rorγt has important functions in thymic development, in the development of lymphoid tissue inducer cells, and in development of IL-22-producing NK cells.[119,120,121,122] In addition to Rorγt, Rorα is also a contributor to Th17 differentiation.[123]

Other transcription factors expressed by Th17 include the aryl hydrocarbon receptor, Batf, I kappaB zeta, IRF-4, and Runx1; absence of any of these impairs IL-17 expression.[39,124,125,126,127,128,129] The key metabolic sensor hypoxia-inducible factor (HIF)-1[130] is also a positive regulator of Th17 differentiation. HIF-1 associates with Rorγt and recruits the acetyl transferase p300 to the *Il17* gene.[130,131] TLR2

signaling also promotes Th17 differentiation.[132] As indicated previously, mTor signaling via mTorc1 also promotes Th17 differentiation.[45]

IL-2 acting via STAT5 is a potent negative regulator of IL-17.[133] Regulatory T (T_{reg}) cells can promote Th17 differentiation, and they appear to do so by limiting IL-2.[134,135] IL-2 activates STAT5, which binds to the *Il17a/f* locus and displaces STAT3.[136] IL-4 and IFN-γ also inhibit Th17 differentiation.[84]

Foxp3 negatively regulates Th17 differentiation and does so by directly binding Rorγt and inhibiting its function.[137] The transcription factors Gfi-1, Ets-1, T-bet, and Tcf-1 also inhibit Th17 cell differentiation.[39,138,139,140,141]

Th22 Cells

IL-22 is an IL-10-related cytokine located in proximity to the *IFNG* gene, but regulated in a distinctive manner.[142] It acts on epithelial barrier cells, having both pro- and anti-inflammatory effects.[143,144,145] It is important for host defense against *Klebsiella pneumonia*.[49] Although IL-22 is produced by Th17 cells, some cells produce IL-22 and not IL-17.[146,147,148,149] This is especially prominent in skin-homing cells that express the chemokine receptors CCR10, CCR6, and CCR4.[150,151] IL-22 is also produced by mucosal innate immune cells including lymphoid tissue inducer and so-called NK-22 cells.[59,119,152,153,154,155,156]

Production of IL-6 and TNF by plasmacytoid DCs promotes IL-22 production without inducing

IL-17 and IFN-γ. Unlike other Th subsets, no clear master regulator that directs this phenotype has been identified, but the aryl hydrocarbon receptor[157] and Roryt are important for IL-22 production.[125,158] Notch drives IL-22 production by enhancing Ahr expression.[159] Conversely, Tgfβ inhibits IL-22; it does so by inducing Maf, which directly represses IL-22.[160]

Th9 Cells

Adding TGF-β to cultures of T cells incubated with IL-4 generates a population of cells that produce IL-9 but not IL-4. Such cells have been referred to as Th9 cells.[161,162,163,164] IL-2 promotes IL-9 production.[165] In addition, Th9 cells express the receptor for IL-25 (IL-17RB) and IL-25 promotes IL-9 production.[166] Innate cells are major sources of IL-9.[167]

IL-9 acts on mucosal cells to enhance mucus production.[168,169] IL-9 has also been reported to have variable effects on Th17 differentiation and Th17-dependent pathology.[170,171] The transcription factors PU.1 and IRF-4 are required for development of IL-9-producing T cells and allergic inflammation.[164,172,173]

Follicular Helper T Cells

For the subsets of CD4 T cells discussed, activation and instruction by cytokines is associated with the acquisition of particular chemokine receptors that promote exit from lymph nodes and recruitment to sites of inflammation. However, some antigen-experienced CD4 T cells, called follicular helper T cells (Tfh), stay in the lymph nodes and provide "help" to B cells.[174,175,176] The signature cytokine for Tfh cells is IL-21. However, this cytokine is not exclusively produced by Tfh cells; it is also produced by other subsets including Th1 and T_H17 cells. IL-21 promotes germinal center development and also contributes to the generation of plasma cells in the germinal center reaction.[177] Tfh cells promote B-cell Ig class switching and maturation of B cells to plasma cells.

Tfh cells also selectively express PD-1, CXCR5, BTLA, PSGL-1, and high levels of the costimulatory molecule inducible costimulator (ICOS). Other molecular interactions including signaling lymphocytic activation molecule-associated protein/signaling lymphocytic activation molecule and CD40/CD40L are also important for germinal center reactions.

The mechanisms that drive the development of Tfh cells from CD4+ cells are not fully understood. IL-6 and IL-21 promote Tfh cell differentiation via activation of STAT3; however, these factors are not absolutely required for Tfh differentiation. In fact, IL-12 acting via STAT4 also promotes Tfh differentiation.[43,178] ICOS promotes expression of c-Maf, which regulates IL-21 production.[179] Complete differentiation of Tfh is thought to require a signal derived from B cells in the follicle.[176]

The master regulator of Tfh cells is the transcriptional repressor Bcl6, which is induced by IL-6 and IL-21 via activation of STAT3.[180,181,182,183] Bcl-6 promotes expression of CXCR5, CXCR4, and PD-1. It also binds and represses *Tbx21* and *Rorc* genes (that encode T-bet and Rorgt, respectively). Bcl-6 also represses IL-4, IFN-γ, and IL-17 production.[183,184] As discussed subsequently, the extent to which Tfh should be considered a distinct lineage versus a flexible state is still a topic of debate. Tfh cells can secrete other cytokines that are characteristic of T_H1, T_H2, and T_H17 cells, and as indicated these cytokines regulate isotype switching.

Factors that negatively regulate Tfh characteristics of cells include *PRDM1*, which encodes the transcriptional repressor Blimp1.[182] In addition, T-bet negatively regulates IL-21 and Bcl6 expression.[42,43,185,186]

Regulatory T Cells

Foxp3+ Regulatory T Cells

Although multiple T-cell populations possess various suppressive activities, the major professional CD4 cell with essential regulatory activity is the FoxP3+ $CD25_{high}$ T_{reg} cell.[187] In the mouse, expression of Foxp3 is a reliable indicator of suppressive function, but this is not necessarily the case in humans.[188] Nonetheless, in both species absence of *Foxp3* (*FOXP3*) leads to fatal autoimmunity. Foxp3+ T_{reg} cells produce IL-10 and TGF-β, but low levels of other cytokines. However, the production of IL-10 and TGF-β is by no means unique to T_{reg} cells as other subsets also produce these cytokines. FoxP3+ T_{reg} cells also typically express high levels of CTLA-4, which is required for their proper function.

T_{reg} cells that arise in the thymus are designated natural T_{reg} (nT_{reg}) cells, whereas CD4 T cells that acquire Foxp3 expression in the periphery are termed induced T_{reg} (iT_{reg}) cells. IL-2 and TGF-β are important for the growth and survival of Foxp3+ T_{reg} cells.[189,190,191] Retinoic acid also induces expression of Foxp3.[192,193,194,195,196]

Activated by IL-2, Stat5 plays a pivotal role in regulating T_{reg} differentiation by directly

binding the *Foxp3* gene and inducing its expression. Foxp3, in turn, directly regulates many genes involved in the program of T_{reg} cells.[197] One action of FoxP3 is to bind Roryt and interfere with Th17-cell development.[137] A trimolecular complex comprising Runx1, Roryt, and Foxp3 can form with the net result being inhibition of IL-17 production.[129]

Runx/CBF also promotes expression of Foxp3,[198] and the transcription factors Nrfa2, Foxo1, and Foxo3 also promote T_{reg}-cell differentiation.[199,200] Eos, a member of the Ikaros transcription factor family, associates with Foxp3 and helps repress gene expression. Helios is expressed by iT_{reg} but not nT_{reg} cells, but its function is not clear and can be induced in other helper-cell subsets.[201,202] Lack of mTor or inhibition with rapamycin favors T_{reg}-cell generation.[44]

Cytokines, like IL-6, that activate STAT3 inhibit Foxp3 expression.[89,203,204] HIF-1 also binds Foxp3 and promotes proteasomal degradation.[130]

Other Cluster of Differentation 4 Subsets with Regulatory Activities

Other CD4 T-cell subsets that have immunosuppressive properties include IL-10- and TGFβ-producing regulatory T cells. Such cells have been referred to Tr1 and Th3 cells.[205,206] These cells are induced in oral tolerance models and do not necessarily express Foxp3. Type I IFN, IL-27, and ICOS induce c-Maf expression, which promotes differentiation of IL-10-producing cells.[207,208,209,210,211,212,213,214,215] Similarly, arylhydrocarbon ligands also reported to induce this subset.[216,217] As discussed in the following, though, it is now appreciated that IL-10 is widely expressed by various CD4 T cells and innate immune cells; whether IL-10-producing cells should be viewed as a separate lineage is therefore debatable.

T_{reg} cells also express the cytokine IL-35.[218] This is a dimeric cytokine that comprises the EBI3 and IL-12α (p35) subunits. IL-35 has suppressive activity and induces its own expression in CD4 T cells.[219,220] However, IL-35 expression does not require coexpression of Foxp3. No "master regulator" has been described for IL-35-producing cells.

EPIGENETIC REGULATION OF HELPER-CELL DIFFERENTIATION

Once cells have attained a differentiated fate, they tend to maintain that phenotype through multiple rounds of cell division without continued instructive signals. Equally important for the acquisition of a differentiated state is the active silencing of genes that contribute to alternative fates.

An important determinant in gene expression is whether the gene is accessible or not. Deoxyribonucleic acid (DNA) is associated with octameric histone molecules forming nucleosomes, which may be in a condensed (heterochromatin) or open (euchromatin) configuration. Genes residing within regions of condensed chromatin are inaccessible and are therefore silenced, whereas genes that reside in open chromatin are readily expressed. The accessibility of genes is influenced by adenosine-triphosphate-dependent remodeling of nucleosome complexes, as well as covalent modifications of histone tails (including acetylation, methylation, and phosphorylation). Another important factor that influences gene expression is DNA methylation. These various modifications contribute to epigenetic control of gene expression and when measured on a genomewide scale are referred to as the "epigenome."

Epigenetic modifications, especially DNA methylation, are relatively stable and may persist in the absence of continued exogenous signals and even the transcription factors that initially induced them. This allows a cell to "remember" its distinctive transcriptional profile and, by extension, its cellular identity.

The differentiation of CD4 T cell has long been recognized to be associated with the dismantling of condensed chromatin structure and the acquisition of accessible chromatin structures at the signature cytokine loci and other key genes expressed by effector CD4 T cells.[221,222,223,224,225,226] This makes sense as the preservation of phenotype would be desirable with the massive clonal expansion that accompanies T-cell activation. Extensive profiling of histone marks in CD4 T cells has been now been accomplished, and the epigenomic view of T cells confirms early work regarding accessible and repressive marks of signature cytokine genes.[227,228,229] Once this remodeling occurs, it tends to persist in daughter cells, and the accessibility of these genes helps explain the ability differentiated CD4 to rapidly express selective cytokine genes. Equally, the silencing of other cytokine genes help to explain why genes can be effectively shut off and CD4 T cells can behave like "lineages" in terms of phenotypic stability. However, as will be discussed in the following, the epigenetic regulation of master regulator genes is more complicated and allows for flexibility in expression.

As might be expected, genetic deletion or knocking down expression of factors involved in histone modifications, nucleosome positioning, or DNA methylation impact CD4 differentiation.[230] For instance, impaired expression of constituents of the Trithorax complex, which is responsible for histone 3 lysine 4 trimethylation, a mark of accessible chromatin, is associated with aberrant Th2 differentiation.[231,232] Mice that lack components of polycomb

repressor complexes, which are responsible for histone3 lysine 27 trimethylation, have impaired helper-cell differentiation.[233,234,235] Chromatin remodeling complexes, which contain Brahma-related gene 1 (Brg1), displace nucleosomes. This is important for regulating the accessibility of the *Ifng* promoter in Th1 cells and knocking down *Brg1* results in decreased IFN-γ production.[236] The cohesin complex of proteins is also important for maintenance of gene architecture and knocking down the expression of one component of this complex, *RAD21*, also reduces *IFNG* transcription.[237] Finally, conditional ablation of the DNA methyl-transferase, DNMT1, or methyl-CpG binding domain protein 2 leads to increased expression of IFN-γ and Th2-type cytokines and inability of Th1 or Th2 cells to properly silence the expression of opposing cytokine genes.[238,239,240]

Like cytokine genes, the expression of key transcription factors can also be regulated by epigenetic modifications. For instance, a conserved CpG-rich region resides upstream of the *FoxP3* promoter. This region is fully demethylated in nT_{reg} cells. In contrast, there is residual methylation of

this region in iT_{reg} cells.[241,242,243] This correlates well with the finding that nT_{reg} cells tend to be more stable in their phenotype than their induced cousins.

Cis regulatory elements are the DNA elements that control gene expression and constitute an integral part of gene structure.[222] These elements may be located in promoters, introns, or in distal enhancers; are enriched for transcription factor-binding sites; and are sites of epigenetic modification. In differentiating Th cells, much attention has been focused on the structure of lineage-defining cytokine genes including their distal cis regulatory elements. In fact, the structure of many cytokine genes is remarkably complex. The *IFNG*/*Ifng* locus encompasses approximately 200 kb, with multiple distal enhancers.[222,244,245,246,247,248,249] Similarly, the *IL4 Il4* locus comprises multiple enhancers as well as a silencer element (HS-IV), which binds Runx/CBFbeta.[250,251,252,253] Likewise, the *Foxp3* gene also has a complicated structure, which is critical for appropriate, stable expression.[254]

Taken together, there is strong evidence that epigenetic regulation is a key aspect of helper-cell differentiation; however, it should also be clear that epigenetics refers to a diverse group of mechanisms and that not all of the genes expressed in helper cells are regulated in the same manner.

LINEAGE COMMITMENT VERSUS PLASTICITY AND FLEXIBILITY

With the initial discovery of Th1 and Th2 cells, the impression was that these cells tended to have reasonably stable phenotypes and thus began to be viewed as distinct lineages in much the same way that we think of CD4 and CD8 cells as being distinct and phenotypically stable. T_{reg} cells can be stable in terms of their phenotype, so they too came to be viewed as another helper-cell lineage. With the rapid discovery of new fates for CD4 T cells delineated previously, many were also elevated to the status of new lineages; however, their phenotypic stability has not been as firmly established. On the contrary, recent research also points to substantial phenotypic flexibility of the “newer” helper T cells and indeed, previously indentified subsets also appear to be more flexible than initially thought.[255,256,257,258,259,260] Attention will now be turned to the ways in which helper subsets exhibit flexibility and some of the mechanisms responsible. This is not to say that older views should be abandoned; rather, one needs to have an open mind regarding what CD4 subsets can and cannot do as they continue to surprise us.

Some Cytokines are Made by Many Subsets of T Cells

Originally thought to be a Th2 cytokine, IL-10 is now known to be made by Th1, Th2, T_{reg} cells, and a variety of innate immune cells.[261,262] Likewise, TGF-β is made by both effector cells and regulatory cells. Conversely, some suppressive cells can express IL-17.[92,263] Conversely, granulocyte macrophage colony stimulating factor made by Th1 and Th2 cells is also made by Th17 cells and is important in immune-mediated disease.[264,265]

IL-21, the “signature cytokine” of Tfh, can also be made by Th17 and Th1 cells.[27,43,178,266] Likewise, despite the nomenclature, IL-9 and IL-22 are made by cells other than their namesake “lineage.”

Even for the classical subsets, Th1 and Th2 cells, it is recognized that IL-4-producing cells are present early in the Th1 response against *Leishmania*. While the cassette of genes encoding IL-4, IL-13, and IL-5 are typically coordinately regulated in Th2 differentiation, there are circumstances in which Th1 cells can produce IL-13 but not IL-4. The transcription factor NF-IL3 (E4BP4) appears to regulate IL-13 independently of IL-4.[267]

Helper Cells can Change Their Phenotype

Although IL-17-secreting Th cells were suggested to represent a new lineage because they did not make other lineage-defining cytokines like IFN-γ and IL-4, it is now well recognized that Th17 cells often become IFN-γ producers.[268,269,270,271] Although the subject is far

from resolved, T_{reg} cells can lose FoxP3 expression and acquire the capacity to produce proinflammatory cytokines.[228,272,273] Even committed GATA-3+ Th2 cells can be reprogrammed to express T-bet+ and IFN-γ+ in the setting of viral infection.[274]

Tfh cells are perhaps the most fluid subset.[174,275] In vitro, Tfh cells can become Th1, Th2, and Th17 cells, and conversely, Th1, Th2, and Th17 can acquire attributes of Tfh cells.[276,277,278] In vivo isolated Tfh cells can also express cytokines characteristic of other Th cells.[174,276,279] In Peyer patches, FoxP3+ T cells can convert to Tfh cells.[280] Thus, it remains an open question whether Tfh cells should be viewed a distinct lineage parallel to other subsets of helper T cells or as a metastable state of differentiation that can be superimposed upon Th1, Th2, Th17, or T_{reg} cells.

Collectively, the data indicate that although helper cells may exhibit features of phenotypic stability, it is clear that they also have the capacity for considerable plasticity. This then raises the broader question of what factors preserve the phenotype of specialized cells.

Mechanistic Explanations

Helper T Cells can Express More than One "Master Regulator"

Implicit in the notion of lineage-defining master regulators is that their expression dictates a distinctive phenotype. In the strictest sense, expression of a master regulator in a given subset is equally distinct; the expectation is that specific lineages express one lineage-defining master regulator whose expression equates with the distinctive phenotype and does not overlap among the different subsets. However, this is not the case for CD4 T cells. For example, Foxp3+ cells can express T-bet, GATA3, STAT3, IRF4, Rorγt, and Bcl6, all of which are functionally relevant.

Expression of the Th1 master regulator, T-bet, in Foxp3+ cells is important for trafficking of the cells to sites of Th1-associated inflammation.[281] The Th2 master regulator, GATA3, is expressed in T_{reg} cells that reside in barrier sites such as the gastrointestinal tract and the skin, but is also induced by TCR and IL-2 stimulation.[282,283] Although not required for basal T_{reg}-cell homeostasis and function,

T_{reg}-cell expression of GATA3 is critical during inflammatory responses where it maintains Foxp3 expression and limits T_{reg}-cell conversion to an effector T-cell phenotype. Considerable numbers of human CD4+ T cells coexpress FOXP3 and RORGT. These T cells express CCR6 and produce IL-17 upon activation, but also have suppressive activity.[284] Although IRF4 is important for Th2 and Th17 differentiation, deletion of this factor in T_{reg} cells leads to autoimmunity associated with overproduction of Th2 cytokines.[285] Similarly, T_{reg} cell-specific deletion of Stat3, a factor that drives Th17 and Tfh differentiation, also leads to autoimmunity.[286] Finally, T_{reg}cells present in the GC that express Bcl6 function to constrain B-cell responses.[287,288]

Likewise, inflammatory Th17 cells can be generated that express both Rorγt and T-bet and GATA3.[110,136,289,290] In experimental autoimmune encephalomyelitis, T-bet+, Rorgt+ cells are highly pathogenic, and in this model expression of T-bet is associated with pathogenicity, even when IFN-γ is not.

Bcl6 and T-bet can be coexpressed and in fact, can cooperate to repress gene expression.[291] GATA3 and Bcl6 are coexpressed in the setting of helminth infestation[279]; in fact, Bcl6 is broadly expressed in CD4 T cells and not just expressed by bona fide Tfh cells. Moveover, even though IL-6 and IL-21 acting via STAT3 can drive Tfh-cell generation, they are not essential. Tfh can differentiation can occur in the absence of these factors.[292,293] This can be explained by the fact that IL-12 is capable of driving IL-21 production and Bcl6 expression.[43,178] So, some of the "master regulator" transcription factors have diverse stimuli that induce their expression.

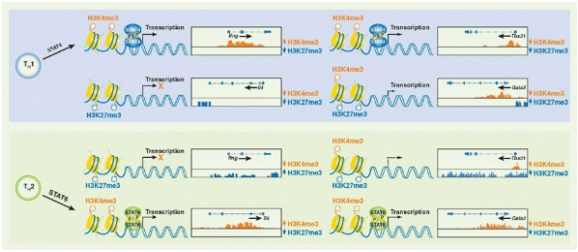

FIG. 29.2. Epigenetic Regulation of Helper-Cell Phenotype. Once differentiated, the distinct T-cell subsets have a propensity to maintain their distinctive patterns of gene expression. The tendency to "remember" this phenotype is controlled by the selective expression of key transcription factors, but also the chromatin configuration of the target

genes. Deoxyribonucleic acid forms nucleosomes, which can be compacted and inaccessible (heterochromatin) or open and accessible (euchromatin). Specific modifications of the histone molecules that make up the nucleosomes are associated with accessibility. That is, genes that are accessible exhibit histone 3 lysine 4 trimethylation (H3K4me3). In contrast, genes that are silenced and inaccessible exhibit histone 3 lysine 27 trimethylation (H3K27me3). Typically, cytokine genes exhibit accessible (H3K4me3) marks in the subsets in which they are expressed (eg, *Ifng* in Th1 cells and *Il4* in Th2 cells) and repressive (H3K27me3) in subsets in which they silenced (eg, *Ifng* in Th2 cells and *Il4* in Th1 cells). In contrast though, master regulators genes such as *Tbx21* (which encodes T-bet) and *Gata3* can exhibit both marks indicative of the fact that they can have more flexible expression. Although they are not necessarily expressed, they may not be completely silenced.

Thus, for all these reasons, it should be clear that there is not a simple relationship between phenotype and master regulator expression and that expression of more than one master regulator is frequent event.[258]

Epigenetic Explanations

As discussed, consistent with the standard "lineage commitment" model of helper-cell differentiation, cytokine genes typically show permissive (H3K4me3) marks on lineage-appropriate cytokines in the corresponding lineages (eg, *Ifng* in Th1 cells) and are accompanied by repressive (H3K27me3) marks in other subsets (Fig. 29.2). However, this simple scenario is not always the case. After the recognition of Th17 cells as a new subset, it was quickly realized that these cells are intrinsically unstable.[268,269] Indeed, this instability is correlated with the rapid remodeling of the *Ifng* locus when Th17 cells are stimulated in the presence of IL-12.[294]

Even more striking is that the histone methylation patterns of genes encoding several master regulators do not confirm to this simple "on or off" mode of regulation (Fig. 29.2). They exhibit both repressive and accessible marks, even when these transcription factors are not expressed.[228] For example, the *Tbx21* gene is associated with accessible H3K4me3 marks in Th1 cells. Although, repressive H3K27me3 marks are present in Th2 and Th17 cells, H3K4me3 marks are also present. Such regions, marked by both chromatin modifications, are termed bivalent domains and have been seen in genes poised for expression in stem

cells.[295,296] This then can help explain how T-bet might be induced in T_{reg}, Th17, and even Th2 cells. Similarly, the *Bcl6* locus has H3K4me3 marks in polarized Th1, Th2, and Th17 cells, and conversely, the *Tbx21*, *Rorc*, and *Gata3* genes have accessible marks in Tfh cells.[278]

Micro-Ribonucleic Acids and Phenotypic Stability

Micro-ribonucleic acids (RNAs) are small RNAs that bind to target messenger RNAs (mRNAs) and lead to inhibition of translation or mRNA degradation.[297,298] Drosha and Dicer are two key components of the machinery responsible for microRNA generation. Loss of these factors is associated with autoimmune diseases and loss of T_{reg}-cell stability.[299,300] Our understanding of how microRNAs regulate helper-cell differentiation is expanding rapidly. It is clear miR-146a is important for suppressive function of T_{reg},[301] whereas miR-155 influences Th1, Th2 differentiation, and T_{reg}-cell development.[302,303,304,305,306,307] By contrast, miR-326 enhances T_H17 differentiation, whereas miR-29 regulates T_H1 differentiation.[308,309,310] Bcl-6 represses expression of many microRNAs predicted to control the Tfh cell signature, including miR-17-92, which represses CXCR5 expression.[183] Yet another microRNA, miR-125b, contributes to maintaining the naïve state of helper T cells and miR-182 promotes clonal expansion.[311,312] This is surely an area that will continue to provide new insights into control of CD4 phenotypic stability.

In summary, although there are aspects of helper-cell behavior in which these cells appear to be stable subsets, there is also no shortage of molecular mechanisms that permit flexibility in their repertoire of responses.

HELPER T CELLS IN IMMUNE-MEDIATED DISEASE AND CANCER

There are increasing numbers of examples in which what we have learned about CD4 helper cells has direct bearing on health and disease in humans.

Immunodeficiency

The critical importance of CD4 T cells is exemplified by the range of infections seen in human immunodeficiency virus and acquired immunodeficiency syndrome. In addition, other immunodeficiency disorders are also linked to derangement in the function of specific subsets of Th cells. For example, STAT3 is critical for Th17 differentiation in humans and accordingly, dominant negative mutations of *STAT3* underlie the human disorder hyperimmunoglobulinemia E, or Job syndrome. The failure to generate Th17 cells is an

important aspect of this disorder that likely contributes to *Staphylococcal* and fungal infections.[313,314,315,316,317]

IFN-γ inhibits Th17 differentiation and activates STAT1; interestingly, gain-of-function mutations of *STAT1* result in the disorder chronic mucocutaneous candidiasis, which is associated with impaired Th17 differentiation.[318,319,320] Conversely, loss of function of *STAT1* mutations are associated with atypical mycobacterial infection.[321]

Recently, production of anticytokine autoantibodies has come be recognized as an underlying cause of susceptibility to various infectious diseases.[322,323,324]

Autoimmunity

Coupled with the discovery of IL-23, the recognition in mouse models that a simple Th1/Th2 paradigm did not adequately explain autoimmunity led to important insights into the role of Th17 cells in immune-mediated disease[81,82,325]; in reality, different types of helper T cells can elicit different types of pathology.[326]

Importantly, the lessons learned in mice appear to be very relevant to human disease. First, a number of human diseases are associated with increased levels of IL-17.[90] These include a wide range of autoimmune diseases including systemic lupus erythematosus, rheumatoid arthritis, psoriasis, multiple sclerosis, and other disorders.[327,328,329,330,331] It should be noted, however, that autoimmune disease in humans is often not a pure "Th17" disease and that IL-17, IFN-γ, and other cytokines are overproduced. Moreover, dysregulated Tfh cells can cause systemic autoimmunity and autoantibody production or contribute to T cell-mediated organ-specific autoimmunity.[177,332]

In addition, there are strong genetic clues linking these pathways with human autoimmunity. Polymorphisms of *IL23R*, *STAT3*, and *JAK2* are associated with inflammatory bowel disease, spondyloarthropathy, and Behcet disease.[333,334,335,336] Polymorphisms of *STAT4* are associated with systemic lupus erythematosus and rheumatoid arthritis.[337] Mutations of *FOXP3* underlie the disorder immune polyendocrinopathy and endocrinopathy syndrome. As is the mouse, this is associated with loss of T_{reg} cells resulting in severe systemic autoimmune disease.[338] A critical role for STAT5 is regulation of FOXP3 and accordingly, *STAT5* mutations are also associated with autoimmunity due to impaired T_{reg} function.[339]

Perhaps most importantly, targeting IL-12 and IL-23 with the drug ustekinumab is efficacious in inflammatory bowel disease and psoriasis, but curiously not multiple sclerosis.[340,341,342] Anti-IL-17 (secukinumab) is currently being studied in a variety of human autoimmune diseases.[343] Interestingly, the drug digoxin appears to target Rorγt and inhibits Th17 differentiation[344]; whether it will be feasible to target Th17 cells with small molecule inhibitors remains to be determined.

Asthma and Allergy

In contrast to perplexing relationship between Th1 cells and autoimmunity, the connection between Th2 cells and allergies and asthma was more straightforward. Nonetheless, as we learn more about the complexities of helper-cell differentiation, even this straightforward association starts to fray at the edges. For example, IL-17 and IL-22 appear to be important players in allergic disease[345]; in fact, asthma severity correlates with serum IL-17 levels.[346,347,348] Likewise, IL-9 and IL-21 are also relevant components to allergic and Th2-mediated disease.[349,350,351]

Cancer

The importance of IFNs, including IFN-γ, in tumor surveillance and cancer immunoediting is well appreciated.[352,353] In adoptive transfer models though, Th17 cells appear to be more effective than Th1 cells in eliminating cancer cells.[354,355] However, given the role of IL-17 in driving inflammation, there are also data suggesting that IL-17 promotes oncogenesis; clearly, this will be an important area to follow closely.[354,356]

Chapter 30

Programmed Cell Death

Andrew L. Snow

Michael J. Lenardo

INTRODUCTION

Nontransformed cells have a finite lifespan. After a characteristic number of divisions, cells generally undergo senescence, stop dividing, and subsequently die. Considering adult vertebrates, and their internal organs, generally stay a constant size, a form of homeostasis is required.[1] In certain organs, this involves a constantly fluctuating dynamic equilibrium of cell proliferation and death. A prime example is the immune system, which employs cell renewal, expansion, and elimination in carrying out its functions.[2,3,4,5] These changes can be systemic or localized to anatomic sites proximate to an antigen stimulus, and may affect specific subsets of immune cells as dictated by the conditions.

Programmed cell death (PCD) denotes a set of internal biochemical mechanisms that cause specific cells to die under defined conditions that are typically advantageous to the organism.[6] Reasons for cell elimination include cell excess, improper cell differentiation, cell transformation, genetic damage to cells, and infection. In addition to this operational definition, considering a death event “programmed” usually means that one or more genes are required. This chapter has been organized to start with a broad overview of general immunoregulatory principles and then cover details of the molecules involved in PCD in specific sections. Although there are conceptual antecedents from the 19th century, the selection of cells for survival or death by specific external stimuli was introduced by Levi-Montalcini for neural cells in the 1940s and later by Burnet for lymphocytes. Investigation into the molecular mechanisms of PCD began in the mid-1980s and accelerated rapidly. Deoxyribonucleic acid (DNA) sequence databases permitted the rapid identification molecules involved in PCD.[7] Although PCD is a large and contentious area of cell biology research, molecular advances have established a firm and tractable theoretical foundation. Remarkably, much of what we will discuss was almost completely unknown two decades ago. Yet these pathways are at work every day in our bodies to control responses to infectious agents, establish cellular homeostasis, prevent autoimmunity, and avert lymphoid malignancies.

OVERVIEW: CELLULAR HOMEOSTASIS AND PROGRAMMED CELL DEATH IN MULTICELLULAR ORGANISMS

Internal programs of death exist in all mammalian cells that likely require constant and active

suppression.[8] For experimental investigation, it is thus important to discriminate between accidental cell death and that initiated or "programmed" by an internal genetically determined biochemical mechanism. The term "*apoptosis*," a Greek word meaning "falling off," as in leaves from a tree, was introduced in 1972 by Andrew Wyllie and coworkers to describe the normal, presumably programmed, attrition of cells.[9] It was defined microscopically as cell shrinkage with nuclear and cytoplasmic condensation within a cell membrane that forms blebs but stays intact until late in the death process[10] (Fig. 30.1). This cell phenotype has long been associated with cell death.[11] Apoptosis is now mainly identified by the biochemical effects of the caspase family of proteases.[12] Caspases are important in two respects. First, they are a feature of most, if not all, apoptosis pathways. Second, once highly activated, they usually represent a commitment to apoptosis that is not reversible, although we now recognize that low-level caspase activation participates in lymphocyte activation.[13,14] For these reasons, caspases have been regarded as a final common pathway of apoptosis. In fact, the concept of PCD was significantly illuminated by the identification of caspases and other molecules that regulate these internal biochemical death pathways. In general, the molecular components of the death mechanism are preassembled and available without new gene transcription or protein synthesis.[6] For example, caspases are constitutively expressed in the cytoplasm of the cell as zymogens. Once proteolytically activated, caspases carry out specific protein cleavages leading to the morphologic changes of apoptosis. The proteolytic substrates of caspases are highly selective because most proteins remain uncleaved. A panoply of molecular events entrained to caspases includes cleavage of chromosomal DNA, nuclear chromatin condensation, exposure of phosphatidylserine on the exterior of the cell membrane, proteolysis of specific proteins including other caspases, and mitochondrial changes. These processes are detectable by simple assays in tissue culture cells in vitro or, in some cases, in vivo. Protocols for these assays have been well described.[15,16]

Cells that die without the characteristics of apoptosis typically undergo what is usually called *necrosis*. While necrosis is often associated with accidental cell death such as physical or chemical trauma, it may also result from programmed mechanisms. In certain cases, nonapoptotic mechanisms of cell death can be promoted by caspase inhibition.[17] The appearance of a necrotic cell differs dramatically from that of an apoptotic cell. Necrotic cells swell and lose the integrity of internal organelles with early plasma

membrane breakdown, giving an enlarged "fractured" appearance under the microscope (see Fig. 30.1D). Recently, various research groups have begun to define molecular programs resulting in necrotic death.[18] Several varieties of "programmed" necrosis that share the hallmarks of early loss of plasma membrane integrity and excessive reactive oxygen species (ROS) have been described. Programmed necrosis that involves receptor-interacting protein (RIP) serine/threonine kinases has been well documented in lymphocytes, especially under conditions of caspase inhibition.[17,18] A closely related variant of this cell death program termed "necroptosis" is inhibitable by necrostatin, a compound that inhibits RIP kinases.[19] Finally, the induction of autophagy has been genetically linked to a necrotic program of death.[20] Autophagy is induced by starvation or other stimuli and involves internal membrane rearrangement leading to engulfment of portions of the cytoplasm, which are then degraded

by fusion with lysosomes. Under death conditions, this mechanism leads to membrane damage and necrosis by ROS, which overaccumulate because of accelerated catalase degradation.[21] The precise role of these necrosis programs, especially autophagic cell death, in immune function has not yet been worked out. However, they are often provoked by the inhibition of caspase-dependent apoptosis. Caspase inhibition, perhaps by blocking constitutive low-level caspase activity, can actually trigger these necrotic death programs.[20]

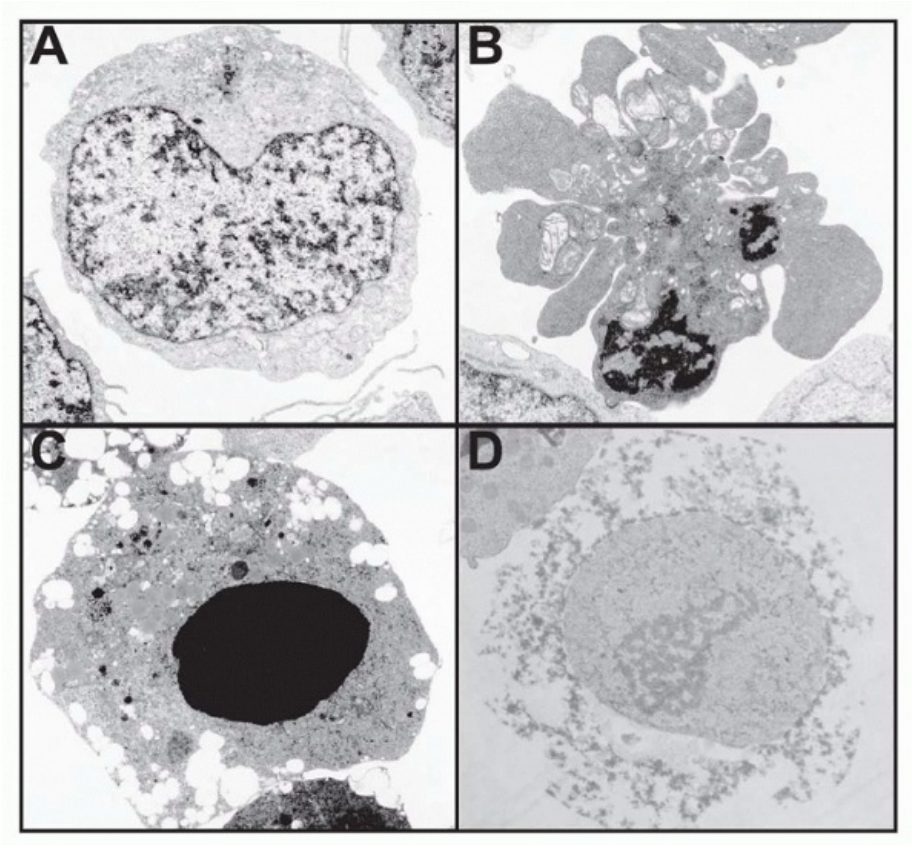

FIG. 30.1. Electron Microscopy Elucidates the Morphology of Different Forms of Programmed Cell Death. A: A normal, unstimulated Jurkat leukemia cell. **B:** Jurkat cell undergoing apoptosis in response to Fas receptor stimulation. Notice the condensed chromatin and the blebbing with maintenance of plasma membrane integrity. **C:** Jurkat cell undergoing apoptosis in response to staurosporine treatment. Note the prominent nuclear condensation. **D:** Necrosis of human peripheral blood T-lymphocyte infected with the human immunodeficiency virus. Notice the general loss of cellular integrity as well as the lack of chromatin condensation in the dying cell. (Figure courtesy of Diane Bolton and Jan Orenstein.)

Thus, it is important to distinguish between “programmed” necrosis and necrosis due to accidental causes as these involve very different molecular events. It has been generally argued that apoptosis, which preserves membrane integrity, prevents inflammation from released cellular contents, whereas necrosis results in total cellular breakdown and content release, which causes an inflammatory response.[22] Recent evidence suggests this paradigm is oversimplified and that the immunogenicity of a dying cell varies with cell type and

activation status, the nature of the phagocytic cell that engulfs it, and/or the specific death stimulus. The release of inflammatory damage-associated molecular patterns that may accompany apoptosis or necrosis of stressed cells (eg, heat shock proteins, high-mobility group box 1, oligonucleotides, uric acid) may be particularly important for invoking a strong immune response.[23] These distinct immunologic effects due to apoptosis and necrosis remain the subject of continued experimental exploration.

As we will argue in the following, the necessity of cellular homeostasis as well as the acute need to eliminate cells that are harmful or nonfunctional led to the early emergence of conserved cell death mechanisms during evolution.[11]. Work by Horvitz and colleagues genetically identified several molecules essential for the death of specific cells during the development of the roundworm *Caenorhabditis elegans* that have subsequently been found to be homologues for mammalian PCD genes.[24] It is clear from this simplified system that the molecular logic of one form of cell death was likely established early in evolving multicellular organisms.[25] PCD mechanisms are now evident in most contemporary multicellular organisms from plants to humans, although it is not clear whether convergent evolution or conservation of function is responsible. However, the molecular pathways in worms and other simple organisms are rudimentary compared with the complexity found in mammalian PCD systems. To understand how these mechanisms contribute to immunity, we focus on mice and humans, which are the subjects of most immunologic research. Also, while we focus mainly on research carried out on B- and T-lymphocytes, similar themes and mechanisms govern death programs for other hematopoietic cells including dendritic cells (DCs), macrophages, natural killer cells, granulocytes, and mast cells, among others.

PROGRAMMED CELL DEATH AND IMMUNE REGULATION

The fundamental unit of immune responsiveness is the cell. Lymphocytes, the major adaptive immune cells, are distinguished by expressing a unique clonotypic antigen receptor. A large number of lymphocytes with different receptor specificities are generated during ontogeny, providing a diverse “immune repertoire,” and these cells can be programmed to expand or die throughout the life of the organism. Somatic hypermutation during B-cell expansion in the germinal center can expand the repertoire. Although the level of antigen presentation, the degree of lymphocyte responsiveness (versus unresponsiveness or anergy), and other factors also play important roles, the presence or absence of cells with

specific recognition properties at any given time is a primary determinant of the quantitative response to any antigenic stimulus. The homeostasis of major lymphocyte populations is independently regulated such that deficits in B cells, T cells, or even major T-cell subpopulations (αβ versus γδ or cluster of differentiation [CD]4 versus CD8) may qualitatively alter but do not prevent the normal homeostasis of the remaining populations. During thymic development, lymphocytes respond to the antigenic environment with either survival or death.[26] Developmental PCD eliminates lymphocytes that cannot recognize antigen appropriately or have potentially dangerous self-reactivity.[26,27] In the mature immune system, death is principally a negative feedback response that counterbalances proliferative responses to antigen.[28] Although the clonal selection theory of F.M. Burnet encompassed clonal elimination during ontogeny, it allowed only selective expansion of antigen-stimulated

lymphocytes in the mature immune system. However, antigen-specific regulation of mature lymphocyte survival also powerfully controls immune responses and tolerance.[4,28,29] Because the organism encounters an unpredictable universe of antigens in a lifetime, it is essential that there is feedback regulation of adaptive immune responses. Feedback is an essential element of any dynamic system in which final outcomes cannot be predicted from the starting conditions.[30] To achieve measured immune responses, proliferation and death are coordinated by feedback regulation to control the number of responsive immune cells. Feedback death mechanisms can also eliminate potentially harmful specificities that increase unexpectedly during immune reactions. Hence, homeostasis of both lymphocyte numbers and reactivities can be continuously maintained.

Thymic Deletion: Positive and Negative Selection

Thymic selection represents an intriguing example of apoptosis in which the same receptor —the clonotypic T-cell receptor (TCR)—can lead to diametrically opposite outcomes depending on the level of stimulation.[26,27] During development, when thymocytes (ie, T-cell progenitors in the thymus) express the TCR and both the CD4 and CD8 coreceptors (the "double positive" stage), thymocytes will undergo apoptosis if they receive no TCR stimulation. This process, called "death by neglect," will eliminate thymocytes that have not productively rearranged the TCR genes or have no capacity to recognize antigen in the context of self-major histocompatibility complex.[31] "Low-level" stimulation of the TCR antagonizes death by neglect. This protective event insures major histocompatibility complex-specific antigen recognition by T cells and is called *positive selection*.[32] While weak TCR signals can deliver an antiapoptotic stimulus, strong TCR engagement of double positive thymocytes delivers a proapoptotic signal. This event, termed *negative selection*, prevents the emergence of strongly autoreactive lymphocytes from the thymus.[31] This deletion step is a major mechanism of central tolerance and the prevention of autoimmunity.[33] These processes of selection employ caspase-dependent apoptosis and rapid phagocytosis of the dead thymocytes.[34,35] Hence, thymocytes travel a narrow bridge of TCR avidity during development and will die if they deviate from it.

The differences between the neglect (or null), weak, and strong signals that result in life or death appear to be determined at early stages of TCR signaling.[36,37] Death receptors (DRs; see the following discussion) appear not to be crucial; instead, there is a direct connection of the TCR signaling apparatus to mitochondrial death pathways.[38,39,40,41] Though there is not complete certainty how the TCR dictates life or death at specific antigen levels, the answer to this puzzle will almost certainly reside in the complex signal pathways emanating from this receptor. TCR engagement that causes transient induction of the Erk kinase is associated with positive selection, whereas slow but constant Erk activity is associated with negative selection.[42,43,44] Other distinctions in TCR signaling have been identified. Signaling through phosphotidylinositol-3 kinase, the antiapoptotic Akt kinase, and the retinoid orphan receptor-gamma may promote thymocyte survival.[36,45] Genetically modified mice have revealed that several transcription factors, such as E2A, Nur77, Id3, and IRF-1, can affect thymic cellularity, indicating that differential signaling may trigger transcriptional events that regulate cell survival.[46,47,48,49,50] Finally, Andreas Strasser has emphasized that

various forms of physiologic cell death are likely to involve the subset of BH3-only proteins in the Bcl-2 family.[51,52] The activation of proapoptotic BH3-only proteins, such as Bak, Bid, and especially Bim, by TCR signals initiates mitochondrial apoptosis during thymic selection processes. Thus, early TCR-induced signaling differences directly entrain transcriptional events that modulate BH3-only regulators of mitochondrial apoptosis. These distinct signals are tied to specific microenvironments within the thymus in which positive and negative selection occur.[53] Hence, by intracellular communication with distinct apoptosis regulatory molecules, the TCR has a remarkable ability to signal life or death by the apparent strength of stimulus it receives.

Programmed Cell Death and the Homeostasis of Peripheral T Cells

Death of peripheral T cells differs markedly from thymocyte selection in that PCD of mature lymphocytes occurs mainly in cells that have proven usefulness (ie, they have been already selected in the thymus and activated by antigen). This is because PCD of mature T cells is employed primarily to counter antigen-driven proliferation of activated T cells, including those that could be autoreactive. In general, most naïve lymphocytes survive and circulate in the body in a resting state (G_0). The survival of such resting T cells is constitutively maintained by the presence of contact with major histocompatibility complex, the cytokine interleukin (IL)-7, and expression of the antiapoptotic protein Bcl-2.[33,54,55,56] During an active immune response, T-lymphocyte proliferation can involve as much as a 10,000-fold expansion within days. Such explosive proliferation is necessitated by the extraordinarily rapid propagation of microbial pathogens. However, these activated and cycling T cells are potentially damaging due to toxic effector functions and potential

cross-reactivity with self-antigens. Activated T-cell expansion does not go unchecked and is subject to negative feedback in the form of cell death. However, because immune responses are directed at specific antigens, they must be independently regulated because some responses might expand while others contract. The immune system has developed propriocidal mechanisms to control independent populations of activated T cells. *Propriocidal regulation* refers to the various negative feedback death mechanisms that maintain homeostasis of mature peripheral T cells in an antigen-specific manner. These potently restrain antigen-activated T cells and tightly control lymphocyte numbers during and at the conclusion of immune responses.

Propriocidal regulation of T cells is triggered by remarkably simple attributes of T-cell activation: the level of cell cycling and the level of antigen restimulation.[28,54] These two features are ideally suited for triggering negative feedback death because they provide both a “sensing” mechanism for the level of active T-cell proliferation and a negative response mechanism sensitive to the level of antigen stimulation. There are essentially two different mechanisms: 1) active or antigen-stimulated PCD and 2) passive or lymphokine withdrawal PCD (Fig. 30.2).[4,57,58] These have different roles and occur at different times, as will be described in detail in the following. In some respects, it is paradoxical that lymphocytes that respond well to foreign antigen and presumably could have protective value are actively eliminated. However, it is vital to constrain the number of activated T cells to prevent unhealthy effector or autoimmune reactions. During a robust immune response, lymphocytes that cross-react with self-antigens may also proliferate. The propriocidal mechanisms that

cause these cells to die upon encountering self-antigens could be an important mechanism of preserving self-tolerance. By this formulation, tolerance is a quantitative effect that is due to the low number of significantly self-reactive lymphocytes in the naïve organism. Clonal expansion during immune responses can unleash dormant or infrequent self-reactive clones, called “forbidden clones” by Burnet, creating an autoimmune diathesis. Propriocidal death reduces these clones and thereby promotes tolerance. Active antigeninduced propriocidal death, which is induced by high or repeated doses of antigen, is especially well suited for the elimination of self-reactive clones because self-antigen is likely to be present in continuous and potentially high amounts.[28,54]

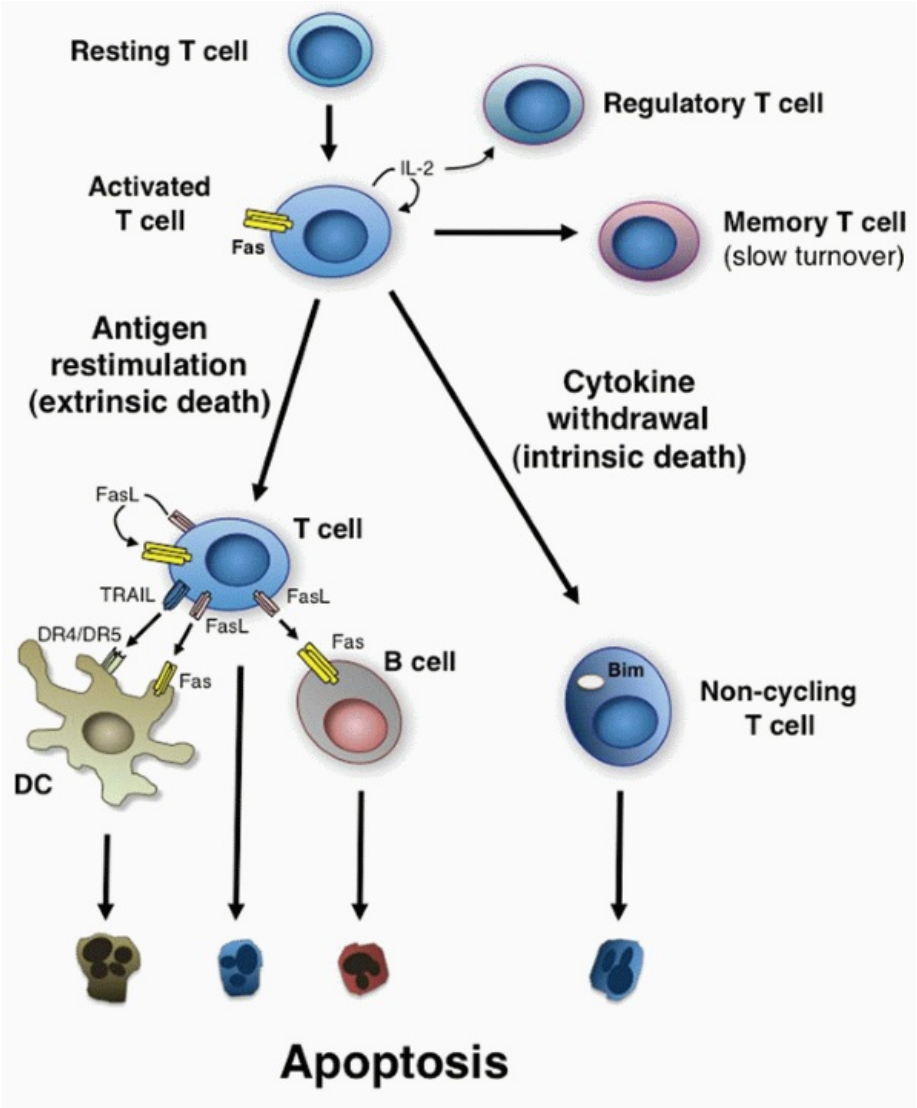

FIG. 30.2. Propriocidal Regulation of Immune Cells. Shown are the apoptosis pathways that govern T-lymphocyte homeostasis by the antigen-restimulated (extrinsic death) and no antigen (cytokine withdrawal [intrinsic death]) pathways of apoptosis. Also shown is the regulation of B cells by FasL expressed by T cells, dendritic cells by Fas ligand/tumor necrosis factor-related apoptosis-inducing ligand expressed by T cells, and T cells by regulatory T cells competing for cytokines.

Extrinsic or Antigen-stimulated T-Lymphocyte Death

The extrinsic death mechanism involves apoptosis of mature T cells in response to antigen stimulation. This requires the T cells to be activated and cycling at the time that they undergo strong antigenic restimulation.[28,54] The death is indirect in the sense that it requires the antigen-induced secretion of death ligands that engage specific apoptosisinducing DRs in the tumor necrosis factor (TNF) receptor (TNFR) and ligand superfamilies (see Fig. 30.2).[59,60] Current evidence suggests that Fas ligand (FasL) as well as TNF are the key death ligands that mediate this process in mature CD4+ and CD8+ T cells.[4,5,61] However, DR-independent apoptosis mediators also contribute in specific contexts. For example, Th2-differentiated CD4+ cells are less sensitive than their Th1-differentiated counterparts to Fas-mediated killing.[62] Instead, they preferentially die through a suicidal pathway that triggers internal release of granzyme B.[63,64] Nagata originally observed that the lymphoproliferative and autoimmune phenotype of *lpr* mice was due to genetic alterations of Fas and a similar disease was due to a mutation in FasL.[65,66] Defects in Fas (CD95) or FasL in mice and humans cause severe derangements of lymphocyte homeostasis and tolerance, which will be detailed subsequently. However, activated Fas-deficient T cells can be induced to die through other apoptotic signals, including cytotoxic granules containing perforin and granzymes, and/or TCR-induced upregulation of Bim. These alternative mechanisms may be particularly relevant to clearance of activated CD8+ T cells.[67,68,69,70,71,72,73] Often, these forms of death are called “activation-induced cell death,” but this is a misnomer.[74] Activation-induced cell death has been used to describe any form of death of activated T cells, thus causing confusion among investigators working on molecularly distinct death pathways.[4,75] Activation per se

does not directly cause cell death; instead, extrinsic death induction requires antigenic restimulation of activated T cells (ie, TCR reengagement after initial activation). For resting T cells, antigen encounter under costimulatory conditions leads to activation with very little cell death. Obviously, if the initial activation directly induced death, this would preclude immune responses. On the contrary, activated, cycling T cells do not spontaneously die by FasL or TNF unless they are strongly restimulated by antigen in the activated state, which causes upregulation of the genes for these death cytokines and responsiveness to them.[76] For these reasons, we prefer to use the term “restimulation-induced cell death” (RICD) to clarify this important distinction.[77,78]

Extrinsic death is a negative feedback mechanism, which explains why it is triggered by lymphokine-induced cell cycling (usually caused by IL-2) and reengagement of the TCR. IL-2-induced cell cycling indicates that there has been a productive antigen response and the T cells are multiplying. Because T cells can expand rapidly to great numbers, a large fraction of cycling T cells dictates a need to downregulate the response to any further antigen exposure. The presence of repeated or continuously high amounts of antigen would be a powerful stimulus to greater proliferation. Under these conditions, the system programs a fraction of the restimulated cells to undergo apoptosis via RICD. RICD sensitivity is dictated in part by the relative strength of the TCR restimulation signal, which must meet a certain “threshold” to fully activate proximal signaling proteins like CD3ζ and induce sufficient expression of

proapoptotic molecules.[79,80] It remains unclear how this apoptosis threshold is calibrated in any given T cell, although additional signals provided through certain signaling lymphocyte activation molecule receptors and the small SH2 adaptor signaling lymphocytic activation molecule-associated protein appear critical for potentiating TCR signal strength in RICD.[81] Another key determinant of death in this context is T-cell phenotype. Specifically, among CD4+ T cells, those with an effector memory phenotype are highly sensitive to Fas- and TCR-induced apoptosis, whereas central memory and activated naïve CD4+ T cells are comparatively resistant.[82] The molecular basis of this sensitivity to Fas-induced apoptosis depends on the enrichment of Fas in lipid raft microdomains in the plasma membrane of effector memory T cells, which leads to more effective nucleation of the Fas signaling complex. Thus, Fas-/TCR-induced apoptosis can specifically cull extraneous effector memory T cells without diminishing subsequent immune responses by a simple and specific feedback loop. Like most negative feedback systems, the propriocidal response directly reverses the ongoing process of proliferation by eliminating activated T cells. Antigeninduced death provides an explanation for many historical observations in the literature that show that reapplication or continuous presence of high concentrations of antigen can lead to specific suppression rather than augmentation of an immune response.[54]

Sensitivity to this extrinsic death mechanism is also directly connected to the effect of IL-2 in inducing cell cycle progression into late G_1 or S phase, which confers susceptibility to death.[83,84,85] The requirement for cell cycle progression has not been fully explained but appears to be necessary for apoptosis induced by TCR engagement or with direct Fas stimulation. Other cytokines that augment T-cell cycling, such as IL-4, IL-7, and IL-15, can also promote cell death to some degree but none with the potency of IL-2.[76] Hence, the theory of propriocidal regulation advanced the concept that IL-2 would have an important regulatory role in the elimination of activated T cells in addition to its previously known role in lymphocyte proliferation.[54] This concept was later validated when genetic deficiencies of IL-2 and IL-2 receptor in mice were found to have defective apoptosis of activated T cells and autoimmunity.[86,87] Although the immunopathology in these animals is also attributed to loss of T regulatory (T_{reg}) cells, the latter constitutes another form of polyclonal deletion by cytokine competition, which we explain in detail subsequently. This surprising property of IL-2 is important to consider in the use of IL-2 as a therapeutic agent or vaccine adjuvant. It also underscores an important feature of feedback regulation: that to achieve a maximal response for, say, a vaccine, more stimulation is not necessarily better. In a variety of test situations, extrinsic antigen-induced death decreases the number of T cells but does not completely eliminate the T-cell immune response.[28,29] In certain extraordinary conditions, such as high levels of a noncytopathic or chronic virus, essentially all responding T cells can be eliminated.[88] FasL expressed on T cells also causes the death of B cells, which do not themselves express FasL.[89] This causes a parallel regulation of B-cell proliferation by Fas-induced death that can be antagonized by B-cell receptor engagement (see Fig. 30.2). Antigen-induced death therefore provides a mechanism to eliminate specific antigen-reactive lymphocytes under chronic stimulatory conditions when they might cause the host more harm than good.

Antigen-induced expression of death ligands and other proapoptotic molecules shunts a

proportionate fraction of the antigen-specific activated cells, but not bystander cells, into the death pathway. The activated T cells still carry out their effector function when restimulated by antigen, but their ultimate fate is death instead of proliferation.[76,88] Because the primary agents of T-cell death, Fas and other TNFRs, have no inherent antigen specificity, it is important to consider how the clonal specificity of antigen-induced apoptosis is achieved.[28] For the death of activated T cells, the simple engagement of Fas by its ligand is insufficient.[90,91] Efficient death induction also requires a "competency" signal from the TCR delivered at the same time FasL binds Fas.[90,92] However, these signals do not require new protein synthesis and are delivered rapidly in a few hours or less.[90,91] The requirement for simultaneous engagement of Fas and TCR plays a critical role in establishing the antigen specificity of death. For example, it was shown that TCR stimulation of a specific subpopulation within a pool of Fas-expressing T-cell blasts, such as with agonistic anti-Vβ8 antibody, leads only to the death of that subpopulation despite the apparent exposure of other subtypes of T cells to the Vβ8-expressing cells that have been induced to express FasL.[28,90] Also, deletion in vivo is antigen-specific.[93]

The molecular nature of the competency signal is presently unknown.

Intrinsic Growth Factor Withdrawal T-Cell Death

As important as it is to avert cellular overexpansion during an immune response through extrinsic, TCR-induced death, it is equally important for the immune system to downmodulate the immune reaction after successful elimination of the pathogen. Lymphokine withdrawal death is a form of T-cell apoptosis that occurs naturally at the end of an immune response when the accumulation of effector cells becomes unnecessary and potentially damaging.[94] When the trophic cytokine for activated T cells, typically IL-2, decreases because of reduced antigen stimulation, the excess T cells undergo apoptosis.[95] This form of negative feedback death may affect specific classes of T cells, for example, "effector" versus "memory" cells, though this distinction may be difficult to discern experimentally. As most T cells in the expanded population are antigen-specific, this represents clonotype-specific T-cell propriocidal regulation controlled by antigen and cell cycle progression. The activated cells can "sense" decreased antigen drive and decreased trophic cytokine, which programs them for apoptosis. The elimination of the expanded pool of activated cells, except for a small amount of memory cells, reestablishes homeostasis in T-cell numbers. It has been shown that if IL-2 is exogenously delivered during a proliferative response to superantigen, the reactive T cells persist as long as lymphokine is provided.[96] Therefore, the lack of IL-2 is a key element in the feedback regulation of the cellular response. Antigen and IL-2 therefore mediate propriocidal regulation, in the midst of an immune response and at its conclusion to reduce T-cell numbers.

Genetic studies reveal that the molecular mechanism of lymphokine withdrawal death is different than antigen-induced apoptosis.[57,58] Although this event is often confused with extrinsic cell death mediated by Fas, DRs are not involved. Rather, cytokine withdrawal for as little as 2 to 4 hours commits the cell to a death pathway requiring new protein synthesis.[97] Apoptosis is initiated through the mitochondrial pathway and is orchestrated by the Bcl-2

family of proteins. In fact, the ratio between the pro- and the antiapoptotic Bcl-2 family members is believed to determine the fate of the cells. In the presence of growth factors, the antiapoptotic Bcl-2, Bcl-X_L, and Mcl-1 proteins maintain viability via retrotranslocation of the executioner molecules Bax and Bak from the mitochondria into the cytosol, precluding oligomerization and permeabilization of the mitochondrial outer membrane (see following section).[98] Proapoptotic, "BH3-only" activators like Bim and Bid can bind to antiapoptotic Bcl-2 family proteins and disrupt this process to allow Bax-/Bak-mediated mitochondria depolarization. Bim is an essential regulator upstream of Bax and Bak during cytokine withdrawal-induced apoptosis in lymphocytes.[99] CD4+ and CD8+ T cells from mice homozygously deficient for Bim survive much longer than their wild-type counterparts following in vitro and in vivo activation with the superantigen *Staphylococcus aureus* enterotoxin B.[100] Moreover, Bim is critical for cell death of T cells induced by both IL-2 and IL-7 withdrawal.[51,100,101] Bim dysregulation also underlies the overaccumulation of lymphocytes due to failed cytokine deprivation apoptosis in the lymphoproliferation disorder caused by activating mutations of Ras.[102] Cytokine deprivation rapidly upregulates Bim messenger ribonucleic acid levels through activation of the forkheadlike transcription factor FOXO3A. Bim is also subject to sophisticated posttranscriptional regulation in T cells. For example, removal of IL-2 shuts down the Ras-ERK signaling cascade emanating from the IL-2 receptor, which normally promotes Bim protein degradation and destabilization of Bim messenger ribonucleic acid.[103,104] PUMA, another BH3-only protein, functions synergistically with Bim downstream of FOXO3A and accounts for Bim-independent death.[105,106] When the trophic cytokine is present, the Ser/Thr kinase Akt also phosphorylates key substrates and prevents mitochondrial collapse. For example, Akt suppresses FOXO3A activity. Akt also phosphorylates the pro-apoptotic Bad protein, which is then sequestered by the 14-3-3 scaffold protein.[107,108] Another target inactivated by Akt is glycogen synthase kinase-3, which phosphorylates Mcl-1 on residue S159 when cytokines are removed. The rapid degradation of phosphorylated Mcl-1 by the ubiquitin-proteasome pathway disrupts the fragile equilibrium between the pro- and the antiapoptotic Bcl-2 family members, and promotes cell death.[109] Thus, Akt can preserve viability by targeting appropriate Bcl-2 family members. Ultimately, the relative balance of proapoptotic (Bim, Puma) versus antiapoptotic (Bcl-2, Mcl-1, etc.) proteins expressed regulates mitochondrial stability and apoptosis sensitivity in response to cytokine withdrawal.

T Regulatory Cells

Research on the intriguing subset of CD4+ T cells known as T_{reg} cells, and their role in immune tolerance, continues to expand vigorously. These cells express the forkhead box P3 transcription factor and suppress the expression of many TCR-induced genes including cytokines and cytokine receptors.[110,111] Similar to other subsets of T cells in their "activated" state, T_{reg}s require common gamma chain cytokines for survival. In particular, they characteristically express the IL-2 alpha chain receptor (CD25) and require IL-2 to persist in the periphery.[112] IL-7 can also act as a survival factor for T_{reg} cells.[113] The mechanisms by which T_{reg} cells "suppress" immune responses have remained somewhat obscure. However, recent evidence suggests that the direct T_{reg}-mediated suppression of

other T cells can be attributed in large part to their large appetite for survival cytokines, which T_{reg}s themselves cannot produce.[114,115] T_{reg}s absorb significant amounts of trophic cytokines like IL-2 at a site of an immune reaction, which induces Bim-dependent, intrinsic lymphokine withdrawal death of nearby activated and cytokine-requiring T cells.[116] Consistent with historical observations, this phenomenon is not antigen-specific but requires T_{reg}s to be in close proximity to IL-2-producing T cells to effectively consume the cytokine and preclude autocrine/paracrine signaling in

targeted responder T cells.[115,117] T_{reg}s can also consume other common gamma chain cytokines involved in lymphocyte survival and effector function, such as IL-4, IL-7, IL-15, and IL-21.[118] Therefore, this form of T_{reg}-mediated polyclonal deletion constitutes a form of dominant tolerance dependent on intrinsic PCD. This mechanism allows a productive immune response to unfold while the ratio of effector T cells to T_{reg}s remains high. Subsequent IL-2-mediated expansion of T_{reg}s then establishes a natural brake on effector cell expansion via competition for available cytokines and culling of excess effectors deprived of IL-2. As polyclonal deletion is enforced, T_{reg}s may also utilize alternative strategies for functional suppression of remaining responder T cells or antigen-presenting cells, including the production of suppressive cytokines (eg, transforming growth factor-β, IL-10) and cytotoxic T-lymphocyte antigen-4 effects on costimulatory molecules (CD80, CD86).[119]

T-Cell Memory

T cells, once activated, can persist as “memory” cells. One view is that this process involves an escape from propriocidal mechanisms of apoptosis.[35,120,121,122] Increasing evidence supports the concept that memory is due to the long-term survival of antigen-specific T cells even without further antigen exposure. Several means to achieve such survival are possible. To escape killing by Fas and other death receptors, T cells could express cellular FLICE inhibitory protein (FLIP), which is a homologue of caspase-8 and -10 located in the same genetic locus as these caspases that has no enzymatic function but can interpose itself into the death receptor complex and block caspase activation.[123] This type of inhibition has been demonstrated in B cells by the ability of B-cell receptor (BCR) stimulation, which upregulates cellular FLIP,[124,125] to block Fas killing.[126] Specialized T-cell subsets, including proinflammatory Th17 cells, may escape Fas-mediated RICD through cellular FLIP overexpression.[127] Various “inhibitor of apoptosis proteins” (IAPs) might also interfere with DR-mediated killing.[128,129] Furthermore, the mitochondrial death pathway could be attenuated by upregulation of Bcl-2 and Bcl-X_L. These antiapoptotic molecules, which are upregulated in CD8+ and CD4+ memory cells,[122,130] have been shown to block lymphokine withdrawal apoptosis.[131] The necessity of these inhibitory molecules for the persistence of a memory population of T cells is unknown. Moreover, it is mainly the central memory rather than effector memory T cells that become refractory to RICD.[82]

Another view is that long-term survival in a nonproliferative “resting” state characteristic of “virgin” (naïve) T cells is never reestablished by memory cells. Work by Phillipa Marrack, Rafi Ahmed, and others reveals a surprisingly dynamic T-cell memory pool. Their study proposes

a constant, low-level proliferation of memory CD8+ T cells that is antigen-dependent and maintained by IL-15 and to a lesser extent by IL-7.[132,133,134] Also, the fraction of memory cells remains constant over time, indicating that death is continuously maintaining a balance. Hence, the balance of slow proliferation and slow death ensures memory cell maintenance. As the molecular mechanism of the memory state is further elucidated, the differing views of "memory" are likely to be reconciled.

The mitochondrial pathway of death is likely to play a prominent role in the generation of memory cells. In addition to their proliferative effects, the cytokines IL-15 and IL-7 appear to promote survival of memory cells through their induction of antiapoptotic molecules such as Bcl-2.[135,136,137] This countervailing effect is consistent with a recently demonstrated Bim-dependent mechanism for limiting memory CD8+ T cells.[138] In addition, a Bim-independent mechanism for expunging memory T cells was shown.[138] The nonmitochondrial pathways of death contributing to memory cell generation may involve death receptors. For instance, CD4+ T-cell help is required for CD8+ T-cell memory. In the absence of CD4+ help, TNF-related apoptosis-inducing ligand (TRAIL) is expressed on and mediates apoptosis of CD8+ cells upon antigen restimulation.[139] TRAIL deficiency, however, only delays the loss of CD8+ memory cells, revealing that non-TRAIL mechanisms also contribute to the homeostasis of CD8+ memory cells.[140] Further studies are needed to dissect the PCD mechanisms contributing to T memory cell generation and homeostasis.

B-Cell Homeostasis

We have focused most of our attention on T-lymphocyte apoptosis thus far because it has received the greatest experimental examination and more details are known. However, PCD also governs B-cell homeostasis and is regulated in ways that have similarities and differences with T cells. Both DR triggering and withdrawal of trophic stimuli contribute to B-cell elimination. Similar to T cells, B cells developing in the bone marrow undergo a series of proliferative expansion and apoptotic contraction events to shape the final B-cell repertoire.[141] Immunoglobulin (Ig) gene rearrangement starting at the pro-B-cell stage generates the BCR. The cytokine IL-7, which promotes the survival of developing thymocytes,[142,143] is also crucial for sustaining survival at the pro-B/pre-B juncture.[144,145] IL-7 induces transcription of the antiapoptotic molecule Mcl-1, which selectively binds to and antagonizes the proapoptotic Bcl-2 family member Bim.[146,147] Then selection for B cells occurs in two developmental steps with successive gene rearrangements at the heavy and light chain Ig loci. B cells that fail to generate a productive BCR, due to abortive Ig gene rearrangements, are eliminated by PCD. At the other end of the spectrum, B cells that express BCRs directed against self-antigens are eliminated by apoptosis or undergo receptor editing to acquire new antigen specificity.[148] The survival and antigen responsiveness of immature B cells can also be increased by lipopolysaccharide exposure, presumably to enhance B-cell production during infections.[149] Fas, TNFR-1, and perforin are not involved in the death of developing B cells.[150] Rather, death appears to be a consequence of a direct signaling event generated by the BCR.[151]

In contrast to B cells in development, mature B cells rely heavily on TNFR family receptors

such as CD40, Fas, and BAFF for regulating their survival and death. It is also

clear that T cells control PCD of mature B cells. Christopher Goodnow and colleagues have illustrated the importance of CD40 and Fas in the balance of life and death in B cells using the hen egg lysozyme (HEL)-transgenic and HEL-specific TCR transgenic mice.[152,153] Naïve, HEL-specific B cells undergo proliferation in the presence of HEL and HEL-specific CD4+ T-cell help. Hence, proper B-cell activation requires triggering of the BCR as well as "help" in the form of CD40L expressed on activated T cells. The primary function of CD40L is to prevent anergy and/or death of activated B cells in the germinal center, allowing further differentiation and function.[154] However, anergic HEL-specific B cells from HEL transgenic animals undergo apoptosis in the presence of the same HEL-specific CD4+ T-cell help. This antigen-specific B cell death is absent in Fas-deficient B cells,[152] thus suggesting a role for Fas in causing the death of anergic antigen-specific B cells. Fas killing of mature B cells can also be abrogated by BCR engagement and IL-4, which promote antibody responses.[155,156] An imbalance of CD40 and Fas signals might contribute to autoantibody production consequent to Fas and FasL mutations in both human and mouse. Indeed, ablation of Fas in murine B cells alone recapitulates the same autoimmune and lymphoproliferative phenotypes noted in *lpr/gld* mice, illustrating the importance of Fas in enforcing B-cell tolerance.[157]

More recent studies using similar transgenic systems suggest that whereas Fas can mediate apoptosis of activated B cells by engaging CD4+ T cells, BCR-induced death of immature or resting mature B cells is primarily Fas-independent. As in T cells, differential expression of pro- and antiapoptotic Bcl-2 family members control mature B-cell fate at different stages. For example, Bcl-2 and Bcl-xL are critical for naïve B-cell survival, whereas Mcl-1 sustains germinal center B cells that persist into memory B cells.[158] As for T cells, knockout mouse experiments reveal that both Bim and Puma are central regulators of mature B cell PCD.[159,160,161,162] The critical B-cell survival and maturation factor BAFF, in combination with BCR signaling, ultimately controls mature B-cell homeostasis via NF-κB-mediated induction of antiapoptotic genes like A1 and Bcl-xL.[163] BAFF signaling also promotes naïve B-cell survival by sustaining the MAPK signals that block Bim accumulation.[164]

The attenuation of B-cell responses at the end of an immune reaction is likely to involve cytokine withdrawal death similar to that of T cells, but this phenomenon is less well characterized. Deprivation of cytokines such as IL-7 and IL-15, which enhance cellular survival through the upregulation of Bcl-2, Bcl-X_L, or Mcl-1, may be responsible.[147,165] Lymphokine withdrawal death in B cells, like T cells, requires de novo ribonucleic acid/protein synthesis.[166] An interesting observation is that a secreted lipocalin, identified through microarray analysis of an IL-3-dependent pro-B-cell line, was implicated as a potential mediator for IL-3 withdrawal death.[167] This protein appears to regulate intracellular iron levels, which may modulate Bim levels for apoptosis induction.[168] However, it remains to be seen whether lipocalins or other similar molecules are involved in lymphokine withdrawal death in primary mature B or T cells. As we will discuss later in this chapter, survival genes such as Bcl-2 can protect cells against lymphokine withdrawal death and therefore play an important role in mature B-cell homeostasis. Moreover, Bcl-2 can contribute to the survival of

B lymphoma cells as revealed by the t(14:18) translocation of Bcl-2 to the Ig locus in follicular B-cell lymphomas.[169]

Dendritic Cell Homeostasis

Understanding the cell fate regulation of DCs is still in its infancy. However, emerging evidence suggests that these highly efficient antigen-presenting cells are also subject to homeostatic regulation by PCD. The natural turnover of DCs was demonstrated in the mouse by Jenkins and coworkers.[170] Using elegant cell-labeling experiments, they showed that antigen-laden DCs stimulate the formation of a cluster of activated antigen-specific T cells and then disappear. This process was antigen- and T cell-dependent. Later, it was shown that the TNF homologue TRAIL, which is produced by activated T cells, could induce apoptosis in DCs and that this mechanism could be defective in patients harboring mutations in caspase-10.[171] Together, these data introduced the concept that there is homeostatic regulation of DCs involving differentiation and recruitment followed by their active elimination by stimulated T cells. Early removal of DCs has the benefit of allowing the activation of T cells but avoiding T-cell restimulation and propriocidal death too soon in the response to antigen. Recent work in mice genetically engineered to selectively express the p35 apoptosis inhibitory protein in DCs reveals that apoptotic removal of DCs is essential to preserve tolerance and prevent autoimmunity.[172] Moreover, forced p35 expression in DCs accelerated autoimmunity on the autoimmune-prone *MRL* background, similar to what is observed for T- and B-cell apoptosis defects. Thus, impaired DC apoptosis can collaborate with other genetic and environmental factors to powerfully predispose to autoimmunity. Similar to B cells, specific ablation of Fas in DCs also gives rise to autoimmunity and excessive lymphocyte proliferation in mice.[157]

On the other hand, PCD of DCs may also serve to promote inflammation and clearance of intracellular pathogens. This is achieved through a distinct pathway of PCD known as "pyroptosis."[173] This pathway is selectively induced in DCs and macrophages upon caspase-1 activation in inflammasomes, cytosolic protein complexes designed to detect microbial components and other "danger" signals. Although it shares some morphologic features with apoptosis, pyroptosis is a distinct proinflammatory, lytic process designed to expose intracellular pathogens and recruit neutrophils. Thus pyroptosis appears necessary for effective clearance of intracellular pathogens that would otherwise replicate and avoid immunosurveillance.

Impaired Programmed Cell Death in Lymphoproliferative Disease and Autoimmunity

Genetically modified mice continue to provide invaluable insights into the molecular underpinnings of PCD in immune cells. The recent description of Bim-deficient *lpr*

mice provides overwhelming evidence that Fas and Bim are the most important proapoptotic genes governing immune homeostasis.[174,175,176] Loss of either Fas or Bim function in isolation manifests in lymphoproliferative disease and autoimmunity. Loss of both results in strikingly accelerated fatal lymphocyte accumulation, early-onset lupus-like autoimmune disease, and failed contraction of antiviral T-cell responses. These findings indicate that Fas

and Bim must cooperate in ensuring immune homeostasis through proper PCD. This corroborates earlier work showing that *lpr* combined with Bcl-2 overexpression caused a synergistic increase in lymphadenopathy and autoimmunity.[57,58]

The study of inherited human lymphoproliferative diseases has further cemented the importance of FAS- and BIM-mediated PCD in maintaining immune homeostasis. Autoimmune lymphoproliferative syndrome (ALPS) was the first genetic disorder of impaired lymphocyte apoptosis (and perhaps the first inherited disease of apoptosis ever described) initially linked to debilitating mutations in FAS. We now appreciate the existence of several forms of ALPS caused by germline or somatic mutations in FAS, FASL, and caspase-10.[177] A similar syndrome known as RAS-associated autoimmune leukoproliferative disease is caused by somatic gain-of-function mutations in NRAS, which impair lymphokine withdrawal apoptosis by suppressing upregulation of BIM.[102] Patients with ALPS typically present early in life with lymphadenopathy and splenomegaly, including the unique expansion of atypical CD4- CD8- "doublenegative" T cells. Autoimmune cytopenias and increased incidence of lymphoma are also characteristic of ALPS and RAS-associated autoimmune leukoproliferative disease, underscoring the significance of Fas- and Bim-induced apoptosis for culling excess lymphocytes to maintain tolerance and prevent malignancy.

Other lymphoproliferative disorders with ALPS-like features have been linked to faulty PCD. The recently recognized immunodeficiency linked to loss of caspase-8 (caspase-8 deficiency syndrome) also features abnormal lymphocytosis due to impaired Fas-induced apoptosis. The unexpected requirement for caspase-8 in lymphocyte activation explains why patients with caspase-8 deficiency syndrome suffer from recurrent infections rather than autoimmune manifestations.[178] Similarly, lymphoproliferation and increased susceptibility to bacterial and viral infections characterizes with a recently-identified family with homozygous FADD-deficiency, reflecting a critical function for FADD in Fas-independent immune cell effector functions.[179] Excessive accumulation of T cells deficient in signaling lymphocytic activation molecule-associated protein in X-linked lymphoproliferative disease is also ultimately the result of impaired RICD, explained by insufficient induction of FASL and BIM.[81] Defective RICD may partially explain why many patients with X-linked lymphoproliferative disease succumb to fulminant infectious mononucleosis upon Epstein-Barr virus infection, marked by lethal overexpansion of activated, Epstein-Barr virus-specific CD8+ T cells that fail to die after repeated encounters with Epstein-Barr virus-infected B cells. Furthermore, defective PCD may be partially responsible for T-cell hyperproliferation and multiorgan infiltration in patients with immunodysregulation, polyendocrinopathy, and enteropathy, X-linked syndrome, and the equivalent "scurfy" mouse model. In this disease, T_{reg} cells are lost due to Foxp3 mutations, hampering polyclonal, Bim-directed T-cell apoptosis induced by T_{reg}-mediated consumption of IL-2.[116] As new pathologic mutations are rapidly uncovered by rapid whole-genome sequencing, similar disorders featuring unwanted accumulation of activated lymphocytes, including self-reactive autoimmune clones, may eventually be tied to related defects in cell death programs. The investigation of these disorders of apoptosis and immune homeostasis has provided useful lessons on contemporary human genetic investigation which have been summarized elsewhere.[180]

Programmed Cell Death and Development of Lymphoid Malignancy

Here we return to the question of why the mature immune system assiduously eliminates activated lymphocytes that have proven their utility in recognizing and responding to specific antigen. Why can't the immune system adopt a laissez-faire economy of previously activated cells, which might have great value if the same pathogen is re-encountered? Several lines of evidence strongly suggest that in addition to the potential loss of tolerance and autoimmunity, lymphoid malignancy is also promoted by defective apoptosis. Hence, the accumulation of immune cells that have a propensity to proliferate and can undergo additional genetic changes may be deleterious to the organism. The association of translocations of the Bcl-2 gene with diffuse large B cell lymphoma suggested that somatic aberrations in apoptosis pathways might be important in the transformation process. Since then, somatic changes in a variety of apoptosis molecules including Fas, caspases, and Bcl-2 family members have been documented in lymphoid tumors.[181] By contrast, the well-known inheritable apoptosis defect in p53 in the Li-Fraumeni syndrome seems to cause predominantly solid tumors but not lymphomas. Examination of large kindreds of patients with ALPS has revealed a 15-fold greater incidence of lymphomas relative to the general population. It is striking that these families have several different classes of lymphoma, suggesting that Fas protects against transformation not for a single cell type but generally for B- and T-lymphocytes.[182] Moreover, Fas stimulation not only results in death induction, but also stimulation of signals for survival and proliferation such as NF-κB and MAPK activation; these dichotomous signals may have different thresholds that can contribute to lymphomagenesis.[183] Patients with X-linked lymphoproliferative disease are also at greater risk for developing B-cell lymphomas, which may be linked to impaired B-cell PCD attributed to poor T or natural killer cell cytotoxic capability, including hampered FasL induction.[184] Thus, besides autoimmune manifestations, we can infer that protection against lymphoid malignancy demands strict control over the accumulation of activated lymphocytes.

Programmed Cell Death as an Immune Effector Mechanism

Although this topic will be covered authoritatively elsewhere in the book, it is important to recognize that the same pathways that participate in homeostatic cell death also are used as immune effector mechanisms. The Fas pathway is the principal calcium-independent pathway of cytotoxic T-lymphocyte killing.[68] Fas ligand displayed by either CD4+ or CD8+ T cells can eliminate Fas-bearing cells that may be infected or malignant. Similarly, the calciumdependent cytotoxic T-lymphocyte killing mechanism involving perforin and granzymes also can induce PCD in target cells. The two main proteases are granzyme A and granzyme B, the latter being the only serine protease capable of processing caspases.[185,186,187,188,189] Following endocytosis into a target cell, perforin forms pores in endosomal membranes through which granzyme B gains access to the cytoplasm and proteolytically activates caspases, leading to apoptosis.[190] Though this cytoplasmic pathway of death does not emanate from the mitochondria, the latter may amplify the death signal by Bid cleavage.[191,192,193,194,195] These parallels may provide an insight into why lymphocytes have evolved mechanisms in trans, involving the surface interaction of FasL and Fas or perforin/granzyme release to homeostatically control their numbers by apoptosis. This permits the T cell to simultaneously regulate itself and other immune cells, and to expunge nonlymphoid cells that require immune

elimination such as those that are infected or malignant. Natural killer cells may also use PCD mechanisms for selfregulation and expunging infected or malignant cells.[196,197] Hence, for mature T cells, the same molecules can subserve several death functions. By contrast, a more direct connection of the TCR or BCR to death pathways is present in developing lymphocytes, which have no use for effector mechanisms or propriocidal regulation.

Programmed Cell Death as Immune Therapy

Because of its exquisite antigen specificity, the possibility of using antigen-induced death, particularly of T-lymphocytes, for the treatment of immunologic diseases has been suggested.[198,199] In particular, the T-cell components of graft rejection, autoimmune diseases, and allergic reactions could potentially be suppressed by antigen-induced elimination. This concept has been tested in both mice and monkeys with clearly beneficial effects on disease outcome. For example, it was found that the repetitive administration of a myelin basic protein antigen could suppress experimental allergic encephalomyelitis in mice by deleting the diseasecausing T cells.[93] This suggests that antigen-specific therapy is achievable if antigens relevant to the disease process are sufficiently well-defined and death of the culpable T cells can be triggered without exacerbation of symptoms.[29]

Because these requirements have limited further evaluation of antigen-specific therapy in human clinical trials, other ways of triggering death have been explored. Fas or TNFR1 agonist administration results in systemic toxicities limiting their potential utility.[200,201] However, TRAIL receptor agonists potentially induce death of neoplastic cells preferentially.[202,203] Intracellular apoptosis signaling molecules targeted in preclinical or clinical trials include caspases, IAPs, SMAC, and proapoptotic or antiapoptotic Bcl-2 family members.[204,205,206,207] Many of these are rationally designed small molecules or peptidomimetics, which have demonstrated promising results, particularly against lymphoid and other malignancies.

CELLULAR AND MOLECULAR MECHANISMS OF PROGRAMMED CELL DEATH

Apoptosis Initiation Mediated by Caspase Complexes: Two Principal Pathways

Caspases must be highly active within the cytoplasm to cause apoptosis. Like all proteases, these potentially destructive proteins are first produced as zymogens that are then proteolytically activated. Elucidating these complex mammalian pathways provides a window into the myriad of molecular abnormalities of apoptosis that contribute to immunologic diseases and cancer (Fig. 30.3). Also, it is necessary to understand the important nonapoptotic functions assigned to caspases including cellular activation, suppression of necrotic pathways, and cytokine processing as key enzymatic functions of inflammasomes. Fortunately, mammalian apoptosis can be understood with a few key concepts. Most importantly, the processing enzymes that activate caspases are mainly caspases themselves. As explained in the following, activation and autoprocessing occur when caspase zymogens are brought into specific signaling complexes. In general, there are two main forms of caspases. Those with long prodomains that have protein interaction domains capable of bringing them into activating platforms for autoprocessing are called initiators, upstream, or apical caspases. Those with short prodomains that must be cleaved by other proteases

(caspases or granzyme B) are called effector, downstream, or executioner caspases. Key adaptor molecules harbor domains that specifically recruit caspases into complexes: the death effector domains (DEDs) or the caspase recruitment domains (CARDs).[208,209] The DEDs and CARDs are protein-protein interaction domains found in the caspase prodomains and other adapter molecules that generate the specific intermolecular assemblies. In contrast to executioner caspases, which require processing to become active, initiator caspases are activated by multimerization.[210,211] When juxtaposed at the receptor complex, initiator caspases become proteolytically active and will cleave one another. This "proximity-driven model" posits that specific intra- and intermolecular cleavage triggered by procaspase dimerization drives initiator caspase activation.[212] This leads to the maturation of the enzyme through separation of the large and small enzymatic subunits. Autoprocessing also cleaves the enzymatic units from the prodomain, thereby liberating the highly active enzyme from the receptor complex. As discussed later in the chapter, structural studies suggest that active caspases are tetrameric species composed of two small and two large subunits.

To initiate the caspase cascade, the enzyme must dock onto the appropriate adapter molecules. The adapter/caspase complex presumably provides a conformation that facilitates

the initial autoprocessing step of the caspase zymogen. Adapter/caspase complexes originate from two principal sites in the cell: 1) the plasma membrane (through DRs), also known as the extrinsic pathway or 2) the mitochondrion, or intrinsic pathway (see Fig. 30.3). We will employ this primary dichotomy of extrinsic and intrinsic pathways as it recapitulates the two major forms of propriocidal apoptosis: antigen-induced and lymphokine withdrawal, respectively.

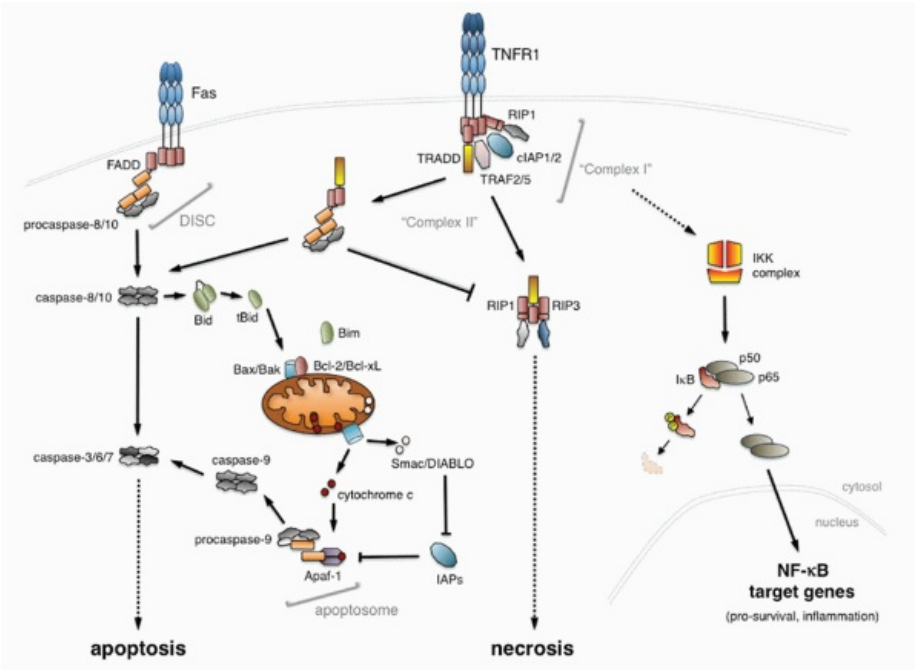

FIG. 30.3. Signal Transduction Pathways of Death Receptors. Shown are the two principal apoptosis pathways associated with death receptors (Fas and tumor necrosis factor receptor-1) and the mitochondrial pathway of caspase-9 activation. The *solid arrows* indicate direct association of the steps involved, whereas the *dashed arrows*

indicate that multiple steps are involved. Inhibitory interactions are shown by a *barred line*.

DR engagement by cognate ligand causes the formation of the death-inducing signaling complex (DISC), which comprises the cytoplasmic tail of the receptor, the FADD adapter protein, and caspase-8 or -10.[213,214] The recruitment of caspase-8 or -10 into the DISC triggers the processing of these proteases into their active form. An 80-amino acid death domain (DD) present in the Fas cytoplasmic tail and FADD causes their interaction. The DD contains a "hexahelical bundle" that nucleates this complex, as described in the following. FADD then recruits caspase-8 or -10 by homotypic interaction between DEDs present in each of these molecules. The DED has a hexahelical bundle homologous but not identical to DDs. Sensitive energy transfer techniques have demonstrated that both caspases can enter the same receptor complex.[215] Recent work shows that the signaling likely involves an asymmetric oligomeric complex of five to seven Fas DDs and five FADD DDs, forming a flexible helical structure that may adjust to the level of agonist simulation.[216,217] Molecular modeling studies show that the Fas pathway appears to be governed by a threshold of signal required for the commitment to death.[218] This may arise from the oligomeric assembly of each individually liganded Fas complex that then form larger assemblies of engaged Fas receptors, leading to the formation of microscopically visible clusters of Fas termed signaling protein oligomerization transduction structures. These structures enhance caspase-8 recruitment and activation.[219] Fas receptor capping and internalization in endosomal vesicles follow signaling protein oligomerization transduction structure formation and may promote the killing process.[220]

The signal complex for TNFR-1 is different from that for Fas as it includes the DD-containing adapter TRADD in addition to FADD and caspase-8 and -10 (see the following discussion). Similar signaling complexes are likely formed with other DD-containing members of the TNFR superfamily including DR3, TRAIL receptors DR4 and DR5, and DR6.[221,222,223] Our knowledge of the physiologic significance of apoptosis-inducing receptors besides Fas and TNFR-1 in immune regulation remains incomplete. DR3 was once shown to participate in negative selection of thymocytes,[224] although DR3 is better known for its proinflammatory, pathogenic role in autoimmune disorders.[225] DR6 has been implicated in attenuating Th2 responses.[226,227] It has been proposed that DR4 and DR5 may mediate the preferential killing of tumor cells (including lymphoid tumors) through TRAIL.[202]

Activation of the mitochondrial pathway of apoptosis during lymphokine withdrawal or during development achieves the same end as DRs: caspase activation. However, signal complex formation occurs in a different way. Intrinsic signals converge on the mitochondria, resulting in mitochondrial fission and outer membrane permeabilization and the release of the proapoptotic molecules from the intermembrane space (IMS) into the cytosol.[228] Cytochrome c, a protein involved in the electron transport chain, is liberated into the cytosol where it binds in a heptameric complex with the apoptotic protease-activating factor 1 (Apaf-1) in the presence of ATP/dATP, often referred to as the "apoptosome."[229,230] This complex

nucleates caspase-9 recruitment and activation.[231,232,233] There are specialized regulatory proteins for caspase-9 that provide additional levels of control: X-linked IAP (XIAP), which inhibits caspase-9, and Smac/Diablo which counteracts XIAP.[234,235] These mitochondrial events are tightly regulated as caspase-9 activation commits the cell to die.

The Central Role of the Mitochondrion

A special role for the mitochondrion in apoptosis was first suggested by the finding that Bcl-2 and related molecules were anchored predominantly in the outer mitochondrial membrane (OMM). The inner mitochondrial membrane (IMM) is devoted to energy conversion and adenosine triphosphate generation, but the OMM has emerged as a primary regulator of cell viability. A diversity of death inducers, including trophic factor withdrawal, drugs such as staurosporine or steroids, or DNA damage, can all generate signals that converge on the mitochondrion. Their principle effect is to induce mitochondrial fission and increase OMM permeability to large proteins, leading to the release of apoptogenic factors into the cytosol.[228] The critical role of cytochrome c release was elegantly demonstrated by generating “knock in” mice expressing a mutant cytochrome c (K72A).[236] This mutant version of cytochrome c retains its electron transfer function but cannot activate Apaf-1. The mutant mice display developmental abnormalities similar to Apaf-1- or caspase-9-deficient animals, and the surviving mice exhibit impaired lymphocyte homeostasis. In contrast to Apaf-1-/- cells, thymocytes from mice with mutant cytochrome c were normally sensitive to intrinsic stimuli such as γ-irradiation, dexamethasone, and etoposide. This reveals a cytochrome c- and apoptosome-independent but Apaf-1-dependent mechanism of caspase activation and cell death.[236]

Interestingly, 85% of cytochrome c is sequestered inside the intracristae region formed by the convoluted folds of IMM, with limited access to the IMS.[237] Therefore, the sudden “all-or-nothing” release of cytochrome c requires two steps: 1) a BH3-only protein-dependent remodeling of the cristae structure allowing cytochrome c to access the IMS and 2) the Bax and Bak-dependent permeabilization of the OMM. The cristae structure was recently shown to be controlled by the IMM presenilin-associated rhomboidlike protein (PARL) and by the IMS resident, dynaminrelated optic atrophy 1.[238,239] In yeast, homologues of these proteins, Rbd1 and Mgm1, respectively, regulate mitochondrial fusion, a process of mitochondrial metabolism. Mice deficient in PARL die between 8 and 12 weeks of age due to progressive cachexia, and their lymphocytes undergo massive apoptosis. Moreover, mouse embryonic fibroblasts derived from these animals were significantly more sensitive to intrinsic stimuli, demonstrating the antiapoptotic function of PARL. Normally, PARL cleaves optic atrophy 1, and both cleaved and uncleaved optic atrophy 1 form heterooligomers that maintain a tight bottleneck configuration of the cristae, keeping cytochrome c sequestered.

How the OMM releases its mortal poison is still unclear, and two models have been proposed. In one, the proapoptotic Bcl-2 family proteins Bax and Bak selectively permeabilize the OMM, without affecting the IMM. In the second model, a pore in the IMM known as the mitochondrial permeability transition complex opens and allows water and solutes up to 1.5 kDa to accumulate into the matrix. The matrix swells as water enters and the OMM bursts.[240,241] Cells from mice lacking cyclophilin D, a critical component of the mitochondrial permeability transition complex, remain sensitive to intrinsic death insults,

favoring the first model. Moreover, the first model fits with recent data that the mitochondrial fission leads to weakening of the outer membrane and can be controlled by Bcl-2 family proteins.[228] However, the mitochondrial permeability transition complex appears to be essential for stimuli promoting necrosis such as calcium overload and ROS. Perhaps this accounts for the fact that cyclophilin D knockout mice were resistant to ischemia/reperfusion-induced cardiac injury.[242,243] As detailed in the following, OMM permeability is regulated by the large family of proteins related to Bcl-2.

In addition to cytochrome c, several other proapoptotic proteins from the IMS are released outside the mitochondria during apoptosis. The flavoprotein "apoptosis-inducing factor" (AIF) translocates from the mitochondria to the nucleus, causing DNA fragmentation and chromatin condensation in response to apoptotic stimuli.[244,245] Genetic deficiency of this protein in mice inhibits the death of embryonic cells in response to serum starvation and appears to be responsible for embryonic morphogenesis and cavitation of the embryonic cell mass. The observation that these processes did not depend on caspase-3, caspase-9, or Apaf-1,

showing that unlike *C. elegans*, not all programmed death in mammalian cells depends on caspases.[246] Further work will be needed to determine if AIF has any role in immunity. Another mitochondrial protein important in apoptosis is endonuclease G, a mitochondrial nuclease that is released and translocates to the nucleus in response to death stimuli. Once situated in the nucleus, endonuclease G cleaves DNA into nucleosomal sizes independent of caspases, differing from the caspase-dependent activation of another apoptotic nuclease, caspase-activated DNase[247] (see subsequent discussion). Other mitochondrial proteins released into the cytosol, Smac/DIABLO and Omi/HtrA2, neutralize the IAPs and thus promote caspase activation.

Studies on the mitochondrion have also focused on caspaseindependent apoptosis, which AIF, endonuclease G, and Omi/HtrA2 were proposed to mediate. In general, this concept stemmed from examples of apoptosis that could not be blocked by small peptide caspase inhibitors such as zVAD.[248,249] However, conclusions drawn from such experiments are limited by the short half-life of such inhibitors and the fact that they do not block all caspases. Also, kinetic experiments show that AIF release is slower than that of cytochrome c, Smac/DIABLO, and Omi/HtrA2.[250,251] Finally, cells from caspase-3 and -7 knockout mice exhibit a delayed translocation of cytochrome c and AIF, indicating that caspases act as an amplification loop necessary to fully permeabilize the mitochondria.[252] Thus, it is uncertain if a truly caspase-independent form of apoptosis exists.

Programmed Necrosis

While PCD has generally been equated with apoptosis, recent evidence suggests that necrotic or alternative forms of death may also result from internal death programs.[248,249,253,254] This is different from secondary necrosis that occurs in the late phase of apoptosis when membrane integrity is lost. Rather, PCD leading to a necrotic morphology without any intermediate stage of apoptosis or caspase activation is now well documented.[18,246] For example, it has been found that DRs can trigger necrotic death rather than apoptotic death under certain circumstances.[248,249,253] Although TNF

stimulation through TNFR-1 can trigger caspase-dependent, classical apoptosis, necrosis may well be the dominant pathway for TNFR-1, at least in certain cell types.[248,253] By contrast, Fas predominantly triggers apoptosis but can also induce necrosis.[18] A shift from apoptosis to necrosis can be induced by tetrapeptide caspase inhibitors, suggesting that necrosis causes cell elimination when apoptosis fails or is blocked.[249] Moreover, the discovery of a specific inhibitor of necrosis but not apoptosis points to a distinct biochemical pathway for programmed necrosis.[19] These observations have physiologic relevance as propriocidal death of mature T cells is partly refractory to inhibition by caspase blockers and can manifest features of necrosis.[18] For these reasons, we utilize the term "programmed necrosis" to describe death by necrosis (or at least a clearly nonapoptotic phenotype) that results from a specific molecular pathway and appears to be advantageous to the host. "Necroptosis" may be considered an equivalent moniker used more often in recent literature.[255]

Programmed necrosis can be triggered through Fas and other DR stimulation in a process that requires RIP (also known as RIP1).[18] Originally identified by a yeast two-hybrid interaction screen using the DD of Fas as bait,[256] RIP1 was later identified as a component of the TNFR-1 signaling complex that could induce the antiapoptotic transcription factor NF-κB.[257,258,259] Besides a carboxyl-terminal DD that is required for homotypic binding to the receptor-signaling complex, RIP also contains an amino-terminal serine/threonine kinase domain that is dispensable to its apoptosis-inducing activity but is essential for its necrotic function. Both direct Fas engagement or TCR stimulation (which presumably indirectly triggers Fas by FasL induction) can stimulate necrosis in vitro.[18] Although Fas-induced PCD has not been investigated extensively in the RIP1-deficient animals, the physiological role of RIP1-dependent programmed necrosis is gradually becoming clear. It appears to enhance inflammatory processes and may restrain replication of certain classes of viruses such as poxviruses and cytomegaloviruses.[260]

A similar form of RIP-dependent, caspase-independent necrosis is now well described for TNFR-1.[17,255,261,262] Initial binding of TNF induces a membrane-proximal "complex I" containing TRADD, RIP1, and cellular IAP 1 and 2. cIAPs in complex 1 are E3 ligases that mediate ubiquitination of RIP1, a required step for TNFR1-induced NF-κB activation. Once bound TNFR1 is internalized, however, cylindromatosis enzyme deubiqitinates RIP1 and allows it to incorporate into a cytosolic "complex II" containing TRADD, FADD, caspase 8, and RIP3. Active caspase-8 triggers apoptosis and is capable of directly cleaving RIP1 and RIP3. New data suggest heterodimers of unprocessed procaspase 8 and cellular FLIP, which display attenuated proteolytic activity, are essential for blocking RIP3-dependent necrosis.[263] Thus, caspase-8 prevents TNFR-mediated necrosis. However, inhibition of caspase-8 catalytic activity permits phosphorylation of RIP1 and RIP3 and subsequent stimulation of necroptosis, which requires RIP1 kinase activity. Small molecule inhibitors of programmed necrosis, known as necrostatin-1 and -3, allosterically block RIP1 kinase activity.[19] Thus, RIP1 appears to be a bifunctional signaling molecule with stimulatory and necrosis-inducing effects. Paradoxically, RIP1-deficient mice are severely runted and die shortly after birth, apparently due to increased TNF-induced death from impaired NF-κB induction.[264]

Nevertheless, RIP1 appears to be the clearest talisman of a molecular pathway of programmed necrosis. Several groups recently reported that RIP3 is also essential for programmed necrosis, and may be capable of inducing necrosis in the absence of RIP1.[265,266,267] Signals downstream of the RIP1-RIP3-associated "necrosome" are only now being elucidated, but are distinct from the TRADD-dependent, caspase-dependent apoptotic TNF pathway[262] and likely involve oxidative stress, cytosolic calcium flux, and substantial alterations in mitochondrial bioenergetics.[255,262,268]

What is the potential role of DR-induced necrosis in immunity? Many viruses, including vaccinia and other poxviruses, encode inhibitors of caspases.[17,269] Infection by poxviruses blocks caspases and apoptosis, sensitizing cells to TNF-induced necrosis.[270] Therefore, programmed necrosis may counteract viral antiapoptotic mechanisms by

eliminating virally infected cells. RIP3-deficient mice succumb to uncontrolled vaccinia infection linked to defective programmed necrosis.[265] Also, vaccinia infection induces extensive inflammation and necrosis in visceral fat pads, which primes the antiviral adaptive immune response. From an immunologic standpoint, necrotic cells often have a superior stimulatory activity than apoptotic cells for DC maturation.[271,272] During viral infection, TNFinduced necrosis may indirectly enhance the cytotoxic T-lymphocyte response to the virus by promoting DC maturation. Inhibition of programmed necrosis by expression of virally encoded FLIPs and/or inhibitors of the RIP1/RIP3 necrosome complex (eg, murine cytomegalovirus protein M45) may represent a strategy for evading these immune responses.[17,273]

Another important reason to further understand necrosis in the context of the immune system is that it may be responsible for the pathogenesis of viruses such as human immunodeficiency virus. Although many claims have been made that human immunodeficiency virus causes apoptosis of either directly infected or bystander T cells, most dying infected cells do not manifest hallmarks of apoptosis. Furthermore, these cells undergo cell cycle blockade and appear necrotic when examined by electron microscopy (see Fig. 30.1).[274,275] Hence, apoptosis does not appear to be the major mode of death. Human immunodeficiency virus-induced necrosis is not impaired by the absence of RIP1, thus distinguishing it from DR-induced necrosis. Further studies on identifying the molecules involved in virally induced necrosis are needed to determine whether it involves a specific molecular program or simply lethal cell injury.

FAMILIES OF MOLECULES PROVIDE PRECISE REGULATION OF PROGRAMMED CELL DEATH

Caspases

PCD was so important to the successful evolution of multicellular organisms that a specific set of genes was dedicated to the task. Chief among these genes were those encoding caspases. Junying Yuan and H. Robert Horvitz in 1993 first observed that a gene crucial for PCD in *C. elegans*, ced-3, was related to a mammalian caspase, IL-1β-converting enzyme, thus implicating specific proteolysis in the death program.[276] The "caspase" moniker is a

rubric indicating that these enzymes contain an active site *c*ysteine, cleave substrates on the carboxyl side of *asp*artate residues, and are prote *ases*. Caspases have been called the "executioners" of apoptosis. Once activated, their cleavage of various cellular substrates, including other caspases, results in the morphologic features of apoptotic cell death. Earnshaw et al.[277] authoritatively discussed the detailed biochemical features of caspases and their substrates. There are 15 caspases in mammals, all of which can induce apoptosis.[278] Although caspase-1 and caspase-4 (caspase-11 in the mouse) also proteolytically process proinflammatory cytokines such as IL-1β into their mature forms, they cause pyroptosis and endoplasmic reticulum stress-induced apoptosis, respectively.[173,279] In addition, caspase-12 was recently proposed to inhibit the proinflammatory functions of caspase-1. Indeed, caspase-12 functions as a FLIP, and directly binds to caspase-1 to suppress its activity. Functionally, mice deficient in caspase-12 are resistant to sepsis and clear bacterial infection more efficiently, whereas humans with a caspase-12 polymorphism demonstrate hyporesponsiveness to lipopolysaccharide and increased susceptibility to sepsis, due to an attenuated proinflammatory innate immune response.[280,281]

Much early work equated caspase enzymatic activity with processing. While true for the so-called downstream "effector" caspases, recent studies have established that cleavage is neither necessary nor sufficient for activation of initiator caspases.[210] Rather, oligomerization of procaspases-8 or -10 within the DISC, procaspase-9 within the apoptosome, or procaspase-2 within an Apaf-1-independent complex is sufficient for activity.[282,283,284,285] We now understand that full-length caspase-8 becomes partly active upon antigen receptor engagement on lymphocytes, which is required for downstream NF-κB activation.[178,286] The proximity-induced dimerization of the initiator caspases due to their long N-terminal prodomains allows them to form multimeric complexes that generate active proteases (as described subsequently).

Because of the thermodynamic irreversibility of proteolysis, downstream caspase activation is a commitment to death that cannot be undone. Hence, caspases are tightly regulated. This regulation is achieved by three principal means: 1) caspases are zymogens requiring proteolytic processing; 2) caspase "prodomains" control access to complexes with adaptor molecules; and 3) specific inhibitors exist.[6] How these mechanisms work is clear from the structures of caspases (Fig. 30.4). Caspases have an NH_2-terminal "prodomain" that is removed in the active enzyme. The COOH-terminal protease domain comprises two subunits of the mature enzyme that are denoted by their processed molecular weights, for example, p20 and p10. The processing sites between these parts occur at short specific tetrapeptide sequences ending in aspartate residues that dictate that the major processing enzymes are caspases themselves.[277] For caspases with short prodomains, namely caspases-3, -6, and -7, this event is believed to be the primary mode of regulation. Those with long prodomains harbor protein-interaction domains that allow them to enter activating complexes for specific death pathways, as described previously. Caspase-8 and -10 have DEDs and caspases-1, -2, -4/-11, -5, -9, -12, and -13 have CARD domains. Upon recruitment to relevant activating platforms, the proenzyme chains adopt a specific stoichiometric conformation that facilitates autocatalytic processing. For example, homodimerization of procaspase-8 is sufficient for enzymatic competency, with the dimer being more susceptible to processing than the

monomer.[287] In contrast, caspase-9 engineered to constitutively dimerize exhibits far less proteolytic activity than Apaf-1-activated caspase-9, suggesting an induced conformation model applies to caspase-9 activation within the apoptosome.[288] Following these initial cleavage events, the liberated subunits form a heterotetramer of two large and two small enzyme subunits as reflected in the crystal structures of processed caspases.[289,290,291,292,293] The consequences of subunit cleavage are dramatic: there is a 180-degree shift of the NH_2-terminus of the small subunit to bring it into

apposition with the catalytic cleft.[294] Once a processed heterotetramer is formed, it will be thermodynamically stable and can move away from the activating complex to find apoptotic substrates within the cell.

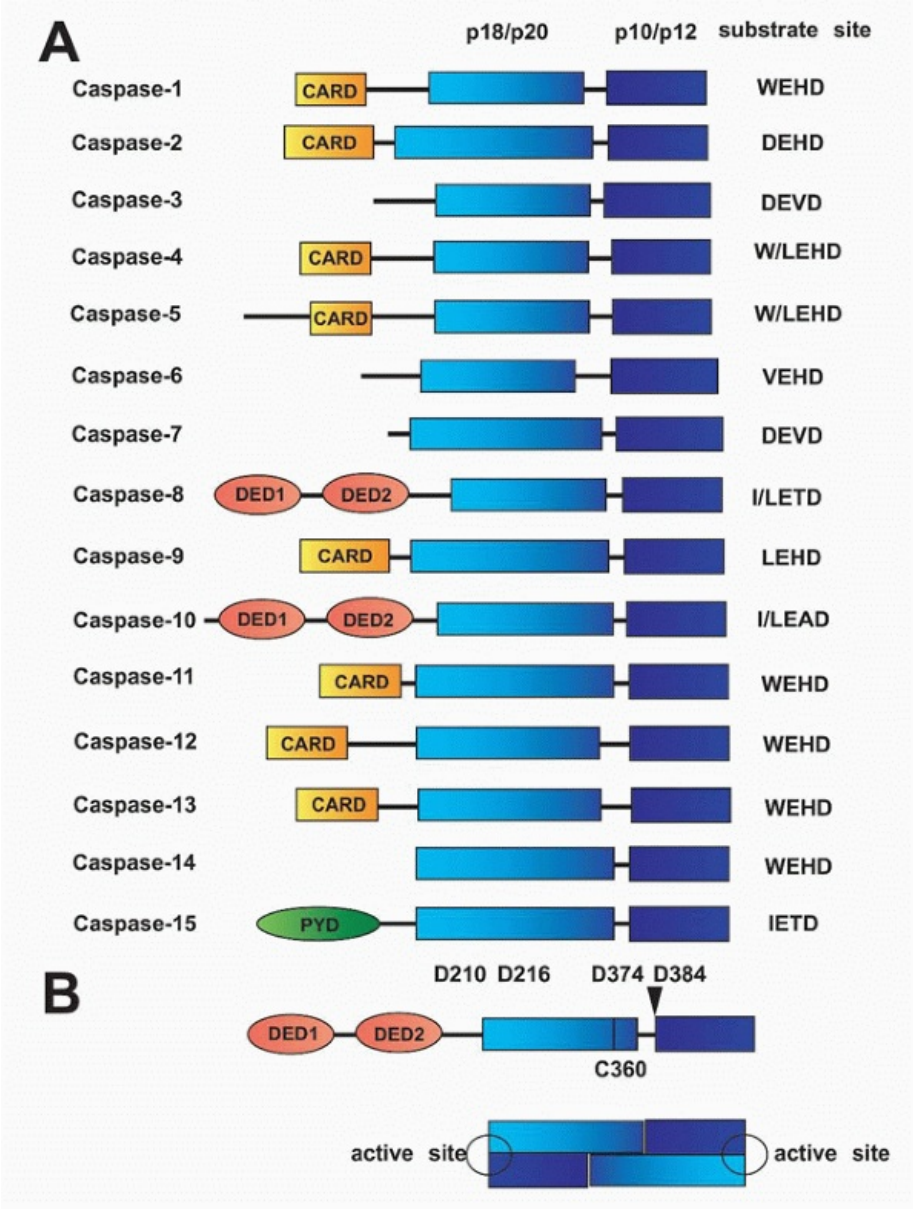

FIG. 30.4. Mammalian Caspases. A: The structures of the 15 known mammalian caspases are shown. Many of the caspases contain a caspase recruitment domain at

their NH2-terminus. Caspase-8 and caspase-10 contain a tandem copy of the death effector domain at the NH2-terminal end of the proenzyme, which is essential for recruitment to the death-inducing signaling complex. Caspase-15 contains a pyrin (PYD) domain at the NH2-terminus. The large (p18/p20) and small (p10/p12) subunits near the COOH-termini are also shown. The optimal tetrapeptide substrate specificity of each caspase is shown on the right-hand column. Notice that the caspase-4 and caspase-11 are human and mouse homologues, respectively (*asterisks*). **B:** Proximity-induced oligomerization is crucial in activating initiator proenzymes, which also undergo autoproteolytic cleavage. Shown in the diagram by the *arrows* are the proteolytic cleavage sites of caspase-8 at aspartate residues 210, 216, 374, and 384, as well as the active site cysteine (C360), indicated by a *bar*. Two of each of the large and small subunits of the enzyme form the active enzyme in a head-to-tail conformation, resulting in a tetramer that contains two catalytic sites at the two ends of the molecule. The active sites of the enzyme, which are made up of residues from both the large and small subunits, are designated by the *circles* at the ends of the processed enzyme.

Proteolytic activation can be regulated by a variety of proteins. These inhibitors, including the CrmA protein, its homologs found in other viruses, and IAPs, interact with the fully formed enzyme and remain bound as competitive inhibitors.[269,295] Other viral proteins that harbor DEDs can enter the DR signaling complexes and inhibit cleavage of caspases-8 and -10.[123,296] Initially, it was thought that these inhibitors, termed viral FLIPs, inhibit apoptosis by competing with caspase-8 and -10 for entry into the DR complex. However, it is now clear that the inhibitor and the caspase join the complex together. Resolution of the crystal structure of MC159, a viral FLIP from the poxvirus *Molluscum contagiosum* virus, reveals that it cooperatively assembles with FADD and Fas through an extensive charge surface encompassing a conserved charge triad. This prevents FADD self-aggregation and disrupts higher order oligomerization of Fas signaling complexes.[297] Cellular FLIP is structurally homologous to caspase-8 and -10 (indeed, it is encoded in the same locus on human chromosome 2 as these caspases) but has multiple amino acid differences that inactivate its protease function.[125] It also enters Fas signaling complexes and prevents caspase activation.[297,298] For example, the ability of antigen receptor stimulation to block Fas-induced death in B cells is regulated in part by cellular FLIP.[126] However, cellular FLIP can also induce apoptosis under certain conditions, which may be due to its ability to heterodimerize with and thus activate procaspase-8.[299] Recent studies suggest that under physiologic conditions, cellular FLIP heterodimerization with caspase-8 triggers sufficient catalytic activity for NF-κB activation and/or suppression of RIP-dependent necrosis but disrupts caspase-8 homodimerization required for full processing and cleavage of apoptotic substrates.[263,300]

Another class of caspase regulators is the cellular IAPs that can directly inactivate mature caspases to avert the deleterious effects of inadvertent caspase activation.[128,129] IAPs are characterized by the presence of up to three baculovirus IAP repeats (BIRs). Originally identified in baculovirus, the BIR domains are characterized by the presence of cysteine and histidine residues in defined spacing arrangements ($Cx_2Cx_6Wx_3Dx_5Hx_6C$).[128] The

mechanisms of inhibition by IAPs on different caspases are quite distinct. For caspase-9, inhibition by XIAP depends on binding of the BIR3 domain with the tetrapeptide sequence ATPF at the NH_2-terminal of the p12 subunit that is exposed only in the mature enzyme. Hence, XIAP specifically inhibits active caspase-9 but not procaspase-9.[234] By contrast, XIAP inhibits caspase-7 and -3 by forming contacts in the catalytic groove with little involvement of the BIR domains.[301] Interestingly, this mechanism of XIAP association is adopted by Smac/Diablo to inhibit the antiapoptotic function of XIAP during the onset of mitochondrial PCD pathways.[235] Smac/Diablo is a protein that resides in the intermembrane space of the mitochondria. It functions as an elongated dimer of α helices that adopts the shape of an arch. Mutation of a specific alanine to methionine abolished the binding and inhibitory activity of Smac/Diablo on XIAP.[234,235] This IAP-binding motif is also shared by other IAP antagonists (Omi/HtrA2 and GSPT1/eRF3) and by caspase-9, suggesting that IAP antagonists and caspase-9 compete for binding to XIAP.[234] The action of XIAP is flexible in order to carry out diverse functions. Instead of the BIR3 domain, XIAP uses the linker region between

BIR1 and BIR2 to interact with and inhibit the function of caspases-3 and -7. In this case, the linker blocks the catalytic groove of the caspase. While BIR2 does not directly participate in the inhibitory activity, it may stabilize the association by making other contacts with caspase-3.[290,302,303]

The death-inducing effect of caspases involves a limited set of targets because most proteins in the dying cell remain uncleaved. Caspases have an absolute requirement for aspartate at the amino side of its cleavage sites (P1 site). Further specificity is dictated in part by the three amino acids preceding the obligatory aspartate in the substrate (P2 to P4 positions).[277] Preferred tetrapeptides have been identified for each of the mammalian caspases so that, for example, caspase-3 is known to preferentially cleave at the sequence DEVD whereas caspase-8 prefers IETD.[12,304,305] Nicholson and coworkers have developed valuable tetrapeptide substrates and inhibitors based on these preferences, but they emphasize that these are not absolutely specific.[12,277] In addition to primary amino acid sequence, additional secondary structural features of target proteins may be recognized. For example, many proteins harboring a DEVD sequence may not be cleaved at that sequence by caspase-3.[129] Thus, the tetrapeptide recognition sequences are required but not sufficient for apoptotic protein cleavage. Nevertheless, model caspase substrates and inhibitors based on short recognition peptides, such as zVAD- or DVED-fmk (*f*luoro*m*ethyl *k*etone), have been useful in assessing caspase function in vitro and in vivo.

Caspase substrates in dying cells have been grouped according to apparent functional importance: 1) cytoskeletal proteins such as actin, gelsolin, and α-fodrin, among others; 2) nuclear structure proteins, especially lamins A and B; 3) DNA metabolism and repair proteins such as PARP; 4) protein kinases such as various isoforms of PKC; and 5) signal transduction proteins such as STAT1, SREBP-1, and phospholipase C-γ1.[277] As PCD typically involves the elimination of somatic cells, there may be little evolutionary constraint on random cleavage sites. Hence, it has been difficult to distinguish functional versus adventitious sites. Key caspase substrates that have unequivocal roles in apoptosis include

caspases themselves, Bcl-2 and Bcl-X_L, the inhibitor of caspase activated deoxyribonuclease of the caspase-activated DNase, which is one enzyme causing apoptotic nuclear fragmentation, and the nuclear lamins.[306,307] Cleavage of the nuclear lamins was shown by Eileen White to be responsible for certain nuclear changes in apoptosis by experiments in which the aspartate cleavage sites were modified and the apoptotic changes were abrogated.[308] This stringent test has been applied to very few proteins cleaved during apoptosis. In fact, evidence weighs against the role of many caspase substrates in apoptosis. For example, the knockout of the PARP gene (a caspase substrate important for DNA repair) in mice revealed no abnormality of development, immunity, or apoptosis.[309] Hence, further work is necessary to determine the importance of specific proteins cleaved during apoptosis.

Genetic analyses of human caspases have provided important information about their function. By contrast, homozygous deficiencies in mice have been associated with embryonic lethality or neurological defects but have not yielded specific immunologic phenotypes.[277] The first two diseases involving inherited mutations of caspases in humans cause prominent effects in the immune system. The first, an inherited mutation in caspase-10, was detected in the human disease ALPS type IIa, now referred to as ALPS-CASP10.[171,310] Individuals with caspase-10 mutations exhibited defects in apoptosis triggered by multiple DRs affecting the homeostasis of T cells, B cells, and DCs. The abnormal accumulation of immune cells leads to the formation of a variety of autoantibodies that cause autoimmune conditions including hemolytic anemia, thrombocytopenia, and others. The second involves mutations in caspase-8, which cause abnormal lymphocyte apoptosis and lymphocyte accumulation in secondary lymphoid tissues.[311] However, unlike a caspase-10 mutant individual, the lack of caspase-8 leads to immunodeficiency manifested as recurrent sinopulmonary and viral infections with minimal autoimmunity. Biochemical analyses show that caspase-8 is required for NF-κB induction by the TCR, BCR, and Fc receptor, which accounts for the T-, B-, and natural killer-lymphocyte activation defects. These patients represent a novel clinical entity, termed caspase-8 deficiency state.[178] The clinical differences between humans having caspase-10 or caspase-8 mutations may reflect differences in substrate specificities of these two closely related enzymes.[204,215]

Tumor Necrosis Factor/Tumor Necrosis Factor Receptor Superfamily Members

The TNF/TNF receptor superfamily contains many key regulators of immunity (Fig. 30.5). These receptors and their cognate ligands facilitate communication between immune cells in the orchestration of immune responses. They also comprise a major class of cellular sensors to external physiologic cues that regulate PCD.[312] The hallmark of these receptors is the presence of “cysteine-rich domains” (CRDs) in the extracellular region, which are required for receptor assembly and ligand binding. Each receptor contains between one (BCMA and TWEAK-R)[313,314] and six (CD30) CRDs. The receptors can be further subdivided into two classes based on sequence homology within the cytoplasmic signaling domain. The DRs contain an 80-residue long DD that is essential for death signaling.[213,315] The majority of the receptors lack a DD and therefore are not called DRs, but have a region that interacts with the TNFR-associated factor (TRAF) proteins.[316] Interestingly, some of the DRs,

including TNFR-1, can indirectly recruit TRAF proteins, which may explain cross-talk between certain DD-containing and DD-lacking receptors.[317,318,319] Signals transduced by the non-DDcontaining receptors are frequently prosurvival while that of the DRs are typically proapoptotic. In all, over 20 members of the TNFR family in human have been identified.[59] With a few exceptions (EDAR and XEDAR), essentially all TNFRs play important regulatory roles in the immune system.

Signaling by the TNFRs is initiated when the cognate ligands, which are obligate trimers, contact the preformed receptor complex.[317,320] Downstream signaling of DRs requires the recruitment of DD-containing and/or

P.734

DED-containing proteins. For Fas, receptor engagement results in rapid recruitment of FADD and caspases-8 or -10 within the DISC, as detailed previously.[214] Other DRs such as TNFR-1 may require recruitment of an additional adaptor molecule like TRADD prior to the docking of FADD.[321] These events rapidly culminate in caspase activation. The non-DD-containing receptors mediate NF-κB induction and the activation of c-Jun kinases through the recruitment of TRAF proteins, a property that is shared by some DRs such as TNFR-1. Recruitment of TRAF proteins by DRs may counter the proapoptotic response through their interactions with cellular IAPs. “Knock-out” analyses in mice reveal that many of these signaling intermediates, including TRAF2,[322] RIP,[258] and components of the NF-κB activation pathway,[323,324,325,326,327] are essential for conferring protection against apoptosis induced by DR ligands. Deficiency of

P.735

NF-κB tends to sensitize cells to TNF-induced death.[328,329,330] TRAF2 and NF-κB induction through RIP may act in concert to promote survival in response to TNF.[331] Interestingly, unlike the TNFR-1- and Fas-deficient mice, which are viable, knockout of the signaling components such as FADD or TRADD often results in embryonic lethality. The discordant results in knockout animals imply that TNFR signaling intermediates are involved in ontogenetic processes other than PCD. Alternatively, other TNFRs may mediate critical PCD events during development using the same set of signaling molecules. However, many other TNFR-deficient animals, including Fas, DR6, or multiply deficient animals (TNFR1-/-, TNFR2-/-, and $Fas^{lpr/lpr}$ together) are viable, thus arguing against the latter hypothesis.[226,227,261]

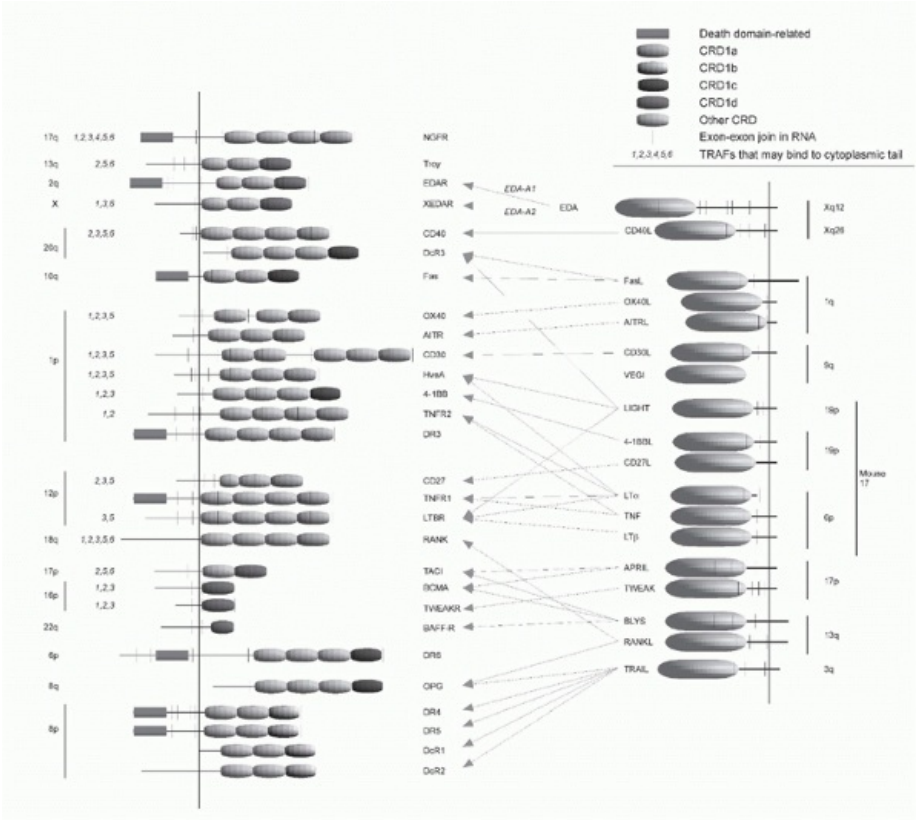

FIG. 30.5. Interacting Proteins of the Tumore Necrosis Factor (TNF)/TNF Receptor (TNFR) Superfamily. TNFR- and TNF-related proteins are shown at the left and right of the figure, respectively, with *arrows* connecting ligand-receptor pairs. Cysteine-rich domains (CRDs) are shown as *small ovals*. The NH2-terminal CRDs (CRD1a, 1b, 1c, 1d) are grouped on the basis of sequence similarity as indicated by the use of *colors* in the figure. *Small vertical lines* denote the locations of intron excision sites from the ribonucliec acids that encode the proteins (this information was not available for RANK, DcR1, and DcR2). *Red boxes* mark the locations of death domain-related sequences in the cytoplasmic regions of the TNFR-related proteins. *Numbers* to the immediate left of the TNFR cytoplasmic regions denote known or inferred interactions with the indicated TRAFs. The locations of the human genes that encode the proteins are provided at the extreme left and right of the figure; the mouse cluster on chromosome 17 is also noted. (Figure adapted from Locksley et al.[59] and Nagata and Golstein,[60] with permission from Cell Press by Nigel Killeen.)

Bcl-2 Gene Family

Bcl-2 and Bcl-X_L are the prototypes of a diverse family of apoptosis-regulatory proteins whose familial relationships are conferred by four impressively short homology regions, termed BH-1 to BH-4 (Fig. 30.6).[332,333] Proteins in this family can be classified into three groups: 1) the "multidomain" antiapoptotic proteins (Bcl-2, Bcl-X_L, Mcl-1, Bcl-w, A1, and BOO), which contain the four BH domains, 2) the "multidomain" proapoptotic Bax, Bak, and Bok that possess BH1-3 domains, and 3) the "BH3-only" proteins (Bid, Bad, Bim, Bik, Noxa, and Puma). Bcl-2 was identified at the chromosomal breakpoint of t(14;18)-bearing follicular

B-cell lymphomas. Vaux and Cory demonstrated that the oncogenic effect of Bcl-2 could be attributed to enhanced cell survival rather than proliferation.[169,334] Consequently, Bcl-2 represented a new class of death-preventing oncogenes that collaborates with growth-promoting oncogenes, such as Myc.[335] Abnormal overexpression of Bcl-2 is common in lymphoid and nonlymphoid malignancies.[336] Bcl-2 and Bcl-X_L regulate various types of immune cell death caused by lymphokine withdrawal, γ-irradiation, and chemical death inducers such as glucocorticoids, phorbol esters, DNA-damaging agents, and ionomycin, all of which provoke mitochondrial apoptosis.[337] Apoptosis induction is one means by which cancer chemotherapeutics exert an antitumor effect. Thus, as apoptosis antagonism may be as important in transformation as mitogenesis, new therapeutic strategies aimed at antagonizing Bcl-2 may be effective in cancer therapy (see following discussion).

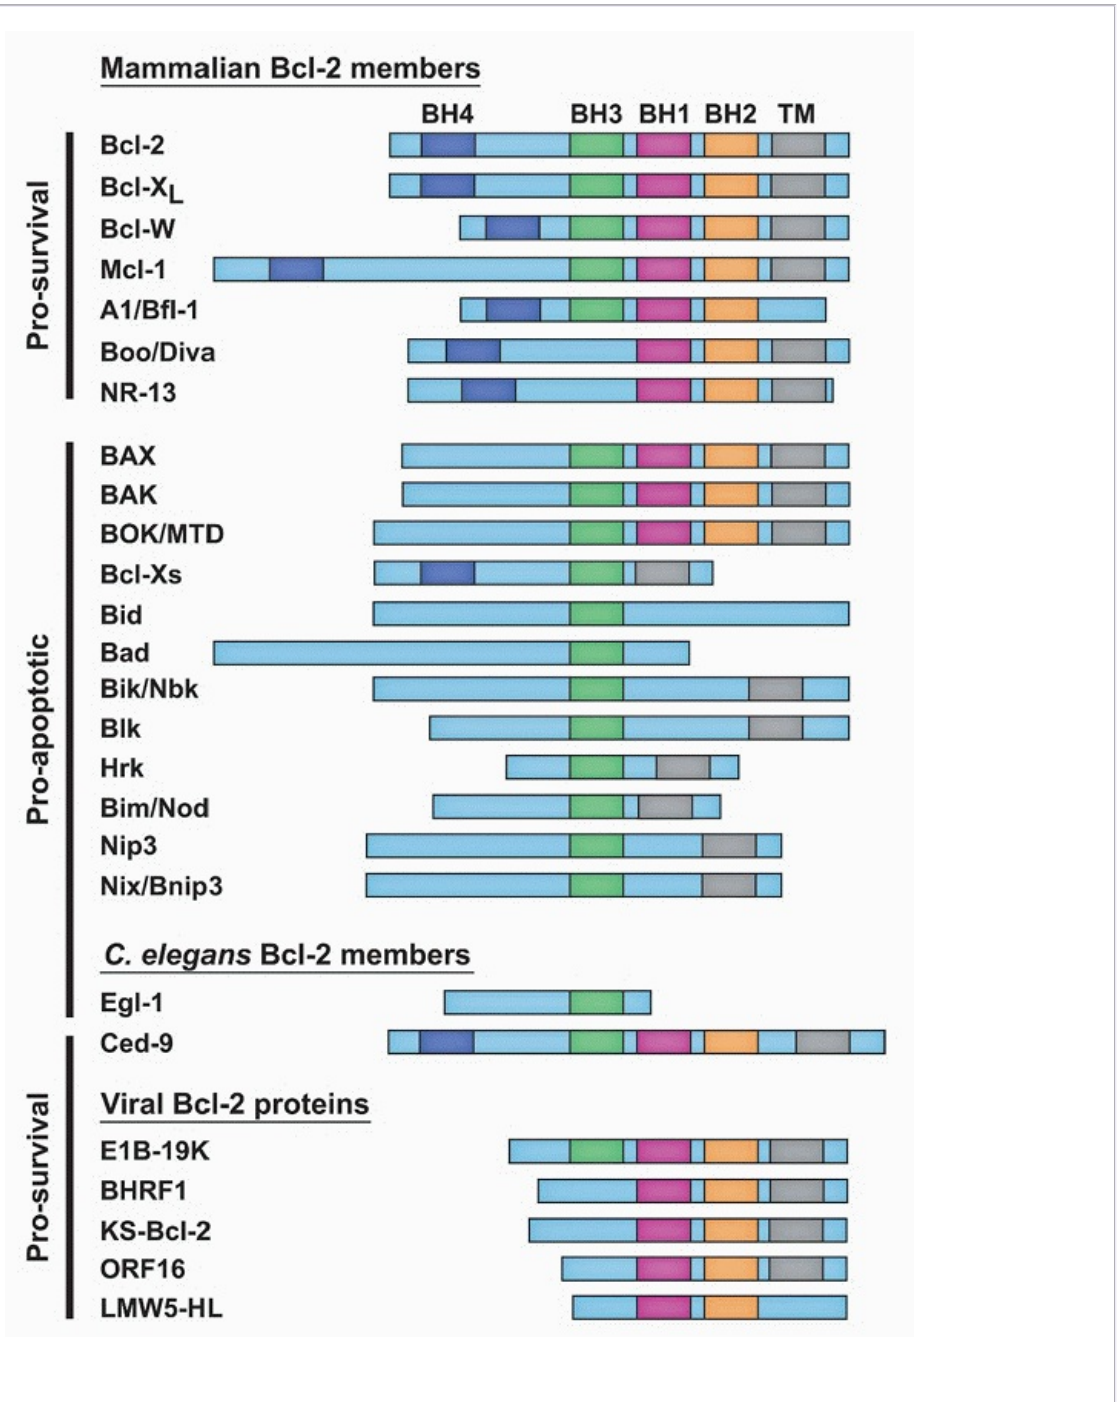

FIG. 30.6. Schematic Diagram of Members of the Bcl-2 Family. The *dark blue, green, red, and orange boxes* represent the different Bcl-2 homology domains, and the *gray boxes* designate the hydrophobic transmembrane region that is required for insertion into the mitochondrial membrane.

Mechanisms by which Bcl-2 family proteins regulate cell death remain unclear, but several regulatory principles have been delineated.[332] Key family members, including Bcl-2, Bcl-X_L, Bak and Bax, associate with intracellular membranes, especially the OMM, via a carboxy-terminal hydrophobic domain.[338,339,340,341] Death regulation by the Bcl-2 family ultimately involves controlling the permeability and integrity of the OMM. Bax and Bak directly participate in the formation of an "apoptotic pore" upon activation and oligomerization, which permeabilizes the OMM. This critical step results in mitochondrial release of cytochrome c, activation of cytosolic caspases, and commitment of the cell to apoptosis.[342] Bcl-2 family members form homotypic and heterotypic dimer complexes. The balance between pro- and antiapoptotic members determines cell fate probably through direct interactions with each other.[343,344,345,346,347,348] The precise stoichiometry of these associations that leads to survival or death has not been defined. For example, it remains unclear whether BH3-only proteins bind and directly activate Bax/Bak, or instead serve to displace prosurvival Bcl-2 proteins to facilitate indirect activation.[349] Recent data demonstrates that prosurvival Bcl-2 proteins prevent Bax oligomerization by directing constant retrotranslocation of Bax from mitochondrial membranes into the cytosol, lending credence to the latter model.[98] Regulation by these proteins occurs "upstream" of caspase activation, but they may also control caspase-independent forms of cell death including autophagic cell death.[246] These proteins have their most important effects on mitochondrial death pathways and comparatively less effect on DR-initiated pathways. Diverse pathways, such as transcriptional induction (Bim, Puma, Noxa, and Bcl-X_L), phosphorylation (Bad), processing (Bid), conformational changes (Bax and Bak), or organelle translocation (Bim, Bid, Bax), control the presence and biologic activity of Bcl-2 family members.[108,350] Each of these

principles has reported exceptions, but they constitute the current basis for our understanding of the Bcl-2 family of proteins.

The biologic function of Bcl-2 family members has been examined in genetically engineered mice and tissue culture cells.[99] Bcl-X_L-deficient mice die around embryonic day 13 due to massive neuronal apoptosis.[351] By contrast, Bcl-2-deficient mice survive a few weeks postnatally but then develop polycystic kidney disease, hypopigmentation due to decreased melanocyte survival, and most importantly, massive apoptotic loss of all B- and T-lymphocytes.[352] Thus, while Bcl-2 is not necessary for lymphocyte maturation, it is indispensable for the maintenance of mature lymphocytes. On the other hand, expression of Bcl-X_L is required for the survival of DP (CD4+CD8+) thymocytes, B220+ bone marrow cells, and mature B cells.[332] Mcl-1 deficiency results in peri-implantation lethality.[353] A conditional knockout in the T-cell compartment increases apoptosis at the double negative 2 stage and arrests the development of both B- and T-lymphocytes. Mcl-1 is also essential for mature

lymphocyte survival, and experimental elimination of this molecule triggers their rapid loss.[147] Transgenic experiments in which Bcl-2 or Bcl-X_L were overexpressed suggest, however, that the two proteins can functionally substitute for one another and govern a final common death pathway.[332] Selective transgenic overexpression of Bcl-2 in B or T cells leads to increased numbers of those cells and the late onset of lymphomas.[354,355] Bcl-2 overexpression also blocks Apaf-1- and caspase-9-independent pathways of apoptosis, demonstrating the broad inhibitory effect of Bcl-2.[356] Furthermore, Bcl-2 was recently shown to suppress Beclin 1 autophagic cell death, a novel form of nonapoptotic cell death.[20,357] Deficiency of the proapoptotic Bax protein has a surprisingly mild phenotype in mice, causing only abnormalities in testis development and sterility.[358] Deficiency of the proapoptotic Bak protein also causes very little effect in mice. However, a combined deficiency of Bax and Bak causes multiple organ abnormalities and perinatal death due to failed apoptosis.[359] This includes an accumulation of lymphocytes and other hematopoietic cells, underscoring the importance of the Bax and Bak proteins for normal immune homeostasis.

Recent work has focused on the BH-3-only subset (see Fig. 30.6). Structural analysis has revealed that Bcl-2 family members interact through a hydrophobic pocket formed by the confluence of the BH-1, BH-2, and BH-3 helices. The interactions between Bcl-2 family members have a characteristic selectivity and hierarchy that may depend principally on binding to the BH-3 helix.[360] The BH-3-only proteins may selectively regulate the other family members through interactions at the hydrophobic pocket. Genetic ablation experiments have demonstrated the critical role of this family during developmentally PCD as well as stressinduced death.[99] So far, only one BH-3-only protein, called egg laying defective 1, has been characterized in *C. elegans*. In mammals, the BH-3-only subset includes Bad, Bik, Bid, HRK, Bim, Noxa, Puma, Bmf, and perhaps others as the BH-3 motif is only a 9 to 16 amino acid long of alpha helix. Induction of cell death by BH3-only proteins requires Bax and Bak, indicating that BH3 proteins act upon or upstream of proapoptotic relatives.[361,362] The activity of BH-3-only proteins is governed transcriptionally and posttranscriptionally in a highly regulated fashion according to their function. Bid is cleaved by caspase-8 yielding a 15 kDa fragment that is myristoylated, which can insert into the mitochondrial membrane. This triggers the oligomerization of Bax and Bak thereby connecting the DRs to the mitochondrial pathway of death.[191,195,342,363,364,365] Phosphorylation of Bad and Bim can control their association with 14-3-3 proteins or the microtubule-associated dynein motor complex, respectively.[108] When released, Bad and Bim can induce apoptosis through the mitochondrial pathway. Interestingly, most of Bim is bound to Bcl-2 and Bcl-X_L at the mitochondria in both resting and activated T-lymphocytes.[366] Genetic deficiency of Bim protects against a variety of death inducers, such as cytokine deprivation, γ-radiation, glucocorticoids, ionomycin, DNA damage, etoposide, and Taxol, but not FasL.[51] Deficiency of Bim also significantly impairs TCRinduced thymocyte selection. These diverse forms of regulation provide a mechanism for a variety of different apoptosis inducers to converge on the mitochondrial pathway of death.

The mechanism by which the BH3-only proteins control cell death is still an intense field of research. Studies carried out with peptides corresponding to the α-helical BH3 domains

distinguish two different subgroups of BH3-only proteins.[367,368,369,370] The “activating BH3” proteins (including Bim and Bid) can directly trigger death by Bax and Bak besides counteracting Bcl-2 and Bcl-X_L. The second group includes Bad and Bik and is called “derepressor BH3” or “sensitizing BH3.” These molecules suppress the antiapoptotic activity of Bcl-2 and Bcl-X_L but fail to activate the executioners Bax and Bak. They thus sensitize the mitochondria by increasing OMM permeability but require the intervention of an additional activator of Bax to induce apoptosis. Although it was originally thought that Bax/Bak induced mitochondrial fission and outer membrane permeabilization through the so-called “permeability transition pore,” later studies have contested its role.[371] In general, intrinsic apoptosis is always accompanied by fission of mitochondria, which participates in the release of various inducers of death, including cytochrome c.[228] In fact, fission intermediates may play a direct role in Bax oligomerization and mitochondrial fission and outer membrane permeabilization.[372] Continued study of the mechanism by which these proteins interface with mitochondrial fission should yield further insights into their mode of action.

The development of drugs mimicking “sensitizing BH3” protein associations have been developed to modulate the antiapoptotic Bcl-2 proteins during cancer treatment.[336] A small organic molecule (ABT-737) with mechanistic similarity to Bad is a potent inhibitor of the antiapoptotic molecules Bcl-2, Bcl-X_L, and Bcl-w. Resembling a Bad-derived peptide, ABT-737 can bind antiapoptotic Bcl-2 proteins to block cytosolic retrotranslocation of Bax, but does not directly activate Bax and Bak.[98] ABT-737 exhibits synergistic cytotoxicity with chemotherapeutics and radiation in vitro and in vivo. It displays single-agent activity against lymphoma, small-cell lung carcinoma, primary patient-derived cells, and promotes the regression of solid tumors.[206]

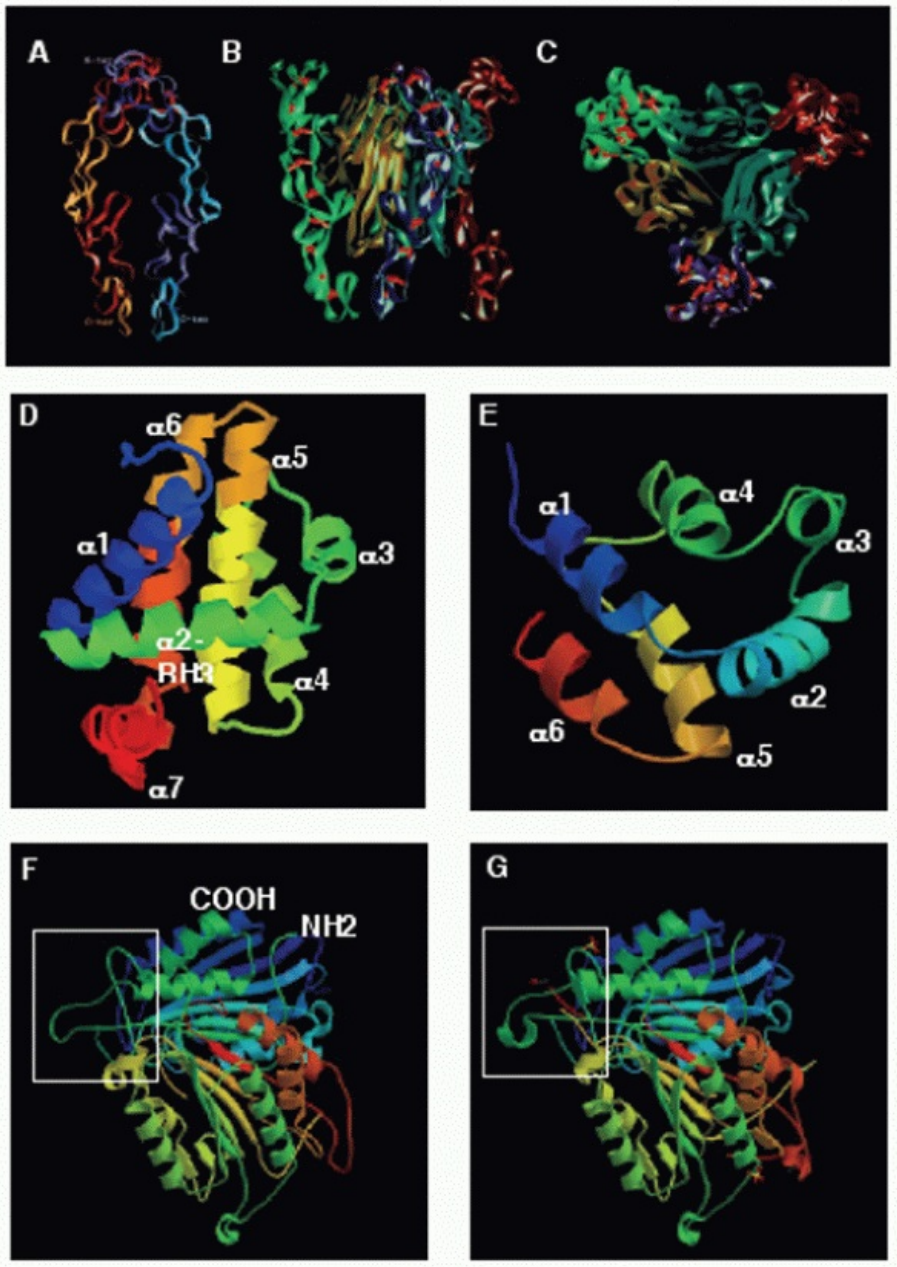

FIG. 30.7. Structural Biology of Apoptosis. A: Structure of the unliganded tumor necrosis factor (TNF) receptor (TNFR)-1. **B:** Side view of the TNFβ-bound TNFR-1 looking from the plane of the membrane. Conserved disulfide bonds that are structurally essential are shown in *red*. **C:** Bird's eye view of the TNF/TNFR-1 structure looking down at the plane of the membrane. **D:** NMR structure of Bcl-X_L. The BH3 (α2) domain runs perpendicularly across the molecule and the two central hydrophobic helices (α5 and α6) are buried in the middle portion of the molecule. **E:** Structure of the Fas DD, a prototypical hexahelical bundle. The bundle is composed of six helices, a structural scaffold that is conserved in also the death effector domain and the caspase recruitment domain. The position of each of the helices is indicated. **F,G:** Structures of caspase-7 before (*F*) and after (*G*) proteolytic autoprocessing. Notice that the catalytic site (*box*) in the proenzyme is relatively "loose" (*F*). Processing of the proenzyme results in substantial "tightening" of the catalytic loops. The *red-colored strand inside the boxed area* in (*G*) denotes the position of the pseudosubstrate tetrapeptide DEVD.

Apoptotic Protease-Activating Factor Proteins

Mammalian Apaf-1 is critical for the mitochondrial pathway of apoptosis. Apaf-1 is structurally and functionally homologous to the *C. elegans* Ced-4 protein.[373] Both Apaf-1 and Ced-4 contain an NH_2-terminal CARD domain followed by a nucleotide-binding oligomerization domain (NOD). Ced-4 can complex with caspase-9 via CARD domains present in both molecules. The NOD domain is essential for binding adenosine triphosphate and homooligomerization. In addition, Apaf-1 also contains WD-40 repeats at the carboxy-terminus, which bind cytochrome c released from damaged mitochondria. Interestingly, *C. elegans* Ced-4 contains no carboxy-terminal WD-40 repeats and does not respond to mitochondrial insults.[374] Apaf-1, cytochrome c, and adenosine triphosphate are all required to properly activate procaspase-9.[230,375] Genetic evidence from knockout animals revealed that Apaf-1 and caspase-9 are obligatory for the apoptosis response through p53 to DNA damage and other mitochondrial death events.[376,377,378]

Other proteins similar to Apaf-1/Ced-4 have been identified, most of which contain regions of homology to the NOD domain. Overexpression studies suggest that several of these (NOD1, NOD2, IPAF, and cryopyrin) may modulate apoptosis but most evidence indicates they chiefly mediate proinflammatory responses. These proteins initiate intracellular responses to peptidoglycan or other bacterial antigens, through NF-κB induction and/or caspase-1 maturation.[379] One of these proteins, NOD2, has been mapped as a susceptibility gene for Crohn disease.[380,381] The CARD domain of NOD2 and related inflammasome components likely involves these proteins in apoptosis as well as inflammatory responses. The adaptor protein ASC, which contains both CARD and pyrin domain, also coordinates divergent inflammasome proteins for caspase-1 processing and pyroptosis induction.[173] Hence, combinations of protein interaction motifs like the CARD, NOD, and other signaling domains in single adapter proteins promotes bifurcation of biological responses from the same receptor.

STRUCTURAL REGULATION OF PROGRAMMED CELL DEATH

Tumor Necrosis Factor/Tumor Necrosis Factor Receptor Structure

The recent determination of structures of components of the PCD pathways has led to a better physical sense of how these death programs work (Fig. 30.7). In almost all cases, the formation of specific stoichiometric protein complexes is crucial for apoptosis signaling. Receptor-mediated apoptosis by DRs within the TNFR superfamily is triggered by receptor-specific ligands within the TNF superfamily.[59] The defining structural motif of the TNFR superfamily, the CRD, is a 40-amino acid cluster of β strands folded back on themselves and pinned in place by three disulfide bonds formed by six cysteines in highly conserved positions (see Fig. 30.7A). Most of the TNFRs have multiple CRDs, and these serve two primary functions depending on location. The membrane-proximal or central CRDs mediate ligand binding. For example, in TNFR-1, the two central CRDs, CRD2 and 3, provide the key ligand-binding contacts. The membrane distal CRD mediates receptor preassembly on the cell

surface.[382,383] This membrane-distal CRD along with adjacent amino-terminal sequences is called the “preligand assembly domain” (PLAD). It promotes the oligomerization of like receptor chains prior to ligand engagement. Preassembly of receptor chains into trimers or perhaps other oligomeric complexes is obligatory for both ligand binding and signal transduction. The PLAD has been identified in both DRs such as Fas, TNFR-1, and TRAIL receptors as well as in non-DD receptors such as TNFR-2.[382,383] The orientation of the receptor chains is likely to change drastically between the unliganded and liganded complexes as reflected in the extant crystal structures for unliganded and liganded TNFR-1 (see Fig. 30.7A and B). The receptor chains are initially attached at the membrane distal CRD, and then these interactions fall apart as the receptor admits the ligand between three receptor chains to interact with the CRDs closer to the membrane. The discovery of the PLAD overturned the prevailing model that TNFR family members signal by the ligand “cross-linking” solitary receptor chains into a trimeric complex. Instead, the ligand will bind to and change the configuration of preassembled receptor complexes. Hence, CRDs can regulate both intra- or intermolecular receptor associations.

The ligands for TNFRs are typically obligate homotrimers that adopt a compact “jelly-roll” conformation with a hydrophobic face where the individual subunits stably interact with each other.[59,384] Certain exceptions, such as LTα and LTβ, can form heterotrimers. The ligand subunits are usually synthesized as type II transmembrane proteins and, following trimerization, may remain membranebound or undergo metalloproteinase cleavage to a soluble form.[385] Binding of the preassembled receptor complex with the trimeric ligand, forms a symmetric three-to-three ligand-receptor complex that is evident in the crystal structures of the liganded TNFR1 and TRAIL receptors.[301,386,387,388,389] Functionally, the ligand interaction appears to reorient the receptor chains so that the intracellular domains adopt a specific juxtaposition favoring the formation of intracellular signaling complexes. The recently solved structure of the TRAIL trimer differs from the TNF structure in that it contains a loop insertion in the first β-strand that is critical for receptor association.[301,386,387,388,389] In both the TNFR-1 and TRAIL-R2 crystals, ligand contacts appear to be restricted to the second and third CRDs. The extensive receptor-receptor interaction in the PLAD region found in the unliganded TNFR-1 receptor structure is absent in the ligand-bound receptor crystal structures.[390,391,392,393] How the ligand initially contacts the preformed receptor complex and initiates chain rearrangement are important unresolved questions.

The fundamental three-fold symmetry of the TNF superfamily ligands and receptors appears to be conserved among the proximal signaling complexes, including the receptor-TRAF2 interaction[394,395] and the TRADD/TRAF2 interaction.[396,397] This not true of the Fas/FADD interaction, however, based on recent structural studies that show that the Fas-FADD DDs associate in an asymmetric oligomeric complex of five to seven Fas DD and five FADD DD in a layered helical

structure comparable to the PIDD-RAIDD DD complex.[217] This interesting oligomeric structure apparently requires hexameric or membrane-bound FasL for assembly during Fas signaling and explains the potent dominant-negative effects observed for Fas mutations occurring in patients with ALPS (see following). The structure also reveals how the FADD

DED can interact with the caspase-8/-10 DEDs for caspase recruitment and activation through aggregation. This helical symmetry common to DD-containing signaling assemblies may regulate the strength of signal transduction by permitting a variable number of binding partners with specificity, while establishing a threshold for signaling through aggregation. 216 The importance of the trifold symmetry in the receptor signaling apparatus is highlighted by genetic mutations found in both human and mouse. For instance, heterozygous mutations in the cytoplasmic DD of Fas found in the *lpr*cg (mouse) or Fas-defective form of ALPS resulted in a greater than 50% reduction in receptor signaling.[398,399,400] This is likely due to the fact that inclusion of at least one bad subunit in the receptor trimer abrogates signaling.[400]

The genetic effect by which a mutant allele encodes a protein that interferes with the same protein encoded by a wild-type allele is called *dominant interference*. Dominant interference is usually observed in proteins that function by forming multiprotein complexes, which is now known to be a common feature in PCD pathways. A dominant-interfering disease mechanism may be especially important in PCD disorders in outbred human populations, where most gene loci are heterozygous rather than homozygous. However, disruptive mutations described in the Fas DD for patients with ALPS-FAS did not localize to interfaces with FADD in the first Fas-FADD DD complex structure. Hence, a structural explanation of dominant interference remained poorly understood.

The recent solution of a new and revised protein complex structure containing the Fas and FADD DDs, crystallized under more physiologic conditions, clarifies this question and underscores the potency of dominant interfering mutations associated with ALPS-FAS.[217] Wu and colleagues demonstrated that the Fas-FADD DD complex contains five to seven Fas DDs and five FADD DDs in a layered structure comparable to the PIDD-RAIDD DD complex.[401] In this structure, debilitating ALPS-associated mutations are localized to specific interfaces between these layered DDs. The severity of the Fas DD mutation correlates with the number of affected interfaces containing it, and typically precludes complex formation with FADD DDs. Based on 5:5 stoichiometry of Fas and FADD DDs, the proportion of wild-type Fas signaling complexes in a patient with heterozygous ALPS-FAS, assuming equal expression of wild-type and mutant alleles, is less than $(1/2)^5$ or ~3% of total signaling complexes. This explains the disproportionately severe effect of heterozygous mutations on function. The new crystallographic information about the Fas signaling complex also implies that two trimers of FasL are required to form this complex in vivo by bringing six Fas DDs in close proximity. These findings are congruent with previous work demonstrating that two FasL trimers, normally presented on an adjacent cell in membrane-bound form, constitute the minimal, competent ligand component for initiating Fas-induced apoptosis.[402,403] Thus, our understanding of the Fas receptor reveals that while higher order oligomeric signaling complexes provide cooperative, rapid, and regulatable signaling for apoptosis induction, they also create a vulnerability to genetic disease. A dominant-interfering disease mechanism may be especially important in PCD disorders in outbred human populations, where most gene loci are heterozygous rather than homozygous.

Bcl-2 Homology Structures

Bcl-X_L has the best-characterized structure, and it suggests interesting hypotheses regarding the function of Bcl-2 family members.[209] It contains a conserved nest of alpha helices

including a backbone of two hydrophobic helices that are encircled by several amphipathic helices including the BH4 helix, which is a key interaction site for members of the Bcl-2 family (see Fig. 30.7D). The structure has revealed a tantalizing similarity to pore-forming domains of bacterial toxins. This has stimulated a wealth of research into whether membrane pore formation is a key element of apoptosis modulation by Bcl-2 family proteins.[404,405] It is interesting to consider that pore-forming toxins of bacteria have homology to regulatory proteins whose primary site of action is the mitochondria (which is believed to have evolved as a bacterialike organism subsumed into eukaryotic cells). Structurally, Bcl-2 homology regions, BH1, BH2, and BH3, are widely spaced in the primary sequence but closely apposed in a hydrophobic pocket. Through this pocket, the proapoptotic and antiapoptotic members of the Bcl-2 family interact and cross-regulate one another. Proteins with only an amphipathic BH3 helix can also interact with this pocket in the antiapoptotic Bcl-2 family members and potentially nullify their protective function.[209] The specific amino acids contained in this pocket dictate a select hierarchy of interactions between various members of the Bcl-2 family. Hence, the structure reveals a possible functional interaction with the mitochondrial membrane and explains associations between members of the Bcl-2 family that determine survival or death.

The Hexahelical Bundle

The DDs, DEDs, and CARDs are critical protein-protein interaction motifs in DR-mediated PCD. Interestingly, all three domains adopt a similar structural scaffold of a compact bundle of six antiparallel α-helices, which we will refer to as the "hexahelical bundle" (see Fig. 30.7E). This structure is an ancient one that is related to the "ankyrin repeat," a protein interaction motif occuring in a plethora of proteins and conserved throughout phylogeny.[59,209] Despite remarkable overall similarity, significant differences exist among the DDs, DEDs, and CARDs, which likely account for their binding specificities. They usually form homotypic associations. For example, the surface of Fas DD is made up of mostly charged residues,[406] whereas the FADD DED contains hydrophobic patches that are important for binding to caspase-8.[208] The six helices in the CARD domain of RAIDD form an acidic surface on one side of the molecule and a basic region on the other side of the molecule, which

may be important for binding of the corresponding CARD domain in caspase-2.[407] Structural and mutagenesis data corroborate the notion that helices 2 and 3 are critical contact regions for homophilic DD and DED interactions. In addition to α2 and α3, homophilic CARD/CARD interactions appear to involve electric dipole interactions between α2, α3, α5 on one molecule and α1, α4 on the partner. Examination of the CARD domain from Apaf-1 yields similar observations.[408,409] Thus, specific molecular pathways are determined by defining residues in DDs, DEDs, or CARDs presented on a common scaffold. It is also important to recognize that DDs, DEDs, and CARDs are primarily protein-protein interaction domains, and although they were initially discovered in apoptosis pathways, homologues of these motifs may be utilized by nature to associate proteins in pathways unrelated to apoptosis. In fact, a class of proteins containing the pyrin domain also appears to use a hexahelical bundle structural scaffold.[410,411,412] The pyrin domain was originally identified in a protein mutated in

patients with familial Mediterranean fever, thus providing a molecular link between apoptosis and inflammatory diseases.

An intriguing feature of hexahelical bundles is that they often occur in two tandem copies in proteins that promote or inhibit apoptosis. For example, the tandem DEDs in caspase-8 or -10 can augment apoptosis, whereas those in viral or cellular FLIPs inhibit apoptosis. The recent solution of the crystal structure of a viral FLIP, MC159, at 1.2 Angstroms resolution revealed a noncanonical fold of DEDs with a rigid dumbbell-shaped structure. Each DED played a unique role in the overall structure to generate an asymmetric interaction with DD proteins over an extensive surface.[297] MC159 assembles into the DISC with Fas and FADD via a surface topology that differs from proapoptotic molecules. This blocks FADD self-association, which disrupts the higherorder oligomerization of the Fas receptors on the cell surface that is required for caspase activation.

Caspase Structure

The recruitment of DD-, DED-, or CARD-containing proteins eventually leads to the complex formation and activation of caspases. The structures of caspase-1, -3, -7, -8, and -9 have been determined.[235,289,290,292,293,294,302,303] Each caspase is composed of small and large subunits of approximately 10 and 20 kDa (generally referred as p10 and p20, respectively). The catalytic subunits of all caspases are similarly comprised of two p10/p20 heterodimers. Each p10/p20 heterodimer is folded into a compact cylindrical structure of six β strands and five α helices. The active site of the enzyme is formed by loops contributed by both the p10 and p20 subunits that come together at the top of the cylinder of β strands. The two heterodimers are aligned in an antiparallel fashion where the β sheet forms the vertical axis of the tetrameric complex (see Figs. 30.6 and 30.7F,G). Despite the overall structural similarity, distinct differences, especially in loops surrounding the catalytic active site, can explain the respective substrate preferences between different caspases.

Regulation of caspases by viral inhibitors has also been elucidated by structural studies. The baculovirus p35 is a potent inhibitor of many caspases that requires cleavage at its caspase recognition residue D87 to manifest inhibitory activity. Crystallographic studies reveal the formation of a thioester bond between the active site cysteine of caspase-8 (C360) and the aspartate of the amino-terminal cleavage product of p35.[413] Lu et al. showed that following caspase-8 processing, the buried p35 NH_2-terminus portion is liberated and undergoes a native chemical ligation reaction between residues D87 and C2. This mechanism, also used by selfsplicing proteins, leads to the formation of a circular NH2-terminal p35 peptide, which is kept bound to the caspase-8 active site to ensure its long-lasting inhibitory effect.[414]

CONCLUSION

The study of PCD has provided insights into many aspects of immune function, particularly in the establishment of central and peripheral tolerance and the numerical homeostasis of immune cells. PCD plays a vital part in the clonal composition, both qualitatively and quantitatively, of the immune repertoire. Immune cells utilize conserved mechanisms of apoptosis and necrosis that are common to perhaps all mammalian cells. Indeed, the immune system has been one of the most instructive model systems for understanding how these networks function. Finally, death is regulated by cues from the environment. For developing lymphocytes, the antigen environment determines cell survival and elimination. For mature

cells, antigen and growth cytokines determine life or death. In this manner, the immune system can develop a wide repertoire of reactive cells, select the most useful members of the repertoire, and then expand and contract specific clonotypes as needed for specific immune responses. Such homeostatic control allows rapid cell proliferation in protective responses while preserving tolerance and avoiding autoimmunity and immune cell malignancies. There are still important challenges in this area of investigation. The molecular mechanisms of antigen receptor-induced apoptosis and necrosis are still not fully understood. Fundamental questions, such as what proteolytic substrates of caspases are crucial for apoptosis, necrosis, or proinflammatory signaling, remain unanswered. Also, the genetic or environmental influences that cause autoimmunity in certain individuals with Fas defects but not others await definition. Finally, harnessing our understanding of PCD in the immune system for the diagnosis, prevention, and treatment of immunologic diseases is an exciting frontier for the future.

MEMORY AS A BIOLOGIC CONCEPT

The Protected State

> *Yet it was with those who had recovered from the disease that the sick and the dying found most compassion. These knew what it was from experience, and had now no fear for themselves; for the same man was never attacked twice- never at least fatally. And such persons not only received the congratulations of others, but themselves also, in the elation of the moment, half entertained the vain hope that they were for the future safe from any disease whatsoever.*[1]

This quote comes from the Greek historian Thucydides (ca. 460 BC to ca. 395 BC) and describes his firsthand account of an ancient plague that struck Athens during a protracted war with Sparta. Although the identity of the causative agent continues to be a matter of speculation,[2] these words transcend the ages to vividly illustrate the concept of *immune memory*—the phenomenon in which prior exposure to an infectious pathogen endows an individual with *immunity*, a durable state of protection against reinfection with the same organism. Unknown to Thucydides and his fellow Greeks, the immunity observed in the survivors of this plague reflected changes in the operational status of their immune systems as a result of the first (primary) response to the infecting pathogen. In the act of responding to the initial infection, the immune system expands a diverse population of antigen-specific B- and T-lymphocyte clones possessing a range of affinities and effector capacities. Through a process that is just now beginning to be understood at the molecular level, a portion of this repertoire is retained within the memory pool in the form of cells that are able to persist for long periods of time at relatively stable numbers by maintaining a slow but steady rate of division that is roughly equivalent to their rate of loss (death). When faced with a renewed challenge from the same (or antigenically related) infectious agents, memory cells mount a strong and rapid effector response that is capable of stopping reinfection at its earliest stages. The functional units of immune memory, therefore, are the long-lived B and T cells that mount rapid secondary (recall) responses upon reencounter with their cognate antigen.

In the broader teleologic concept of memory, however, it is the antigen receptors that were shown to be “useful” in combating the initial infection that are selected and preserved at an increased frequency on clonal progeny that possess enhanced response kinetics and specialized functions. Whether generated through infection or vaccination, the value of the protected state they confer to the individual is self-evident, as preexisting immunity can prevent or limit the potential damage of an otherwise unrestrained infection. This can be of benefit from the earliest days of life, as seen in the example of maternal antibodies transmitted to the neonate in milk and serum that may serve to limit infections and transform them into “natural vaccinations” and thereby diminishing the severity of childhood infections that will be encountered during the next 1 to 2 years.[3]

This chapter will examine the phenomena and mechanisms of long-lasting protection that can develop following infection or vaccination, and will focus on the factors that govern the establishment and maintenance of specialized subsets of lymphocytes generated from the naïve repertoire during the primary response to a given antigen. This concept stands in contrast to the “memory” associated with immune tolerance, through which the adaptive arm of the immune system can prevent inappropriate responses against ubiquitous self-antigens. Immune memory involves a stable increase in the number of antigen-experienced B- and T-lymphocytes that have acquired specialized functional properties, allowing them to generate secondary responses that are more rapid and effective than those made by their clonal antecedents during the primary response. It is in the establishment, maintenance, and execution of memory responses that the adaptive immune system finds its greatest purpose for the preservation of both the individual and population. As will be discussed in this chapter, immune memory depends on a remarkable degree of interaction and cooperation between many different cell types in an elegant division of labor aimed at preserving those T- and B-cell specificities that have proved useful in the battles fought and won against previously encountered pathogens. It is important in considering the concept of immune memory, however, that distinctions be drawn between the protected state, an operational definition that can vary with the nature and magnitude of the antigenic challenge used to test its integrity, and memory cells, the clonal elements of memory whose contribution to the protected state can only be inferred from their phenotypic and functional properties.

Lifelong Memory can be Induced through Infection or Vaccination

Observations of acquired resistance to recurring diseases are recorded throughout the history of human epidemics. The careful observations of the Danish physician Ludwig Panum were among the first to clearly illustrate just how durable the protected state can be in an individual. Working on the

remote Faroe Islands in the North Sea, Panum studied two separate measles epidemics that took place 65 years apart between the 18th and 19th centuries. In the apparent absence of outbreaks in the intervening period, he found that people who had contracted measles in the first epidemic were not affected during the second, while those of appropriate age that were infected during the second outbreak had not been affected during the first.[4] Thus, Panum observed, a single infection was capable of endowing an individual with lifelong immunity through a process that did not require reexposure to the pathogen. Although immune reactivity can be boosted by repeated exposure to a given organism, the extent to which this

determines the maintenance of immune memory remains a source of some controversy.[5] A source of uncertainty in applying this concept to human immunology is the difficulty in determining whether a single or multiple exposures have taken place before the memory state is assessed. With infrequently encountered life-threatening infections such measles, yellow fever, or polio, it is relatively straightforward to infer that a single exposure can establish a state of protection for up to 75 years that appears to be mediated by antibodies.[4,6,7] With less threatening ubiquitous agents such as those causing the childhood infections chicken pox (*Varicella zoster*) and whooping cough (*Bordetella pertussis*), it is unclear whether immune memory may depend on occasional subclinical reinfection.[8]

Given the long history of immunity in survivors of infectious disease, it is notable that even the most rudimentary understanding of how the protected state could be achieved was realized long after methods for its induction had been devised. Among the earliest practices was that of *variolation*, which had long been in practice in China and India as a means for enhancing protection against the deadly smallpox virus, which had been a major source of mortality in humans since recorded history.[9] Variolation involves the intentional inoculation with desiccated material obtained from the open pustules of smallpox victims, in hopes that exposed individual would develop a milder form of the disease and, upon recovery, would be immune to smallpox (variola virus). Although effective in many cases, the procedure was not without risk to the recipient, who risked contracting a more serious life-threatening form of the disease that could be spread to others. In 1796, Edward Jenner famously (and dramatically) overcame these obstacles by using material obtained from the pustules of milkmaids infected with cowpox (vaccinia virus), an antigenically related but less virulent type of poxvirus, to inoculate young James Phipps who subsequently survived his exposure to infectious smallpox patients.[10] In the 19th century, Louis Pasteur further developed the concept of using less-virulent or intentionally disabled forms of infectious organisms to confer immunity to bacterial diseases such as chicken cholera and anthrax, or viral diseases such as rabies. Pasteur used the word *vaccine* as a generic term to describe antigenic preparations administered to produce immunity, in reference to Jenner's earlier work with cowpox (vaccinia) virus (*vacca* is Latin for cow). As described in more detail in the chapter on vaccines (Chapter 43), current vaccines can be generated from organisms that are antigenically related to the one against which immunity is desired, from inactivated forms of the entire disease-causing organism, or from specific constituent portions of the infectious organism such as proteins, polysaccharides, or nucleic acids.

Despite their various compositions, all effective vaccines recapitulate several important aspects of the immune response leading to memory formation: they mimic the threat of an infectious pathogen through stimulation of innate immunity, and they contain distinct antigens that can become recognizable by cells of the adaptive immune system.[11,12] The power of vaccination to induce long-lasting immune memory is best illustrated by the example of the smallpox vaccine (vaccinia). This once-devastating organism has been virtually eradicated since the late 1970s through a worldwide mass vaccination program that still stands as one of the crowning achievements of the 20th century.[13] The immunity induced by the smallpox vaccine is of remarkable durability, with both antibody and cluster of differentiation (CD)4+ and CD8+ T cell responses detectable 50 years after initial priming,[14,15,16] and effectiveness, with a lifelong protection rate of 90% to 95% in vaccinated individuals, and a

fatality rate of only 2% in those vaccinated within a decade before exposure.[17,18] With the advent of modern immunologic tools such as enzyme-linked immunosorbent assay, intracellular cytokine staining, and enzyme-linked immunospot assays for the detection of rare vaccinia-specific T and B cells, a more detailed longitudinal picture of the response to the smallpox vaccine has emerged. These studies suggest that humoral immunity is more durable than cellular immunity, as increased numbers of vaccinia-specific memory B (Bmem) cells remain relatively stable for more than 50 years after vaccination, whereas CD4+ and CD8+ T-cell responses continue to decline over time, with a half-life of 8 to 15 years.[14,16,19] This indicates that Bmem-cell responses, and to a lesser extent memory T-cell responses, are maintained by robust mechanisms.

Given the remarkable longevity of the immunity induced through either infection or vaccination, it is clear that the cells mediating the protected state must possess several key properties in order to preserve useful specificities generated in previous antigenic experiences, with the study of memory T cells revealing insights into a number of these features. First among these is that antigen-specific memory cells must be present in the immune repertoire in greater numbers than in the naïve repertoire as a result of their initial proliferation.[20,21,22,23,24,25] Secondly, they must have undergone a program of differentiation involving alterations in chromatin structure and activation of specific transcription factors to allow the expression of key effector molecules such as cytokines, chemokines or cytotoxic proteins, in the case of cytotoxic T lymphocytes (CTLs), immediately upon recognition of antigen-expressing target cells.[26,27,28,29,30,31,32,33] Memory cells must be able to survive as a clonal population over time; that is, they must be able to replace cells lost to normal homeostatic turnover.[34,35] Memory cells also must perform a sentinel function by occupying specific physiologic niches where naïve cells are not usually found and where antigen exposure will either occur or be detected such as the mucosa of the lung or gastrointestinal tract.[36,37] Consistent with this

sentinel function, memory cells are found to be capable of responding to lower concentrations of antigen than naïve cells through the selective expansion of high-affinity clones and the upregulation of adhesion molecules and reorganization of their T-cell receptor (TCR).[38,39,40,41] Lastly, memory cells should be able to respond quickly to reencounter with their cognate antigen with the induction of rapid effector functions and renewed rounds of clonal expansion.[42] Memory cells have developed a variety of mechanisms to achieve each of these specialized properties. In the following section, we will examine how memory cells are generated during immune responses and how these key features are imparted during priming, maintained over long periods of time, and expressed when needed to confer rapid protection from reinfection (Fig. 31.1).

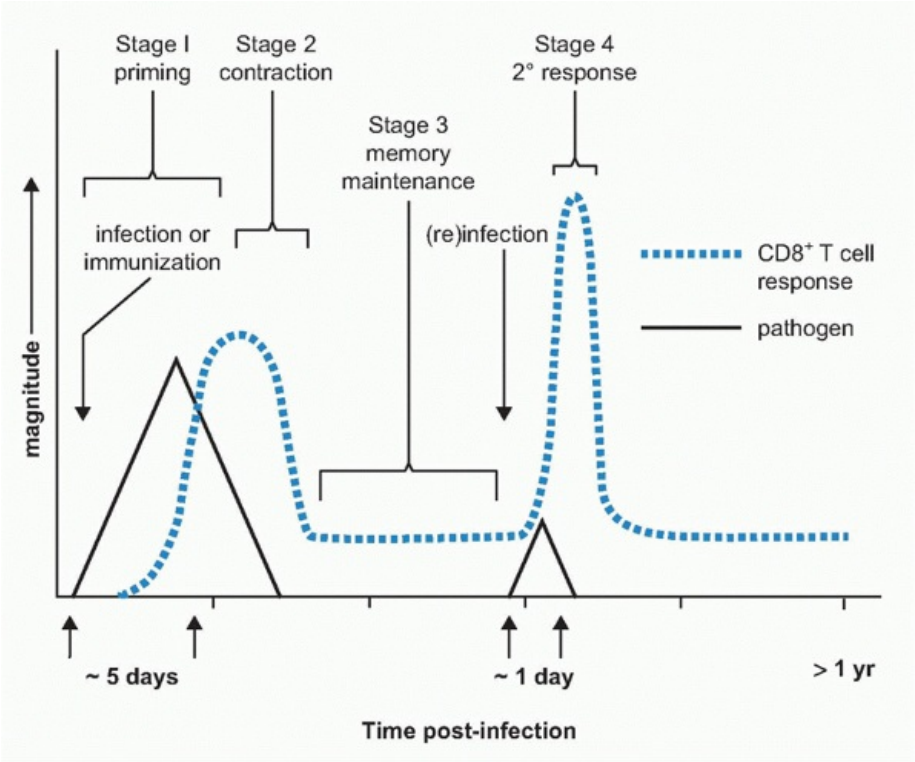

FIG. 31.1. Stages of the T-Cell Response to Infection. Antigen-specific T cells clonally expand during stage 1 and differentiate into effector T cells. After viral clearance, the majority of the cells die over the next 2 to 4 weeks (ie, stage 2, the bulk contraction phase). Soon thereafter, the number of virus-specific T cells stabilizes and the cells enter the memory phase and are maintained for long periods of time (stage 3). The majority of the memory T cells undergo slow, periodic basal homeostatic proliferation in response to interleukin-15 and interleukin-7. Upon reinfection, the memory T cells rapidly produce effector cytokines and other antimicrobial molecules and proliferate robustly to thwart infection.

THE GENERATION OF MEMORY T CELLS

Introduction

Antigen-driven T-cell responses can be broadly categorized as having two main components: a comparatively shortlived effector arm that comprises large numbers of cells that mediate direct functional response against target cells, and a smaller but longer-lived memory population that insures the potential of rapid and potent recall responses against the inducing antigen. The memory component can itself be distinguished into two separate activities: one that resides mainly within lymph nodes where it can respond to antigenic challenge by renewed clonal expansion and production of secondary effectors ("central memory" phenotype T cells [T_{CM}]) and one that is largely disseminated throughout peripheral tissues where the first contact with infectious pathogens is likely to occur ("effector memory" [T_{EM}] or "resident memory" [T_{RM}] phenotype T cells), which are capable of mediating immediate effector functions upon antigen recognition.[36,42,43,44] Memory T cells disseminate widely throughout the body and circulate passing from blood to tissues and lymphoid organs, but

more tissue resident T_{RM}, noncirculating memory T cells, can also be found in the brain and mucosal tissues such as the gut and skin that reside long-term in the tissues following infection.[45] The specific roles in immunity and the signals that may govern the development of these subsets will be discussed in subsequent sections in this chapter.

Models of Effector and Memory T-Cell Development

There are several models for how both effector and memory populations could be concomitantly generated, either in parallel or sequentially (Fig. 31.2). 1) The first model suggests that memory cells are the clonal progeny of a distinct precursor population that follows a separate differentiation fate from that of the primary effectors, and instead survive to execute these effector functions during the recall phase (separate precursor model). However, little support for this model exists currently because elegant lineage tracing experiments have demonstrated that the progeny of a single, naïve antigen-specific CD8 T cell can have diverse fates.[46,47] 2) The second, the "decreasing potential model," postulates that increasing amounts or prolonged periods of TCR stimulation causes the effector T cells to progressively lose memory cell potential and, ultimately, reach a terminally differentiated state.[48] This may occur in a linear or step-wise manner, driving the T cells through several distinct differentiation steps. Although this model was originally based mostly on antigenic signaling (signal 1), it is likely the collective history of signaling through costimulatory receptors (signal 2) and

inflammatory cytokines (signal 3) that determine the differentiation set-points of the T cells during infection. 3) The third model also allows for formation of heterogenous effector cell populations dependent on the overall "strength" of the signals 1, 2, and 3 encountered early during T-cell priming as first described by Lanzavecchia and Sallusto.[49] High or excessively strong signals drive greater clonal expansion, but might also cause terminal effector T-cell differentiation. This model differs conceptually from the decreasing potential hypothesis in that different cell fates can be specified early according to the intensity of the signals received, but do not necessarily require multiple rounds of stimulation to create heterogeneous cell fates. 4) This model is also conceptually similar to an alternative "asymmetric cell fate model"

that supports the notion that T_{EM} and T_{RM} fates can arise from a single precursor T cell via asymmetric cell division that occur as the activated T cells clonally expand, and may even begin as early as the first cell division.[50] This fourth model envisions memory as a cellular fate governed by the same common biologic strategy used during ontogeny and development to specify distinct functional properties in selected cells and their clonal progeny.[51] The latter three models are not mutually exclusive, and elements of each of these models most likely occur simultaneously during an immune response. Moreover, although there is some experimental evidence for early cell fate commitment, a more likely scenario is that signals encountered early during T-cell priming setup or specify T-cell fates, but that some plasticity remains in the dividing cells and their differentiation states and fates become determined through the subsequent contact with antigen-presenting cells (APCs) or other signals over the next several days of infection.

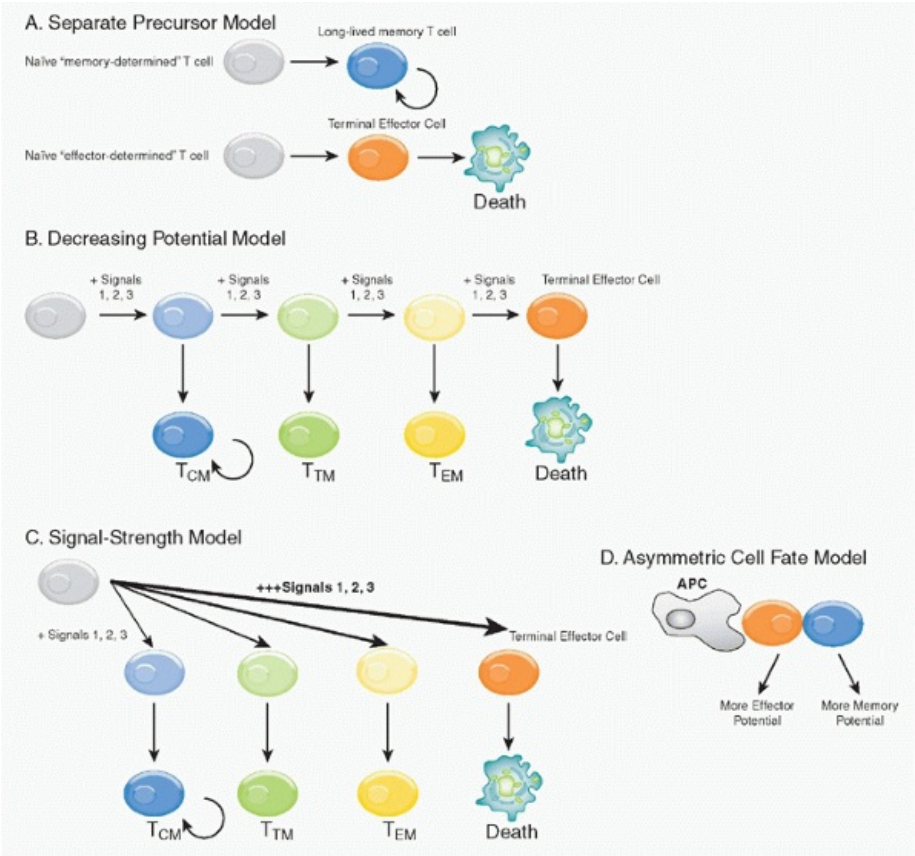

FIG. 31.2. Models of Memory T-Cell Generation. Four models are proposed to describe the formation the memory T cells. Please see text for detailed descriptions of each model. **A:** Separate precursor model. This model suggests that naïve T cells can be preprogrammed following thymic development to develop into memory T cells or terminal effector cells that die following infection. **B:** Decreasing potential model. This model states that a short duration of antigenic stimulation favors development of effector cells that will give rise to greater numbers of central memory phenotype T cells (T_{CM}; *blue*), whereas longer durations of stimulation promotes terminal effector cell differentiation (*red*) and death. According to the number of interactions with antigen-presenting cells and possibly cell divisions, intermediate stages of effector differentiation can also be acquired, giving rise to memory T cells with more effector memory phenotype T cell (TEM)-like (*orange*) or transitional memory (T_{TM}; *yellow*) phenotypes that can convert from $T_{EM} \rightarrow T_{CM}$ phenotypes overtime. *Curved arrow* denotes basal homeostatic proliferation. **C:** Signal strength model. This model proposes that the effector cells differentiate according to the "strength of signal" they receive at the time of priming (or possibly later). Larger amounts of antigen, costimulation, and inflammation (*thicker arrow*) drive cells toward a more terminal differentiation state, whereas weaker signals (*thinner arrows*) promote formation of T_{CM}, T_{TM}, or T_{EM} cells in a progressive manner. **D:** Asymmetric cell fate model. This model proposes that T-cell fates are specified (or possibly even determined) as early as the first cell division by the asymmetric portioning of cell fate determinants.

In each of these models, the initiating event leading to memory cell development is the

primary activation of a naïve T cell in response to immunization or infection. We shall therefore begin our consideration of memory T-cell generation within the different phases of the immune response: 1) the first phase of naïve T-cell priming, clonal expansion, and effector cell differentiation (the naïve to effector T-cell transition); 2) the second phase of effector cell contraction and formation of a surviving pool of memory T cells (the effector to memory T cell transition); 3) the third phase of memory T-cell maintenance and homeostasis; and 4) the reactivation of memory T cells during reinfection. Within each phase, we will discuss the similarities and differences between CD4 and CD8 T cells in effector and memory T-cell development.

Methods of Detecting Effector and Memory T Cells

Before discussing the factors responsible for the development of effector and memory T cells, it is important to understand the types of experimental approaches that have been used in their study and how these influence the various conclusions that can be drawn from the experimental data. In general, there have been two main experimental settings through which memory T-cells have been studied in vivo. One involves enumeration of cells that express markers associated with antigen-experience such as $CD44^{hi}$ or $CD62L^{lo}$ for activated cells, in either immunized or nonmanipulated normal mice. In an immunized host, the antigen-specific T cells can be generated from the endogenous polyclonal repertoire or adoptively transferred monoclonal transgenic T cells. In the latter case (a naïve host), the cells in question are the spontaneously arising “memory phenotype” (MP) T cells of unknown derivation and specificity, which increase in frequency with age.[52,53] In contrast, antigenspecific effector and memory T cells can be distinguished and tracked longitudinally in mice and humans using major histocompatibility complex (MHC) class I or II tetramers, which are soluble forms of the ligand structure recognized by T cells and allow the detection of cells recognizing a specific antigenic determinant.[54,55] Alternatively, antigen-specific T cells can also be identified functionally using intracellular cytokine staining, which allows enumeration of cells secreting cytokines in response to their cognate peptide antigen. Finally, the use of TCR-transgenic T cells has allowed the fate of a monoclonal population of antigen-specific T cells to be followed throughout their development from naive to memory cells during immune responses in mice. This typically involves the adoptive transfer of relatively small numbers of naïve TCR-transgenic T cells into a wild-type mouse that is subsequently immunized or infected to activate the T cells.

Phase I. Naïve to Effector T-Cell Transition: T-Cell Priming, Clonal Expansion, and Effector Differentiation

T-Cell Priming

The process of generating T-cell memory begins at priming, which is the initial activation of mature postthymic precursors (ie, naïve T cells) by foreign antigens presented by professional APCs. This is not a simple task, as a T cell recognizing any one single antigen is rare in the naïve repertoire, occurring with a frequency of perhaps 1 in 10^5 to 10^6 among the total population.[56,57] The antigen-bearing APCs are also likely to be infrequent among the (tens of) millions of cells within a given lymph node or in the spleen, as in most cases they must first obtain their antigenic cargo at peripheral sites of infection and then migrate via the

lymphatics to lymph node or via the bloodstream to the spleen.[58] As will be described, the complex interaction of rare and migrating cell types necessary to the generation of immune responses is facilitated by highly regulated patterns of migration and by the structural features of the secondary lymphoid organs themselves.

Naïve T cells are produced at a modest rate by the thymus, with approximately 1 to 2 × 10^6 cells per day emerging into the bloodstream in young mice.[59,60] The survival of naïve cells/recent thymic emigrants requires at least two types of extrinsic signals: 1) MHC molecules that are presumably occupied with low-affinity ligands (self- or environmental peptides) and provide tonic TCR stimulation, and 2) a critical cytokine, interleukin (IL)-7, which has many roles in B- and T-cell lymphopoeisis.[61,62,63,64,65,66,67,68] Mice or humans deficient in either IL-7 or IL-7Rα have considerably reduced numbers of T cells.[69,70,71,72,73,74] IL-7 is a member of the common γ-chain (γ_C) cytokine family that signals through a heterodimer comprised of γ_C and IL-7Rα.[75] Neither of these components are unique to IL-7, as γ_C is shared with IL-2, IL-4, IL9, IL-15, and IL-21, and IL7Rα is shared with thymic stromal lymphopoietin (TSLP).

To become stimulated (primed), naïve T cells must recognize antigens in the form of peptide fragments bound to MHC molecules on professional APCs, such as dendritic cells (DCs), in lymphoid organs. In response to microbial pathogens, immature DC migrate to sites of infection and inflammation in response to a range of CC and CXC chemokines and acquire soluble and particulate antigens. The immature DCs become activated by recognition of pathogen-associated molecular patterns or host molecules released by tissue damage and transition into an APC by

increasing expression of MHC:peptide complexes, the chemokine receptor CCR7 to facilitate migration toward T-cell areas of secondary lymphoid organs, and costimulatory ligands and cytokines to aide in T-cell activation and effector cell differentiation.[76] Once a naïve T cell recognizes its cognate peptide/MHC ligand on an activated DC within the secondary lymphoid organs, the interactions of priming (ie, the “antigenic signal”) can take place. The molecular details of this process involve the formation of immune synapses at the T/APC contact site that are composed of rapidly-clustering of TCR molecules binding peptide/MHC complexes on APC plus the local accumulation of intracellular signaling molecules such PKC-θ, LAT, and LCK.

Activation of T Cells by Antigen (Signal 1) and Costimulatory Receptors (Signal 2)

Another critical consequence of DC activation is the upregulated expression of numerous costimulatory molecules and cytokines that contribute to T-cell priming by promoting cell division, survival, and differentiation.[58,77,78,79] The primary activation of naïve T cells has traditionally been believed to require at least two signals: an antigen-specific “signal 1” that is transmitted upon TCR-mediated recognition of its cognate peptide/MHC complex, and an antigen nonspecific “signal 2” costimulus.[80,81] This “two-signal” model predicted that engagement of the TCR in the absence of costimulation is insufficient for sustained clonal expansion and cytokine production, and cells instead become anergic and unresponsive to

further stimulation.[82] While this outcome has been demonstrated in a number of studies, the number of ligand/receptor pairs capable of functioning as “signal(s) two” has grown considerably in the last decade. CD80 and CD86 are considered to be the prototypical costimulatory molecules expressed on APC capable of transmitting “signal 2” through their interaction with CD28 expressed on T cells. CD80/86-mediated ligation of CD28 produces signals in T cells that are distinct from those of the TCR and enhances clonal expansion, effector functions, and memory development.[83,84,85,86] Although many CD4+ and CD8+ T-cell responses depend on CD28, the requirement is not absolute, as many types of T-cell responses can occur in its absence in vivo, including allograft rejection, induction of allogeneic graft-versus-host and delayed-type hypersensitivity responses, and the generation of cytotoxic CD8+ T cells.[87,88,89,90,91] These observations suggest that additional pathways exist for costimulation of T cells other than CD28.[92] A number of these have emerged from the tumor necrosis factor receptor (TNFR) family (CD27/CD70, 4-1BB (CD137)/4-1BBL, OX40 (CD134)/OX40-L, HVEM-LIGHT, CD30/CD30-L, and GITR), each of which can provide costimulatory stimuli that synergize with TCR signals to sustain T-cell activation after priming, and that have been shown to be important for the magnitude and longevity of CD8+ T-cell responses in vivo in studies of knockout mice lacking either ligand or receptor.[92,93,94] Interestingly, the costimulatory requirements for CD4 and CD8 T cells are not completely overlapping. For example, CD8+ T-cell activation and clonal expansion occurs efficiently in mice lacking CD28, CD40L, or OX40, whereas CD4+ T-cell responses are substantially reduced. The opposite situation is seen in mice lacking 4-1BB-/-, which mount normal CD4+, but diminished CD8+, T-cell responses to lymphocytic choriomeningitis virus (LCMV) infection.[95] It should be pointed out that the influence of costimulatory interactions on the regulation of CD8+ T-cell responses is by no means limited to the priming event, as several receptor-ligand pairs, notably 4-1BB/4-1BBL, OX4O/OX40L, BTLA/HVEM, and PD-1/PDL1/PDL1, can act on the expanded population, with either positive or negative effects on T-cell function and survival.[94,96,97]

Inflammatory Cytokines (Signal 3) and Effector T-Cell Specification

In addition to contact-dependent costimulation, a number of inflammatory cytokines including interferon (IFN)α, IFNβ, IFNγ, IL-1, IL-4, IL-6, IL-12, and IL-21 have been implicated in the transmission of a “signal 3” that is required for optimal proliferation and differentiation of effector T cells.[98,99] Signal 3 cytokines are produced mostly by innate immune cells in response to pattern recognition receptor activation, but the types of cytokines produced will vary according to the pathogen, its tropism, and the types of pattern recognition receptors and sentinel cells activated during infection or vaccination. This selectivity of cytokine production ensures development of the appropriate types of effector T cells to defend against the given infecting pathogen.[99] For instance, intracellular pathogens, such as viruses and certain bacteria, elicit production of IFNα/β, IL-12, and IFNγ, which drive development of type I immune responses that mainly consist of cell-mediated defenses aimed at direct killing of infected cells via CD8+ CTLs or suppression of viral replication and activation of macrophages through T_H1-polarized CD4+ responses.[100] Infection by extracellular pathogens including parasites and helminthes produces TSLP and IL-4, which induces development of more humoral-based type 2 responses that generate Th2-polarized CD4+

effector T cells and recruitment of eosinophils, basophils, and mast cells. Other extracellular pathogens, including gram-negative bacteria, fungi, and some protozoa, induce IL-6 and IL-1; in the presence of basal transforming growth factor (TGF)-β, this instructs development of Th17 CD4+ T cells that recruit neutrophils and macrophages to sites of infection.[101,102,103,104] Additionally, as discussed in greater detail subsequently, CD4 T cells also form follicular helper T cells,which are specialized for B-cell help and control of germinal center (GC) responses and antibody production.[105] Lastly, regulatory T (T_{reg}) cell populations that develop in the thymus or in the periphery prevent autoimmunity and, during infection, keep effector T cells in check to reduce the amount of collateral damage (ie, tissue damage) associated with immune responses. Additional varieties of CD4 T cells have been proposed that differ based on cytokine production or localization.[106,107]

Much progress has been made in elucidating the genetic programs that govern development of CD8+ CTLs and CD4+ T_H1, T_H2, and Th17 effector T cells. During type I responses (eg, antiviral responses) TCR and IL-12, IFNαβ, and IFNγ signaling act together to activate transcription factors such as signal transducer and activator of transcription factor (STAT) 4 and T-bet in CD4+ T cells to induce formation of IFNγ-producing T_H1 cells. Likewise, in CD8+

T cells STAT4, T-bet and eomesodermin expression are needed to generate CTLs to directly kill infected cells.[107,108,109,110] Similarly, during type 2 responses, IL-4-dependent activation of STAT6 and GATA-3 creates T_H2 effector cells that produce IL-4, IL-5, and IL-13 as “signature cytokines” to trigger immunoglobulin (Ig)E production by B cells and activate eosinophils, basophils, and mast cells.[107] This, for example, creates a “weep and sweep” mode of defense to combat infection of helminths.[111,112,113] Although the exact details of T_H17 development remain to be elucidated, the cytokines IL-6, IL-1, and TGF-β play an instructive role in their differentiation through engagement of STAT-3 and the nuclear orphan receptor RORγ.[114,115,116,117,118] The development of T_H17 or T_{reg} cells appears to be reciprocal and dependent on the ratio of IL6:TGF-β as well the abundance of vitamin A metabolite retinoic acid.[119,120,121] For example, steady-state production of TGF-β may favor T_{reg} formation, but upon bacterial infection, the combination of newly synthesized IL-1 and IL-6 will favor Th17 differentiation.[122] Signals for Tfh cell differentiation are incompletely characterized, but IL-6 and ICOS are important factors in most cases.[105,123,124,125,126] In addition, Tfh cells depend on multiple stages of APC interactions, first requiring signals from DCs and then subsequent interactions and signals from B cells.[125,127,128,129]

Clonal Expansion of Effector T cells

The kinetics of T-cell clonal expansion can be remarkable. In murine model systems of *Listeria* and LCMV infection, it has been documented that CD8 T cells undergo between 15 to 20 sequential rounds of division within the first 7 days of infection, at rates as fast as ˜4 to 8 hours, and increase the frequency of antigen-specific T cells more than 10,000-fold over their initial frequency in the naïve.[32,130,131,132,133,134,135,136,137] CD4 T cells also undergo profound clonal expansion, but their burst sizes are typically smaller than that of

CD8 T cells. The factors that govern the magnitude of T-cell proliferation in vivo are numerous, but several studies have demonstrated a direct relationship between antigen load and the number of effector cells generated.[135,136,138,139,140,141,142] However, it is important to point out antigen-driven T-cell proliferation cannot be sustained indefinitely, as in the case of chronic infections (such as human immunodeficiency virus [HIV] and hepatitis C virus infection in humans and LCMV infection in mice), where antigen persists for prolonged periods. That is, despite the presence of antigen, the antigen-specific T cells still undergo contraction 1 to 2 weeks post infection. In these situations, it has been postulated that this occurs due to "programmed" contraction of activated CD8 T cells, but another critical element is that these cells differentiate into senescent, less functional "exhausted" T cells that may be sensitive to apoptosis.[143,144,145,146] Another difference observed between CD4+ and CD8+ T cells is that CD8+ T cells require a comparatively shorter period of stimulation (2 to 4 hours) for commitment to clonal expansion and effector development than do CD4+ T cells (~20 hours).[135,137,147,148] CD8+ T cells also begin dividing earlier after priming than CD4+ T cells and have a faster rate of division.[148,149,150,151] Additionally, and in contrast to CD8+ T cells, it has been observed that CD4+ T cells require continued antigenic stimulation throughout their period of expansion in order to achieve full proliferative and effector potential.[152,153] Based on these and other findings, Lanzavecchia and Sallusto have suggested that the optimal development of memory T cells will occur in cells that receive a specific level of antigenic stimulation during their priming and subsequent expansion that enables them to utilize and access survival signals in a process termed progressive differentiation.[49,147,154,155]

In addition to the effects of the inflammatory cytokines on effector T-cell specification, some of these cytokines also play a critical role in effector cell survival and clonal expansion. For instance, studies on CD8+ T cells primed in vitro with peptide/MHC and CD80 showed that optimal expansion and development of lytic functions required addition of IL-12 or IFNα.[156] IFNαβR-deficient LCMV GPspecific CD8+ T cells transferred to wild-type mice showed dramatic reductions in their ability to undergo clonal expansion and to generate a memory pool following infection with LCMV.[157,158] When the LCMV GP was expressed from a recombinant vaccinia virus, however, only a modest defect in CD8+ T-cell expansion and survival was observed, suggesting that the IFNαβ-dependence of CD8+ T-cell memory is influenced not by the target antigen, but rather by the immunogen.[157,159] This idea has found support in a recent study showing that the response of IFNαβR-deficient transgenic CD8+ T cells to the same peptide-pulsed DC vaccine offered in the context of four different infections (LCMV, vaccinia virus, vesicular stomatitis virus, and *Listeria monocytogenes*) were most severely inhibited for LCMV infection.[158,160] IFNγ has also been shown to support optimal CD8+ T-cell expansion after LCMV infection or peptide vaccination, and transgenic CD8+ T cells lacking the IFNγR1 display reduced expansion compared to wildtype cells in the same host.[161,162,163] Thus, multiple types of innate-immune induced cytokines can boost expansion of activated T cells.

CD4+ T Cells Help CD8+ T-Cell Priming

Although DCs increase their immunogenicity in response to inflammatory stimuli delivered at

peripheral sites of antigen uptake, their stimulatory capacity can be further enhanced within the lymph node through the action of CD4+ "helper" cells (T_H) that recognize peptide antigens bound to MHC class II molecules at the surface of the same APC presenting to the CD8+ T cell[164,165,166] (Fig. 31.3). The contribution of T_H to CD8+ priming had initially been thought to be conditional (ie, required for response to some immunogens but not others) and limited in mechanism to the production of paracrine IL-2 for the benefit of CD8+ T cells present in a "three-cell cluster" together with APCs.[167,168,169] More recent evidence, however, has shown that CD4+ T cells make important contributions to the generation and maintenance of CD8+ T cell responses at a number of discrete steps.[165,170] CD4 T cells can produce IL-21 and IL-4, in addition to IL-2, to support CTL expansion.[171,172,173,174,175] Several studies have shown that a key function of T_H is that it involves the engagement of CD40 on DCs that leads to a number of immunostimulatory alterations, including high-level expression of

costimulatory and adhesion molecules, among them CD80, CD86, 4-1BB, OX40, and CD70, as well as high-level production of IL-12.[94,176,177,178,179,180] CD4+ T cells can also help guide naïve CCR5-expressing CD8+ T cell precursors to relevant APCs within secondary lymph nodes by enhancing production of the chemokines CCL3 and CCL4 at the CD4+ T-cell/DC interface.[181,182]

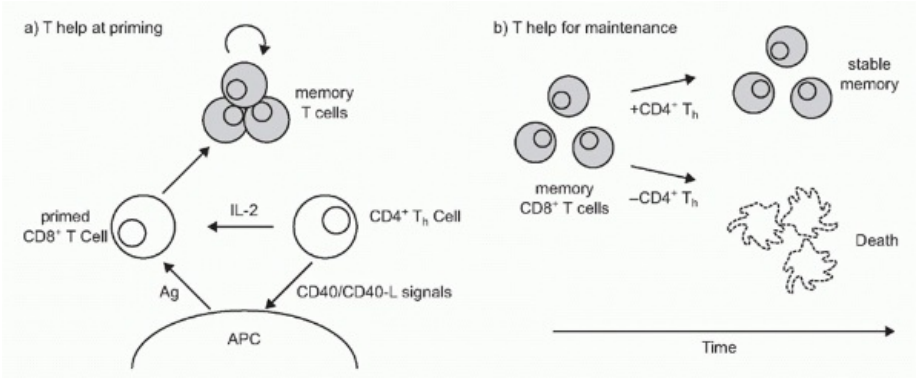

FIG. 31.3. Models of CD4+ T-Cell Help for CD8+ Memory Formation. CD4 T cells can help at two different stages of effector and memory CD8 T-cell development. **A:** CD4 T cells can help CD8 T-cell activation via multiple putative mechanisms including CD40:CD40L interactions between CD4 T cells and antigen-presenting cells (APCs), interleukin-2 secretion, or enhancing chemokine production by causing APCs. **B:** CD4 T cells also help generate functional memory CD8 T cells that are maintained long-term.

The absence of T_H can have different effects on the CD8+ T-cell response depending on the immunogen and the functional parameter measured. In certain settings of noninfectious immunizations using heat-killed or fixed preparations of pathogens or cocktails of foreign protein plus adjuvants, the extent of antigenic stimulation and inflammation can be relatively weak compared to immunization with live, replicating pathogens. In these cases, the antigens will often be cross-presented to CD8 T cells and their response will be CD4 T-cell dependent.

In contrast, the primary CD8 T-cell response to many, but not all, acute viral or bacteria responses are only modestly decreased in the absence of CD4 T cells. It is thought that the overt stimulation of the innate immune response, and perhaps, more prolonged and widespread inflammation and antigen presentation delivers a stronger signal to the CD8 T cells to overcome the need of CD4 T cells for activation during infection. However, in chronic viral infections, where antigen persists, CD4 T-cell help becomes essential to sustain virus-specific CD8 T-cell survival and function overtime.[183,184,185,186,187,188,189]

Effector T-Cell Migration

Following commitment to clonal expansion and acquisition of effector functions, CD8+ T cells begin to express new surface patterns of chemokine, homing, and adhesion receptors that mediate their egress from lymph node and facilitate their migration to peripheral sites. An initial event in this process is the downregulation of CD62L and CCR7, the receptors used by naïve precursors to enter the lymph node, and restoration of the chemotactic response to the lysophospholipid sphingosine-1-phosphate through reexpression of its receptor (sphingosine-1-phosphate-receptor-1), which promotes migration to blood and lymph by distinct sources of its ligand.[36,190,191,192] Following this, the migration of effector CD8+ T cells to nonlymphoid tissues will be largely determined by homing receptors and chemokines.[193] These include chemokine receptors such as CCR2 and CCR5 that guide cells to inflammatory sites through recognition of a variety of chemokines induced by inflammatory cytokines. In some cases, and for reasons that are poorly understood, a subset of these cells will reexpress CD62L and CCR7, thereby allowing their reentry into the lymph node where they can function as T_{CM}, the functional properties of that will be described in the following section.[194] Others will migrate to the spleen via the blood and take up residence in the red pulp and are largely excluded from the white pulp.[195] The ultimate “address” to which the cell will migrate, however, can be influenced by the conditions under which it was activated. For instance, in the intestine, DC from Peyer patches—specialized secondary lymphoid organs within the intestine—have been shown to induce the selective expression of the integrin α4β7and CCR9 chemokine receptor, both of which are essential for gut homing, in CD8+ T cells.[196,197,198,199] Likewise, epicutaneous priming of T cells enhances expression of E-and P-selectin ligands and their subsequent homing to the skin via chemokine receptors CCR4 and CCR10, which bind CCL17 expressed by skin vascular epithelium and TACK expressed on keratinocytes.[200,201,202] Thus, DCs not only “alert” naïve T cells to the presence of an infectious pathogen, but also instruct T cells to express the appropriate homing

receptors that enable their migration to the specific anatomic site where they are needed.[37]

Phase II: Effector to Memory Transition: Resolution of Immune Response and Formation of Memory T Cells

Contraction of Effector T-Cell Populations

Coincident with pathogen clearance at the end of the primary response, the majority of effector T cells are eliminated through a complex and poorly understood process that

involves their orderly apoptosis (programmed cell death) via interactions between growth factors, various member of the TNFR superfamily and elements of the mitochondrial pathway of apoptosis.[203,204] The contraction phase leaves a small population of cells, ~5% to 10% of the numbers present at the peak of the response, to survive as memory cells, which in some cases remain stable for the life of the animal.[205,206] The removal of effector cells achieves two important goals for the immune system: it prevents the T-cell repertoire from being overly populated or "focused" with T cells specific to a particular pathogen, and it restores homeostasis to the available environmental niches for support of T cells so that new antigenic challenges can be met. The magnitude of expansion of different epitope-specific T-cell populations can vary during an infection, creating what is referred to as "immunodominant" or "subdominant" T-cell populations based on their relative cell numbers. Interestingly, for CD8 T cells, the magnitude of contraction remains fairly constant across both immunodominant and subdominant clones such that a similar frequency of cells (~90% to 95%) die during the contraction phase.[21,131,132] These data suggest that the process of contraction occurs fairly equally across various populations of effector T-cell clones, irrespective of differences in precursor frequency and/or the number of times the cells may have divided during clonal expansion.

The loss of antigen-specific T cells at the end of immune responses is largely attributable to apoptotic death, a process traditionally characterized by the activation of a caspase cascade that results in the death of the host cell by cleavage of critical cellular proteins and creation of deoxyribonucleic acid double-stranded breaks.[207] There are two main pathways by which caspases can be activated in T cells: the death receptor pathway and the mitochondrial pathway.[206,208,209] Although the regulation of these pathways in activated T cells in vivo is not entirely clear, several chief factors are thought to be involved: 1) The abundance and duration of antigen is a major determinant of clonal burst size of activated T cells, and stemming from the original observation that restimulation of activated T cells with antigen in vitro can induce cell death, a process known as activation-induced cell death (AICD), antigenic stimulation likely also modulates T-cell death during infection.[210] For example, in certain cases of chronic viral infection, such as LCMV infection in mice, it is thought that persistent antigenic stimulation can lead to the physical deletion of certain epitope-specific CD8 T-cell populations, leaving holes in the repertoire of pathogen-specific T cells.[187,189] However, this does not happen to all virus-specific CD8 T cells during chronic LCMV infection, as virus-specific CD8 T cells directed against other viral epitopes are spared but develop into less functional CTLs, referred to as "exhausted" T cells that express inhibitory receptors that reduce TCR signal transduction.[146,189] In contrast, during other latent infections, such as the murine cytomegalovirus (a herpes virus), some epitope-specific populations contract like normal, but others recognizing latently produced viral proteins may actually "inflate" after the acute phase of infection due to low-grade antigen persistence from viral reactivation.[211,212] 2) Likewise, subsequent encounter with death receptor ligands during or near the end of their clonal expansion phase can also affect effector cell contraction.[213,214,215] 3) The third is the decline in T-cell growth factors and survival signals, such as IL-2, following resolution of infection. In this scenario, it is postulated that the effector cells compete for the dwindling supply of resources. 4) The fourth is the intrinsic heterogeneity of the effector cell population and the balance of proapoptotic (Bim, FADD,

FLICE, etc.) and antiapoptotic (c-FLIP, Bcl-2, Bcl-X_L, etc.) proteins they express.[207,216] 5) Lastly, the anatomic location of the T cells within tissues may also regulate the exposure of effector and memory T cells to signals that promote survival or apoptosis.[34,35,36,217,218,219] In the following, we will outline the major molecules that have been found to control effector T-cell apoptosis following infection.

Extrinsic Control of Effector T-Cell Apoptosis. The death receptor pathway activates apoptosis via the interaction of TNFR family receptors with protein activators such as TNFα and effector caspases 3 and 7.[208,220] With regard to the death receptor pathways, fewer effector cells died following viral infection in mice lacking both p55 and p75 TNFRs, but surprisingly, there was little effect of deleting Fas or Trail.[213,214,221,222,223,224] This result was unexpected given the critical role of Fas in T-cell homeostasis and the in vitro process of AICD.[210,225] However, Fas was found to play an important role in contraction of antigen-specific T cells during chronic infections or autoimmune situations where prolonged interaction with antigen occurs.[215,226,227] Moreover, Trail also plays a more prominent role in controlling the survival of memory CD8 T cells that are formed without robust CD4 T-cell help.[224,228,229] Thus, control of effector and memory T-cell survival operates differently according to the type of situation encountered.

In addition to the death-inducing signals delivered by some TNFR family members, others also serve a role in costimulating T cells during priming, as discussed previously, and inducing survival signals for activated CD8 T cells during the contraction phase. In particular, interference with or deletion of 4-1BB or OX40 on T cells impairs effector cell expansion and augments their contraction following viral infection. Consequently, fewer memory T cells develop in the absence of these receptors.[230,231,232,233] Interestingly, 41BB preferentially functions in CD8+ T cells and OX40 preferentially functions in CD4+ T cells, albeit OX40 also has a role in promoting effector CD8 T-cell differentiation and survival.[234,235] Additionally, the cytokines IL-7 and IL-15 upregulate the costimulatory TNFR family members, OX40 and 4-1BB, respectively, and this may provide additional survival signals to activated T cells.[236,237] Thus, distinct

niches may be created between DCs and antigen-specific T cells during the contraction phase whereby the interactions between cytokines, cytokine receptors, and TNFRs sustain T-cell survival.[236]

Intrinsic Control of Effector T-Cell Apoptosis . Another form of T-cell apoptosis referred to as activated T cell autonomous death (ACAD) differs from the death receptor pathway in that it does not initiate from a specific receptor, but rather from disruption of the mitochondrial or lysosomal membranes, leading to activation of proteases such as caspases or cathepsins, respectively.[238] The mitochondrial-regulated pathway of apoptosis is well characterized and initiates upon disruption of the mitochondrial membrane and release of cytochrome c into the cytoplasm. This integrates into a multisubunit complex (the apoptosome) to activate the downstream effector caspases 3 and 7,[205,208] an endpoint common to the death receptor pathways mentioned previously.[206,239] ACAD also involves the proapoptotic activities of the Bcl-2-related protein Bim and PUMA (p53-upregulated modulator of apoptosis) that are

induced by a variety of cellular stressors including the withdrawal of key survival cytokines such as IL-2, IL-7, or IL-15.[204,221,240,241,242,243,244,245] BIM can bind Bcl-2, BCL-X_L, and MCL-1 on the mitochondrial membrane, and promote the release of cytochrome *c* and the induction of cell death.[246,247] During their expansion phase, T cells also decrease their expression levels of Bcl-2 and Bcl-X_L and thereby allow for activation of the intrinsic ACAD pathway.[248] Indeed, ACAD, rather than AICD, is thought to be responsible for the contraction of CD8+ T cells that follows the expansion phase because a single deficiency in Bcl-2 results in greater death of effector T cells, and conversely, single deficiency in Bim or double deficiency in Bax and Bak profoundly enhances effector T-cell survival following infection.[215,227,242,249,250,251,252,253,254] Interestingly though, Bim-/- T cells do gradually decay, approaching near wild-type numbers several months after infection.[215,227,251,252] This finding suggests that alternative homeostatic control mechanisms and/or possibly competition for survival niches or factors, ultimately control T-cell numbers in the face of Bim deficiency.

The actions of effector T cells themselves, especially cytotoxic T cells, can cause self-inflicted injury and promote cell death. For instance, effector molecules such as perforin, granzymes, and IFNγ play a role in contraction, as mice deficient in either of these have increased numbers of CD8+ T cells in both the expansion and contraction phases.[161] A set of proteins involved in protecting CTLs from their own cytotoxic machinery are the serine protease inhibitors Spi2a and Spi6.[255,256,257] Spi2a inhibits the activation of cathepsin B in the lysosomal cell death pathway, a lesser-characterized cell death program that may involve both caspase-independent and -dependent mechanisms.[257] When overexpressed, Spi2a was cytoprotective and reduced effector CD8 T-cell contraction following LCMV infection. In contrast, “knockdown” of Spi2a increased the magnitude of effector cell death and fewer memory CD8 T cells formed. Another serine protease inhibitor, Spi6, that targets granzyme B, maintains the integrity of cytotoxic granules by inhibiting the release of granzymes into the cytosol and preventing CTL “suicide.”[256,258] Consequently, Spi6-deficient CD8 T cells have substantially reduced clonal expansion during viral infection.[256]

Heterogeneity of Effector T Cells and Memory Cell Potential

The previous section described numerous mechanisms that determine *how* effector T cells die following clonal expansion, but the factors that actually determine *which* of the effector cells die or live to populate the memory T-cell pool remains to be better resolved. Traditionally, it was proposed that effector T-cell death was more or less random and dependent on the competition between cells for limiting T-cell survival factors, such as common-gamma chain cytokines (IL-7, IL-2, IL-15). This permissive model implied that all the effector cells were equipotent in their ability to persist and give rise to memory T cells, and it was availability of extrinsic signals that ultimately determined their fate. Although competition for survival signals in cellular niches does impact effector and memory T-cell homeostasis, it is also evident that the effector cell population is heterogenous and contains effector cells that are intrinsically more “fit” to survive long-term and develop into memory T cells. These cells have been referred to as memory precursor cells (MPCs) and have best been characterized in CD8 T-cell populations based on IL-7Rα expression following acute viral and

bacterial infections. Both naïve and memory CD8+ T cells express high levels of IL-7Rα, but this receptor is downregulated in the majority of effector CTLs during clonal expansion.[64,70,259,260,261] However, a small percentage of the effector cells express relatively higher amounts of IL-7Rα and separation of virus-specific IL-7Rα^{hi} and IL-7Rα^{lo} CD8 T cells from LCMV-infected animals demonstrated that IL-7Rα^{hi} effector cells had the greatest capacity to give rise to long-lived memory CD8 T cells that could proliferate and protect against secondary infection.[260,262,263] Subsequent experiments have indicated that this is more likely due to a survival advantage mediated by IL-7Rα expression in conferring enhanced sensitivity to ambient IL-7 and increased expression of bcl-2, and that CD8+ memory T cells are not selected solely on the basis of IL-7/IL-7Rα interactions, but result from a more complex series of differentiation events, as described subsequently.[264,265,266,267,268] Although the IL-7Rα^{hi} effector CD8 T cells preferentially survive following infection compared to IL-7Rα^{lo} cells, there is some death in this population as the memory CD8 T cells form, and therefore this does not represent an absolute determinant of memory T-cell potential.[142,249,269] Moreover, not all types of immunizations lead to distinguishable populations of IL-7Rα^{hi} and IL-7Rα^{lo} effector cells.

Memory CD4+ T-cell development may be considered more complicated than that of CD8 T cells because of the diversity in the types of effector T cells formed (eg, Th1, Th2, Th17, Tfh, T_{reg} cells) during immune responses.[107] It is unclear if all types of CD4 T cells can generate memory and if so, whether the pathways involved are similar or

distinct. Like CD8 T cells, IL-7Rα is also critical for formation of memory CD4 T-cell populations, and it is similarly repressed in effector CD4 T cells and then reexpressed on memory CD4 T cells during infection.[270,271,272] It remains to be determined if IL-7Rα^{hi} CD4+ effector T cells have greater memory cell potential following infection. It is likely that other IL-7Rα-dependent cytokines (such as TSLP) are involved as blockade of IL-7 or STAT5 had little effect on short-term effector CD4 T-cell survival.[273,274] Other factors known to regulate activated CD4 T-cell survival long-term are Akt and CD44, one of the most widely used markers for memory T cells.[275,276]

How are heterogeneous populations of effector and memory CD8+ T cells established? It is clear that the duration of infection, level of inflammatory signals, time point at which naïve cells are recruited into the response, and tissue localization can impact both the type of effector T cell generated as well as the memory potential of the activated T cell.[142,262,277,278,279,280,281,282] The vast phenotypic and functional heterogeneity observed in antigen-specific CD8+ T-cell populations (as described previously) indicates that this differentiation process is not based on a simple binary cell fate decision, for instance to become a terminal effector cell versus becoming a memory precursor cell. Rather, a more appropriate model for T-cell differentiation may be one in which activated T cells can occupy not just two differentiation states, but a whole spectrum of differentiation states, and these cells can transition from one state to another according to changes in signal input. Indeed, recent in vivo lineage-tracing studies using transgenic mice that express reporter genes indicate that different types of effector CD4+ T cells are likely not fixed lineages as previously

thought, but contain cells with greater plasticity that can acquire certain features and functions of other types of CD4+ effector T cells.[106,283] For instance, IL-4-producing Th2 cells and IL-17-producing Th17 cells can acquire IFNγ production when restimulated under Th1-conditions, respectively,[284,285] and FoxP3+ T_{reg}s can acquire IFNγ and IL-17 expression.[286,287,288]

Transcriptional Control of Effector and Memory Cell Fates

Although memory T cells share many features with shortlived effectors, their capacity for self-renewal and recall response suggests that they are guided by a distinct program of gene expression. Moreover, the distinction between MPCs and other effector cells that are less fit to populate the memory T-cell pool indicate that variations in effector T-cell differentiation govern these cell fate choices early during the immune response. Investigations into the molecular events that guide the generation memory T cells and their precursors are at a relatively early stage in comparison to the phenotypic studies through which these phenomena have been defined. Nonetheless, a framework for understanding the genetic program of memory is beginning to emerge through the identification of genes and regulatory elements that control key functional parameters of T-cell memory.[30,289] Initial studies focused on performing genomescale gene expression analysis in T cells using gene array hybridization techniques, first to resting versus activated T cells, and subsequently to T cells undergoing homeostatic proliferation.[31,138,290,291] These studies revealed that the gene expression in T cells is a dynamic process that undergoes substantial alterations in response to TCR-mediated and environmental stimuli during the transition from resting to activated status. The phenotypic features of this process (eg, proliferation, effector differentiation, survival) are matched in the global patterns of genes expressed (eg, cyclins, effector molecules, antiapoptotic factors, etc.).

A key study on the transcriptional profile of memory T cells comes from Kaech et al., who performed genomewide analyses of gene expression on naïve, effector, and memory transgenic CD8+ T cells activated in vivo by LCMV.[30] Among the findings emerging from a comparative analysis was that each phase of development was characterized by specific patterns of gene expression directly related to the development or function of the cells at that stage of differentiation, with roughly 30% of the genes expressed by effector cells were also maintained in the memory cells, supporting the direct lineage relationship between these cell types.[30] In some cases, the expression level of the genes was set at the peak of the effector response (d8), but in others the level of expression decreased as the gradual conversion to memory occurred, perhaps reflecting a global reduction in transcriptional activity in these cells. Whereas the distinction of T_{EM} and T_{CM} subsets have traditionally been defined by phenotypic markers, Willinger et al. used transcriptional profiling to analyze the molecular signature of these subsets in human CD8+ T cells and found that the T_{CM} subset had a pattern of gene expression that was intermediate between naïve and T_{EM} and effector/T_{EM} phenotype cells.[292] It has long been appreciated that memory T cells share several notable features related to self-renewal with long-term hematopoietic stem cells. Consistent with this, Luckey et al. have found that memory T cells appear to share many elements of their transcriptional program with long-term hematopoietic stem cells, with notable increases in the

expression of prosurvival and antiapoptosis genes.[293]

In parallel with the genomic-scale studies of gene expression at the population level in T cells, efforts have been made to define the genetic program of memory in single cells or with respect to specific transcription factors. The recent study of Peixoto et al. is notable in its study of gene expression patterns at the level of single cells at various stages during an immune response.[294] This study revealed surprisingly heterogeneous and dynamic patterns of gene expression from the earliest point in the response, with both proinflammatory and effector functionality revealed in discrete cells, and was followed by a more uniform pattern in secondary responders. It is unclear if the reduction in heterogeneity at later time points reflects a selection process or progressive development of the entire memory populations. A number of studies have analyzed the contribution of specific transcription factors to the enhanced longevity and function of memory T cells. These include T-bet and eomesodermin, the transcription factors that coordinately regulate a number of genes related to lineage commitment and effector differentiation in both CD4+ and CD8+ T cells.[108,109,295,296,297] T-bet-/-

eomesodermin+/- mice have a near-total loss of effector and memory T cells through a mechanism that is believed to involve their role in regulating the expression of CD122 and thereby responsiveness to IL-15.[298] The roles of T-bet and eomesodermin in determining whether effector cells are selected for memory development may involve their reciprocal regulation in response to inflammatory signals via IL-12. In response to pathogen-induced IL-12, eomesoderminis repressed and T-bet levels increase which can lead to inhibition of IL-7Rα and MPCs, but increased clonal expansion and formation of terminal effector cells.[50,299,300] When IL-12 signals are reduced, eomesodermin levels rise while T-bet levels decrease, favoring the development of long-lived MPCs.[142,299] Another pair of transcription factors that are relevant for memory formation is inhibitor of deoxyribonucleic acid binding 2 (Id2), and Id3, antagonists of E protein transcription factors that are upregulated in CD8+ T cells during infection and appear to have somewhat reciprocal expression patterns and temporal modes of actions.[301,302] Id2 plays in important early during clonal expansion in sustaining viability of proliferating CD8+ T cells, and it is expressed to a higher level in terminal effector CD8 T cells, whereas Id3 is expressed to a higher extent in memory precursor cells and is required for their survival following infection during the effector to memory transition.[301,302,303] Id2- and Id3-deficient CD8+ T cells have altered patterns of expression in genes that influence cell survival, but they appear to operate on distinct sets of genes.[301,302,303]

In addition to the transcription factors described previously, several transcriptional repressors have emerged as regulators of T-cell memory. Bcl-6, first described as a transcriptional repressor with pleiotropic functions in B-cell differentiation,[304] appears to play a role the generation of both CD4+ and CD8+ T-cell memory, as the survival of Bcl-6-deficient CD4+ effector T cells was greatly diminished compared to wild-type controls after priming, and Bcl-6-deficient mice were found to lack T_{CM} memory phenotype CD8+ T cells following immunization.[305,306,307] The Bcl-6 homologue Bcl-6b, known to repress IL-2-induced B-cell differentiation, is expressed by a small subset of CD8+ T cells and regulates their capacity

for secondary expansion in response to antigenic challenge.[308] Another transcriptional repressor first described in B cells that influences T cell homeostasis is Blimp-1, which is required for terminal differentiation of B cells through coordinate regulation of hundreds of genes.[309,310] Mice lacking Blimp-1 suffer from a variety of immune-mediated pathologies including colitis and multiorgan inflammatory diseases that are characterized by accumulation of effector and memory T cells.[311,312] Moreover, Blimp-1 represses Id3 expression and promotes the formation of highly functional, yet terminal, IL-7Rα^{lo} CTLs during viral infection.[301,313,314] In the absence of Blimp-1, many more IL-7Rα^{hi} memory CD8 T cells and their precursors form; however, these cells are less efficient in migrating out of the lymphoid organs and defending against respiratory infection. Therefore, the Blimp-1:Bcl-6 axis is an important regulator of effector and memory CD8 T-cell fates. Interestingly, the balance between Blimp-1 and Bcl-6 also regulates T_H1:follicular helper T cell fates during viral infection.[128]

Phase III. Maintenance and Function of T-Cell Memory

The small fraction of effector T cells that survives contraction will initiate the memory pool that confers, in many cases, lifelong protection to the individual. Despite their extensive culling from peak numbers, antigen-specific cells in the postcontraction population are found at a far higher precursor frequency than in the naïve repertoire, a fact that undoubtedly impacts the increased speed and intensity that is characteristic of secondary responses. Although they possess some features associated with memory, having arisen in response to an antigenic challenge and being able to persist after the majority of their fellow effectors have been eliminated, the postcontraction T cells nonetheless comprise a heterogeneous population whose maintenance in the memory pool is a dynamic process involving phenotypic changes that will determine their function, distribution, and protective capacity over time.[36,42,315] A central theme governing this process involves adaptation to the homeostatic control mechanisms that regulate the equilibrium of naïve versus memory T cells. These pathways appear to be distinct and under independent control, as the homeostatic mechanisms that regulate the naïve and memory T-cell pools differ in their requirement for extrinsic factors such as TCR stimulation by self-MHC molecules (presumably occupied with peptide derived from self- or environmental antigens) and signals provided by the γ_c cytokines IL-7 and IL-15.

T cells sense each other and maintain homeostasis by competing with one another for survival signals, likely in the confines of cellular niches within tissues. When the T-cell compartment is “full,” as normally found in lymphoreplete states, naïve T cells are fairly quiescent and memory T cells divide periodically, approximately once every 2 to 4 weeks. This slow turnover of memory T cells is referred to as “basal proliferation” or “homeostatic turnover,” and is thought to be important for maintaining the pool of memory T cells.[259] In contrast, in lymphopenic states, such as following irradiation or transfer into immunocompromised mice lacking T cells (ie, recombination activating gene-deficient mice) both naïve and memory T cells will divide more rapidly to fill the available “space.” This “homeostatic expansion” more commonly referred to as “homeostatic proliferation” is polyclonal and occurs independent of foreign antigen recognition. For the purposes of this section, we shall refer to the slow turnover of T cells in a normal immunocompetent host as

"basal homeostatic proliferation" and the faster, more extensive division of T cells within lymphopenic hosts as "homeostatic expansion."

The Role of Major Histocompatibility Complex in Memory T-Cell Homeostasis

As discussed previously in this chapter, adoptive transfer studies have shown that the long-term survival of naïve T cells in lymphopenic hosts requires contact with self-MHC.[62,63,64,65,66,67] Whereas initial studies in the 1990s suggested that both types of memory cells were maintained by occasional TCR contact with undetectable amounts of sequestered foreign or cross-reactive environmental antigens,

more recent studies have shown that antigen-specific CD8+ memory T cells can survive and remain functionally competent in the absence of either antigen, TCR signaling adaptors, or MHC molecules, arguing against any *obligatory* role for TCR signaling in their maintenance.[32,67,316,317,318,319,320,321] However, the same may not be true during cases of chronic antigen exposure, such as during chronic infections. One study has demonstrated that virus-specific CD8 T cells isolated from mice with a chronic LMCV infection require antigen for their persistence,[145] and a similar situation may be evidenced after control of viremia by highly active antiretroviral therapy in patients with HIV.[322,323] Moreover, in another study, inducible ablation of the TCR on mature MP T cells showed that MP CD8+ T cells declined slowly over time, possibly indicating differences between antigen-derived versus MP T cells. The situation for CD4+ memory T cells is less clear, because while the antigen-specific CD4+ T cells do not strictly depend on MHC for their maintenance, the rate of both basal homeostasis and homeostatic expansion of MP CD4+ T cells does appear to depend on the TCR-MHC interactions, and declines significantly when these signals are extinguished, leaving the cells in one study critically dependent on IL-7 or less responsive to antigen reencounter in vitro and in vivo.[62,324,325,326,327,328,329] Thus, it is likely that the homeostasis of memory CD4 and CD8 T cells depends on some common, but also distinct, signals.

The Role of Common γ-Chain Cytokines in Memory T-Cell Homeostasis: Interleukin-7 and Interleukin-15

These findings of MHC-independent survival of memory T cells have brought cytokines into focus as the main extrinsic factors responsible for their maintenance, with particular emphasis on the common γ_C family members IL-7 and IL-15. One of the important initial observations linking cytokines with memory T-cell survival came from studies in which agents capable of stimulating IFN production by cells of the innate immune system, such as lipopolysaccharide and Poly I:C caused a transient burst of TCR-independent proliferation from the major $CD122^{hi}$ $CD44^{hi}$ subset of antigen-experienced CD8+ T cells through the IFNαβ-induced production of IL-15.[330,331,332,333,334,335] Importantly, the IFN-induced proliferative burst of $CD122^{hi}$ $CD44^{hi}$ CD8+ T cells was not observed in IL-15-/- mice, and the in vivo administration of exogenous IL-15 was found to mimic the effect of IFNs in stimulating the bystander proliferation of the MP CD8+ T-cell subset.[331,336,337]

The receptor for IL-15 is composed of three subunits: a unique α chain, a β chain shared with the IL-2 receptor and γc, the latter sheared with the receptors for with IL-2, IL-4, IL-7, IL9, and

IL-21.[338,339,340] Although a soluble cytokine under in vivo conditions, IL-15 is presented in trans via cell-associated complexes bound to IL-15Rα that are preassembled in the cytoplasm of the (non-T) cells that make both molecules.[341,342,343] Paradoxically, CD8+ T cells also express IL15Rα, and although this is not essential for them to respond to IL-15 (which requires expression of only the β and γ chains), it may enable them to activate other cell types such as T cells or APC via transpresentation.[341,342,344,345] The expression of CD122 is selectively elevated on the MP ($CD44^{hi}$) subset of CD8+ T cells that undergo bystander proliferation in response to IL-15, and both IL-15-/- and IL-15Rα-/- mice contain significantly reduced numbers of $CD44^{hi}$ $CD122^{hi}$ MP CD8+ T cells.[331,346,347,348] The effect of IL-15 on MP CD8+ T cells may reflect its role in cell survival rather than development, as these fail to proliferate and disappear rapidly upon transfer to IL-15-/- recipients.[331] Consistent with this view, IL-15 transgenic mice were found to contain elevated numbers of MP CD8+ T cells.[337,349] Taken together, these findings have led to the current view that the generation, survival, and basal homeostatic proliferation of MP CD8+ T cells is mediated through contact with ambient IL-15. At steady state, DCs and macrophages are the most important cell types that need to express IL-15:IL-15Rα complexes to sustain memory CD8 T cells in lymphoid organs, and intestinal epithelial cells are critical in the gut.[217] However, this does not exclude the production of IL-15 by a variety of other cell types including skeletal muscle, kidney, placenta, and hematopoietic stromal cells under conditions of innate immune activation via the IFN pathway.[334,350,351]

Studies of Ag-specific CD8+ T-cell responses following viral infection (LCMV or vesicular stomatitis Indiana virus) in IL-15-/- or IL-15Ra-/- mice have shown that, similar to MP CD8+ T cells, IL-15 is also important for the maintenance of Ag-specific memory CD8+ T cells.[259,352,353] These studies found that although Ag-specific CD8+ T cells were generated in the absence of IL-15 signals, they did not proliferate and their numbers declined over time.[352,353] Taken together, these observations show that IL-15 mediates the homeostatic turnover of both MP and Ag-specific memory CD8+ T cells. Although important for memory CD8+ T-cell homeostasis, IL-15 does not appear to be required for their function, as LCMV-specific memory CD8+ T cells are able to produce IFNγ and TNFα and respond to secondary infection.[352,353] The main effect of IL-15 on the homeostatic survival of CD8+ T cells is likely mediated through upregulation of antiapoptotic factors such as BCL-2 and BCL-X_L, and avoidance of death via the mitochondrial pathway of apoptosis, a common mechanism of γ_C cytokines described previously.[68,354,355,356] With regard to CD4 T cells, IL-15 was initially considered irrelevant for the development and homeostasis of MP CD4+ T cells, as these express low levels of CD122 and can be found in normal numbers in IL-15-/- mice.[335,347,357] However, recent studies using transgenic and endogenous LCMV-specific CD4+ memory T cells have shown that memory CD4+ T cells, are dependent on IL-15 for their basal homeostatic proliferation and long-term survival.[270] Consistent with this view, it has been shown that human and mouse CD4+ T cells respond to exogenous IL-15 and that IL-15- transgenic mice display enhanced CD4+ T cells responses to infectious pathogens.[349,358] Taken together, these data indicate that both CD4+ and CD8+ memory T cells are dependent on IL-15 for their homeostatic survival.

The other cytokine known to affect the homeostatic survival of memory T cells is IL-7. As discussed previously, IL-7 is constitutively produced by nonhematopoietic cells and is recognized by a heterodimeric receptor consisting of the IL-7Rα chain and γ_c.[359,360] IL-7 protects T cells from death by maintaining glucose uptake and inducing the antiapoptotic

factors Bcl-2 and Mcl-1, and inhibiting the proapoptotic factors Bax, Bad, and Bim.[69,361,362,363,364,365,366,367] Furthermore, the T-cell developmental defect in IL-7- or IL-7Rα-deficient mice can be rescued by a Bcl-2 transgene or deletion of Bax, and addition of anti-IL-7/anti-IL-7Rα to memory cell cultures was found to reduce Bcl-2 expression.[271,361,368,369] IL-7:IL-7Rα signaling is critical for the survival of antigen-specific memory CD8 T cells in most but not all cases.[64,259,260,265,370] However, in lymphoreplete animals, unlike IL-15, IL-7 does not seem essential for basal proliferation, but increasing the level of IL-7 in vivo through transgenic expression can overcome the requirement for IL-15 in promoting survival and homeostatic expansion of $CD122^{hi}$ memory CD8+ T cells.[259,371] Within a lymphopenic host, IL-7 and IL-15 appear to have redundant roles in promoting memory CD8+ T-cell homeostatic expansion because single deficiency of either gene alone does not impair memory T-cell proliferation; however, when both IL-7 and IL-15 are removed through gene knockouts and use of antireceptor antibodies, homeostatic static expansion ceases and memory CD8+ T cells rapidly die.[259,260,273] Together, these results indicate that IL-7 plays a more dominant role in memory CD8+ T-cell survival and IL-15 plays a more dominant role in basal proliferation, but these roles are not entirely separable and alterations in the levels of these cytokines or the numbers of lymphocytes competing for these cytokines can modulate the effects these cytokines have on memory T-cell homeostasis.

Similarly, multiple studies have shown the requirement for IL-7 in the long-term maintenance of Ag-specific memory CD4 T cells. For instance, the basal proliferation Agspecific memory CD4 T cells was heavily reliant on IL-7, in addition to IL-15,[248,270,357] and homeostatic expansion of such memory T cells in irradiated, lymphopenic hosts was acutely dependent on IL-7.[270] Interestingly, homeostatic expansion of polyclonal MP CD4+ T cells was initially found to occur independent of IL-7 or IL-15.[372] However, subsequent work revealed that the proliferation of MP CD4+ T cells in these circumstances was not due solely to lymphopenia, but likely also involved antigen-dependent proliferation occurring in response to commensal-related antigens.[373] In addition to its effects on basal proliferation of Ag-specific memory CD4+ T cells, IL-7 is also important for the longevity of memory CD4 T cells. Transfer of Ag-specific memory CD4 T cells into mice lacking IL-7 or blocking IL-7 with antibodies showed that IL-7 was needed for survival of the donor memory T-cell population.[270,271,272] However, the role for IL-7 in memory CD4+ T-cell survival may be temporally regulated because in contrast to the previously discussed experiments depriving Ag-specific effector CD4 T cells of both IL-7 and IL-15—or deletion of STAT5, a critical molecule downstream of γ_c cytokines—during the contraction phase following viral infection had little effect on effector CD4+ T cell apoptosis.[273,274] In contrast, the effector CD8 T cells were acutely sensitive to these cytokines during the contraction phase and the magnitude of contraction was increased by IL-7, IL-15, or STAT5 deficiency.[273] These results suggest that there may be

other factors that regulate effector CD4 T-cell survival early after infection, but IL-7 and IL-15 are essential to sustain Ag-specific memory CD4+ T cells long term.

Related to this point, compared to memory CD8 T cells, the pool of memory CD4+ T cells may be less stable, in general, because gradual erosion of Ag-specific memory CD4 T cells has been observed in several longitudinal studies following acute infection in mice. For instance, LCMV- and *Listeria*-specific CD4+ T cells initially contract rapidly, but then show a continual slow rate of disappearance whereas the CD8+ T response in these studies achieved a stable "set-point" of memory after approximately 30 to 40 days.[374,375] Similarly, the numbers of CD4+ Sendai virus-specific T cells in the lung declined during the first 3 months after pulmonary infection, while the CD8+ T-cell response remained relatively stable during this period.[376] There are several potential reasons for this difference between CD4 and CD8 T cells, such as 1) the rate of basal proliferation of memory CD4 T cells is slower than that of CD8 T cells and 2) although not essential for memory T-cell maintenance, CD4 T cells may compete more for MHC interactions because MHC class II has more limited array of expression compared to MHC class I. Additionally, several reports have implicated IFNγ as a regulator of T_H1 effector cell contraction. For example, IFNγ-deficient mice generate 30% to 50% more activated CD4+ T cells in murine models of bacterial, mycobacterial infection, and experimental autoimmune encephalitis.[377,378] Moreover, activated CD4 T-cell longevity can be extended when IFNγ signaling is blocked during priming in vitro or *Listeria* infection in vivo.[379,380,381] The mechanism underlying the selective susceptibility of IFNγ-producing T_H1 cells appears to involve the induction of apoptosis via a caspase 8-dependent pathway and is selective for this CD4+ T-cell subset, as T_H2 cells display a greater propensity for memory formation.[382,383] However, it is important to mention that elegant lineagetracing studies have clearly shown that T_H1 cells that expressed IFNγ can populate the memory pool and, therefore, IFNγ may influence, but it is not the sole determinant of effector CD4+ T-cell apoptosis.[384] Lastly, there is currently little information on the ability of the T_{reg} and T_H17 subsets to form memory. Functional Th1, Th2, Th17, and Tfh cells can be found in the memory T-cell compartment in humans, suggesting they can form memory cells.[385,386,387] However, the functional polarization of human T_{CM} Th1, Th2, or Tfh cells is modest compared to that of effector cells, suggesting functional heterogeneity in different types of human memory T cells.[385,388] It is less clear if memory T_{reg}s exist, and if so, a number of observations suggest that their differentiation state is unstable.[389,390]

Lastly, there is currently little information on the ability of the T_{reg} and T_H17 subsets to form memory, although this will certainly change in the near future due to active experimentation in these fields.

CD4+ T-Cell Help for Memory CD8+ T-Cell Development

CD4+ T cells have also been shown to be important for the function and maintenance of memory CD8+ T cells whether they were primed in the presence or absence of

CD4+ T_H cells.[391] The presence of CD4+ T cells during the priming of CD8+ T-cell precursors endows their clonal progeny with the ability to undergo secondary proliferative

responses upon reencounter with antigen.[392] That is, in the absence of CD4+ T_H cells, memory CD8 T cells can, in some circumstances, display a “helpless” or “lethargic” phenotype in which they proliferate less and produce fewer cytokines, especially IL-2, during primary responses, and are defective in their ability to mount secondary proliferative responses, a hallmark of immune memory.[392,393,394,395,396] The “help” under these conditions apparently need not be cognate (antigen-specific) as it is in the case of help for priming, suggesting that its role may involve the direct or indirect provision of homeostatic survival factors (discussed in the next section).[35]

How do CD4 T cells actually help memory CD8 T cells persist and function? In the case of memory CD8 T cells formed after a cellular vaccine, one mechanism involves the T_H-mediated modification of the CD8+ T-cell developmental program to avoid apoptosis upon secondary stimulation by TNF-related apoptosis-inducing ligand.[229] The role of TNF-related apoptosis-inducing ligand in this process may be limited in its duration, because although TNF-related apoptosis-inducing ligand appears to regulate the secondary expansion defect of “helpless” CD8+ T cells for at least 4 weeks after priming in the absence of T_H, additional factors supplied by CD4+ T cells are required for their homeostatic survival in the months afterwards.[224] Cytokines like IL-2 and IL-21 also help memory CD8 T cells. For example, CD8+ T cells deprived of IL-2 signaling due to CD25 deficiency have reduced secondary expansion after some, but not all, types of immunizations.[397,398,399] Although CD4 T cells are a likely source of IL-2, a more recent study showed that autocrine-production of IL-2 by memory CD8 T cells themselves, rather than CD4+ T_H cells, was necessary for optimal responses to secondary infection. 398 However, this does not rule out the possible role of CD4 T cells or other IL-2-producing cell types in other situations.[400,401,402,403] IL-21 also helps memory CD8 T cells develop and form protective CD8 T cells, and CD4+ T cells are the predominant producers of IL-21, but it is not known which types of CD4 T cells may be the physiologically relevant source CD4 T cells.[307,404,405]

*Despite being a marker of naïve T cells, CD45RA is reexpressed on some memory T cells. Initial evidence suggested these cells were terminally differentiated effector cells, but more recent data suggests that CD45RA may also become reexpressed on resting memory CD8 T cells.653,654

†α4β7needed for entrance into intestine, but may not be maintained on resident memory T cells.

‡PD-1 is also a marker on "exhausted" CD8 T cells and follicular helper T cell CD4+ T cells, but recent work also shows it is prevalent on functional T_{EM} cells in humans.

The Phenotypic Heterogeneity of Memory T Cells

There is substantial heterogeneity within the memory population with regard to phenotype, function, and anatomic location, both in CD4+ and CD8+ compartments (Table 31.1). Moreover, the phenotypes of memory T cells, and likely also their differentiation states, are not completely stable and can change over time in response to various environmental stimuli. It has long been appreciated that memory T cells express surface markers that distinguish them from naïve cells.[406,407] Much early work was focused on the high- and

low-molecular-weight isoforms of the surface-expressed tyrosine phosphatase CD45, which can be generated through differential splicing of three extracellular exons, called A, B, and C, which are differentially expressed on naïve versus memory T cells.[408] In the human system, naïve T cells express the high-molecular-weight form called CD45RA that contains all three of the spliced exons, while memory cells tend to more often express the low-molecular-weight form called CD45RO, with the different phenotypes assigned based on reactivity with isoform-specific monoclonal antibodies.[409,410] There is significant heterogeneity in CD45 expression, however, with variation in surface levels of the low-molecular weight isoforms on memory T cells as a result of reexpression of CD45RA after its initial downregulation, which itself occurs at different rates on CD4+ versus CD8+ T cells.[411] Furthermore, although murine T cells also express variant isoforms of CD45, this has also proven to be a less reliable marker of naïve versus memory cells.[412,413,414] A number of studies have attempted to correlate the upregulation of adhesion molecules on memory cells, including members of the β1 (CD49d, CD40e, CD29) and β2 (CD11a, CD11b, CD18) family of integrins, as well as CD2, CD44, CD54, and CD58.[53] Among these, however, most appear to reflect recent activation status of the T cells, and only CD44 appears to be a stably expressed marker of memory cells that is expressed at high levels when T cells are transferred to antigen-free recipient mice.[317,321,415,416,417] However, high-level CD44

expression is also found on the MP T cells discussed in a previous section that may have developed from lymphopenia or exuberant cytokine production, so that CD44 expression alone cannot serve as an informative marker for antigen-specific memory cells. When used in conjunction with other markers, however, CD44 can be used to more specifically distinguish memory from naïve T cells. A number of other molecules can also differentiate between naïve and antigen-experienced cells. On CD8 T cells, these include both CD122, a component of both the IL-2 and IL-15 receptors, CD49d (a4 integrin), and Ly-6c, a small GPI-linked surface protein.[335,418,419,420,421] CD8+ T cells have also been shown to undergo changes in their cell-surface glycosylation that can help distinguish effectors from resting memory cells,[422,423] which may influence their reduced TCR signaling threshold.[424,425,426]

In addition to these phenotypic markers of memory T cells, efforts have been made to identify these cells based on their function, usually defined by the parameters of protection, proliferation, and persistence. The heterogeneity is broad and there are no absolute sets of defining characteristics, but generalizations or trends are emerging from the numerous investigations on different subsets of memory T cells identified. For example, increased expression of CD57 or KLRG1 or decreased expression of CD27 and CD28 identify subsets of T cells with heightened effector functions that typically express higher amounts of perforin, but appear to be terminally differentiated effector cells with reduced proliferative capacity and shortened telomeres.[42,427,428,429,430,431] Increased expression of inhibitory receptors such as PD-1, lag3, or TIM3 also identify CD8 T cells that have encountered high amounts of or prolonged periods of antigenic stimulation, such as during chronic viral infection or in tumors.[146,432,433,434,435] Memory T cells that produce the most IL-2 and have the greatest proliferative responses to antigen or rates of basal homeostatic proliferation express higher amounts of CD27, IL-7R, CXCR3, and CD62L.[278,436,437,438,439,440] These cells also tend to have longer telomeres compared to the $CD27^{lo}$ $CD28^{lo}$ $CD62L^{lo}$ cells.[42,427,441] The physiologic location of memory cells has been thought to represent a defining feature, as naïve T cells are not normally thought to occupy extralymphoid environments.[442] Recent studies using sphingosine-1-phosphate-receptor antagonists, however, have revealed that naïve cells may pass through peripheral tissues as part of their normal recirculation pattern.[442,443,444] Furthermore, T_{RM} cells that reside in the brain and mucosal tissues (gut, skin, and lung) also display a specialized phenotype characterized by increased expression of CD103, CD69, and granzyme B, and protect against pathogen reentry at these sites.[45,445,446,447,448,449]

Chemokine receptors represent another class of molecules used to functionally define different subsets of memory T cells, in this case based on their specific homing behavior.[450,451,452] Skin-homing memory T cells, for example, do not express lymph node-homing receptors CCR7 and CD62L, but do express high levels of β1 and β2 integrins and CLA, a molecule involved in lymphocyte homing to the dermis, as well as a number of inflammatory chemokine receptors including CCR1, CCR3, and CCR5.[42] CCR7+ memory T cells, in contrast, tend to express chemokine receptors that will guide them to lymphoid tissues such as CCR4, CCR6, and CXCR3, as well as CD62L. Based on the distinct homing potential of these two subsets (eg, CCR7+ CD62L+ and CCR7- CD62L-), it was proposed

that they represent two specialized types of memory T cells, each charged with a specific task in host defense.[453] The CCR7-CD62L-T_{EM} resides in peripheral tissues where pathogens are likely to first gain access to the body and can mediate direct effector functions against infected cells. The CCR7+ CD62L+ T_{CM} is found mostly within lymph nodes where it responds to antigenic stimulation by renewed proliferation and the generation of secondary effectors. It should be pointed out that expression of both CD62L and CCR7 also define naïve T cells, so that additional markers are required to distinguish T_{CM} such as high-level expression of CD44 in the mouse or the absence of CD45RA in the human. Extending from this work, differential expression of CXCR3, CCR4, CXCR5, and CCR6 can help to crudely distinguish polyclonal populations of human Th1, Th2, Tfh, and Th17 central memory cells, respectively.[385,387]

Although CD62L and CCR7 do not represent a perfect set of phenotypic markers with which to define memory subsets, the concept of a functional division of labor between T_{EM} versus T_{CM} has been remarkably influential idea with numerous studies dedicated to elucidating their lineage relationship and relative role in maintaining the protected state. Some of these have concluded that T_{EM} and T_{CM} arise sequentially through a linear pathway of differentiation, while others support the idea that they are separate populations that arise independently.[282,436,454,455,456,457,458,459] More recently, it has been suggested that the initial precursor frequency of antigen-specific T cells may influence the commitment

of T cells to one or the other lineage, or that changing the anatomic location (eg, from lymphoid to peripheral tissues) can cause the conversion from T_{CM} to T_{EM} phenotype.[277,456] Numerous laboratories are working on the elucidation of the origins and lineage relationships of T_{EM} and T_{CM} phenotypes, their relative roles in protective immunity, and their potential for interconversion.

Function of T-Cell Memory: The Secondary Response

From an operational perspective, it can be argued that the ultimate purpose for the long-term maintenance of memory T cells is found in the secondary response to previously encountered antigens, which comprises both direct effector functions and renewed proliferation. The structures and signals required to elaborate the secondary responses differ somewhat from those involved in the priming of naïve T cells. For many infections, the secondary response to antigenic challenge can proceed in the absence of encapsulated lymph nodes or spleen,[460,461] but nonetheless appear to require DCs and, depending on the model, can require costimulation by molecules such as CD28, OX40, and 4-1BB.[462,463,464] As described previously, the types of memory T cells present in mucosal tissues or other peripheral organs differ from each other and those predominantly found in lymph nodes, and it is likely that these different subsets will play, to a varying degree, different roles in protection against secondary infections. For example, T_{EM} cells (including the more restricted T_{RM} cells in mucosal tissues) can be found in the blood and in a variety of peripheral tissues such as bone marrow, liver, gastrointestinal tract, lung parenchyma, and fat pads where they can mediate immediate effector functions, and T_{CM} cells are found mostly within the lymph nodes where they are able to produce IL-2 (in addition to IFNγ in

some cases) and expand to a greater degree than T_{EM} cells.[436,465,466,467] Although initial studies supported a clear division of labor between these subsets, it has become clear that some degree of overlap exists in their location, function, and phenotype. In the CD8+ lineage, T_{EM} can undergo substantial secondary expansion, and conversely, T_{CM} can display cytotoxic potential and production of effector cytokines equivalent to that of T_{EM}.[436,468,469,470] The relative contribution of T_{EM} versus T_{CM} subsets to recall responses and effective immunity can depend on the nature of the antigenic challenge. For example, in some cases T_{CM} cells are better able to protect from challenge with a virulent forms of LCMV (eg, Cl.13) or vesicular stomatitis Indiana virus, predominantly lymphoid-trophic pathogens, while T_{EM} are superior in mediating protection from a less virulent form of LCMV (eg, Armstrong), vaccinia virus, Sendai virus, and *Listeria*, which predominantly replicate in the marginal zones of the spleen or peripheral organs.[440,471,472,473,474,475,476] The timing of the challenge can also play a role, as T_{EM} in the lung have been shown to be more effective at mediating protection against Sendai virus at early time points, while T_{CM} are superior at later time points.[477]

In addition to the increased frequencies of antigen-specific cells, the T cells that comprise the secondary response display a higher functional avidity and lower signaling thresholds than primary responders, and consequently can mount faster and more effective responses to infection that the naïve repertoire.[27,478,479,480] This “faster and better” response of memory T cells involves alterations in TCR signal transduction components that results in enhanced sensitivity to antigen, as well as epigenetic modification of key cytokine gene targets for TCR-mediated transcriptional activation, such as IFNγ and IL-2, resulting in more efficient and higher-level production.[23,478,479] In the case of the some effector molecules including IFNγ and RANTES, memory T cells contained stored messenger ribonucleic acid that is rapidly translated upon TCR stimulation.[30,481,482,483,484,485] The enhanced functionality of the memory cells at the population level may reflect a mechanism in which antigen-driven clonal selection is controlled by affinity-based thresholds.[41,480,486] Additionally, a number of studies have shown that the secondary T-cell response is prolonged compared to the primary, with emerging evidence suggesting that renewed exposure to antigen can further improve the function of the available repertoire, as secondary memory CD8+ T cells have been shown to provide better per-cell protective immunity after some reinfections.[32,143,279,465,487,488,489,490,491] Thus, the vast heterogeneity of memory T cells formed after an infection creates a multiple layered backup scheme to maximize containment. And given that pathogens differ in their tropism and pathogenesis, it will be important to identify which types of memory T cells offer the greatest protection for each.

THE GENERATION OF MEMORY B CELLS AND LONG-LIVED PLASMA CELLS

Introduction

B cells are the source of antibodies, and antibodies are efficient at protecting the body from reinfection by a previously encountered pathogen. Vaccines are predicated on the existence of immunologic memory, and 25 of the 27 licensed human vaccines protect primarily or exclusively on the basis of protective antibody responses.[492,493,494] B cells are also

important effectors of many human autoimmune diseases, and B-cell memory drives the maintenance or relapsing-remitting cycles of those diseases. Many allergies and allergic diseases are also defined by the antibody responses against the allergens, and B-cell memory is central to the recurring cycles of allergic responses. Hence, B-cell memory is central to a wide range of protective immunologic responses and pathologic immunologic responses.

Immunologic memory in the B-cell compartment consists of two very different cell types: Bmem cells and long-lived memory plasma cells (PCs). These two cell types perform two different functions. Long-lived PCs can be considered “active memory” as they continuously secrete voluminous quantities of antibodies that circulate in the blood. Bmem cells can be considered “quiescent memory” as these cells are resting, waiting for a second infection or reexposure to antigen to reactivate them. The proposed basic lineage relationship between naïve mature B cells, Bmem cells, and plasma cells is shown in Figure 31.4. Different stages of B-cell differentiation occur in histologically defined locations, as illustrated in Figure 31.5. In this basic model, shown in Figures 31.4 and 31.5, naïve mature B cells are activated by antigen (protein

in adjuvant, viral infection, or autoantigen) and CD4 T-cell help. These initial interactions occur at the border between the T- and B-cell areas of the lymphoid organ (spleen or lymph node).[495,496] Both Bmem and memory PCs are primarily generated in GCs. This chapter section will describe the generation of B-cell memory in GCs, the capabilities of B-cell memory, and the maintenance of B-cell memory.

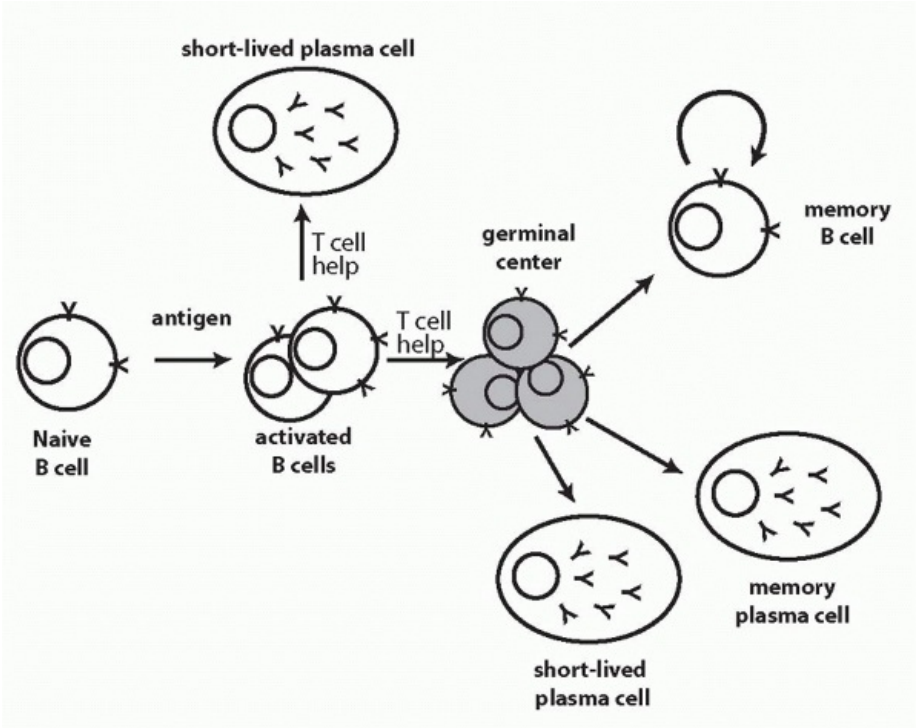

FIG. 31.4. Development of B Lineage Immune Response and Memory. Following antigenic stimulation, naïve B cells undergo clonal expansion and may differentiate into multiple different cell types, including the two cell types of B cell memory: memory B cells and plasma cells.

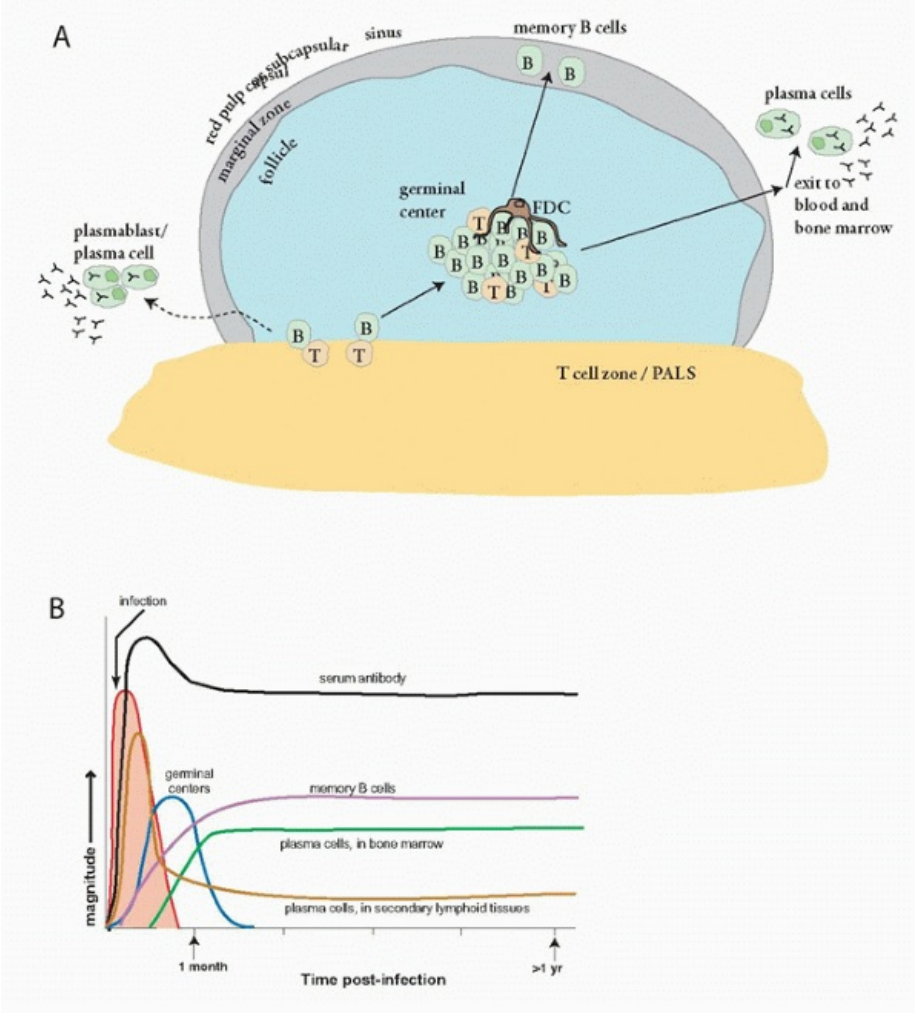

FIG. 31.5. Anatomic Features of Effector and Memory B-Cell Differentiation. A: Locations of stages of B-cell memory development in spleen or lymph node. See text for details. **B:** Kinetics of a conventional T cell-dependent B-cell response to an acute viral infection or protein immunization.

Germinal Centers: The Foundry of B-Cell Memory

B-cell memory is primarily generated in GCs. This is most evident in humans by the severe reductions in total Bmem cells as well as loss of vaccine and pathogen-specific longterm circulating antibody responses seen in humans with genetic immunodeficiencies that cause a loss of GCs, such as CD40L, CD40, SAP, and ICOS.[497,498,499,500,501,502] GCs are distinct microanatomic sites of B-cell selection in response to antigens (see Fig. 31.5).[503,504] B cells undergo clonal expansion, Ig gene hypermutation, and affinity maturation within GCs.[505] The purpose of a GC is two-fold. First, it is the site of rapid evolution of high affinity B-cell clones. The second job of the GC is to produce Bmem cells and plasma cells for long-term humoral immunity.

During an immune response, B-cell clones within the mature B-cell repertoire respond to an antigen, a pathogen component, on the basis of their affinity for the antigen. Those activated B-cell clones inherently have suboptimal affinity for the pathogen component they are responding against, given the universe of possible pathogen structures. It is important to improve that affinity to then generate antibodies with maximal capacity to neutralize the infecting pathogen and give the host the highest chance of survival. GCs are the site of the affinity maturation process. B-cell clones that randomly mutate an Ig gene that encodes a B-cell receptor (BCR) (and hence secreted antibody) with higher affinity for the pathogen are positively selected for survival and further rounds of proliferation in the GC. Cycles of affinity maturation can occur approximately every 6 hours (nonsynchronously),

allowing for > 20 generations of mutation and affinity maturation within a week. This powerful GC process of generation of genetic variation and selection of the most fit clones has been termed “evolution in miniature.”[506]

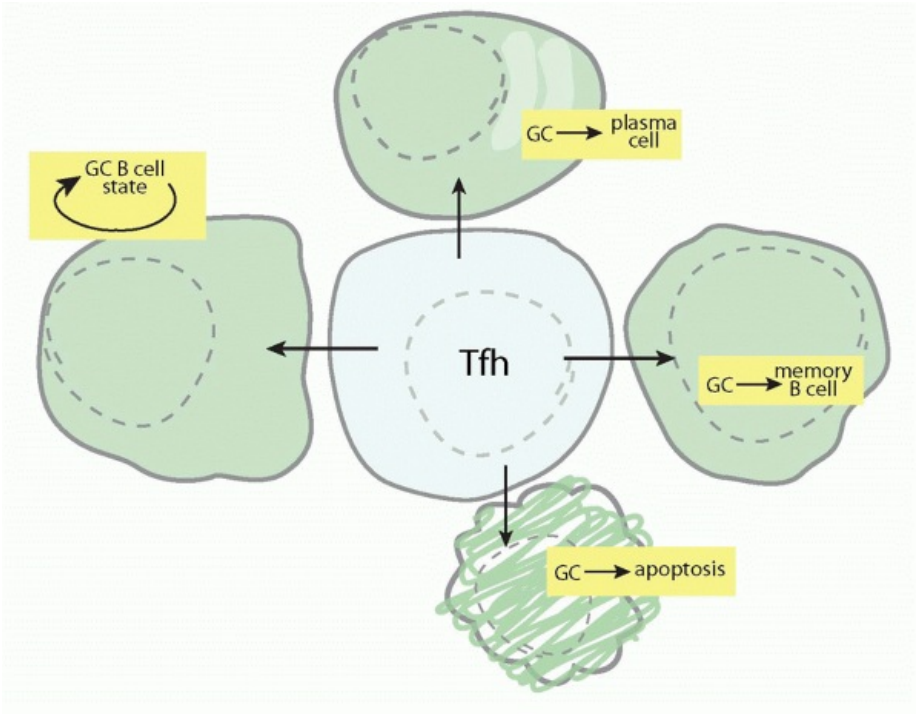

FIG. 31.6. Regulation of Germinal Center (GC) B-Cell Fate Decisions by T Follicular Helper (Tfh) Cells. Tfh cells regulate multiple different B-cell differentiation processes within the GC, via numerous molecular signals. Tfh cells are required for maintenance and proliferation of GC B cells (*left*). Tfh cells are also required for induction of differentiation of GC B cells into plasma cells (*top*). Tfh kill GC B cells that fail to present cognate antigen (*bottom*). Tfh may also signal GC B cells to differentiate into memory B cells (*right*). See text for details.

What is the mechanism of selection in GCs? In the absence of T-cell help, GC B cells rapidly die by neglect within hours.[507] Tfh cells are the uniquely specialized CD4 T cells for B-cell help.[105,505] Tfh cell help is the primary limiting factor for the magnitude of GC responses in

most settings.[105,128,508,509] The function of Tfh cells is to provide B-cell help. However, that is a vast oversimplification of the complex tasks Tfh cells perform. B-cell help is not a singular molecular signal or even a single process. Tfh cells are required for the formation of GCs, the maintenance of GCs, and for the generation of virtually all Bmem and PCs.[105] The control of these processes hinges on Tfh cells regulation of four B-cell fate decisions (Fig. 31.6) and the bidirectional communication between the Tfh cell and GC B cell.[105]

As stated previously, GC B cells rapidly die by neglect within hours without T-cell help, highlighting their critical dependence on continuous extrinsic survival signals.[507,510] To survive, GC B cells must bind antigen, process the antigen, present the antigen in MHCII, and obtain Tfh-cell help. Within a population of GC B cells, all specific for the same antigen, competition for Tfh cell help occurs. Tfh cells distinguish which GCB cells have the highest affinity BCRs by the amount of peptide-MHC complex each GC B cell presents. GC B cells presenting more cognate peptide to Tfh cells receive more survival signals from Tfh cells. The Bcl2 family member Mcl1 is required for GC B-cell survival.[511] The primary role of GC B cells in this selection process is to present antigen.[505,508] The observation that BCR-mediated antigen endocytosis or mitogenic signaling are mutually exclusive events supports this interpretation.[512] The role of Tfh cells in the process of B cell evolution in a GC center is to sample the population of GC B cells, interpret the environmental signals, rescue only the highest affinity GC B cells for survival, and potentiate further affinity maturation. Tfh cells physically bind cognate B cells in interactions that are sustained for long durations due to TCR and SLAM-associated protein (SAP, SH2D1A) dependent adhesion and development of immunologic synapse.[105,499,513] This allows for extensive signaling between Tfh and GC B cells in each round of interaction.

It is at this point that a critical decision occurs: simultaneously with the Tfh survival signals, each surviving GC B cell is provided an additional set of instructions by a Tfh cell to either undergo an additional round of somatic hypermutation and proliferation (maintain the GC B cell program), or differentiate into a PC or Bmem cell (see Fig. 31.6).[105,506,514,515] This is an iterative process constantly performed by the Tfh cells for the duration of a GC. (Tfh regulation of the B-cell response starts even before the GC,[105,516] but the discussion here focuses on the GC stage, as both high- and low-affinity BCR B cells enter GCs.[517,518]) For further information on the molecular processes of somatic hypermutation and class switch recombination, please see chapters 5, 7 and 9. Here, we focus on the GC as the foundry of B-cell memory.

The signal strength of “help” provided by the Tfh cells to the B cell will increase in proportion to the amount of antigen being presented by the GC B cell in the T-B conjugate. There is likely a threshold of antigen affinity at which the B cell presents sufficient amounts of peptide-MHC to the Tfh cells to elicit stronger Tfh signals that preferentially induce differentiation to plasma cell (or Bmem cell) and exit from the GC cycle.[514] As BCR affinity evolves, it becomes intrinsically more and more difficult to retain the B cell in the GC. Signals from the Tfh cells influence Bmem cell versus plasma

cell differentiation by GC B cells. Signals from follicular DCs (FDCs) may also be involved.

Tfh cells are capable of producing large amounts of IL-21 during interactions with B cells. GC B cells express high levels of IL-21R. IL-21 acts directly on GC B cells and is important for maintenance of GC B-cell proliferation and Bcl6 expression.[519,520] However, IL-21 is also the most potent known cytokine for induction of plasma cell differentiation, in a STAT3-dependent manner.[521,522,523,524,525,526] Therefore, combinatorial signaling must be involved in the cell fate decision of a GC B cell to maintain the GC B-cell program or initiate plasma cell differentiation. CD40 signaling inhibits plasma cell differentiation and potently enhances B-cell proliferation.[527] CD40L and IL-21 are both expressed at high levels by Tfh cells, and surface expression of CD40L and secretion of IL-21 are both induced by TCR signaling during Tfh-GC B cell interactions.

Numerous signals involved in T:B interactions have been proposed to modulate the likelihood of generation of PCs versus Bmem. These signals include CD70,[528] OX40,[529] PD-1,[530] and others. When comparing Bmem and bone marrow PCs specific for the same antigen, evidence of affinity maturation is strong for PCs but less so for Bmem.[531] In addition, experimental manipulation reducing the susceptibility of GC B cells to apoptosis results in larger GCs, more Bmem cells, and more plasma cells; however, affinity maturation is not equally affected.[532,533] An abundance of low-affinity Bmem are observed, but the PC compartment primarily contains high-affinity cells.[532,533] Based on these and other data, it has been postulated that a bias exists for PCs to primarily derive from GC B cells late in a GC reaction, due to development of high-affinity BCRs, whereas Bmem are generated throughout the GC reaction irrespective of increases in BCR affinity.[515] Nevertheless, high-affinity PCs can be generated early in GC responses.[531]

A parallel process occurring in the GC is class switch recombination (isotype switching). Loss of IgD expression occurs immediately after initial B-cell activation, before GC formation. Class switch recombination from IgM to any IgG isotype, or IgA, can occur before the GC reaction or during the GC reaction. Class switch recombination is regulated by signal strength and isotype specifying switch factors. All class switch recombination depends on activation-induced cytidine deaminase expression, as does somatic hypermutation. Multiple signals can induce activation-induced cytidine deaminase expression in B cells, including strong BCR crosslinking and CD40L-CD40 signaling from CD4 T cells. Activation-induced cytidine deaminase expression does not specific which isotype switch occurs. Cytokines, primarily from CD4 T cells, are potent switch factors, regulating which heavy chain constant region recombination event occurs. For example, in mice IFNγ enhances IgG2a class switch recombination, and IL4 enhances IgE and IgG1 class switch recombination. For further information on the molecular and cellular processes of class switch recombination, see chapters 5, 7 and 9..

Differentiation and Phenotype of Memory Plasma Cells: Active Memory

There are at least two populations of PCs: memory (longlived) and short-lived. Memory PCs are a central part of immune memory, as these cells are largely responsible for the long-term continuous secretion of antibody. In contrast to Bmem, PCs are terminally differentiated and cannot be stimulated by antigen to either divide or increase their rate of antibody production. Because preexisting antibody provides the first line of defense against infection by microbial pathogens, the importance of PCs in protective immunity cannot be overstated.

PC development starts in a GC when a GC B cell downregulates Bcl6 and begins to upregulate XBP1 and Blimp1.[534] The developing PC downregulates CXCR5 and other migration-associated molecules while increasing responsiveness to CXCR4, thereby allowing the cell to leave the GC environment and leave the B-cell follicle.[535,536] Blimp1 is considered the master regulator of PC differentiation.[534,537,538] Blimp1 orchestrates a program of PC gene expression, including maximal XBP1 expression,[536,539] which is required for synthesis and maintenance of the massive endoplasmic reticulum and Golgi apparatus necessary to power the extraordinary amounts Ig secretion accomplished by PCs.[534,540,541] Blimp1 is also required for survival of PCs.[542] There are steps of PC development that can occur before upregulation of Blimp-1, including partial upregulation of XBP1.[539] At this point of development, the PC is CD20^{low}CD3 8++CD27+++ Blimp-1+.[536] The PC is still MHCII+ (human leukocyte antigen-DR+) and is still likely CD138-.[536,543,544,545] Cells with this phenotype in vitro can still undergo some amount of proliferation and are therefore sometimes termed plasmablasts.[536,546] As PC development progresses further, with greater upregulation of Blimp-1, the PC stops dividing. The PC can further mature by downregulating MHCII and through additional gene expression changes.[536,547] During this period, the PC may migrate through the blood to the bone marrow.[531,535,536,546] Plasma cells are only in the blood for a brief period of time. Antigen-specific PCs are a vaccination or infection that can be found in human blood during brief windows of time representing the peak of PC production.[543,544,545,548] Once in bone marrow, human PCs upregulate CD138.[549,550] Memory PCs are identified as PCs in bone marrow, as CD138+ PCs, or functionally as PCs that have survived well past the time of the peak PC generation.[551,552,553,554] Memory PCs can also be readily observed in murine or human spleen,[550,555] as well as inflamed tissues.[556,557,558] First focusing on the bone marrow PCs, these cells can survive for prolonged periods in vivo, measured experimentally to have a 3- to 4-month half-life[554,559] or to live indefinitely.[547] However, it has been determined that PCs in bone marrow are not intrinsically long lived but are highly dependent on continuous provision of multiple extrinsic survival signals.[506,553] There is a PC survival niche in bone marrow consisting of a rich environment of survival cytokines and adhesions molecules,[553,560] such as IL-6,[549,550,557,560,561] CXCL12/SDF-1,[560] the ligand for CD138,[546] LFA-1, VLA-4,[562] APRIL,[557,563] and additional poorly defined cues that have been difficult to reproduce in vitro.[546,564] Efforts to maintain PC survival in vitro have met with limited success.[557,561] As long-lived PCs are not intrinsically long-lived, these cells may be referred to as bone marrow PCs or memory PCs.[565] Memory PCs of similar phenotype can be found in spleen[550]

and lamina propria of the small intestine.[557] Inflamed tissue can also possess memory PCs, particularly in the context of an autoimmune condition such as systemic lupus erythematosus. Such cells are identified as postmitotic PCs, having been in residence for a substantial period of time.[556,558]

PCs can come from other sources besides GC B cells. There are myriad pathways for B cells to flow into PC differentiation.[566] Most focus on memory PC development has fixed on the generation of memory PC from GC B cells or Bmem, but it has not been excluded that there can be other sources. For example, during an immune response, an activated B cell may either enter a GC or instead migrate outside the follicle and form extrafollicular foci, which rapidly develop into clusters of PCs (see Fig. 31.5).[567] These are predominantly short-lived PCs that survive for days[568] and are IgM in most cases; however, extrafollicular PCs can be IgG+, are localized adjacent to blood vessels, and could potentially migrate to bone marrow.

Many more GC-derived PCs are generated than become memory PCs.[547,554] What distinguishes a PC that will live long term versus a PC that will not? A prominent model is "competence and competition."[553] Bone marrow plasma cells predominantly possess high-affinity BCRs, even when selective pressure on the GC reaction is relaxed,[569] indicating that high affinity for antigen contributes to the programming of a PC to become a memory PC. Emigrating PCs from the GC are affinity matured, suggesting that affinity maturation is a prerequisite for exit. Short-lived PCs and memory PCs can coexist in the same environment during a chronic autoimmune response.[556] Those observations indicate there are development signals that mark a PC as "competent" to enter the memory PC population. The difference may involve differences in migration, responsiveness to survival signals, or both.[553] However, no cell surface or intracellular marker has been identified to distinguish a precursor shortlived PC from a precursor memory PC,[536,539,546,553] indicating either that the difference is subtle or a stochastic process is likely dominant for development of "competence" to enter the memory PC population. The stochastic process could be a probabilistic occurrence based on the location of the PC and the survival signals it receives at a specific, transient point in time.

The second challenge facing a PC that is competent to become a memory PC is competition. It appears there are a limited number of survival niches in the bone marrow and other tissues for memory PCs.[553] In that case, competition must occur between PCs of different specificities and affinities for those survival niches. This is discussed further in the following.

DIFFERENTIATION AND PHENOTYPE OF MEMORY B CELLS

Bmem cells are primarily generated in GCs.[515,570] The signals that induce a GC B cell to differentiate into a Bmem cell remain unclear.[105,515,570] Bmem cells can be found in spleen, blood, bone marrow, other lymphoid tissues such as tonsils, and mucosal sites.[571,572,573,574,575] Within spleen, Bmem cells largely localize to the marginal zone of the follicles.[573]

Human Bmem selectively express CD27,[573,576,577] a member of the TNFR superfamily.[578] Surface expression of CD27 is now widely used as a specific marker, in conjunction with lack of IgD expression, to discriminate human Bmem cells from naive B cells. CD27 was initially determined as a marker of human Bmem cells in both peripheral blood and spleen by demonstrating that CD27+ B cells express somatically mutated Ig V genes, while CD27- B cells do not.[573,577] This was also consistent with the observation that nearly all isotype

switched B cells in peripheral blood are CD27+, and the majority of IgD+ B cells are not.[576,577] Bmem cells in tonsillar tissue can be identified as IgD- CD38- B cells as well as IgD- CD38- CD27+.[571,572] Vaccine induced antigen-specific Bmem cells have also been shown to be predominantly CD27+.[548,579] Antigen-specific Bmem cells in humans can be identified by fluorescent antigen binding and flow cytometry,[545,580] or functional identification by in vitro reactivation.[548,579] Antigen-specific Bmem cells are present at low frequencies (approximately 0.005% to 0.2% of total peripheral blood B cells[14,581]). Using either approach, antigen-specific human Bmem cells have been identified to many antigens, including the smallpox vaccine,[14] the anthrax vaccine,[582] the tetanus vaccine,[19,548,581,583] measles,[19,548] rubella,[19] malaria,[584] influenza,[585,586] rotavirus,[545,587] severe acute respiratory syndrome,[588] and wasp venom allergen.[581] Substantially higher percentages of human B cells in spleen are Bmem cells,[574] and it has been calculated there are 10 to 100 times more antigen-specific Bmem in spleen than in blood.[570]

Human Bmem exhibit extensive heterogeneity. Bmem can be unswitched IgM[570] or switched to any IgG isotype, or IgA, and therefore have different effector and activation properties. Bmem can have no evidence of somatic hypermutation and affinity maturation, or evidence of sequential accumulation of a massive series of mutations.[589,590] CD27+ Bmem have extensive diversity in their surface phenotype, expressing many different surface receptors and homing receptors in a highly heterogeneous fashion.[591] Furthermore, not all human Bmem are CD27+. There are substantial populations of CD27- Bmem that themselves exhibit significant heterogeneity in surface phenotypes.[570,592] FCRL4+ Bmem are an additional population of Bmem predominantly localized to mucosal tissue.[575] In the context of chronic viral infections (eg, HIV and hepatitis C virus) and chronic autoimmune diseases (eg, lupus) additional populations of B cells have been observed that have been categorized as “exhausted” or “aberrent” Bmem.[593,594,595] These cells have evidence of recent activation and poor responsiveness to restimulation, and therefore appear related to exhausted CD8 T cells found in chronic viral infections due to continuous antigenic stimulation.

Similar observations of extensive heterogeneity have now been made for murine Bmem. There is no single cell surface marker that can identify murine Bmem. Murine Bmem are not selectively CD27+. Indeed, there is no set of surface markers that can identify all murine Bmem. Murine Bmem exhibit a wide range of polymorphic cell surface phenotypes,[596,597] and gene expression analysis has not found a consistent gene expression profile that defines B-cell

memory.[598,599] Murine Bmem may be IgM or IgG.[597,600,601] Generation of murine Bmem does not depend on affinity maturation.[306,596] While the majority of Bmem are generated in GCs, it is possible to generate GC-independent memory[306] and even T cell-independent memory in some cases,[602] which is further evidence of the immense heterogeneity possible in the Bmem population. Altogether, human and murine B cell data show that Bmem are not a

singular cell type with a singular phenotype, but are instead an extraordinarily varied population of cells, united only by their property of having previously recognized antigen. The various phenotypes of Bmem may or may not be stable. Bmem cells generated at different times during an immune response can have different phenotypes.[597] This observed diversity suggests that diversity of Bmem phenotypes and functions are biologically valuable for protection against infectious disease.[515] By having Bmem specific to the same antigen with different effector functions (isotypes), epitope specificities and affinities (divergent selection and affinity maturation), homing properties (tissue localization and recruitment to sites of inflammation), and responsiveness to restimulation (modulated by the multitudinous surface receptors with various functions in cell-cell interactions), the Bmem may be better poised to more effectively respond to rechallenge and unpredictable changes in the pathogen.[597,600]

Function of Memory B Cells: Quiescent Memory

What is the value of long-term maintenance of Bmem cells? Bmem cells have several features that indicate they are valuable for protection against infections. First, Bmem cells are present in much greater numbers than naive mature B cells of a given antigen specificity.[548,581,603,604,605] Second, Bmem cells respond to reactivation faster than naive B cells,[548,550] differentiate into PCs faster,[550] and have a larger burst size, indicative of resistance to apoptosis.[606] Third, Bmem cells have undergone affinity maturation and therefore produce antibodies after reactivation that have substantially higher affinity and/or avidity than antibody produced from naive B cells. Each of these properties likely make Bmem cells highly valuable for protection against reinfection, as the Bmem cells are able to make a rapid recall response and produce high levels of high-affinity antibodies quickly to limit the spread of the infecting microbe and quell the infection.

In situations where antibodies are known to be protective but are not present at high enough levels for sterilizing immunity (sterilizing immunity defined as a complete prevention of infection of any cells or tissue), Bmem cells are likely to contribute to the observed protection against disease. The hepatitis B virus (HBV) vaccine is a well-characterized example of a known situation where antibody titers that drop within 5 years.[607,608,609] Antibodies against HBsAg are the defined correlate of protection for the HBV vaccine, and the minimum protective level has been established as 10 mIU/mL.[492,494] When serum anti-HBsAg antibody levels drop below that level, booster immunization was recommended for many years. However, it is now recognized that booster immunizations are not required, because previous vaccination is protective even if anti-HBsAg titers have fallen to undetectable levels.[494,610] Why? Bmem cells provide protection.[610,611,612,613,614] HBVsAg antibodies are the correlate of protection for the vaccines, and high-affinity HBsAg-specific Bmem will rapidly differentiate into anti-HBsAg antibody secreting cells within 3 to 5 days of virus exposure.[611,612,613] This is sufficient for protection against disease because the kinetics of the HBV infection are slow enough so that the anamnestic antibody response generated by the Bmem occurs rapidly enough to quell the spread of the virus and prevent clinical disease. In any situation where antibodies contribute to protective immunity, reactivation of Bmem cells is likely to contribute to protection as long as the infectious agent is not so virulent as to cause disease before the Bmem cells have time to proliferate and differentiate into PCs.

Longevity of Humoral Immunity

There are several classic examples that clearly documented long-term protective immunity lasting up to 75 years in humans in the absence of reexposure to the pathogen (Table 31.2).[6,615,616] Those observations were crucial in shaping our ideas about immunologic memory because they showed that the immune system could remember an encounter that occurred many years ago. As antibodies are the main protective mechanism for measles, sustained measles immunity on the Faroe Islands suggested that B-cell memory to measles lasts at least 65 years.[615] A similar situation was observed with rare polio outbreaks in a remote Eskimo village. Three serotypes of poliovirus exist, and antibodies against one serotype were observed only in Eskimos more than 40 years old and antibodies against a second serotype were observed only in individuals older than 20. This epidemiologic observation indicated that production of antipoliovirus antibodies is long-lived even in the absence of reexposure to the virus.[6] Similar epidemiologic data of long-lasting antibody responses to specific influenza strains has been used extensively in more recent studies to predict immunity to new influenza strains.[617,618,619] Numerous human serologic studies of antigen-specific IgG have directly established that antibody responses against a variety of agents can be sustained for decades.[14,16,19,617,619,620,621,622] Astonishingly, substantial antibody levels can be sustained for 90 years in numerous instances.[619,621] At the cellular level, studies have

established that Bmem survive long term in mice and for many decades in humans.[14,548,623] Cellular studies have also shown that PCs can survive for the life of a mouse.[547,554,559] The mechanisms for maintenance of these cell types are described in the following.

TABLE 31.2 Long-Term Human Immunity in the Absence of Reexposure to the Pathogen

Infection	Duration of Immunity
Measles on the Faroe Islands615	65 years
Yellow fever virus in Norfolk, VA616	75 years
Polio in remote Eskimo villages6	40 years
Inactivated poliovirus vaccine in Sweden620	30+ years
Smallpox vaccine14,16,621,645	30 to 60+ years

Longevity of Memory B Cells

Bmem have been demonstrated to survive in the absence of antigen in mice.[623] In humans, Bmem are found in peripheral blood and spleen for decades after smallpox vaccination.[14,574] Bmem specific for numerous other immunizations or infections have been detected decades after exposure.[19,548,614,619] For the antigen-specific responses tested, circulating Bmem numbers decline slowly over a period of decades.[19]

There are four models for how human Bmem cells are maintained: 1) antigen-dependent, 2) intermittent stimulation by cross-reactive antigens, 3) bystander activation, and 4) programmed homeostatic maintenance. These models are not mutually exclusive, and all are topics of active research in the field to determine their importance in memory maintenance. The first model is antigen-dependent maintenance. Reinfection or reimmunization is one clear mechanism to maintain memory via recall. Microbial persistence is another clear mechanism to maintain memory. A number of microbes (herpesviruses being the most wellknown examples) can persist at low levels in healthy individuals, and this chronicity can provide either a continuous or intermittent antigenic stimulus to the immune system. Antigen depots are an antigen-dependent mechanism for memory maintenance that does not depend on reinfection or reexposure or microbial replication. The antigen depot model of memory maintenance relies on the ability of FDCs to trap antigen-antibody complexes on their cell surface and retain them for extended periods of time.[624,625] FDCs express Fc receptors on their cell surface, and antigen-antibody complexes can bind to these Fc receptors. It appears that FDCs do not internalize these antigen-antibody complexes but instead display them on their cell surface, thus promoting maintenance of GCs.[504,510,626,627] Some studies have suggested that antigen can persist on FDCs for greater than 1 year, and it has been proposed that after the generation of Bmem, the cells are maintained by periodic reencounter with antigen on FDCs.[624] However, data from the only study directly tracking antigen in GCs after a viral infection, using a mouse model, indicated that GCs are sustained by antigen on FDCs for ~30 days after clearance of the virus.[625] This was corroborated by a second study with a nonreplicating antigen,[559] indicating that FDCs were critical for maintenance of GCs but not Bmem. Furthermore, a genetic study demonstrated that murine Bmem are maintained in the absence of antigen.[623] This is analogous to murine CD8 T cells.[321]

A second model proposes that memory is maintained by stimulation of Bmem cells by cross-reactive environmental or self-antigens. B cells are stimulated by direct interaction of the BCR with antigen, and the specificity of a BCR is not absolute; cross-reactivity is observed. Therefore, it is possible that Bmem cells are maintained long term by intermittent interaction with environmental antigens (ie, allergens, food products, unrelated pathogens) or self-antigens. This hypothesis is exceptionally difficult to test. Rajewsky and colleagues have shown that mature naïve B cells must constantly maintain BCR expression for survival,[628] presumably due to a need for tonic signaling through the BCR. Tonic signaling may or may not be dependent on low-affinity binding of the BCR to self-antigens. If the signaling is dependent on self-reactivity, Bmem BCRs may also have a requirement for low-grade self-cross-reactivity. On the other hand, Bmem cells may have different requirements for BCR stimulation and may no longer require antigen for their survival or homeostatic proliferation. This would be similar to the differential requirements observed between naïve and memory T cells. A third potential mechanism for the maintenance of Bmem cells is bystander polyclonal

activation. This model is based on the observation that Bmem cells stimulated in vitro with toll-like receptor ligands or select polyclonal activators will undergo several rounds of proliferation and differentiate into plasma cells, whereas naïve B cells will not.[548,629] If this same process occurs in vivo, Bmem cells would be likely to proliferate in response to irrelevant microbes containing toll-like receptor ligands or proliferate due to production of cytokines secreted by responding cells of the immune system.[548,630] Intermittent bystander activation in this manner would result in small-scale expansion of Bmem cells, thereby maintaining the population by replacing any Bmem cells dying over time. This model is mechanistically plausible but currently seems unlikely. While one study observed bystander activation of human Bmem cells in vivo, as measured by increased antigen-specific serum antibody titers,[548] three others human studies have observed no bystander activation in vivo.[583,631,632] Bystander activation was not observed in a mouse model system.[633,634]

A fourth potential mechanism for the maintenance of Bmem cells is programmed homeostatic proliferation. This hypothesis draws from the known mechanisms of CD8 T-cell memory maintenance in mice.[352,635] As discussed earlier in the chapter, murine memory CD8 T cells accomplish prolonged maintenance by proliferation primarily via IL-15 signals. Memory CD8 T cells are thought to undergo homeostatic proliferation when they migrate through the bone marrow, where there are high concentrations of IL-15 and other proliferation and survival signals.[219,636] Therefore, antigen-specific Bmem cells may maintain themselves by a similar programmed homeostatic maintenance involving intermittent proliferation triggered by certain paracrine cytokines or other as yet unknown factors. Data from both mice and man indicates that Bmem cells undergo a slow rate of proliferation in the absence of rechallenge.[559,592,603,637,638] This is consistent with slow homeostatic proliferation and does not require CD4 T cells.[639]

Longevity of Memory Plasma Cells

Serum antibody titers have long been used as a surrogate measure for the presence of PCs, but that measurement is not sufficient for assessing the longevity of PCs, because the population of PCs may consist of a stable number of

long-lived cells or may be partially or fully replenished by Bmem differentiating to PCs. Therefore, it is necessary to directly quantify PCs and their longevity. The acute PC response to an immunization or acute infection peaks within 1 to 2 weeks and then declines within 2 to 4 weeks after infection.[531,536,555] After the GC reaction subsides, bone marrow becomes the predominant site of long-term antibody production, with bone marrow PCs responsible for 80% to 95% of the host's antibody production[547,555,640] (see Fig. 31.5). A seminal study on PC longevity determined that antigen-specific plasma cells can survive in bone marrow for the lifespan of a mouse (1.5 to 2 years) with a half-life of 3 to 4 months, even when Bmem were ablated.[554] A separate study concluded that murine bone marrow PCs have an indefinite lifespan.[547,552]

Due to obvious technical constraints, there is limited data on the longevity of PCs in humans. PCs that phenotypically match murine memory PCs, including evidence of somatic mutation,

are present in human spleen and bone marrow.[550,641] Regarding longevity of the cells, this can be inferred by anti-CD20 therapy (rituximab) studies. Anti-CD20 is used in human to deplete all mature B cells and Bmem in order to treat autoimmune diseases or malignant B-cell tumors, but anti-CD20 therapy does not deplete PCs. Serum antibody titers to some vaccine antigens remain unchanged in rituximab-treated individuals for at least 1 year.[642,643] These results indicate that human memory PCs survive for substantial periods. Murine studies utilizing B-cell depletion techniques found similar results of PC maintenance for months in the absence of mature B cells or Bmem.[562,644]

A difficulty in interpreting the longevity of PC in humans comes from serologic studies of different vaccines and infectious diseases. Serum antibody titers against the smallpox vaccine,[14,16,621,645] polio vaccine,[620] rubella vaccine,[19] and measles vaccine[19] are sustained indefinitely, consistent with indefinite survival of PCs (see Table 32.2). However, serum antibody titers against tetanus and diphtheria decline.[19,620] Serum antibody titers against HBV regularly decline to undetectable levels within 5 years.[492,494,607,608,609] Therefore, not all PC memory is of equivalent duration. This may be due to differing capacities of PC to compete with newly generated PC over time.[553] After an infection or other event inducing inflammation, some PCs may become dislodged from their survival niche, opening up availability of the niche to new PCs.[553]

Interplay between Memory B and Plasma Cell Compartments

Bmem and PCs appear to be independently maintained cellular compartments in the absence of antigen. While in many situations there is an overall correlation between Bmem and PC numbers (or serum antibody levels, as a surrogate for quantitating PCs),[14,19,548,646] the correlation is often modest,[19] and sometimes no relationship is observed between the abundance of Bmem and PCs specific for an antigen.[492,611,612,613,614] Data from humans having undergone splenectomy or B-cell depletion therapy has convincingly shown that serum antibody titers can be maintained for many years even with very reduced levels of Bmem.[574,642,643] Data from mice have shown that depletion of Bmem does not have a major impact on the memory PCs,[554,644] and depletion of PCs but not Bmem does not result in a rapid replenishment of PC by the Bmem in the absence of antigen.[562] Therefore, once Bmem and memory PCs are generated, they are maintained by independent processes in the absence of antigen.

CONCLUSION

Immunologic memory represents a remodeling of the immune system that allows the immune system to be “imprinted” with a memory of exposure to infectious pathogens as well as noninfectious foreign molecules. Much progress has been made identifying the signals and genes that induce T- and B-cell activation and differentiation during an immune response that ultimately results in the formation of memory T and B cells. However, less is understood about the permanence or plasticity of memory cells and how their differentiation states are achieved and maintained over time, or how phenotypically and functionally distinct memory T and B cells contribute to protection. These are important areas of ongoing research.

With the knowledge of immunologic memory that had been developed over the past decade, a move toward more rationale forms of vaccine design has begun. Nevertheless, the field is left with many hurdles for generating optimal numbers of memory cells in the right locations that form the most effective response, while avoiding excessive immunopathology. Formulating vaccines that balance these objectives remains a challenge, and having a "universal" vaccine design for different types of pathogens is likely unrealistic as the approaches taken will be varied and tailored toward each pathogen of interest. Moreover, we are finding a more intricate relationship between our immune system and the metabolic fitness and function of organs and tissues. The tissue environment can affect the phenotype, function, and longevity of memory T and B cells, but much remains to be learned about how organ function is, conversely, affected by the memory T cells that dwell within. This may have important implications on tissue homeostasis, inflammatory disease, obesity, and aging. The next advances in our understanding of immune memory will come from the application of more integrated molecular approaches to the study of physiologic immune responses in vivo, which will allow for the study of the activities of the whole *immune system*, as opposed to a specific *immune cell*. Although this might seem a daunting task in terms of its complexity and sheer volume of information to be obtained, the results will be transformative in terms of our fundamental understanding of the immune system and our ability to manipulate it for the prevention of disease.

Chapter 32

Immunologic Tolerance

Christopher C. Goodnow

Pamela S. Ohashi

INTRODUCTION

How the immune system tolerates molecules that are part of our body yet mounts a destructive response against molecules that are foreign has been a major biologic and medical conundrum for decades. The idea that the repertoire of lymphocytes is made actively tolerant to each individual's unique set of self-molecules has posed many practical and conceptual challenges. If all lymphocytes that have the potential to respond to self-antigens are silenced or eliminated, will the residual repertoire be sufficient to respond to the enormous array of unknown pathogens? If all self-reactive lymphocytes are actively tolerized, why then do a bewildering array of autoimmune diseases collectively affect more than 5% of people? If we are programmed during development to eliminate tissue-specific lymphocytes, how does immune surveillance against tumors occur? Most importantly, how can we harness the physiologic processes of immunologic tolerance either to prevent transplant rejection and allergy or to promote rejection of tumor cells? In this chapter, we will cover our understanding of the basic mechanisms that are currently known to promote immunologic self-tolerance.

HISTORY

The history of immunologic tolerance illustrates superbly how scientific progress wobbles and sways between two pillars: what people can conceive and what they can test experimentally.

The Discovery of Actively Acquired Tolerance

“Horror autotoxicus” was the insightful term used by Paul Ehrlich early in the 20th century to describe the immune system's avoidance of producing autoantibodies.[1] There were nevertheless much more pressing issues at that time defining the nature of protective antibodies against microbes and the production of vaccines, and little consideration was given to the problem of avoiding autoantibodies.

A key turning point came in 1948 and 1949 in the form of a book and a genetics article synthesizing all that was known about *The Production of Antibodies* by Burnet and Fenner.[2,3] Owen had published in 1945 an extraordinary analysis of antibody production against blood cell alloantigens in cattle.[4] He discovered that nonidentical twins had become hemopoietic chimeras in utero and that as adults they avoided making antibodies against the foreign alloantigens that were continuously presented on their sibling's red blood cells. Traub had earlier observed that mice infected with lymphocytic choriomeningitis virus (LCMV) in utero became lifelong carriers of the virus without producing neutralizing antibodies.[5] Burnet and Fenner put these observations together[2]: “This finding … has the important implication that cells foreign to the host may be tolerated indefinitely provided they are implanted early in embryonic life.”

How the immune system could distinguish self- from foreign antigens was clearly a big problem for Burnet and Fenner's theory. They proposed that tolerance-inducing antigens would be recognized by antibody on lymphocytes alongside a second receptor for a “self-marker.” It is ironic that Burnet and Fenner, as microbiologists first and foremost, locked onto this idea and did not conceive the reciprocal mechanism: that microbial antigens provoke immunity because they are seen by antibody on lymphocytes together with a second receptor for a “microbe marker.”

The failure to conceive of specific receptors for microbes, other than antibody-like molecules, proved to be a prolonged conceptual handicap for the field of actively acquired tolerance and immunity. It stemmed from a turn-of-thecentury rivalry between the schools of thought spearheaded by 1908 Nobel laureates Ehrlich and Metchnikoff, which artificially divided immunologists into those focused on adaptive immunity, exemplified by Ehrlich's antibodies with their extraordinary antigen specificity, and students of Metchnikoff's innate immunity which was viewed by those that followed Ehrlich as “nonspecific.”

In 1963, Claman[6] and Talmage[7] published experiments and theory that bacterial lipopolysaccharide (LPS) or similar components of acid-fast bacilli used in adjuvants provided a second “nonspecific” signal needed to switch lymphocytes from tolerance to immunity. Citing Talmage's theoretical work, Claman concluded,

> These experiments may nevertheless be regarded in the framework of a theory which considers that the production of antibody requires two stimuli, one specific and (at least) one nonspecific. The specific stimulus (or antigenic determinant) designates which specific antibody will be produced. The nonspecific stimulus (or adjuvant factor) carries the ability to stimulate cell proliferation, and is concerned with the quantity of antibody produced.

In 1975, Moller published further experimental and theoretical evidence for this idea, naming it the "one nonspecific signal" model.[8] Their use of the term "nonspecific" to describe the effects of LPS exemplifies the erroneous assumption held by most adaptive immunologists, but not

by those that studied innate immunity, that the adjuvant effects of microbial products like LPS were not mediated by specific receptors. Janeway articulated the need for a collective *mea culpa* among adaptive immunologists in 1989, describing the attitude to microbial adjuvants as "the immunologist's dirty little secret,"[9] and went on to hypothesize a parallel set of pathogen-associated molecular pattern receptors.[10] The question of how LPS, and by extension many microbial adjuvants, were recognized by the vertebrate immune system was answered dramatically with the discovery of precise mutations in the signaling domain of a receptor that looked nothing like antibody, toll-like receptor (TLR) 4, in strains of mice that were specifically unable to respond to LPS.[11] Mouse molecular genetics subsequently illuminated specific sensing functions for a diverse family of vertebrate TLRs and other receptors for "microbe markers."[12]

Partly because of this conceptual gap, Burnet's experiments to test the "self-marker" theory that tolerance was specifically acquired in utero yielded negative results. Chickens[13] or mice[14] exposed to foreign antigens *in ovo* or *in utero* were still fully capable of making antibodies against those antigens. However, most of the experiments employed influenza virus and bacterial flagellin that, like LPS, are recognized by antibody-like receptors and by various members of the TLR family, and would have resulted in the induction of immunity rather than tolerance. Although nonmicrobial antigens were also employed, they were not of the type that persisted long-term to maintain tolerance, unlike the allogeneic blood stem cells that had been exchanged *in utero* between Owen's twin cattle. True to the Popperian tradition of attempting to falsify one's hypothesis, Burnet noted that these results "may mean that the whole conception of the development of selfmarker recognition during embryonic life is wrong."[13]

Burnet and Fenner's book had nevertheless triggered Medawar to approach the problem of immunologic tolerance from a different angle, as a transplant scientist seeking to solve the problem of human skin graft rejection in burn patients. He extended Owen's findings to show that nonidentical twin cattle also accepted skin grafts from each other, representing extraordinary evidence for immunologic tolerance as allogeneic skin grafts remain to this day the most difficult to block from rejection. Medawar's team then performed the famous experiment of injecting allogeneic blood cells from one inbred mouse strain into newborn mice of another.[15] The blood cells would have engrafted to establish lifelong chimerism like the twin cattle and would not have stimulated the TLR system, allowing Medawar to reveal profound tolerance to skin grafts that was extraordinarily specific for the foreign tissue antigens encountered neonatally. In their 1953 paper, Medawar crystallized the concept: "This phenomenon is the exact inverse of actively acquired immunity and we therefore propose to describe it as actively acquired tolerance."[15]

These concepts and experimental findings are now employed in clinics around the world, with greatest success in children with primary immune deficiency diseases where tolerance is acquired so completely to semiallogeneic bone marrow transplants that immunosuppressive drugs can be withdrawn several months after transplantation.

The Clonal Selection Theory

While Medawar's experiments put the phenomenon of actively acquired tolerance on firm foundations, it opened up an even more perplexing problem: how were both tolerance and immunity acquired at the cellular level? Talmage[16] and Burnet[17,18] independently arrived at the "one cell-one antibody" concept of clonal proliferation to explain acquisition of immunity. Burnet's PhD student at the time, Gus Nossal, soon obtained the first experimental evidence for that concept using single cell micromanipulation methods with the bacterial geneticist Lederberg.[19] Many experiments followed in the 1960s, 1970s, and beyond that affirmed the role of clonal proliferation in acquired immunity. Clonal proliferation itself made the experiments feasible, by increasing the frequency and the specificity of antigen-reactive cells so that they could be accurately enumerated, micromanipulated, and experimentally studied.

The reciprocal mechanism—clonal deletion to explain the acquisition of tolerance—was Burnet's elegant mirror image concept in *The Clonal Selection Theory*.[18] Lederberg[20] extended the concept by pointing out that the timing of antigen encounter, at an immature stage of lymphocyte development, could itself be the "self-marker" that triggered clonal deletion or maturation arrest to prevent the cells from making antibody: "The distinction between the function of an antigen as inhibitor (self-marker) or as inducer of antibody formation is … the time when the antigen is introduced into the potential antibody forming cell."

Talmage[7] and Claman[6] proposed a prescient alternative: that antigen alone would trigger exhaustive differentiation of specific lymphocytes without clonal expansion, depleting the pool of lymphocytes left to respond to a second challenge. In their view, antigen plus a second "nonspecific" signal from LPS, other adjuvants, or protein aggregation was necessary for clonal expansion of specific lymphocytes to prevent depletion of the pool of responders when some differentiated into effector cells.

Testing for the disappearance of self-reactive clones in tolerant animals was nevertheless like asking if a needle had been eliminated from a haystack. It was confounded for 30 years by the fundamental technical barrier that antigenbinding lymphocytes are rare and heterogeneous in the preimmune repertoire.

The Experimental and Conceptual Swing against Clonal Deletion in the 1960s and 1970s

Experiments were performed in the 1960s and 1970s to see if lymphocytes capable of binding self-antigens were absent from the circulating repertoire, either by direct antigenbinding measurements, by polyclonally activating cells into antibody secretion in culture, or by immunizing with foreign antigens that resemble self-antigens. Lymphocytes with self-antigen binding antibodies could be found,[21] leading many to question the idea of clonal deletion.

We know now that many B cells in the preimmune repertoire bear antibodies that are polyreactive, binding with low and variable affinity to many different antigens including self-antigens.[22,23,24,25,26,27,28] The same is true for most circulating

T cells, which are indeed biased to be weakly self-major histocompatibility complex (MHC) reactive. Many of these polyreactive receptors do not pose a risk of autoimmune disease unless made in extraordinary concentrations, and when expressed in transgenic mice some have an affinity for self that falls below that which invokes actively acquired tolerance, as described later. But the assays used at the time could not distinguish between lymphocytes bearing frequent but harmless polyreactive receptors and much rarer cells bearing potentially destructive receptors with higher affinity and specificity, which we know now are usually controlled by active tolerance mechanisms. In other cases, highaffinity receptors were isolated but the assays used confused genuine autoantibodies with antibodies that bound to misfolded, proteolytically cleaved, or posttranslationally modi-fied "altered self."[29]

Contemporaneous experiments in the 1970s supported clonal deletion or inactivation of immature lymphocytes, but the necessary experimental contrivances made it hard to shift the growing consensus that self-reactive lymphocytes were not deleted. Cooper neatly bypassed the problem of varying antigen affinity by showing that treatment of developing chicks or neonatal mice with antibodies to the constant region of immunoglobulin (Ig)M completely blocked B-cell development and antibody formation.[30] He noted: "Acting at an early stage of differentiation, anti-mu antibody might inactivate or eliminate…cells at the time that they begin to express IgM surface antibody. This concept is analogous to the elimination of 'forbidden clones' recognizing self-antigens."[30] Nossal[31] and Klinman[32] performed sophisticated tissue culture experiments that showed immature B cells exposed to haptenic antigens, but not their mature counterparts, were actively incapacitated from making antibody-secreting progeny, although they could not see the fate of the antigen-specific cells directly.

Set against these findings of clonal deletion or inactivation in immature lymphocytes, Claman,[6] Dresser,[33] Weigle,[34] and others showed that even mature antigenspecific lymphocytes were somehow incapacitated when chronically exposed to nonimmunogenic forms of antigenlike xenogeneic gammaglobulin, provided these persisted in the body, were deaggregated so that they did not provoke inflammatory responses, and were free of the bacterial ligand for TLR 4, LPS.

Miller's discovery of helper T cells in the 1960s provided an alternative way to reconcile the presence of self-antigen binding B cells with Burnet's concept of clonal deletion or inactivation. While B cells might not actively acquire tolerance, the repertoire of helper T cells could still be purged of self-reactive clones. This revised view was made poignantly by Miller when he received the inaugural Burnet Medal in 1971[35]: "Specific tolerance can be induced much more readily in T cells than in B cells and, in many cases, tolerance in B cells in vivo is just not demonstrable. It may in fact turn out that tolerance to self-components is a property

confined exclusively to the T cell population, tolerance in B cells being merely a laboratory artifice." Effectively, this allowed the goalposts of clonal deletion to be moved from B cells to T cells. But that solution soon came into doubt as well: the 1974 discovery of MHC restriction by Doherty and Zinkernagel[36] indicated that all circulating T cells were inherently self-reactive.

Tolerance by Cell-Cell Interaction Networks and Suppressor T Cells

The inherent self-MHC reactivity of T cells was probably the final trigger that drove many to discard clonal deletion altogether and conceive alternative mechanisms for actively acquired tolerance. By 1983 when Nossal reviewed the field of immunological tolerance,[37] he noted that most immunologists had discarded Burnet's concept of clonal deletion as well as Nossal's "clonal anergy." One camp pursued alternative ideas of Jerne, who hypothesized that tolerance was achieved by complex networks of consultation between lymphocytes through idiotype-anti-idiotype interactions.[38] It is fair to say that experimental studies have yet to establish the importance of idiotype networks for actively acquired tolerance.

An important alternative school of thought was fostered in the 1970s by Cohn's two-signal model.[39] Its inception hypothesized that antibody responses were only triggered when a newly introduced antigen was recognized simultaneously by two antigen-binding lymphocytes: the B cell and a helper T cell that delivered a second signal to the B cell. In this model, tolerance could still be actively acquired in the B cell by deletion, anergy, or some other mechanism that paralyzed antibody formation if it encountered antigen (signal 1) without receiving signal 2 from the helper T cell. Cohn's model extended to include T cells the two-signal concepts developed 10 years earlier by Dresser, Claman, and Talmage, that recognition of antigen alone promoted tolerance whereas immunity required a second signal coming directly from microbes through the mitogenic action of LPS and other microbial components.[6,7,8,40] This still left the question of how T cells might select between tolerating or rejecting an antigen. Based on transplantation tolerance experiments, Lafferty initiated the conceptual leap that T-cell proliferation and rejection of foreign tissue depended upon recognizing antigen and MHC alongside a second "costimulator" signal unrelated to antigen, on specialized antigenpresenting cells that lay as sentinels in each tissue of the body.[41] Steinman discovered dendritic cells as fulfilling this property in the 1970s.[42]

An intensely popular new idea was that self-reactive helper or cytotoxic T cells could be controlled by suppressor T cells that were actively induced by self-antigens or idiotypes, and were marked by CD8 and a distinctive MHC molecule, I-J.[43,44] Thousands of publications appeared in the 1970s and 1980s on suppressor T cells, including more than 300 referring to I-J. However, the experimental tools available at the time to test these ideas were not up to the task, and this period illustrates the potential for even the best minds to be engulfed in mass hallucination when our ideas are not grounded by falsifiable experiments. As molecular genetics revolutionized the field in the 1980s, "suppressor T cell" became a tainted term: Steinmetz and Hood sequenced the MHC and showed there was no

I-J molecule,[45,46] and antigen-specific suppressor T-cell clones were found to lack a T-cell receptor (TCR).[47] While molecular genetics swept I-J+ CD8+ suppressor T cells away in the 1980s, in 2001 these same powerful experimental methods gave back CD4+ Foxp3+ "regulatory T (T_{reg}) cells" and showed these were critical for tolerance, when Ramsdell and colleagues revealed that deficiency of the Foxp3 transcription factor unleashed lethal autoimmunity in the scurfy mutant mouse and in human immune dysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome.[48,49,50]

Effectively, this turbulent history has laid out a conceptual landscape comprising three general ways to govern tolerance and immunity: 1) "individual choice" where tolerance is acquired by cell-autonomous processes of clonal deletion or inactivation; 2) "committee governance" where cell-cell interactions and additional signals are needed to launch immune reactions; and 3) "governance by police" where tolerance is imposed through the action of dedicated inhibitory cells. As detailed in the following, modern molecular and cellular methods have established important roles in actively acquired self-tolerance for each of these three fundamental concepts.

THYMIC TOLERANCE

T Cells are Positively Selected for Self-Reactivity

The finding that T cells were self-MHC restricted[51,52] was soon followed by transplantation studies demonstrating their self-MHC requirement was imprinted during immature T-cell development in the thymus[53,54,55]: a result that ran entirely contrary to the idea of clonal deletion. The transplantation experiments involved construction of bone marrow chimeras or thymus chimeric mice, where bone marrow of MHC type A × B gave rise to T cells within a mouse or a transplanted thymus of MHC type B or MHC type A. Although controversial, the

resulting T cells primarily recognized antigen when it was presented by cells that bore the same MHC type as the thymus in which they had differentiated.[53,54,55] These experiments showed T cells were somehow positively selected during their development to recognize self-MHC, triggering intense discussions about whether T cells employed two receptors—one for antigen and one for self-MHC—or if there was one receptor for "altered self." While we take "altered self" for granted now, it is important to bear in mind that these discoveries took place 7 years before biochemical experiments showed that antigen peptides bind MHC molecules[56] and 9 years before the peptidebinding groove of MHC was revealed crystallographically.[57]

The key event that opened up experiments on thymic tolerance was the identification and cloning of the TCR.[58,59,60,61,62,63,64] This led to key experiments that established that there was a single receptor for antigen and MHC,[65,66,67,68] and also resulted in the development of two key experimental approaches to analyze the cellular basis of T-cell self-tolerance: antibodies specific for TCR Vβ regions and the ability to generate TCR transgenic mice.[69,70,71,72,73] Both of these approaches allowed investigators to follow the fate of T cells with defined specificity during thymocyte development.

The series of experiments that conclusively demonstrated positive selection of self-MHC reactive T cells was the use of TCR transgenic mice. TCRs were cloned from T-cell lines of a defined specificity, and TCR transgenic mice were generated from these receptors. Here, the prediction would be that the rearranged transgenic TCRs would only mature in mice that had the same MHC type as the original donor T cell. Studies using a TCR from a female $H2^b$ CD8+ T cell, which was restricted to recognizing H-Y male-specific antigen associated with the H2-D^b MHC molecule, clearly demonstrated that CD8+ T cells bearing this TCR matured in female mice expressing $H2^b$ but not in mice with other MHC types.[74] These studies demonstrated that the transgenic TCR was positively selected and skewed the repertoire to the CD8 lineage during development, as the receptor was specific for the class I MHC molecule.

T Cells are Negatively Selected for Self-Reactivity

One reagent that turned out to be critical in defining T-cell clonal deletion as a mechanism of self-tolerance was the generation of TCR-specific antibodies. The majority of TCR antibodies were specific for Vβ regions. Kappler et al. evaluated the T-cell populations that react with a monoclonal antibody specific for Vβ17. They showed that Vβ17+ T cells react with the class II MHC molecule I-E and are not present in the peripheral lymphoid tissues of mice that express I-E. Importantly, in I-E+ mice, immature CD4+8+ thymocytes were present bearing Vβ17, but these were eliminated from the mature CD4+8- single-positive (SP) thymocyte subset, demonstrating that the self-MHC-specific T cells were deleted during development in the thymus.[70] Other studies showed that the infusion of tolerizing agents such as staphylococcal enterotoxin B (SEB) led to clonal deletion of specific cells in the thymus.[75] These experiments clearly supported the idea that self-reactive T cells are removed from the repertoire because they encountered their antigen when still immature in the thymus.

Similar studies were done using other Vβ-specific antibodies that correlated the absence of particular Vβ with the presence of self-antigens. One of the most popular models to evaluate tolerance in this way used different strains of mice that expressed minor histocompatibility antigens known as minor lymphocyte stimulatory (Mls) antigens. This group of molecules was defined by Festenstein in the early 1970s[76] and later shown to associate with endogenous retroviruses. Mice were characterized as expressing Mls-1^a, Mls-1^b, or Mls-1^c antigens, by the ability of T cells to generate a proliferative response against cells from different strains of mice. Early studies demonstrated that T cells expressing Vβ6 or Vβ8.1 were absent in mouse strains that express Mls-1^a.[77,78] Collectively, these studies demonstrated that clonal deletion of T cells occurred in the presence of a defined self-antigen.

Conceptually, it is surprising that antigen specificity could be associated with a particular Vβ segment independent of the Dβ, Jβ, and Vα segments of the TCR. Importantly, antigens such as Mls-1^a or SEB defined a unique class of antigens dubbed "superantigens" because they were able to stimulate a much higher proportion of T cells than conventional antigens and in a way that did not obey the rules of MHC restriction, although certain MHC types were shown to preferentially present superantigens.[79] Research has shown

that superantigens bind the sides of MHC II and TCR Vβ segments in an unconventional way that does not involve the conventional peptide-binding groove of MHC and complementarity determining regions of the TCR.

Although Vβ-specific monoclonal antibodies provided key evidence for clonal deletion, it was essential to demonstrate that this also occurred for self-reactive T cells recognizing conventional peptide antigens bound to self-MHC. The first study to demonstrate clonal

deletion of conventional selfreactive T cells employed a TCR transgenic mouse.[73] In this model, the TCR α and β transgenes were taken from a CD8+ T-cell clone that was specific for the H-Y male antigen and H-2D^{b}. When female transgenic mice were examined, many T cells with the H-Y specific TCR were positively selected to the CD8 lineage due to the class I H-2D^{b} restriction, as noted previously. In TCR transgenic male mice, however, no T cells developed with the characteristics of the original H-Y T-cell clone bearing high levels of CD8 and the H-Y TCR, although many unusual T cells developed bearing the H-Y TCR and low levels of CD8. In the thymus of male TCR-transgenic mice, there was a drastic reduction in the number of immature CD4+8+ double-positive (DP) thymocytes, implying that thymic deletion occurred at or before this stage. However, follow-up studies established that the loss of DP cells and accumulation of unusual H-Y T cells in male mice was due to premature expression of the TCR alpha chain at the CD4-8-double-negative stage, which caused lineage misdirection at this stage as opposed to clonal deletion.[80] When the H-Y TCR alpha chain transgene was controlled so that it was only activated at the DP stage, there was little decrease in the DP population in male mice and negative selection occurred at the CD8+CD4- SP stage of thymocyte development,[80] comparable to the findings with superantigens.[70] The H-Y studies were reinforced by parallel TCR transgenic experiments with other conventional TCR specificities, providing solid evidence that self-reactive T cells are eliminated from the T-cell repertoire during thymic development.[72,81]

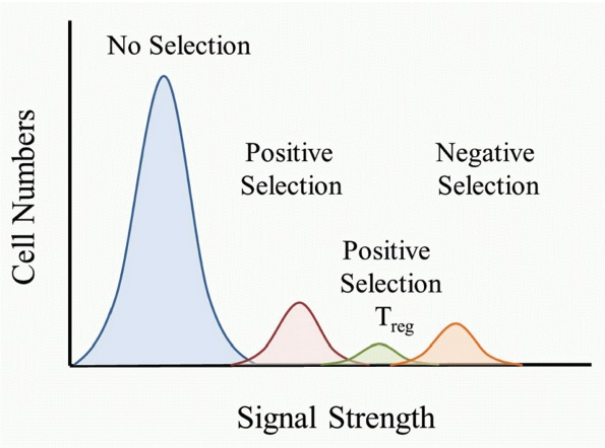

FIG 32.1. The Strength of T-Cell Receptor (TCR) Peptide/Major Histocompatibility Complex (MHC) Interactions Programs Tolerance Mechanisms. The random rearrangements of TCR gene segments lead to a wide range of specificities. Thymocyte fate will be determined by the strength of interaction between the TCR and peptide/MHC complexes that are found in the thymus. The majority of cells will not meet the threshold for positive selection. Stronger TCR interactions lead to the maturation of regulatory T cells or T-cell tolerance resulting in anergy or clonal deletion. The relative proportion of selected T cells is estimated.

Anergy as a Mechanism for Thymocyte Tolerance

Anergy is a term proposed by Nossal to describe lymphocytes that were present but rendered intrinsically unable to respond to stimulation with cognate antigen because of earlier exposure to the same antigen.[37] In T cells, evidence for anergy as an alternative mechanism of self-tolerance came from studies using parent into F1 bone marrow chimeras.[82] In these studies, Mls-1^{b} bone marrow was transplanted into irradiated Mls-1^{a} Mls-1^{b} hybrid recipients. In this case, where synthesis of the Mls-1^{a} self-superantigen was limited to radioresistant cells in the thymus, Vβ6+ T cells that would normally be deleted in Mls-1^{a} mice were able to mature and emigrate from the thymus but were unresponsive to Mls-1^{a}. This demonstrated that an unresponsive state to self-antigen could be induced in the thymus and suggested that anergy versus deletion were alternative fates for selfreactive thymocytes depending upon the amount of TCR stimulation or the cell type presenting the self-antigen.

T-Cell Affinity/Avidity Defines Thresholds for Positive and Negative Selection

The observation that T cells were positively selected for selfreactivity during thymic development and also negatively selected for self-reactivity drew into sharp focus the central paradox for actively acquired tolerance and immunity. How would a TCR be able to transmit signals for differentiation and survival (positive selection) versus death (negative selection)?

Lederberg's[20] and Nossal's[31] earlier concept of a developmental window for deletion could not be invoked here because the alternative fates were both acquired in immature T cells. Over the years, evidence accumulated to support an affinity/avidity model that suggested that T-cell fate was determined by the strength of the signal transmitted by the TCR (Fig. 32.1).[83,84,85] The absence of a detectable signal in thymocytes would result in a process called death by neglect. A T cell expressing a receptor that could not engage

self-peptide/MHC complexes (pMHC) would be destined to die because it would be a "useless" TCR to have in the repertoire. TCRs that bound only weakly to self-pMHC complexes in the thymus would send a signal sufficient for the T cell to survive and differentiate to either the CD4 or CD8 lineage. According to this model, a strong signal would be sent if the TCR bound strongly to self-pMHC complexes and would lead to the death of the T cell. It is important to keep in mind that as the thymocyte undergoes positive selection and matures, the TCR level increases, and therefore the T cell would have increased sensitivity to self-pMHC complexes as they progress through thymocyte selection.

Studies to evaluate the affinity/avidity models of thymocyte selection were again dependent upon the development of new technologies. In the 1980s, Smithies and Capecchi reported a way to generate knockout mice, where the expression of a defined gene was disrupted.[86,87] This led to a flurry of activity with several groups generating a variety of genedeficient mice. Amongst the early gene knockout mice were animals with a defect in MHC class I protein display due to the absence of the β2-microglobulin subunit of MHC I molecules or the absence of self-peptides available to bind and fold MHC I molecules because of disruption of the transporter associated with antigen processing.[88,89] These mice were the basis for a very unique set of experiments in fetal thymic organ cultures, where defined peptides could be added in culture to evaluate their consequences for thymic selection.[90,91] When a TCR transgenic model was combined with the class I mutant mice, this provided a novel way to evaluate the consequences of defined peptides on positive selection as well as negative selection.

A series of experiments were done with the OT-1 TCR transgenic mice, that are specific for the ovalbumin (OVA) peptide SIINFEKL and H-2D^{b}.[83] The OT-1 TCR transgene was bred onto the transporter associated with antigen processing-deficient background. Fetal thymic organ culture was done using OT-1 transporter associated with antigen processing-1-/- (Tap1-/-) thymic lobes. In this model, no mature OT-1 T cells were generated in the thymus due to the absence of class I expression. However, a series of variant peptides resembling the OVA SIINFEKL peptide could be added to the culture and these would restore class I expression, with the resulting MHC molecules homogeneously complexed with a defined peptide. In this model, the SIINFEKL peptide itself and related peptide sequences that were capable of activating mature OT-1 T cells (agonist peptides) triggered negative selection of immature thymocytes bearing the OT-1 TCR. By contrast, variant peptides that were unable to activate mature OT-1 cells but instead antagonized activation by SIINFEKL itself (antagonist peptide ligands) promoted positive selection of immature thymocytes to accumulate in the cultures as CD8 SP T cells.

At the same time, other studies were done using P14 TCR transgenic mice that express a TCR specific for the LCMVglycoprotein (gp). These studies bred the TCR transgene on a β2-microglobulin-deficient background. Two groups demonstrated that different concentrations of the same agonist peptide promoted positive selection at low concentrations and negative selection at high concentrations.[84,85,92] Notably, in the P14 model, antagonist peptide ligands could not support positive selection of the P14 TCR.[93] Collectively, these studies provided key evidence that supported an affinity/avidity model for thymocyte selection.

The affinity of TCR binding to MHC molecules bearing the various peptides was subsequently measured by surface plasmon resonance. Using this approach for the OT-1 TCR, Alam et al. demonstrated that the difference between positive selection and negative selection was a threefold difference in affinity for pMHC.[94] Interestingly, the agonist peptides (A4Y, L6F) that could support positive selection of the P14 TCR had a similar affinity to the antagonist peptides that supported positive selection of the OT-1 TCR.[95] Further studies have also shown that in some models, agonist ligands lead to the differentiation of T cells bearing a CD8αα homodimer and this population of cells have innate-like properties.[93,96,97] Collectively, these studies support the concept that a certain affinity/avidity is required to promote positive selection and that increasing the affinity/avidity leads to the induction of negative selection (see Fig. 32.1).

What are the biochemical differences in the signal transmitted by the TCR that leads to survival and differentiation of weak pMHC binding thymocytes but death of strongly self-reactive thymocytes? Several studies demonstrated a critical role for the ERK MAP-kinase signaling pathway for positive selection.[98,99] Further in-depth studies to follow TCR signaling events used the OT-1 and P14 models to evaluate differences in peptide-specific interactions that were known to result in positive or negative selection. Interestingly, positive

selection was shown to occur as a result of sustained low level ERK signaling, while negative selection resulted a stronger, yet transient peak of ERK activation.[100,101,102,103] Accordingly, studies have shown that there was impaired thymocyte positive selection in the absence of ERK1 and ERK2.[104,105] Evidence also suggests that calcineurin has an impact on Erk activation and positive selection,[106] but not negative selection. An essential upstream activator of ERK, RasGRP1, was also found to be essential for positive but not negative selection of thymocytes.[107] Further studies have identified downstream ERK-activated transcription factors that are also important for positive selection.[108,109]

Recent studies also provided evidence that the outcome of thymocyte positive or negative selection is correlated with a different TCR conformation.[110] Further in-depth analyses have observed that signals that induce negative selection lead to the membrane compartmentalization of molecules involved in signal transduction such as ZAP-70, LAT, and ERK1/2. Importantly, similar changes in localization of signaling components were not observed under positively selecting conditions.[111] Therefore, the different thymocyte fates of positive or negative selection involve detectable molecular changes on the cell surface and in intracellular compartments.

Regulatory T Cells are Selected by High Affinity/Avidity Interactions

T_{reg} cells were first identified as a critical population that prevented autoimmunity and arose during thymic development. Early studies demonstrated neonatal thymectomy of some

inbred rodent strains led to the development of autoimmunity targeting the gonads and thyroid gland.[112,113,114] Further studies using various markers identified a subset of cells, first in the rat and then in the mouse, that had the potential to block the induction of autoimmunity. Mason's team demonstrated that adoptive transfer of naïve T cells to immunodeficient rats resulted in autoimmune diabetes and inflammatory bowel disease that was blocked if a subset of CD4 T cells with markers of activated or memory T cells was cotransferred.[115,116] These findings were extended to mice by Powrie[117] and by Sakaguchi, whose group demonstrated that the transfer of CD4+CD25- cells into 6-week-old BALB/c nude mice resulted in the development of autoimmune oophoritis, gastritis, and thyroiditis that was suppressed by the cotransfer of CD4+ CD25+ cells.[118] While these experiments suggested the existence of a new type of suppressor T cell (dubbed a T_{reg} cell to avoid confusion with the CD8+ suppressor T cells of the 1980s), their interpretation was uncertain: suppression by cells with markers of activated or memory T cells could simply reflect better control of microbial flora in the immunodeficient recipients, so that there was less stimulus for inflammatory bowel disease and autoimmunity.

The critical turning point establishing the existence of T_{reg}s came from the identification of the transcription factor, FoxP3, as a specific marker of mouse T_{reg}s that was required for CD4+25+ T cell differentiation in the thymus. Foxp3 was first identified by genetic mapping of an autoimmune mutation in the scurfy mouse strain.[48] That led to the identification of *FOXP3* mutations as the cause of a human inflammatory disorder known as IPEX syndrome.[49,50,119] Foxp3 was necessary and sufficient for T_{reg} differentiation, and thymic-derived Foxp3+ "natural T_{regs}" were shown to be critical to suppress autoimmunity, allergy, and inflammation of mucosal and cutaneous barriers.[120,121,122,123,124] However, it should be noted that the marker FoxP3 is not exclusively linked to T_{reg} cells in humans.

Caton's group was the first to show that natural T_{reg} differentiation was an alternative fate to clonal deletion for CD4 thymocytes with a strongly self-reactive TCR, further complicating the question of how alternative cell fates are determined in developing thymocytes.[125] The strength of TCR signal has again been invoked as an instructive in-fluence, supported by additional studies that indicate that T_{reg}s bear TCRs that bind to self-pMHC more strongly than TCRs that promote positive selection of helper T cells 126-129 (see Fig. 32.1). However, other studies argue that Foxp3 expression may be stochastic and protect strongly self-reactive CD4 cells from deletion.[130]

MOLECULAR PATHWAYS INVOLVED IN THYMIC CLONAL DELETION

The precise molecular pathway that leads to the death of self-reactive T cells remains unknown. Evaluating the role of a given signaling molecule in positive and negative selection often points to a role for that molecule in both events, supporting the idea that TCR signals are critical for determining T-cell fate.[131,132,133,134,135] However, in general, the role of molecules involved in regulating negative selection has met with controversy, although interesting candidates are beginning to emerge. Some of the uncertainty is likely due to the models that were used to study negative selection. In the early literature, mice were often treated with anti-CD3 antibodies to induce death of T cells. However, because the majority of T cells are activated, this leads to a stress-induced death that is dependent upon

glucocorticoids,[136] and therefore is not a good model to study negative selection.

Controversial Role for Apoptotic Pathways in Negative Selection

Two major mechanisms that regulate apoptotic cell death are known as the intrinsic and extrinsic pathways and are regulated by Bcl2 family members and tumor necrosis factor receptor (TNFR) family members, respectively. Because many members of the TNFR family possess a “death domain” that can interact with other death domain-containing proteins, this family became the focus for studies investigating the mechanisms of death during thymocyte negative selection. TNFR, Fas, CD30, Trail, DR3, as well as the downstream effector molecules have all been investigated, and the results remain controversial.[137,138,139,140,141,142,143,144,145,146,147,148,149,150,151]

The Role for ERK and Nur77 in Negative Selection

Several approaches have been taken to address the question of whether the ERK pathway is essential for negative selection. Experiments using dominant negative forms of RAS or MEK, which limit Erk activation, supported the idea that ERK was important for positive selection but not negative selection.[98] Other studies using pharmacologic inhibitors for the Erk pathway demonstrated that Erk played a role in both positive and negative selection,[101,152,153] whereas yet other studies supported the idea that Erk did not influence negative selection.[154] It is possible that the discrepancies in these studies are related to the strength of the signal required for selection of the TCR in the different models that were being studied. For example, because positive selection requires sustained signaling that results from weak TCR interactions, these signals would be more likely to be perturbed by transgenic forms of dominant negative signaling molecules, because this system would still have the endogenous molecules that could provide some signals.

Studies using mice that were deficient in both ERK1 and ERK2 demonstrated that thymic clonal deletion could still occur by following deletion of the OT-1 TCR transgenic T cells using various models.[155] However, there are many ERK family members and it is therefore possible that only certain members of the ERK family are critical or that the various ERK family members can compensate for each other. Studies using dominant negative or constitutively activated MEK5, which activates the ERK5 pathway, was able to modulate clonal deletion of thymocytes, but had no role in positive selection.[156] Importantly, ERK5 activity correlated with the induction of *Nur77*, which has been previously implicated in thymocyte negative selection.[157,158,159] In several other models, *Nur77* is also upregulated during thymocyte

negative selection, thereby supporting the importance of this molecule.[160] Therefore, studies support a role for ERK5 and *Nur77* in thymocyte clonal deletion.

Bim Links Negative Selection and Autoimmunity

If a particular molecule is essential for the death of selfreactive T cells, one prediction would be that the absence of this molecule may lead to spontaneous autoimmune disease. This prediction would not hold true if that particular molecule was also essential for T-cell differentiation or activation. One such candidate that was considered is the BH3-only-containing protein Bim. Bim is a proapoptotic molecule that gives rise to three alternatively spliced forms: Bim_S, Bim_L, and Bim_{EL}. In general, Bim is thought to promote apoptosis by binding and sequestering survival molecules Bcl-2, Bcl-x_L, and other members of that family. Initial studies reported that Bim-deficient mice spontaneously develop autoimmunity, and that Bim was critical for thymocyte negative selection.[161,162]

Recent studies, however, question the role of Bim in negative selection and autoimmunity. Baldwin's group evaluated negative selection using the HYcd4 TCR transgenic model.[163] They demonstrated that Bim played a role in apoptosis of thymocytes but not in self-antigen-specific negative selection. Other studies used an elegant TCR transgenic model to accurately follow the fate of Bim-deficient thymocytes. Kovalovsky et al. demonstrated that self-reactive Bim-/-T cells undergoing negative selection were arrested at a $CD4^{lo}CD8^{lo}$ immature stage of development.[160] Death of these cells was dependent on an alternative pathway that required the thymic microenvironment. By contrast, evidence from unpublished work has shown that Bim deficiency almost completely abolished negative selection in 3A9 TCR transgenic mice crossed with hen egg lysozyme transgenic mice.[163a] In these animals, the negatively selecting antigen was expressed selectively in Aire+ thymic medullary epithelial cells by the insulin promoter, and in their Bim+/+ counterparts negative selection was induced at the early CD4 SP stage. Thus, the relative dependence on Bim may vary depending on the stage of thymocyte development when self-antigen is encountered, the amount of self-antigen presented in the thymus, or the nature of the antigen-presenting cells that induce negative selection. Further studies using Bim-/- mice have shown that these mice have impaired induction of experimental autoimmune encephalomyelitis. Unexpectedly, Ludwinski

et al. also showed that Bim-deficient CD4+ T cells have a strikingly reduced ability to produce cytokines, particularly interleukin (IL)-6 and interferon-γ.[164]. This adds further complexity as to the mechanism of spontaneous autoimmune disease in Bim-deficient mice.[161]

Many insights have been uncovered by evaluating both animal models for autoimmunity and clinical studies. Several groups have shown that the nonobese diabetic (NOD) mouse strain that spontaneously develop diabetes has impaired negative selection as one of several factors that may contribute to the onset of disease.[165,166] Interestingly, recent studies have evaluated the genes that are expressed in stimulated NOD thymocytes versus wild-type thymocytes. Interestingly, Bim and Nur77 are among the genes that are not upregulated in the NOD background, lending potential support for these molecules in tolerance induction.[167,168,169]

MINK Links Jnk and Bim in Negative Selection

There is compelling evidence published by Cantor's group that a molecule known as MINK plays a role in negative selection but not positive selection.[170] They showed that MINK expression is increased 20-fold in DP thymocytes compared to the double negative subset. Expression of MINK was also shown to be very low in SP thymocytes as well as peripheral T cells. McCarty et al. studied the role of MINK in thymocyte selection by generating chimeric mice with bone marrow that was infected with a lentivirus that expressed green fluorescent protein as well as a small hairpin ribonucleic acid that reduced MINK expression. Three models of thymocyte negative selection supported a role for MINK. These include the superantigen Mtv-9-induced Vβ5 deletion in the C57Bl/6 and BALB/c backgrounds, the male-specific H-Y TCR transgenic model, as well as peptide-induced deletion using OT-II transgenic mice. Interestingly, they provided evidence that MINK acts via c-jun N-terminal kinase activation and the upregulation of the proapoptotic molecules Bim and BimEL.

Several groups have also evaluated the role of the c-jun N-terminal kinase/SAPK or p38 MAPK pathways in negative selection. Using knockout animals or pharmacologic inhibitors, evidence suggests that both of these pathways play a role in the death of thymocytes.[154,171,172] However, further experiments are necessary to solidify a role for Jnk in thymocyte deletion. Importantly, Jnk activation has been linked with Bim expression in neuronal cell types, further strengthening the possibility that Jnk may be involved in thymocyte deletion.[173,174]

EXPRESSION OF SELF-ANTIGENS IN THE THYMUS

Negative selection in the thymus provides a key mechanism to eliminate self-reactive cells early in development. However, this mechanism was thought to be incapable of establishing self-tolerance to the numerous self-antigens that are expressed only in specific organs, such as insulin or elastase in the endocrine and exocrine pancreas, respectively. Pioneering work by Hanahan identified cells in the thymic medulla that he dubbed “peripheral antigen-expressing cells” that were able to express organ-specific genes like insulin and elastase, and induced T-cell tolerance to a transgenic self-antigen controlled by the insulin promoter.[175,176] Several years later, work by Derbinski et al. showed that medullary thymic epithelial cells were able to express a wide array of self-antigens.[177,178]

At the same time as Hanahan's definition of peripheral antigen-expressing cells, two human molecular genetics teams discovered that mutations in a novel gene, dubbed autoimmune regulator (*AIRE*), were responsible for a devastating recessive syndrome known as autoimmune polyendocrinopathy-candidiasis ectodermal dystrophy

(APECED) or autoimmune polyendocrinopathy syndrometype 1 (APS-1).[179,180] APS-1 is remarkable because of the progressive development of multiple organ-specific autoimmune diseases, most frequently autoimmune adrenocortical failure and hypoparathyroidism, but also autoimmune thyroid disease, diabetes, vitiligo, alopecia, ovarian failure, hypogonadism, liver disease, pernicious anemia, and exocrine pancreatic insuffi-ciency.[181] Almost all patients develop mucocutaneous *Candida albicans* infections because they produce neutralizing autoantibodies to IL-17, a cytokine that is essential for immune control of *Candida*.[182,183] While this experiment of nature established that *AIRE* underpinned a critical mechanism for self-tolerance to a wide range of discrete organs, the *AIRE* gene and protein provided few clues to its mechanism of action: it contained motifs that suggested a role in transcription regulation,[179,180] it was mostly expressed in the thymus and not in the organs that were affected by autoimmunity,[180] and in the thymus the protein was primarily expressed in medullary thymic epithelial cells where it was concentrated in nuclear dots.[184]

Aire-deficient mice were generated and were also found to develop spontaneous organ-specific autoimmune diseases, albeit not an identical spectrum to humans.[185,186] No overt abnormalities in T-cell development or T-cell subsets were apparent in *Aire*-knockout mice. Consistent with the predominant Aire expression in medullary thymic epithelial cells,

transplantation studies established that spontaneous autoimmunity resulted even when AIRE was only absent from thymic epithelium and not when it was absent from lymphoid cells.[186] The key turning point connecting Hanahan's peripheral antigen-expressing cells with the human autoimmune disease came when *Aire*-deficient mice were analyzed for expression of organ-specific genes in the thymus[186] and for thymic negative selection of organ-specific T cells,[187] which revealed these processes were selectively and severely disrupted. AIRE has been shown to be an unusual transcription factor that promotes ectopic expression of a variety of organ-specific genes in thymic medullary epithelial cells by relieving the tendency for ribonucleic acid polymerase to stall shortly after the transcription start site.[188]

These studies supported the idea that human APS-1 results from failure of thymic negative selection to organ-specific genes and the development of a T-cell repertoire that is poised to develop organ-specific autoimmunity. To further test this hypothesis, Anderson's group identified an autoantigen that was specifically expressed in the retina of the eye, interphotoreceptor retinoid-binding protein (IRBP), as a target of autoantibodies in AIRE-deficient mice that had developed autoimmune uveitis.[189] By crossing *Aire*-/- mice with IRBP gene knockout mice, they showed that IRBP expression in the eye was essential for spontaneous development of autoimmune eye disease in *Aire*-/- mice but not for other organ-specific autoimmune diseases in the same animals. IRBP messenger ribonucleic acid (mRNA) expression in the thymus was abolished in AIRE-deficient mice, and selective deficiency of IRBP in thymic stromal cells was sufficient to recapitulate the eye specific autoimmunity that occurs in AIRE-deficient mice.[189] With a similar rationale, Trucco's group generated mice where insulin was deleted from thymic epithelial cells while maintaining expression in the pancreas.[190] Importantly, diabetes spontaneously developed in 3-week-old animals. Anderson's group has gone on to identify other genes that are regulated by AIRE, that are also targets of autoimmunity in mice and humans.[191]

An important question concerns the possibility that organ-specific autoimmunity caused by AIRE deficiency might reflect failure to induce organ-specific T_{reg} cells, as opposed to the failure to delete organ-specific helper and cytotoxic T cells. Anderson et al.[192] addressed this question definitively by performing elegant double-thymus transplant experiments in *nude* mice, which lack normal thymic epithelium. When the mice were engrafted with one *Aire*-deficient thymus and one *Aire*-sufficient thymus, half of the circulating T-cell repertoire would have been selected in the thymus that lacked expression of organ-specific genes, while the other half was formed in the thymus that expressed organ-specific genes. If a deficiency of organ-specific T_{regs} was responsible for the organ-specific autoimmunity in *Aire*-deficient mice, this would have been complemented by the production of organ-specific T_{reg}s from the wild-type thymus in the doubly transplanted mice. By contrast, the wild-type thymus would have no impact if autoimmunity resulted from self-reactive effector T cells that escaped deletion in the *Aire*-deficient thymus. Consistent with the latter, autoimmunity developed with the same organ-specific pattern in the doubly transplanted mice. The same conclusion was reached when equal mixtures of T cells from *Aire*-deficient and wild-type mice were cotransferred into immunodeficient Rag1-knockout mice.[192] Further evidence that AIRE mediates self-tolerance through mechanisms that do not involve T_{reg} formation comes from comparing Foxp3-deficient mice with normal AIRE or lacking AIRE, because the latter have markedly accelerated autoimmunity.[193] Likewise, analysis of mice with a T-cell repertoire constrained to junctional diversity between a single TCR Vα and Jα found that the great majority of T_{reg}-specific TCRs were selected independently of AIRE.[194]

Collectively, these studies demonstrate that thymic clonal deletion is an important mechanism for actively acquired self-tolerance in man and mouse. This conclusion is reinforced by the finding that human susceptibility to type 1 diabetes correlates with genetic variants in the insulin promoter that selectively diminish insulin gene expression in the thymus.[195,196] Similarly, a genetic variant in the promoter of the *CHRNA* gene that diminishes its transcription in the thymus contributes to susceptibility to forming autoantibodies against the acetylcholine receptor chain encoded by this gene and development of myasthenia gravis.[197]

PERIPHERAL T-CELL TOLERANCE

Powerful mechanisms exist to regulate mature T-cell responses against self-antigens after they have emigrated from the thymus: a process known as peripheral tolerance. One line of evidence for this conclusion comes from an experiment of nature: most organs and antigens remain unaffected by autoimmunity in *AIRE*-deficient humans and mice despite the failure of thymic tolerance to antigens in almost every tissue. Experimental evidence supporting this conclusion traces back to the demonstration that adult

mice could be rendered tolerant to adjuvant-free, deaggregated gammaglobulin from other species,[6,33,34] and this tolerant state would persist for months provided the animals had

been thymectomized to prevent generation of fresh T cells.[198] However, unlike in the thymus, where the engagement of strong TCR-pMHC interactions leads to clonal deletion or anergy, strong pMHC signals in mature T cells normally leads to the development of an effective immune response. Therefore, with mature T cells we are left with the puzzle of how a strong TCR interaction results in tolerance versus activation. Solving this puzzle holds the most practical potential for overcoming the major clinical problems of transplant rejection and tumor immunology and for restoring tolerance in people with autoimmunity or allergy.

As summarized in the section "History" at the start of this chapter, early work began to lay out two-signal concepts for tolerance or immunity by demonstrating that bacterial LPS, adjuvants, or protein aggregation were required together with antigen for inducing immunity and not tolerance in animal models, although the adjuvant effect was not viewed as a specific sensing pathway.[6,40,199] In the early 1970s, Gery and Waksman discovered that LPS-stimulated macrophages produced a soluble activity that augmented T-cell proliferation, dubbed "lymphocyte activating factor."[200] "Monokines" with other names such as leukocyte pyrogen[201] and mitogenic protein[202] were subsequently observed to have similar T-cell-augmenting activity and shown to represent the same small protein, renamed IL-1.[203] Independently, experiments inducing tolerance to allografts led Lafferty to conclude that T cells need to receive not only an antigen stimulus but also a specific "costimulus" from a dedicated antigen-presenting leukocyte for induction of immunity and not tolerance.[41,204] It nevertheless became apparent that a cell-bound T-cell costimulator that was not IL-1 also existed,[205,206] leading to the discovery of the T-cell costimulatory receptor, CD28, and its membrane bound ligands CD80/B7-1 and CD86/B7-2.[12,207,208,209,210]

The study of T-cell costimulation by IL-1 languished after the discovery of CD28 and its ligands, and only recently has IL-1 been demonstrated to serve as a powerful additional signal that is necessary—in conjunction with CD80 and CD86—for survival and accumulation of large numbers of daughter cells when CD4 T cells are triggered into division by antigen in vivo.[211] IL-12 and interferon alpha and beta, made by antigen-presenting cells in response to bacteria and viruses, similarly provide critical signals for CD8 cells that have received TCR and CD28 stimulation, promoting the survival and accumulation of progeny over successive cell divisions and their acquisition of cytolytic effector functions including interferon gamma and granzyme B expression.[212,213,214,215,216,217,218,219,220] Interferon alpha and beta have also been shown to promote survival of activated CD4 cells.[221]

Much of the early work on T-cell costimulators focused on macrophages as a principal source,[206] but parallel studies by Steinman led to the recognition that another myeloid cell, the dendritic cell (DC), was the key antigen-presenting cell required to induce CD4 and CD8 immunity.[222,223] Furthermore, if the DC had not been stimulated by adjuvants to "mature," then antigens encountered on the "immature" DC induced T-cell tolerance, while antigens encountered on mature DCs induced immunity.[224,225,226] DC maturation was shown to be triggered by pathogen-derived signals, such as TLR signals, and that maturation included the upregulation of a variety of key costimulatory molecules on the DC, including CD80/B7-1 and CD86/B7-2 ligands for CD28,[12,207,208,209,210] as well as the production of IL-1, IL-12, or other cytokines. The theory governing peripheral T-cell tolerance versus immunity in its simplest form often reports signal 1 as the TCR-derived antigen-specific signal, and signal 2 that stems from interactions with mature DCs has been typically thought of as CD28/B7 interactions. However, it is clear that multiple receptor ligand interactions as well as cytokine signals are critical to promote T cell-mediated immunity.

In this section, we will introduce the basic mechanisms of peripheral T-cell tolerance, which include clonal deletion and anergy. Tolerance is also maintained by two other mechanisms. One is known as T-cell ignorance, which is the inability of the T cells to detect sequestered self-antigens. In addition, potentially autoreactive cell function is held in check by T_{reg} cells that arise either in the thymus or may also be induced from the mature CD4 T cell population. It is also clear that CD8 T_{reg} cells exist; however, much less work has been done with this population.

Evidence for T Cell Anergy

The first direct evidence for T-cell clonal anergy came from tissue culture experiments with human T-cell clones that recognized specific influenza virus peptides and MHC II molecules.[227] When these T cells were cultured for more than 3 hours (optimally 18 hours) with high concentrations of the relevant peptide in the absence of stimulatory antigen-presenting cells (an unfractionated mixture that included monocytes, DCs, and B cells), the T cells became profoundly refractory to restimulation of proliferation with antigen presented by stimulatory antigen-presenting cells yet retained a normal proliferative response to IL-2. This selective tolerance to antigen persisted despite culturing the anergic T cells for more than 168 hours in the presence of IL-2. Human T-cell clones express MHC II molecules, so that in the presence of high concentrations of peptide the T cells could present p/MHC II complexes

to each other[228] in such a way that a high proportion of surface CD3 molecules were initially modulated from the cell surface.[229] Whether the long-term unresponsive cells regained normal CD3 expression was not examined in this study.

The concept of T cell anergy resulting from antigen recognition in the absence of a specific costimulatory signal from specialized antigen-presenting cells was extended in experiments where cloned mouse T cells were cultured with the relevant peptide antigen presented on chemically fixed antigen-presenting cells[230,231] or on synthetic lipid bilayers containing only MHC II molecules.[232] Like the human T-cell clones, this also resulted in a persistent state of antigen tolerance that blocked the proliferation response of T cells when subsequently exposed to antigen on unfixed antigen-presenting cells, yet left untouched the proliferative response to IL-2.

This antigen-tolerant state, dubbed T cell clonal anergy by Schwartz and coworkers, was not accompanied by long-lasting downregulation of surface CD3 and TCR. The missing costimulatory signal from the antigen-presenting cells could not be replaced by exogenous IL-1 or IL-2,[232,233,234] but was later shown could be replaced by stimulatory antibodies against CD28.[235] The tolerance-inducing signal from antigen on fixed antigen-presenting cells could be mimicked by selectively elevating intracellular calcium and required calcium-activation of calcineurin and induction of protein synthesis,[233,234] leading to the concept that TCR-induced activation of calcium, calcineurin, and the transcription factor NFAT induced the expression of a lasting tolerance program in mature T cells if it was not accompanied by costimulatory signals.[205,236]

To extend these tissue culture experiments to a more physiologic milieu, an essential requirement for studying peripheral T-cell tolerance was the ability to follow a T cell with a defined TCR specificity in vivo. Early studies using monoclonal antibodies specific for Vβ regions allowed one to evaluate peripheral T-cell tolerance induction to superantigens such as Mls-1^a and others. Pioneering studies performed by Rammensee et al. provided evidence for the induction of T-cell anergy in vivo. Mls-1^a cells were given to $Mls\text{-}1_b$ mice and by following Vβ6+ Mls-1^a-specific T cells, it was shown that the remaining Vβ6+ T cells were unresponsive to the $Mls\text{-}1_a$ antigen.[237] A multitude of studies using superantigens or conventional antigens supported these findings that mature T cells could be present in a functionally tolerant state after encountering a tolerogenic antigen in vivo.[212,213,214,215,238,239,240,241,242,243,244,245,246,247,248,249,250,251,252,253,254,255,256,257,258,259,260,261,262,263,264,265,266,267,268] Examples of these studies are summarized in Table 32.1.

Tolerance by Anergy, Abortive Proliferation, and Clonal Deletion of Peripheral T Cells

Almost all the in vivo examples of peripherally induced T-cell clonal anergy cited previously are embedded in a more dynamic process that includes T-cell division, death, and differentiation. A large body of evidence, examples of which are summarized in Table 32.1, demonstrates that TCR stimulation of mature T cells without CD28 or microbial adjuvant costimulation in vivo does not immediately induce anergy but frequently induces several rounds of cell division. Tolerance nevertheless follows because the burst of T-cell proliferation is aborted by apoptosis, and because the daughter cells fail to differentiate into fully fledged helper or cytotoxic effector cells.

Peripheral Tolerance to Exogenous Superantigens

In a pivotal set of studies analyzing peripheral T-cell tolerance in vivo, mice were thymectomized to prevent new T-cell production and then infused with Mls-1^a+ spleen cells. Vβ6+ Mls-1^a reactive T cells proliferated in response to the antigen, but subsequently were eliminated from the T-cell repertoire presumably by exhaustive differentiation into short-lived effector cells[269] —a fate analogous to an original two-signal model for acquisition of tolerance articulated by Talmage nearly three decades earlier.[7]

These findings of abortive proliferation were reinforced and extended by analyses of tolerance in mice that had been injected with a bacterial superantigen, SEB.[242,243,244,245,246,247,248,249] SEB engages TCRs bearing the Vβ8 element. Twenty-four hours after SEB injection into BALB/c mice, flow cytometric analysis of deoxyribonucleic acid (DNA) content in Vβ8+ CD4 T cells revealed that 30% were in S, G2, or M phase of cell cycle.[245] The same fraction were induced into cell division in CD28-knockout mice, establishing that CD28 costimulation is unnecessary to initiate T-cell proliferation at least in the context of an unconventionally potent superantigen stimulus.[249] CD28 deficiency, nevertheless, had a large effect: it prevented normal levels of CD25 from being induced and caused a rapid drop in the fraction of dividing Vβ8+ CD4 T cells and in their accumulation 48 hours and 72 hours after SEB injection. This effect of CD28 in

promoting the survival of dividing daughter cells can at least partly be explained through induction of the prosurvival protein, Bcl-X_L.[270]

Despite evidence for CD28 costimulation during acquisition of tolerance to SEB, when carboxyfluorescein diacetate succinimidyl ester (CFSE)-labeled Vβ8+ CD4 cells were tracked, the fraction that had divided peaked on day 3 and remained steady on day 4, with most of the cells dividing only three to five times and many displaying the apoptosis marker, annexin V, after their fourth or fifth division.[248] Continuous labeling with BrdU from the time of SEB injection revealed that almost all of the Vβ8+ CD4 T cells that were induced to divide had disappeared by 14 days.[246] Approximately 45% of Vβ8+ CD4 T cells never entered division, despite almost all responding by CD69 induction, and it was these “nondividers” that persisted at later times in an anergic state characterized by diminished proliferation or IL-2 production to restimulation with SEB in vitro. It is conceivable that the “nondividers” to SEB either received a weaker TCR stimulus by chance, by the nature of the antigen-presenting cell they encountered, or because of their particular TCRβ junction sequence or TCRα chain sequence.

Deletion of most of the divided T cells between days 4 and 7 during the response to SEB appears to reflect combined actions of the intrinsic (*Bcl2*-regulated) and extrinsic (*Fas*- or *Tnfr1* -regulated) pathways for apoptosis. Thus, several studies found the decrease in Vβ8+ CD4 T cells was either slower or less marked in mice homozygous for the Fas^{lpr} mutation.[247,271,272] Hildeman et al.,[273] however, found deletion was unaffected in mice with defective Fas-ligand or with a triple deficiency of *Fas*, *Tnfr1*, and *Tnfr2* but was inhibited in *Bcl2*-transgenic mice or in mice lacking Bim, the proapoptotic inhibitor of Bcl-2. Strasser et al.[274] found that complete blockade of peripheral deletion occurred only when both pathways were blocked in $Fas^{lpr/lpr}$ *Bcl2*-transgenic mice, resulting in a dramatic increase in Vβ8+ CD4 T cells 7 days after SEB treatment.

Peripheral Tolerance to Exogenous Peptide Antigens in T-Cell Receptor-Transgenic Mice

Abortive T-cell proliferation and anergy in response to conventional protein antigens has been demonstrated by tracking CD8 or CD4 cells with defined TCR specificities in TCR-transgenic mice (see Table 32.1). One of the first of

these studies was by Kyburz et al.,[254] who compared the fate of TCR-transgenic CD8 cells recognizing a dominant peptide from LCMV presented by the MHC class I molecule, $H2D^b$, after injecting thymectomized TCR-transgenic mice with LCMV peptide in incomplete Freund's adjuvant (which provides no microbial costimulus but creates a reservoir of peptide). The specific CD8 T cells became large, increased in number, and developed cytotoxic T-lymphocyte (CTL) activity transiently, peaking on day 2 when many appeared apoptotic, with a rapid loss of blast cells and ex vivo CTL activity by day 3 and a drop in overall numbers below starting levels on day 5 and decreasing further on days 10 and 20. This abortive activation was independent of CD28, although CD28 deficiency made the response even more transient.[256] The cells present after day 2 appeared functionally tolerant, as they could not be induced to proliferate or form CTLs in vitro from this time onwards, even when their subsequent deletion was abolished by transgenic expression of either Bcl-2 or Bcl-X_L.[255] Deletion of the activated T cells in this model thus resulted from activation of the intrinsic pathway of apoptosis, implying that the peptide-activated T-cell blasts received insufficient external signals for cell growth and metabolism, whereas the extrinsic apoptosis pathways triggered by Fas or TNFR1 had no measurable role.[257,275]

TABLE 32.1 Examples of Experimental Studies Demonstrating Abortive Proliferation, With or Without Anergy, Induced in Mature T Cells by Tolerogenic Antigens in Vivo

Tolerizing Antigen	TCR Population Followed in Vivo	Evidence of Abortive Proliferation	Evidence of Functionally Tolerant Cells	Pathways Involved	Citation
Exogenous Mls-a spleen cells	Vb6+ CD4 cells in thymectomized mice	Increased frequency day 4, 30% of starting	Poor thymidine incorporation		269

		frequency by day 22			
Exogenous SEB	Vb8+ CD4 cells in Balb/c mice	Increased frequency day 4, 75% of starting frequency by day 7	Poor thymidine incorporation and IL-2 on day 7		242,243
Exogenous SEB	Vb8+ CD4 cells in Balb/c or C57BL/6 mice	Increased DNA content day 1, increased frequency day 4, CFSE dilution, BrDU incorporation, frequency below starting by day 7, many CFSE low cells divided four to five times are Annexin V+ day, many subdiploid DNA content day 7	Poor thymidine incorporation and IL-2 protein and mRNA for IL-2, IL-3, IFNg starting day 3	Deletion partly inhibited by Fas-lpr	244,245,246,247,248
Exogenous SEB	Vb8+ CD4 cells in Balb/c mice	Increased DNA content: 30% in cycle day 1 regardless of CD28-/-, sustained day 2 and increased frequency day 4 in CD28+/+ but aborted by day 2 in CD28-/- and frequencies dropped, decline in frequency of CD28-/- on day 3 and 4	Poor thymidine incorporation	CD28-/- diminished survival and sustained division	249
Exogenous SEB	Vb8+ CD4 cells in C3H/HeJ mice	Decreased numbers in wild-type controls on day 7		Deletion fully inhibited in Fas-lpr + Bcl2-transgenic mice resulting in 300% increased numbers day 7. Partial effect of single mutants.	274
Exogenous SEB	Vb8+ CD4 cells in MRL mice	Decline in frequency days 4 to 6		Deletion partly inhibited by Fas-lpr	272

Exogenous SEB	Vb8+ CD4 cells in MRL mice	Decline in frequency days 7 to 14		Deletion partly inhibited by Fas-lpr	271
Exogenous SEB	Vb8+ CD4 cells in C57BL/6 mice	Decline in frequency days 7 to 15		Deletion blocked in Bim-/- and Bcl2-transgenic mice, but not in B6-gld or B6-lpr/lpr Tnfr1-/- Tnfr2-/- mice	273
Exogenous SEB	Vb8+ CD4 cells in C57BL/10 or 129/Sv mice	Increased death of cells isolated 2 days after SEB and placed in culture		In vitro apoptosis suppressed by IFN alpha or beta	221
Exogenous SEA	Vb3+ CD4 cells in Balb/c mice	Increased frequency relative to starting on day 4, decline in frequency relative to day 4 on days 5 to 7		Deletion prevented by LPS independently of CD80-86 blockade but partly reversed by TNFa blockade	280
Exogenous cytochrome c peptide in PBS (I-Ek)	2B4 TCR-Tg CD4 cells in TCR-transgenic mice	Increased numbers 200% to 300% of starting in MRL-lpr/lpr day 7; decreased numbers 30% of starting in MRL+/+ controls day 7		Deletion blocked by Fas-lpr mutation	137
Exogenous OVA peptide in PBS IV (I-Ed)	DO11.10 TCR-Tg CD4 cells transferred to Balb/c	DNA content, BrdU incorporation, and increased numbers days 2 to 3, numbers dropped by day 5 and below untreated controls by day 17	Poor proliferation in vitro or after rechallenge in vivo with peptide/CFA or peptide/IFA; failure to form follicular T cells in vivo, lower surface TCR, diminished IL-2 mRNA, and protein	Complete Freund adjuvant sustains numbers day 5, requiring CD28: reversed by CD80 and CD86 blockade and enhanced by CTLA4 blockade	250,251,252
Exogenous OVA in PBS SC (I-Ed)	DO11.10 TCR-Tg CD4 cells transferred to Balb/c	Increased numbers peaking day 3, declining days 5 to 12, LPS enhanced numbers at all times and		CD28-/- diminished IL-2 production and the increase in numbers day 3, and abolished the effect of LPS. Accumulation of	281

		increased IL2 production per cell 8 to 12 hours after OVA		T cells not decreased by IL-2 deficiency but enhanced.	
Exogenous OVA in IFA SC	DO11.10 TCR-Tg CD4 cells transferred to Balb/c	CFSE dilution on day 3, number of cells day 6		CD80 and CD86 blockade diminished induction of CD25, fraction dividing, and number of divisions, but had little effect on IL-2 production as a function of cell division. BclXL transgene prevented the diminution of cell numbers by CTLA4-Ig on day 6.	282,283
Exogenous OVA or cytochrome c in PBS IV (I-Ad, I-Ek)	OT-II or 5CC7 TCR-Tg CD4 cells transferred to B6 or B10.A	CFSE dilution on day 7 but low accumulation of divided cells		Concurrent IL-1a or IL-1b increased accumulation of divided cells massively, 10- to 50-fold more than LPS alone. Blocked cell autonomously by IL1R deficiency in half the OT-II cells.	211
Endogenous or exogenous lysozyme presented by anergic or activated B cells or via other APCs (I-Ak)	3A9 TCR-Tg CD4 cells transferred to B10. Br mice	Induction of CD69 and in vivo B cell killing via Fas, CFSE dilution, peak numbers of divided cells day 3 declined by day 5		Activation and CD86 induction on B cells did not affect proliferation or loss of divided cells on day 5, whereas lysozyme in CFA promoted large accumulation of divided cells	284
Exogenous lysozyme peptide coupled to anti-DEC205 antibody (I-Ak)	3A9 TCR-Tg CD4 cells transferred to B10. Br mice	Increased numbers of CFSE diluted cells on day 3, decline in numbers of divided CFSE-low cells by days 7 and 20		Agonistic antibody to CD40 prevents deletion of CFSE low cells on day 7	226
Exogenous LCMV peptide in IFA (Db)	P14 TCR-Tg CD8 cells in thymectomized TCR-transgenic mice	Transient cell enlargement, increased numbers, ex vivo CTL activity days	Loss of in vitro proliferation and CTL activity from day 2, loss of CD69 induction	Deletion blocked by Bcl2 and BclX transgenes but not by Fas&TNFR1 double	254,255,256,257

		1 and 2 with peptide, most with subdiploid DNA content day 2 after peptide, decrease frequency relative to starting by day 5 completely blocked by Bcl2 or BclXl transgenes. Slower but sustained and greater increase after LCMV infection.	after in vivo peptide rechallenge, inability to control subsequent challenge with LCMV	deficiency. Persisting cells anergic. Initial proliferation unaffected by CD28-/- but unable to sustain ex vivo CTL activity unless peptide administered every 12 hours.	
Exogenous OVA peptide in PBS IV (Kb)	OT-1 TCR-Tg CD8 cells transferred to C57BL/6	CFSE dilution on day 2 or 3 but little accumulation of divided cells with lower peptide dose and no CTL activity unless ive IL-12 or LPS concurrently.	Little increase in numbers and no CTL activity on rechallenge with peptide+LPS day 40, unless given IL-12 initially	IL-12 as “signal 3” for survival of daughter cells and acquisition of effector function. Sustained exposure to antigen, b7 and IL-12 needed for 1 to 2 days. IFN alpha had similar activity in vitro.	212,213,214,215
Exogenous heart graft expressing ovalbumin (Kb and I-Ab)	OT-1 TCR-Tg CD8 cells and OT-II TCR-Tg CD4 cells transferred to C57BL/6	In absence of helper cells, OT-1 CFSE dilution on day 2 or 5 not accompanied by increase in numbers or acquisition of ex vivo or in vivo CTL activity due to low granzyme B and IFN gamma		Helper cells increased OT-1 CD25 induction, numbers accumulating on day 5, and CTL activity, IFN gamma and granzyme B. Helper effect blocked by IL-12Rb-/- in OT-1 cells, or CD40L-/- in OT-II cells, and mimicked by IL-12 treatment.	216
Exogenous influenza peptide in PBS IP (Dd)	F5 TCR-Tg CD8 cells in thymectomized TCRtransgenic mice	Increased frequency and CTL activity day 4, low frequency after 5 weeks of peptide injections		IL2-/- did not block proliferation in vivo days 2 to 4, but prevented acquisition of ex vivo CTL activity	515,516
Exogenous influenza HA peptide in PBS IP (Kd)	Clone 4 TCR-Tg CD8 cells transferred to Balb/c mice	Higher fraction diluting CFSE on day	CD8 cells on day 4 after highdose peptide have	Propose that low, repeated stimulation with antigen triggers	258,259

		4 with high-dose peptide, and more divisions but no CTL activity or IFN gamma expression	poor ERK phosphorylation in response to peptide in vitro	proliferation followed by deletion, whereas high repeated stimulation desensitizes dividing cells and diminishes deletion	
Endogenous H-Y antigen ubiquitously expressed (Db)	T1.70 TCR-Tg CD8 cells transferred to C57BL/6 nude	Increased number day 5, decline in numbers day 9 and 60	Poor proliferation in vitro days 5 onwards, unable to increase frequency upon secondary transfer to fresh male nude mice	Deletion blocked by Bcl2 transgene but not by Fas-lpr mutation	240,253,286
Endogenous H2-Kb from metallothionein or albumin promoters	DES TCR-Tg CD8 cells in TCR-Tg mice or transferred to B10.A	CD69 induction, BrdU incorporation, CFSE dilution, increased numbers peaking 7 days if LN activation, transient hepatitis, and ALT elevation. Almost complete loss of cells by 30 days after transfer, failure to accumulate cells after emigration from thymus in thymus grafted mice	No evidence for anergy: normal CFSE measured in vitro proliferation of Bim-deficient cells from LN of Alb-Kb on day 15	When antigen presented only by hepatocytes induced almost normal initial CFSE dilution on day 2.5, but poor CD25 or ICAM1 induction, high Bim, and Bim-dependent failure to accumulate in large numbers in LNs or acquire CTL activity ex vivo or based on liver ALT	287,288,289,290
Endogenous LCMV gp33 from H2Kb promoter (Db)	P14 TCR-Tg CD8 cells transferred to C57BL/6	CFSE dilution on day 2 but no detectable expansion or CTL activity unless concurrently give LCMV, VSV, *Listeria*, LPS or poly I:C within 1 to 3 days of T-cell transfer	LCMV-expanded cells day 35 had lower surface TCR, could not be stimulated to proliferate or form CTLs in vitro		268
Endogenous OVA from insulin promoter presented by	OT-1 TCR-Tg CD8 cells transferred to C57BL6.H2-bm1 chimeric	CD69 induction, CFSE dilution, diabetes	No. Persistent cells when deletion blocked by Bim or Bcl2	Deletion not blocked by Fas-lpr but completely blocked by Bim-	292,293,294

DCs (Kb)	mice with H2b marrow	induction if antigen also presented directly by beta cells, decline in numbers after 8 weeks or after thymectomy	proliferated normally in vitro.	/- or Bcl2 transgene resulting in accumulation. Deletion also blocked by OT-II helper T cells.	
Endogenous OVA from keratin5 promoter presented by mature Langerhans and DCs (Kb)	OT-1 TCR-Tg CD8 cells transferred to C57BL/6 mice.	CFSE dilution on day 3, decline in numbers after 6 weeks		High CD86 on mature Langerhans and DCs insufficient to prevent deletion	517
Endogenous OVA from keratin14 promoter presented by mature Langerhans cells, or from actin or H2k promoter systemically	OT-1 TCR-Tg CD8 cells transferred to C57BL/6 mice.	CFSE dilution but little accumulation of OT-1 cells in systemic expressors or in K14-OVA × actin-OVA double transgenics. CTL activity acquired and 100- to 1000-fold expansion of OT-1 cells days 4 to 6 in K14-OVA mice or B6 mice infected with OVA-vaccinia virus, declining to very low numbers by day 21	Normal expansion upon in vivo rechallenge with OVA peptide + LPS on day 21 in K14-OVA animals, but suppressed in Actin-OVA recipients	High CD86 (+ signal 3 cytokines?) on mature Langerhans sufficient to promote accumulation and acquisition of CTL activity	260
Endogenous HSV peptide from insulin promoter presented by CD8+ DCs (Kb)	gBT1 TCR-Tg CD8 cells transferred to C57BL/6 mice	CFSE dilution on day 3, elimination by 7 weeks		Same CD8 + DCs induce tolerance and priming of HSV T cells	518
Endogenous influenza HA peptide from insulin promoter (Kd)	Clone 4 TCR-Tg CD8 cells transferred to Balb/c mice	CFSE dilution day 3 in fraction of cells (transgene dose-dependent) but only slight increase in numbers day 4 and no CTL activity	Ten to fourteen days after transfer of low numbers of T cells, influenza infection no longer precipitated diabetes. Divided cells sorted on day 4 and parked in non-transgenic	Bim-deficiency or Bcl2-transgene increased numbers of divided cells day 4, whereas Faslpr or TNFR1-/- did not. Concurrent influenza infection at time of transfer	259, 296,297,298

		or IFN gamma expression, unaffected by CD80 and CD86 blockade. Numbers fell by day 8.	recipient for 4 weeks expand normally following infection.	precipitated diabetes, greatly increased Cl4 number, CD25 and IFN gamma expression and CTL activity day 4, inhibited by CD80 and CD86 blockade.	
Endogenous influenza HA peptide from insulin promoter (Kd and I-Ad)	Clone 4 TCR-Tg CD8 cells plus HNT TCR-Tg CD4 cells transferred to Balb/c mice	CFSE dilution in fraction of CD4 and CD8 cells, no enhancement of CD8 cell division or accumulation or CTL activity by naïve helper cells. In vitro activated CD4 cells increased accumulation of CD8 cells and IFNg and CTL activity, precipitating diabetes.		CD80 and CD86 blockade negated effects of activated CD4 cells. Agonistic antibody to CD40 did not mimic helper cells despite inducing CD86 on DCs unless accompanied by exogenous IL-12 as “signal 3.”	217
Endogenous influenza HA peptide at low levels from H2K promoter in hemopoietic cells (Dd)	F5 TCR-Tg CD8 cells in RAG1-/- TCR-Tg mice	Induction of CD44 and in vivo CTL activity, but normal numbers	Increased CD5, some with lower TCR, poor in vitro proliferation, IL-2 or IFN gamma production but normal CTL activity	Evidence for elimination of antigen-presenting DCs and macrophages	261
Endogenous SV40 T-antigen expressed by insulin promoter (I-Ak)	TCR1 TCR-Tg CD4 cells in TCR-Tg mice	CD69 and CD44 induction in draining lymph nodes, BrdU incorporation in vivo over 12 days, insulitis at 1 to 3 weeks of age. Decline in frequency and numbers 4 to 12 weeks of age, rapid decline after thymectomy.	Poor proliferation to peptide in vitro		262
Endogenous influenza HA peptide from C3(I) systemic promoter at low or high	6.5 TCR-Tg CD4 cells transferred to Balb/c mice	CFSE dilution on day 5, increased numbers on day 9 in HA-	Poor proliferation and IL-2 secretion in vitro		263,264

levels (I-Ed)		high strain but not in HA-low strain			
Endogenous lysozyme from insulin promoter (I-Ak)	3A9 TCR-Tg CD4 cells transferred to MRL+/+ mice	CFSE dilution in ~20% cells in pancreatic node, one to three divisions after 10 days, increased to ~70% by CTLA4-deficiency but no increase in numbers and no diabetes.	Six days after transfer cells have poor proliferation to HELpeptide in vitro	Coadministration of lysozyme in PBS or alum increases CTLA4-/- numbers in pancreatic node sixfold, and precipitates diabetes. Lysozyme in CFA has similar effect for CTLA4+/+ cells.	266,267

ALT, alanine transaminase; APC, antigen-presenting cell; CD, cluster of differentiation; CFA, complete Freund's adjuvant; CFSE, carboxyfluorescein diacetate succinimidyl ester; CTL, cytotoxic T-lymphocyte; DC, dendritic cell; DNA, deoxyribonucleic acid; HA, hemagglutinin; HEL, hen egg lysozyme; HSV, IFA, incomplete Freund's adjuvant; IFN, interferon; IL, interleukin; LCMV, lymphocytic choriomeningitis virus; LN, lymph node; LPS, lipopolysaccharide; MHC, major histocompatibility complex; mRNA, messenger ribonucleic acid; OVA, ovalbumin; PBS, Phosphate Buffered Saline; SEB, staphylococcal enterotoxin B; TCR, T-cell receptor; Tg, transgenic; TNF, tumor necrosis factor; VSV, vesicular stomatitis virus.

Color codes denote studies involving the following: yellow, exogenous superantigens; orange, exogenous conventional protein antigens; purple, endogenous conventional protein antigens; blue, MHC II-restricted CD4 T cells; green, MHC I-restricted CD8 T cells; red, in vivo evidence of functionally tolerant (“anergic”) T cells.

The *Fas*^{lpr} mutation nevertheless interfered with peripheral deletion of CD4 T cells in a parallel study of peripheral tolerance induced by injecting a peptide from cytochrome c without adjuvant into transgenic mice expressing an MHC II-restricted TCR.[137] Similar studies in TCR-transgenic mice expressing an influenza hemagglutinin (HA)-specific MHC II-restricted TCR found that deletion could only be blocked by injecting an antibody to TNFα combined with the *Fas*^{lpr} mutation.[139] Likewise, other studies also indicate a role for Fas in peripheral tolerance in certain settings.[276,277] Thus, like the studies previously mentioned with superantigens, the relative role of the intrinsic and extrinsic pathways for deleting activated T cells in response to conventional peptide antigens may vary depending upon the TCR specificity and/or the duration and strength of TCR stimulation.

Peripheral Tolerance to Exogenous Peptide Antigens in Adoptively Transferred T-Cell Receptor-Transgenic T Cells

The studies previously mentioned analyzed peripheral T-cell tolerance in situ either in TCR-transgenic mice with very high initial frequencies of antigen-specific T cells or in superantigen treated mice where the starting frequency of Vβ8+ CD4 T cells was also very high. A large number of experiments have nevertheless reinforced and extended these results by tracking acquisition of peripheral tolerance in smaller numbers of antigen-specific T cells that have been adoptively transferred from TCR-transgenic mice into wildtype mice with a normal T-cell repertoire (see Table 32.1).

In one of the first studies of this type, Kearney et al.[250] harvested lymph node cells from DO11.10 TCR-transgenic mice, where most of the CD4 T cells expressed a TCR that could be detected by a clonotypic antibody (KJ1-26) and recognized OVA peptide presented by MHC II I-E^{d} molecules. A total of 2.5 million KJ1-26+ CD4+ cells were injected into the circulation of normal BALB/c mice so that the antigen-specific T cells could just be detected by flow cytometry of lymph nodes, at a frequency of 1 cell in 300. The recipients were then challenged with a tolerizing regime comprising OVA peptide given intravenously in saline or intraperitoneally in incomplete Freund's adjuvant so that the antigen was encountered without a bacterial costimulus. For comparison, other recipients were given antigen as an immunizing regime comprising the same amount of peptide given subcutaneously emulsified in complete Freund's adjuvant containing an extract of *Mycobacterium tuberculosis*.

With either regime, a fraction of the T cells were initially induced into S, G2, and M phase of cell cycle, and increased in frequency and absolute number in brachial and axillary lymph node on day 2 and 3. However, the tolerizing treatment caused the T-cell number to peak at

day 3 and drop precipitously by day 5, so that the frequency of antigen-specific CD4 cells fell below untreated control recipients by day 17. By contrast, in response to the immunizing regime the T cells accumulated to higher numbers at day 3 and sustained these numbers at day 5, then falling gradually by day 17 although still very elevated over untreated controls. In the immunized animals, most of the KJ1-26+ T cells were in B-cell follicles on day 5, reflecting what is now known to be differentiation into T-follicular helper cells that are critical for antibody responses,[278,279] whereas they remained outside the follicles in the T-cell zone in the tolerized recipients. On day 17, compared to untreated control recipients, the T cells in the immunized recipients were hyperresponsive to antigen as measured by recall proliferation in vitro, whereas those remaining in the tolerized animals were hyporesponsive as measured by proliferation or IL-2 production even adjusted for their lower frequency. The latter anergic T cells had diminished surface TCR expression, yet had been induced to proliferate initially based on labeling with BrdU during the tolerizing regime.[252] Profound hyporesponsiveness of the latter was also observed in vivo, upon immunization of the tolerized mice with peptide in complete Freund's adjuvant. Thus, peripheral tolerance to a foreign peptide reflected abortive proliferation of CD4 T cells, failure to differentiate into fully fledged helper cells, and deletion of most of the activated T cells and anergy in the residuum.

Further studies in the DO11.10 adoptive transfer model analyzed the effect of adjuvant and role of CD28 costimulation in the decision between peripheral tolerance and immunization. The effect of complete Freund's adjuvant in increasing the numbers of OVA-specific T cells that accumulated and their persistence was reversed by blocking CD80 and CD86 with monoclonal antibodies or a CTLA4-Ig fusion protein, whereas neutralizing the competing receptor for CD28 ligands, CTLA-4, further enhanced T-cell accumulation.[251] These results are consistent with at least one of the effects of bacterial adjuvant being the induction of CD80 and CD86 to higher levels on DCs, although they contrast with studies of the response to bacterial superantigen where CTLA4-Ig treatment did not block the ability of LPS to sustain the numbers of activated CD4 cells, and instead the bacterially induced cytokine tumor necrosis factor-α had a partial role.[280] More recent studies using adoptive transfer

of TCR-transgenic, OT-I, CD8 or OT-II, CD4 cells bearing other OVA-specific TCRs have demonstrated that two other bacterially induced cytokines, IL-12 and IL-1, have a direct impact on the induction of T-cell proliferation and effector function, in addition to induction of CD28 ligands.[211,212,213,214,215,216]

Along similar lines, peripheral tolerance induced by peptide without adjuvant could not be explained simply by absence of a CD28 costimulus, because when CD28-deficient DO11.10 T cells were adoptively transferred and the recipients treated with the tolerizing regime, the specific T cells exhibited an even more truncated proliferative response.[281] By adoptively transferring CFSE-labeled DO11.10-transgenic Rag1-/- T cells and treating the recipients with the tolerizing peptide regime, Turka and colleagues[282] showed that blocking CD80 and CD86 with CTLA4-Ig had no effect on the percentage of specific T cells induced by the peptide to express CD69, diminished the fraction of T cells that were induced into division on day 3 by only 30%, and had little effect on induction of IL-2 in these cells provided it was measured as a function of cell division. Like CD28 deficiency,[281] CTLA4-Ig treatment nevertheless greatly decreased the number of accumulating daughter cells that had made multiple divisions, and this effect was blocked by transgenic expression of Bcl-X_L.[283] Thus, peripheral tolerance in this setting involves receipt of a limiting CD28 costimulus that sustains the survival of divided progeny through several divisions but is insufficient to sustain them after more than four divisions and for more than a few days. This abortion of proliferation after several cell divisions parallels the results from analyzing peripheral tolerance to SEB.[248]

Complementary studies using a similar adoptive transfer design with other T-cell specificities reinforce this conclusion (see Table 32.1). For example, when CFSE-labeled CD4 cells bearing a lysozyme-specific TCR were adoptively transferred from TCR-transgenic mice into normal B10.BR mice, they underwent abortive proliferation for several divisions but most of the divided progeny disappeared by day 5, even when the lysozyme peptide was presented by activated B cells bearing high levels of CD86[284] or by DCs.[226]

These studies collectively demonstrate that when T cells encounter exogenous antigen in the absence of microbial or adjuvant costimuli, various stages of T-cell induction occur but the response is limited or truncated, leading to the outcome of tolerance. Although CD28 ligands play an important role as costimulators favoring T-cell immunity over tolerance, they are not necessarily sufficient on their own nor are they the only costimuli that favor immunity. Accordingly, the presence or absence of a CD28 signal is not the sole determining factor for whether or not T-cell tolerance is induced.

Peripheral Tolerance to Endogenous Peptide Antigens

These studies have the caveat that they studied acquisition of tolerance in animals exposed

to an exogenous, foreign antigen. Parallel studies nevertheless reinforce these conclusions by analyzing specific T cells during acquisition of tolerance to antigens that are made endogenously by the animal, either as natural self-antigens or in most cases "neo-self-antigens" encoded by transgenes that are present in the test animals but absent from controls and from the TCR-transgenic donor mouse (see Table 32.1). In this way self-antigens could be chosen where the peptide that was presented in a certain MHC type was known and where it was possible to follow the fate of initially naïve peripheral T cells specific for a particular endogenous antigen in vivo. Although TCR-transgenic models have their own caveats,[285] in general this was a tremendous step forward as researchers could now ask the question what happens to self-reactive T cells in mice expressing an "endogenous" self-antigen, as opposed to studying what happens when a foreign antigen is administered to mice in a tolerogenic way.

Rocha and von Boehmer[240,253] were among the first to follow this approach to peripheral T-cell tolerance, taking advantage of a natural self-antigen, HY, that is present in males but absent in females because it is encoded by the *Smcy* gene on the Y chromosome. They harvested HY+D^b-specific CD8 T cells from the spleen of female T1.70 TCR-transgenic mice, where they had matured without any exposure to HY antigen. These were injected into male mice, where they would encounter HY expressed ubiquitously, or into female controls that lacked HY. To facilitate tracking of the transferred T cells, nude mice that lack T cells were used as the recipients. The T-cell lymphopenia in these recipients also introduces a complication, however, because it profoundly alters signals for T-cell proliferation and survival. Nevertheless, the numbers of T1.70 TCR+ CD8 cells remained steady in female recipients but in the male recipients these dramatically increased by day 5 and then declined to half this number by day 9 and 25% of the peak number by day 60. On day 5, and especially days 9 and 20, both CD8 and TCR were decreased on the surface of the cells in male recipients, and the day 9 and day 20 T cells were completely unresponsive to restimulation with male antigen presenting cells in vitro. Secondary transfers to male or female recipients showed that maintenance of the unresponsive state required continued exposure to HY antigen. The authors concluded that peripheral T cells become tolerant through a sequence of activation, proliferation, anergy, and death. Subsequent analysis showed that the deletion of activated HY-specific T cells in these experiments was blocked if they expressed a *Bcl2* transgene but was unaffected by the Fas^{lpr} mutation, indicating it was due primarily to the intrinsic pathway of apoptosis.[286]

Bertolino and Miller[287] were among the first to extend these studies to trace peripheral T-cell tolerance to endogenous antigens after adoptive transfer of TCR-transgenic T cells into animals with a "full" complement of otherwise normal T cells. These studies tracked CD8 T cells bearing the DES TCR, which could be detected with a clonotypic antibody and recognized $H2K^b$ with an unknown self-peptide. While $H2K^b$ is normally expressed ubiquitously and would induce thymic deletion of DES TCR+ cells, to study peripheral tolerance they engineered B10.BR mice expressing $H2K^b$ as a transgene controlled by the metallothionein (MT) promoter, which is predominantly expressed in liver hepatocytes although also at low levels in other cells in thymus and lymph nodes. Two complementary approaches were followed to ensure that they studied only peripheral T-cell tolerance. First, they surgically removed

the *MT-*K^b transgenic thymus and replaced it with a nontransgenic thymus and traced the development of DES TCRtransgenic cells as they emigrated from the thymus and encountered self-peptide+K^b in the liver and lymph nodes. Second, they adoptively transferred naïve T cells from DES TCR-transgenic mice into *MT-*K^b transgenic B10.BR mice. These experiments revealed that the specific CD8 cells were stimulated to proliferate and accumulate transiently in the liver, resulting in hepatitis and release of the liver enzyme ALT into the circulation that was self-resolving and followed by apoptosis and deletion of the T cells in the liver and other tissues, establishing a state of tolerance.

Subsequent studies using this model[288,289,290] revealed that the tempo and transient phase of tissue damage preceding peripheral tolerance were dramatically affected by whether the CD8 T cells had encountered endogenous antigen on hepatocytes or on DCs. When they only encountered selfpeptide plus K^b on hepatocytes, proliferation of DES TCR+ CD8 cells was aborted quickly after a number of cell divisions and between days 2.5 and 6 as a result of Bim-dependent apoptosis, without acquisition of CTL activity or induction of liver damage. The divided CD8 cells were rescued from deletion by Bim-deficiency, but these did not acquire CTL activity or induce liver damage yet also did not appear to have become anergic as they could be stimulated to divide in response to K^b in vitro. By contrast, when transferred DES TCR+ cells also encountered self-peptide plus K^b on hemopoietic cells in lymph nodes (presumably DCs), this induced 100-fold greater accumulation of divided progeny and acquisition of CTL activity and hepatic damage, although that response was also ultimately self-limiting presumably due to exhaustive differentiation. The efficient

induction of peripheral tolerance by hepatocytes compared to other cells potentially explains how cotransplantation of liver with other organs improves acceptance of allografts.

Abortive proliferation as a mechanism for peripheral T-cell tolerance to tissue-specific endogenous antigens has been elegantly analyzed by Heath's group.[291,292] The rat insulin promoter (RIP) was used to express membrane bound OVA in the β-islet cells of the pancreas in C57BL/6 mice. Kurts et al. harvested naïve CD8 T cells from lymph nodes of TCR-transgenic mice bearing the OT-ITCR against an OVA peptide and $H2K^b$, labeled the cells with CFSE, and adoptively transferred them into *RIP-mOVA* transgenic recipients and nontransgenic controls. They made the surprising discovery that when mature OT-1 CD8 T cells reached the draining nodes of the pancreas, they encountered antigen that had been captured from pancreatic beta cells and cross-presented by cells that were later shown to be immature DCs. Cross-presentation by immature DCs did not cause anergy at any point but instead activated the OT-1 cells into more than eight rounds of cell division during the first 3 days, accompanied in this case by acquisition of cytotoxic function that destroyed the pancreatic islet beta cells within 9 days if 5 million OT-1 CD8 cells were transferred. If islet cell destruction was avoided by analyzing chimeric mice where a different $H2K^{bm1}$ molecule was expressed on the pancreatic islets, so that OVA could only be presented by DCs and not by the islet beta cells, proliferation of OT-1 cells was followed 8 weeks later by the loss of most of the T cells, demonstrating peripheral T-cell deletion as a mechanism of T-cell tolerance. Deletion of the activated OT-1 cells was blocked by a *Bcl2* transgene or Bim deficiency but unaffected by the Fas^{lpr} mutation,[293] implying that insufficient survival signals or cytokines or acute cytokine withdrawal was the cause of peripheral tolerance in this setting.

Like the DES-TCR into MT-K^b experiments where lymph node cells presented the self-antigen,[288,289,290] abortive proliferation was extensive in the transferred OT-1 cells and was accompanied by CTL activity, yet a key finding here was that this was only sufficient to cause diabetes if a very large bolus of CD8 cells was introduced synchronously into the animals. If 250,000 OT-1 cells were transferred instead of 5 million, their abortive activation was insufficient to cause diabetes. Physiologically, T cells that escape thymic deletion or anergy will emigrate to the periphery asynchronously in much lower steady-state frequencies, so that their transient proliferation and acquisition of effector activity before deletion may not create any measurable tissue dysfunction. In this regard, a key extension of the RIP-mOVA model was to cotransfer several million naïve CD4 T cells expressing the OT-II TCR, which recognized another OVA peptide presented by $I\text{-}A^b$. While the CD4 cells did not cause diabetes, nor did they appear to increase OT-I cell division, they nevertheless prevented deletion of the activated OT-1 cells and allowed 250,000 transferred OT-I cells to be sufficient to precipitate diabetes.[294] The decision between peripheral tolerance and immunity in this setting corresponds closely to Cohn's idea[39] that immunity requires coincident recognition of two epitopes on an antigen, one by a helper T cell and one—in this case—by a cytotoxic T cell.

Precisely how helper T cells protected cytotoxic T cells from peripheral deletion remains to be fully elucidated, as it could not be mimicked in the OT-1 RIP-OVA experiments simply by activating or “licensing” the DCs using an injection of agonistic antibody to CD40.[295] Parallel findings were also made in another TCR-transgenic adoptive transfer model developed by Sherman's group,[217,259,296,297,298] tracking CD8 T cells bearing the Clone 4 TCR that recognizes an influenza HA peptide presented by $H2K^d$. The Clone 4 T cells were transferred into normal BALB/c mice expressing a transgene encoding HA under the insulin promoter (InsHA transgenic mice), either alone or together with CD4 cells from another TCR-transgenic strain expressing the HNT TCR against an IA^d-presented HA peptide. In the absence of helper cells, a subset of the HA-specific CD8 cells were induced to divide several times in the pancreatic lymph node but the daughter cells failed to accumulate in increased numbers due to Bim-dependent apoptosis and failed to acquire CTL activity or interferon gamma expression. When the HA-specific CD4 cells were cotransferred, a subset of these also divided one to four times in the pancreatic node, but this abortive proliferation of the CD4 cells failed to help the CD8 cells and did not alter their abortive proliferation. However if the HA-specific CD4 cells were activated by influenza-infected spleen cells in vitro for 3 days before adoptive transfer, these fully activated helper T cells greatly increased the accumulation and persistence of divided HA-specific CD8 cells over

the following 4 to 8 days, inducing them to make interferon gamma and precipitating diabetes.[217] Treating the InsHA recipients of HA-specific CD8 cells with an agonistic antibody to CD40 was shown to increase the number of DCs in the draining node and their expression of CD86, but was insufficient to mimic the effect of activated helper cells unless IL-12 was also given. Taken together with other studies mentioned previously,[211,212,213,214,215,216] these results indicate that abortive T-cell proliferation leading to peripheral tolerance is only switched into sustained proliferation and effector

differentiation and tissue destruction when the T cells receive multiple costimulatory signals via CD28 together with other cytokines like IL-12, interferon alpha, or IL-1, and potentially other cytokines that are made directly by appropriately activated helper T cells.

The conclusion that peripheral T-cell tolerance is acquired through abortive proliferation and deletion because of insufficient costimulatory signals is nevertheless unable to explain the fate of peripheral T cells encountering endogenous antigens in all adoptive transfer models. A striking example comes from the experiments of Mayerova and Hogquist,[260] who transferred OT-1 TCR-transgenic CD8 cells into C57BL/6 mice that were either transgenic for a Keratin 14 promoter-OVA peptide minigene that was expressed in skin keratinocytes or were transgenic for an actin promoter-mOVA construct expressed systemically. Although CFSElabeled OT-1 cells divided in skin-draining lymph nodes in both recipients, there was little accumulation of the progeny in the systemic expressors, and the OT-1 cells underwent abortive proliferation, failed to acquire effector function, and the remaining cells after 21 days were anergic. By contrast in the K14-OVA animals, a 100- to 1000-fold increase in OT-1 cells was observed peaking on days 4 to 6 and accompanied by the acquisition of interferon gamma and CTL function. These cells induced autoimmune dermatitis and vitiligo that became lethal if more than half a million OT-1 cells were transferred. Remarkably, the OT-1 T-cell response to endogenous K14-OVA was comparable to that induced in B6 recipients infected with vaccinia virus expressing OVA.

A partial explanation for such strong induction of immunity and not peripheral tolerance in K14-OVA recipients was that the OT-1 T cells were activated by antigen presented by mature Langerhans cells, which had migrated from the skin to the draining node and expressed high levels of CD86 and MHC II. However, given the evidence discussed previously and in Table 32.1 that TCR and CD28 costimulatory signals are insufficient to drive accumulation of large numbers of divided T cells and acquisition of effector function, it is likely that the Langerhans cells were also expressing IL-12 or other cytokines because of their exposure to products of skin bacteria. One might expect the presence of pathogenic stimuli to exert a “dominant” effect, resulting in the induction of immunity when Langerhans cells and immature DCs were both presenting antigen in K14-OVA × actin-OVA double transgenic mice. However, the opposite was observed: OT-1 CD8 cells encountering endogenous antigen from the two sources underwent abortive proliferation, did not acquire CTL activity or cause dermatitis, and became anergic. Like other studies where dividing T cells become anergic when continuously stimulated by endogenous antigen distributed systemically,[240,253,261,263,264,268] the “dominance” of tolerance over immunity in K14-OVA × actin-OVA double transgenic mice may also reflect desensitization of TCR signaling to critical pathways for T-cell growth and differentiation like RAS-ERK-AP1 or NF-κB. When endogenous antigen is only available from rare DCs in particular sites, and especially if these antigen-bearing DCs are eliminated by abortively activated T cells,[299] the frequency of TCR engagement may in this setting not be sufficient to activate TCR desensitization and anergy, explaining the absence of anergy in other examples of abortive proliferation.[289,293,297]

Chronic TCR engagement during abortive T-cell proliferation to endogenous or exogenous antigens also induces inhibitory signaling molecules on the activated T cells, which play an important role in suppressing the accumulation of divided progeny and their acquisition of effector functions. This has been particularly well demonstrated by Probst et al.[300] in the case of PD-1, a negative signaling receptor displayed by chronically stimulated T cells.[301,302,303,304,305] They engineered an elegant transgenic mouse strain that endogenously expressed two dominant peptide epitopes of LCMV in a subset of DCs. Expression was controlled by a drug-inducible genetic switch, which allowed a burst of peptide-presenting DCs to be formed in adult mice that had a normal T-cell repertoire and had not been immunized or infected. In chimeric mice, where half of the T cells lacked the PD-1 inhibitory receptor and the other half were wild-type, switching on peptide display induced accumulation of high frequencies (˜2%) of LCMV peptide-specific CD8 T cells expressing interferon gamma, revealed by flow cytometric straining with p/MHC I tetramers. However, these were all derived selectively from the subset of T cells that were PD-1 deficient, with no measurable accumulation of corresponding T cells from the wild-type T cells in the same animals. If wild-type T cells were exposed to the burst of peptidedisplaying DCs for 12 days, they became actively tolerant as revealed indirectly by infecting the mice with LCMV and observing a 90% decrease in the accumulation of tetramer positive CD8 cells recognizing the two LCMV peptides that had been expressed by DCs endogenously but not a third LCMV peptide that had not been encountered as “self” in the 12 days before infection. By infecting animals with equal mixtures of tolerant and naïve T cells, they excluded T_{reg} induction as a mechanism. While the actual fate of antigenspecific T cells could not be visualized in this setting due to their very low frequency, these studies establish that presentation of antigen by immature DCs leads to actively acquired tolerance by peripheral T-cell deletion or anergy, and this requires induction of inhibitory receptors on the responding T cells to abort their proliferation.

While abortive T-cell activation generally leads to a cell autonomous process of peripheral

tolerance that is limited to the T cells that are deleted or anergic, in some settings partially activated self-reactive T cells accumulate and suppress other self-reactive T cells. This has been revealed by elegant analyses of a prevalent population of CD8 T cells in diabetes-prone NOD mice, which proliferate in response to a pancreatic autoantigen, islet-specific

glucose-6-phosphatase catalytic subunit-related protein (IGRP).[306,307] CD8 T cells bearing TCRs with intermediate affinity for an IGRP peptide are not rendered tolerant in the thymus but, in combination with CD4 cells, are stimulated to proliferate in the pancreatic lymph node and destroy the pancreatic islet beta cells. However, other CD8 T cells with very similar TCRs recognizing IGRP peptide with low affinity are stimulated to accumulate in the lymph nodes in a partially activated $CD44^{hi}$ CD62L+ state expressing interferon gamma and granzyme B but not IL-2. These low affinity self-reactive T cells suppress the islet antigen-induced proliferation of high-affinity T cells, in part by eliminating antigen-presenting DCs and B cells through perforin-mediated killing. This mechanism may explain observations in the 1970s and 1980s of CD8+ suppressor T cells. It also suggests that one of the functions of thymic positive selection is to populate the peripheral T-cell repertoire with low-affinity self-reactive T cells that actively suppress activation of any high-affinity self-reactive T cells that had escaped thymic deletion.

Collectively, the studies summarized in the previous sections demonstrate that peripheral T-cell tolerance induced by exogenous or endogenous antigens is a result of suboptimal T-cell stimulation, that generally leads to the tolerized T cell undergoing rounds of division, acquiring effector function in some cases, but following an abortive sequence that is generally self-limiting. One major distinction between T-cell proliferation to tolerogenic antigens and immunogenic foreign antigens is that the former does not normally leave a population of memory T cells with heightened responsiveness, but instead leaves either a "hole" in the repertoire or T cells with diminished responsiveness that may in some cases be actively suppressive. Costimulatory signals such as those through CD28, and other important cytokine signals that promote T-cell activation, contribute to the overall signals that drive T-cell immunity versus tolerance. However, the ability of specific costimuli to influence T-cell fate varies substantially for reasons that are imperfectly understood.

T Cell Ignorance Toward Undetected Self-Antigens

A number of transgenic models traced the fate of T cells expressing a well-defined transgenic TCR specific for a tissue-restricted antigen and found that tolerance mechanisms such as thymic or peripheral deletion or anergy were not observed.[308,309,310,311] In some cases, animals developed spontaneous autoimmunity and in other situations no spontaneous autoimmunity occurred. This situation has become known as T cell ignorance. In one model, the LCMV-gp was expressed using the RIP. This led to the expression of the LCMV-gp in the β-islet cells of the pancreas. These mice were bred with P14 TCR-transgenic mice, expressing the receptor specific for the LCMV-gp. Importantly, these double transgenic P14/RIP-gp mice and single transgenic RIP-gp mice clearly showed that the islet-specific T cells were not deleted in the thymus or tolerized in the periphery. LCMV infection of either RIP-gp mice or P14/RIP-gp mice resulted in the induction of diabetes, due to the cytotoxic activity of CD8+ gp-specific T cells. Infection with a control virus such as vaccinia or an LCMV strain that did not encode the major gp epitope did not induce diabetes. Studies have suggested that immunologic ignorance is a consequence of low levels of self-antigen presentation.[312,313]

Regulatory T Cell Populations Maintain Tolerance and Limit Autoimmunity

Many studies have shown that a population of T_{reg} cells can also be induced in the periphery. These cells have become known as induced T_{reg} (iT_{reg}) cells. These are also an important population of cells that inhibits autoimmunity. Evidence has shown that transforming growth factor β is an important factor that promotes the differentiation of this population, and that IL-10 production is important for their inhibitory function.[314,315] Further analysis has shown that iT_{reg}s arise upon presentation of low levels of antigen on DCs together with suboptimal maturation signals. Transforming growth factor β promotes the generation of iT_{regs} in this model.[316]

Both natural T_{regs} and iT_{regs} appear to use several molecules to suppress antigen presentation and costimulation of peripheral T cells, thereby contributing to actively acquired tolerance. One of these is IL-10,[317,318] which has long been known to downregulate the surface display of both MHC II and CD86 on DCs and macrophages.[319,320,321] Recently, this action of IL-10 has been shown to be through the induction of the ubiquitin ligase, March1, which attaches ubiquitin molecules to cytoplasmic lysines in MHC II and CD86 and tags these proteins for degradation.[322,323] When DCs mature in response to LPS or other bacterial or viral products, they dramatically increase expression of CD83, and this protein functions by blocking the effects of IL-10 and March1 to tip the balance in favor of T-cell

stimulation.[323] Another critical molecule for tolerance and T_{reg} function in vivo is CTLA-4, which has recently been established to function by stripping CD86 and CD80 from the surface of DCs and other activated antigen-presenting cells.[124,324,325,326]

CTLA-4 and IL-10 from T_{reg}s thus work in concert to suppress delivery of signal 1 and signal 2 to helper and cytotoxic T cells in the absence of microbial costimuli. However, when large numbers of MHC II^{high} $CD86_{high}$ $CD83_{high}$ mature DCs accumulate in a lymph node because of a microbial stimulus, these will exceed the inhibitory capacity of CTLA-4 and IL-10 from T_{reg}s and favor T-cell activation. CTLA-4 and IL-10 are also produced by activated Foxp3- T cells under various circumstances, providing a potential feedback loop whereby clonal expansion and differentiation of activated T cells may similarly dampen signal 1 and signal 2.

Fate of Autoreactive Mature T Cells

These different mechanisms of peripheral tolerance act in different situations (Fig. 32.2). Autoimmunity may be prevented when self-reactive T-cell activity is limited by the influence of T_{reg}s. Alternatively, if self-antigen is presented at a level that is detectable by the T cell, then tolerance may occur either by deletion or anergy. If there is no detectable self-antigen, then T cells remain ignorant of the antigen.

Studies have shown that the level of self-antigen determines the fate of the self-reactive T cell.[313] Further studies have also provided evidence that low-avidity tissue-specific T cells can escape central and peripheral tolerance and potentially cause autoimmune disease.[327,328,329]

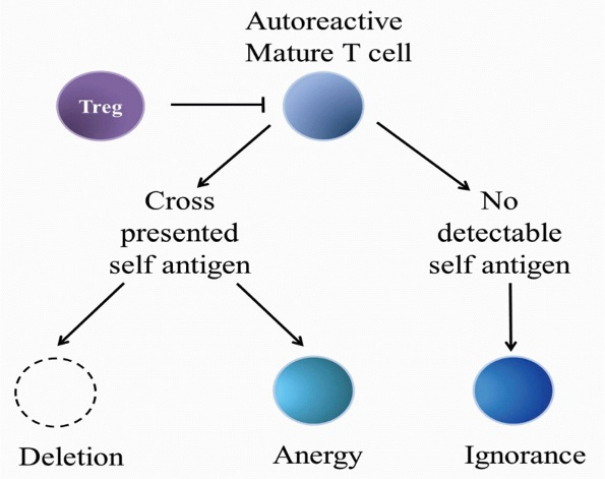

FIG. 32.2. Fate of Potentially Autoreactive Mature T Cells. If an autoreactive T cell does not encounter self-antigen in the thymus, then autoimmunity may be avoided if the T cell is silenced by a number of peripheral tolerance mechanisms. Regulatory T cells may inhibit the activity of the autoreactive T cell. Alternatively, if the T cell engages cross-presented self-antigen on a resting antigen-presenting cell, this would result in T-cell tolerance either by rendering the T cell anergic or by deleting the T cell. If the T cell does not encounter self-antigen, this would be known as T-cell ignorance and the T cell would persist as a naïve T cell in the repertoire.

Why do Anergic T Cells Exist?

Although T-cell anergy has been defined in vitro and in vivo, the idea that nonfunctional T cells remain in the T-cell repertoire is intuitively not attractive. How could the host benefit from having nonfunctional T cells in the repertoire? Several groups have proposed a model where T-cell activation thresholds could be modulated, such that the resting threshold is set by tonic signals in the environment, and TCR engagement with “stronger” antigens could lead to T-cell activation. 330 In this way, the “anergic” T cells would actually be responsive to other antigens, thereby diversifying the T-cell repertoire. Experimental evidence has been published that supports this model.[92,331,332] Others have suggested a model called adaptive tolerance.[333] However, the concept that T cells have tunable activation thresholds still remains unclear.

Importantly, T_{regs} have often been considered to be anergic cells. Consistent with the classic definition of anergy, T_{regs} can proliferate only in the presence of higher doses of IL-2 and

cannot themselves produce IL-2. Whether the mechanism of anergy exists solely for the capacity for T_{reg} function is currently unknown. However, studies have been reported that evaluate connections between anergy and suppression.[334,335]

Molecular Pathways Involved in T-Cell Anergy

Regardless of the functional reason why anergy exists, a tremendous number of studies have addressed the molecular pathway that programs the T-cell unresponsive state. Understanding the molecular basis for anergy may be important for manipulating this state in order to promote antitumor immunity or limit autoimmunity. The signaling events that lead to T-cell anergy have been studied from multiple perspectives. Studies have investigated pathways that fail to be activated in anergic cells. Others have evaluated various knockout animals to determine whether the induction of anergy or activation is impaired. Importantly, inconsistencies may stem from the model that is used to induce T-cell anergy. Experiments that rely on chemicals to induce anergy, such as treating T cells with ionomycin alone, are evaluating a distinct way to disable signaling events in T cells. Furthermore, it is possible that CD4 T-cell anergy is different from pathways that induce CD8 T-cell anergy.

Macian and colleagues have proposed that anergy occurs when NFAT is preferentially activated in the absence or reduced activation of AP-1 and NF-κB. Accordingly, NFAT deficient T cells cannot be anergized. By inhibiting the formation of NFAT-AP-1 complexes, the cells can be shifted from activation to anergy.[336,337] In anergic cells, NFAT induces genes that inhibit TCR signaling cascades as well as inhibit cytokine production. Importantly, NFAT-dependent genes include Itch, Cbl-b, Grail, and caspase-3. Studies using a CD4-dependent system demonstrate that caspase-3 is essential for the development of anergy in T cells.[338] However, other studies demonstrate that caspase-3 is not required for the induction of CD8 anergy in vivo.[151]

Because CD28 is a key costimulatory molecule that promotes full T-cell activation, signaling pathways downstream of CD28 should be critical in limiting anergy. Evidence from several studies has shown that PKCθ is triggered downstream of TCR and CD28 stimulation.[339,340,341] Importantly, anergy of CD8+ T cells can be readily induced in CD28- and PKCθ-deficient mice, and is regulated via the c-Rel

subunit of NF-κB but not NF-κB1 (p50).[342,343] Other models have also supported a role for PKCθ in preventing anergy and promoting T-cell activation.[344] Early studies using a variety of models have also shown that the activation of the transcription factor AP-1, which is downstream of PKCθ,[345,346] is important for regulating anergy.[347] Evidence also supports a role for the Erk pathway in the activation of AP-1 and accordingly has also been shown to play a role in T-cell anergy.[348,349] These and other studies support an important role for NF-κB and AP-1 in regulating CD4+ T-cell anergy.[350]

Early studies examining anergy suggested that this state is an actively maintained state and that continuous TCR derived signals are necessary.[232,253] Therefore, researchers have looked for molecules that are important in maintaining the anergic state. These molecules would be predicted to be upregulated in anergic cells. One candidate is known as Tob. Tob is a member of the APRO (antiproliferative) family and is expressed at low levels in quiescent cells.[351] Another example is diacylglycerol kinase-α. Diacylglycerol kinase-α is upregulated in anergic cells and has been shown to associate with RasGRP-Ras complexes and thereby inhibit signaling via the Ras-GRP/Ras complex and ERK activation.[352] Accordingly, the induction of anergy is impaired in diacylglycerol kinase-α-deficient T cells or in the presence of pharmacologic inhibitors.[353]

Several E3 ubiquitin ligases are involved in regulating anergy. As protein degradation is regulated by ubiquitination, it is possible that a functional T-cell response is regulated by the degradation of proteins involved in signaling and function of T cells. Gene related to anergy in lymphocytes (GRAIL) is an E3 ubiquitin ligase that was identified using an in vitro screen for anergy. A T-cell clone specific for sperm whale myoglobin was stimulated with a fibroblast line transduced with the appropriate MHC molecule and/or CD80 and with or without antigen. In this way, the authors evaluated the expression of genes when the T-cell clone was stimulated with antigen and costimulation (CD80).[354] Grail is expressed in resting CD4 mouse and human T cells and is upregulated in anergic cells. It is required for the induction of anergy in mouse CD4 T cells.[355,356,357]

Another E3 ubiquitin ligase that is important for regulating anergy is Cbl-b. Initial interest in this molecule was piqued when Cbl-b knockout mice were generated.[358,359] Studies showed that the absence of Cbl-b rendered T-cell activation to be independent of CD28. Therefore, it appeared that Cbl-b negatively regulated costimulatory signals. Although *Cblb*-null mice generally do not develop spontaneous autoimmunity, they were more susceptible to experimentally induced autoimmunity. Interestingly, *Cblb* was also identified as a key gene

that was mutated in the KDP rat strain that spontaneously develops type 1 diabetes.[360] Experiments have also shown that Cbl-b-deficient T cells are unable to be anergized in vivo.[344,361] While *Cblb*-deficient B10.BR mice exhibit no evidence of autoimmunity, when it was combined with Aire-deficiency (which also caused little autoimmunity on its own), the combination resulted in autoimmunity directed specifically at the exocrine pancreas and submandibular salivary gland that was lethal by 20 to 30 days of age.[362] These results underscore the importance of peripheral T-cell tolerance through Cbl-b as a failsafe when self-reactive T cells escape thymic deletion. Importantly, studies have also shown that the absence of Cbl-b also results in T cells that are resistant to the regulatory properties of T_{reg}.[363,364,365] However, if the Cbl-b-deficient T cells were resistant to T_{reg} activity, then one prediction would be that these mice develop autoimmunity in a similar way to T_{reg}-deficient mice. This, however, does not occur.

One of the hallmarks of anergy is the reduced proliferative capacity of anergic T cells. This has prompted many groups to evaluate the importance of cell cycle regulation in anergy. Several important studies have been done with anergic cells that demonstrate alterations in the molecules involved in cell cycle progression. For example, rapamycin inhibits the mammalian target of rapamycin pathway, which is important for cell division and can induce anergy in T cells.[366,367] Other studies have focused on a molecule known as p27kip that inhibits cell cycle progression. Forced upregulation of p27kip induces an anergy-like state, and accordingly anergy cannot be induced in p27kip-deficient cells.[368,369] Further studies of the p27kip pathway has identified a role for Smad3 in the induction of anergy.[370]

In general, T-cell anergy is a consequence of impaired signaling capacity in T cells, which has been shown to be regulated at many levels.[371,372,373,374] It is not yet clear how these pathways are interconnected in anergic cells or what internal programming is required to maintain anergy.

Breaking T-Cell Tolerance

Autoimmunity can arise by many different mechanisms, some of which include the failure of tolerance mechanisms described previously. There is much interest in uncovering strategies to break tolerance, either to promote antitumor immunity or limit autoimmunity. In order to reverse an anergic state, several approaches have been taken, including stimulation of T cells through the common γ chain of the IL-2R or triggering costimulatory molecules.[375,376,377,378] Many approaches have also been taken to appropriately activate ignorant T cells. These strategies generally involve activation of the immune system with viruses, the administration of antigen together with other costimulatory signals, or other stimuli that lead to DC maturation.[224,308,379,380,381]

Notably, tumor growth can generate sufficient amounts of antigen to activate ignorant cells and promote immune surveillance in animal models.[382,383] One can speculate that similar tissue-specific “ignorant” cells may be responsible for providing immune surveillance in patients. Correlative studies have been reported by many groups that demonstrate that patients with a defined T-cell signature have a better prognosis.[384,385,386,387] It is compelling to speculate that there are ignorant T cells that exist in the T-cell repertoire that are activated to tumor antigens and can prolong survival of patients by promoting an antitumor response.

Studies have clearly shown that the costimulatory/coinhibitory family of molecules play an important role in T-cell activation and also maintaining tolerance (Fig. 32.3). The absence of CTLA4, PD-1, or PD-L1 results in spontaneous autoimmunity and has been proposed to act largely by controlling autoreactive T-cell activity.[300,301,302,324,388,389] PD-1 has two ligands, PD-L1 (B7-H1) and PD-L2 (B7-DC). PD-L1 is expressed on T cells, B cells, DCs, macrophages, as well as parenchymal cells, whereas PD-L2 expression is induced on DCs and macrophages. Importantly, studies have shown that the expression of PD-L1 on parenchymal cells also plays a role in maintaining peripheral tolerance.[390] There may be many unexplored molecules expressed by tissues that are critical for maintaining tolerance.

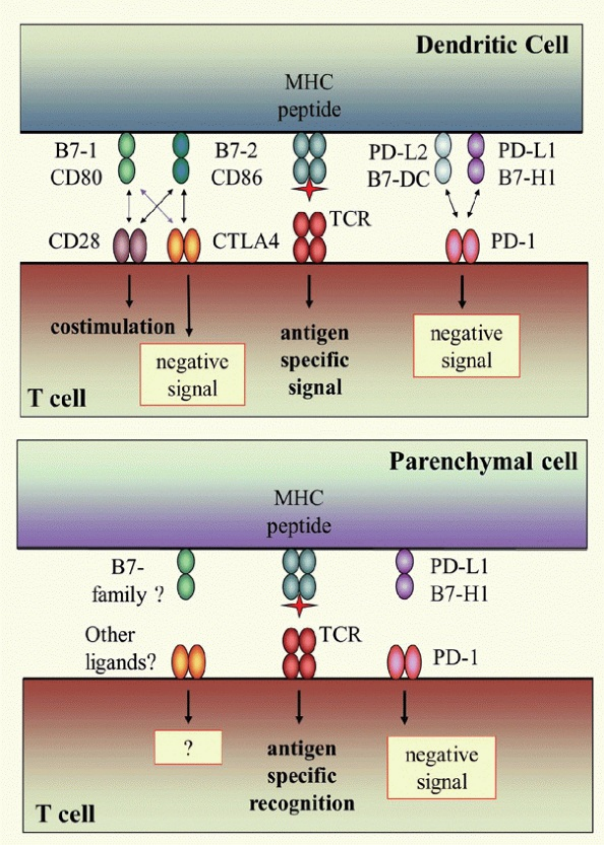

FIG. 32.3. Regulating Tolerance and Immunity by Costimulation and Coinhibition. **A:** Interactions between naïve T cells and mature dendritic cells are critical for inducing the adaptive immune response but are also critical for maintaining tolerance. The costimulatory molecule cluster of differentiation (CD)28, binds to its ligands B7-1 (CD80) and B7-2 (CD86). The coinhibitory molecule CTLA4 is induced after T-cell activation and competitively binds to the same ligands, with a higher affinity. Other members of the immunoglobulin superfamily also regulate these processes. PD-1 binds to PD-L1 (B7-H1) and PD-L2 (B7-DC) and sends an inhibitory signal to T cells. **B:** Members of the B7 family are expressed on a variety of cells other than the hematopoietic system, such as the islets cells in the pancreas. It is possible that the B7 family of molecules contribute to tissue homeostasis in a variety of settings.

B-CELL TOLERANCE: ACTIVELY ACQUIRED TOLERANCE IN THE PREIMMUNE B-CELL REPERTOIRE

Actively Acquired B-Cell Self-Tolerance Varies with Antibody Affinity, Antigen Abundance, and Antigen Form

Tracing the fate of self-reactive B cells accurately and controlling for the confounding effects of antibody heterogeneity, polyspecificity, and affinity, as discussed in the history section, has depended on engineering transgenic mice with rearranged Ig heavy (IgH) and light (IgL) chain genes that encode antibodies of defined specificity and affinity. Initially, these transgenes were introduced in multiple copies cointegrated at a random chromosomal locus. Subsequently, the transgenes were targeted as single copies integrated into the endogenous IgH and IgL chromosomal loci. Collectively, these models have revealed that actively acquired tolerance in B cells is extensive.

The first use of this approach by Goodnow and colleagues in 1988 employed an antibody against hen egg lysozyme, HyHEL10.[391] This antibody-antigen pair had been intensely characterized by Smith-Gill and Davies, including high-resolution crystal structures, and exhibited the monospecificity and affinity typical of highly selected, hypermutated antibodies that dominate long-term immunity against foreign protein antigens.[392,393] In transgenic mice inheriting both the rearranged IgH and IgL chain genes, most of the B cells that developed expressed cell surface IgM and IgD that only bound hen egg lysozyme. These foreign-specific B cells matured and recirculated amongst peripheral lymphoid tissue and, when mice were immunized with the foreign hen egg lysozyme antigen, these B cells were efficiently stimulated into clonal proliferation and antibody formation.

Parallel sets of transgenic mice engineered to express hen egg lysozyme as a “neo-self”

protein displayed actively acquired tolerance and were specifically unable to make antibody upon immunization with lysozyme.[391] In some lysozyme transgenic strains, only trace amounts of the antigen circulated in their blood (˜10^{-10} M), which resulted in tolerance induction only in the helper T cell repertoire and not in B cells themselves.[394,395] This greater sensitivity of T cells for acquiring tolerance, which was also observed in transgenic animals where lysozyme expression was limited to the pancreatic islets or thyroid gland, was later shown to be due to *AIRE*-independent and *AIRE*-dependent expression of the lysozyme gene in thymic medullary epithelial cells, which induced clonal deletion of lysozyme-specific CD4 T cells.[167,396] However, T-cell tolerance could be bypassed and high-affinity antibodies to lysozyme induced in these low-lysozyme animals by immunizing with lysozyme covalently coupled to horse red blood cells, establishing either absence or breakdown of B cell tolerance to low-abundance, low-valency autoantigens.[394] However, in mice with 10^{-9} M or higher levels of circulating lysozyme, the same treatment

elicited only low-affinity antibody-secreting cells, implying that B-cell tolerance was induced as a result of sufficient exposure and affinity to the self-antigen and could not be overcome by strong T cell help to a linked foreign “carrier.” The existence of actively acquired tolerance in individual B cells was clearly shown when lysozyme transgenic mice were crossed with the antilysozyme Ig-transgenic mice, yielding four outcomes depending on the concentration and form of lysozyme expressed as a self-antigen (Fig. 32.4). Self-reactive B cells remained “ignorant” and exhibited little functional or numerical change when they developed in mice with ˜10^{-10} M circulating antigen in their blood, which was only sufficient to engage a few percent of the lysozyme binding receptors on the B cells.[395] This circumstance included transgenic strains with tissue-specific lysozyme expression that was present at greater than 10^{-6} M on thyroid epithelium or the pancreatic islet beta cells, because in these animals the preimmune B cells only encountered trace amounts of lysozyme that had been cleaved and released into the circulation.[397]

When lysozyme circulated at higher concentrations of 10^{-9} M or greater, the monomeric antigen continuously engaged > 40% of the binding sites in the IgM and IgD on the surface of the B cells, starting as soon as IgM was displayed on the surface of immature B cells in the bone marrow.[391,395,398] This did not delete or arrest the maturation of the B cells into IgD_{high} recirculating follicular B cells but caused them to selectively downregulate their surface IgM as they matured and induced a lasting functional change that made them much less responsive to lysozyme immunization as measured by proliferation and antibody secretion. For simplicity, this state is referred to as B cell clonal anergy but, as with T cell clonal anergy discussed previously, this single term should not be mistaken to connote a single mechanism. In fact, there are multiple separate inhibitory processes responsible for actively acquired tolerance in “anergic” B cells that are imperfectly understood, and these appear to vary depending on the nature of the autoantigen and antibody.

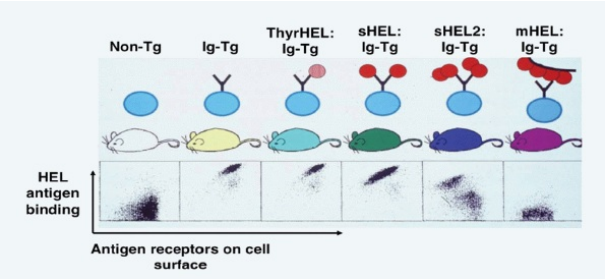

FIG. 32.4. Tracing the Fate of Self-Reactive B Cells in Transgenic Mice. Flow cytometric plots are gated on spleen B cells, with each *dot* representing one cell. These show on the x-axis the $\log_{10}$ relative abundance of surface immunoglobulin (Ig) on each B cell, stained with antibody to kappa light chain. On the y-axis is the $\log_{10}$ relative amount of hen egg lysozyme (HEL) bound to each B cell, detected by staining the cells first with a saturating concentration of lysozyme and then a fluorescent antibody to lysozyme. In normal C57BL/6 nontransgenic mice, the rare lysozyme-binding B cells detected are heterogeneous and probably represent poly-specific or nonspecific binding. In mice inheriting IgH and IgL transgenes, almost all the B cells bind lysozyme monospecifically, and cell-to-cell variation in binding is tightly correlated with variation in the amount of surface Ig on each cell. Clonal ignorance is observed in double-transgenic mice expressing the lysozyme gene selectively in the thyroid epithelium: the frequency of lysozyme binding cells is unaltered and the amount of surface Ig they display is decreased by less than twofold. In double transgenic mice where monomeric lysozyme accumulates to higher concentrations in the circulation and continuously engages ˜50%

of the antigen receptors on the developing B cells, actively acquired tolerance in the B cells is reflected by selective downregulation of their surface IgM receptors but the cells mature to the IgD^{high} recirculating stage. In a matched double transgenic strain where the same proportion of receptors is engaged by dimeric lysozyme, IgM and IgD surface antigen receptors are downregulated accompanied by developmental arrest at the T1-T2 stage, and edited B cells accumulate with normal densities of antigen receptors that do not bind lysozyme. Finally, in a double-transgenic strain where lysozyme is displayed in polyvalent form on the membrane of other blood and marrow stromal cells, lysozyme-binding B cells are almost completely eliminated and replaced by edited B cells.

Dimeric lysozyme, circulating at concentrations that engaged an identical percentage of B-cell antigen receptors, triggered a more extreme surface IgM downregulation and arrested the maturation of the B cells at the immature IgD^{low} CD21^{low} CD24^{hi} CD93+ CD62L- stage that characterizes their first arrival from the bone marrow to the spleen (see Fig. 32.4).[399] These cells were short-lived in the spleen, profoundly “anergic” not only to antigen but to LPS and, because of their lack of the CD62L lymph node homing receptors, very few reached peripheral lymph nodes. Anergic B cells encountering monomeric lysozyme were similarly arrested as a shortlived IgM^{low} IgD^{low} immature population in the spleen in mice that contained normal numbers of competing B cells.[400]

The extreme fate for self-reactive B cells was observed in transgenic mice displaying membrane-tethered lysozyme present on the surface of many bone marrow and blood cells, which resulted in almost complete absence of lysozymebinding B cells in the spleen and peripheral lymph nodes,[401] including cells with very low affinity (˜10^{-6}) for the antigen.[402] This fate was first demonstrated for B cells in Ig-transgenic mice expressing an allo-antibody against MHC I proteins that were ubiquitously displayed on bone marrow cells.[403,404]

The existence of this spectrum of actively tolerant states in B cells has been reinforced and extended through the analysis of Ig-transgenic mice expressing many clinically significant antibody specificities. These are summarized in Table 32.2 and specific mechanisms described in more detail subsequently.

TABLE 32.2 Summary of Fate of Self-Reactive B Cells in Different Immunoglobulin-Transgenic Mouse Models

Fate of B Cells	Antigen	Antibody	Reference
Ignorance characterized by maturation into IgMhi IgDhi follicular and IgMhi marginal zone B cells	Monomeric lysozyme in circulation ˜0.1 nM	HyHEL10 from repeatedly immunized mouse	394,395
	0.1 nM circulating lysozyme cleaved from thyroid or islets	HyHEL10 from repeatedly immunized mouse	397
	IgG2a (low affinity)	AM15, from MRL-lpr lupus mouse	509,510
	IgG, myoglobin, thyroglobulin, actin, ssDNA (low affinity)	SMI VH1-69 germline and Vk3 from human chronic lymphocytic leukemia	473,511
	Human La autoantigen, not crossreactive with mouse La	A3 Vh from mouse immunized with human La	512
	Single-stranded DNA	3H9 anti-DNA VH and Vk8 from MRL/lpr lupus mouse	469

B cells selectively form marginal zone B cells	Thy-1 glycoform at 10% of normal levels	VH3609 and Vk21 germline from spontaneous anti-thymocyte mouse B cell	508
Anergic cells mature to IgMlowIgDhigh CD62L+ CD24- CD93- follicular B cells, recirculate to lymph nodes, desensitized to BCR but retain response to CD40 and LPS	Single-stranded DNA, polyreactive?	HK165 anti-arsgermline VH and mutated Vk from hapten immunized mouse	441,442
	Single-stranded DNA, polyreactive?	ArsA1 anti-arsgermline VH and mutated Vk from hapten immunized mouse	440,453
	Single-stranded DNA, polyreactive?	3H9 anti-DNA VH from MRL/lpr lupus mouse and Vk8	415,438,439
	Sm Ribonucleoprotein	2-12H from lupus mouse with Vk8 or Vk4	443,444
	Insulin	125 H and L chain	445,446
	Monomeric lysozyme in circulation ~1 to 10 nM	HyHEL10 from repeatedly immunized mouse	391,417,452
Anergic B cells in spleen at IgMlowIgDlow CD62L- $CD24^{hi}$ CD93+ transitional stage, short-lived, poor activation to BCR and in some cases anergic to LPS, subset of edited cells preferentially accumulate over time	Erythrocyte membrane antigen	4C8 VH and VL from NZB mouse with autoimmune hemolyticanemia	476,477,478
	Thy-1 membrane antigen glycoform	VH3609 and Vk21 germline natural antibody	479
	MHC cell surface protein Kb expressed in liver or anti-kappa light chain “superantigen” in liver	3.83 H and L from allo-immunized mouse	482,483,484
	Dimeric lysozyme ~1 nM in circulation, or monomer lysozyme 1 nM with competing B cells	HyHEL10 from repeatedly immunized mouse	399,400
	Membrane lysozyme or MHC I Kb on 5% to 10% of blood cells	HyHEL10 or 3-83	412,481
	IgG high affinity rheumatoid factor	Les VH4-34 and Vk328 mutated from chronic lymphocytic	472,473,474

		leukemia	
	Glucose-6-phosphate isomerase (high affinity)	6.121 mutated H and L from TCR transgenic mouse w/ autoimmune arthritis	475
	Double-stranded DNA, nuclear antigens	3H9 VH with Vlambda1 from MRL/lpr lupus mouse	467,468
	Double-stranded DNA, nuclear antigens	3H9 VH with Vlambda2 from MRL/lpr lupus mouse	469
	Double-stranded DNA, nuclear antigens	HKlR anti-Ars Vh with Arg55 in CDR2 and mutated Vk from immunized mouse	441,470
	RNA, ssDNA, cytoplasmic and nucleolar antigens	564 H and L chain from SWRxNZB mouse with lupus	471
Profound downregulation of surface IgM and developmental arrest at small pre-B/immature B cell stage in bone marrow, loss of proliferative response to LPS, followed by editing or apoptosis within 24 to 48 hours	Laminin and single-stranded DNA	LAM nephrotoxic antibody from lupus mouse	435
	a3(IV)collagen NC1 domain	1G6 H and L from mouse hyperimmunized with a3(IV)collagen NC1 domain	434
	IgG2a of a-allotype (high affinity)	20.8.3 H and L chain from allo-immunized mouse	430
	Myelin oligodendrocyte glycoprotein and other	8.18C5 from MOG-immunized mouse with EAE	433
	MHC 1 Kb or Kk on blood or stromal cells	3.83 H&L from allo-immunized mouse	404,413,416
	Membrane-bound lysozyme on blood or stromal cells	HyHEL10 from repeatedly immunized mouse	401,412,417
	Alpha-Gal carbohydrate xenoantigen	M86 H and L from alphaGal-transferase KO mouse	428
	Cardiolipin, histones, cytoplasmic and nuclear antigens	2F5 H and L antibody to HIV gp41 from chronically infected patient	420
	Membrane	3H9 germline VH	432

phosphatidylserine		
Double-stranded DNA, phosphatidylserine	3H9 VH and Vk (Vk4) from MRL/lpr lupus mouse	414,415,438
Double-stranded DNA, nuclear antigens	3H9 VH with Vlambda2* from MRL/lpr lupus mouse	438,519
Double-stranded DNA higher affinity	3H9 VH with 56R CDR2 mutation from MRL/lpr lupus mouse	419,520
Double-stranded DNA	SP6 H and L chain to TNP hapten	431
Sialylated glycolipids, Sialyl-Lewis ×	GAS VH5-51 and Vk1 from Waldenstroms macroglobulinemia cryoglobulin	429

BCR, B-cell receptor; CD, cluster of differentiation; DNA, deoxyribonucleic acid; Ig, immunoglobulin; LPS, lipopolysaccharide; MHC, major histocompatibility complex; RNA, ribonucleic acid.

Green means “go”; yellow means moderate warning (moderately self-reactive); orange means strong warning (strongly self-reactive); and red means “stop” (very self-reactive).

Monospecificity, Polyspecificity, and the Need to Balance Immunity with Self-Tolerance

An overwhelming lesson from the studies summarized in Table 32.2 is that many self-reactive B cells are not eliminated in the bone marrow but reach the spleen and in many cases circulate to lymph nodes. Why are so many self-reactive B cells allowed to reach the spleen and circulation? The likely explanation is that the immune system cannot afford simply to discard antibodies that have unwanted self-reactivity and has the opportunity to remodel these antibodies by hypermutation and purifying selection in germinal centers[405,406] (Fig. 32.5). There are compelling mathematical arguments that germline antibodies need to be polyspecific to provide adequate coverage of microbial epitopes with a finite pool of preimmune B cells. Increasing the crossreactivity and polyspecificity of each antibody minimizes the chance of having a gap in the repertoire due to limited B cells but this is offset by progressively larger holes in the antibody repertoire due to these antibodies also binding self-antigens.[407,408,409,410]

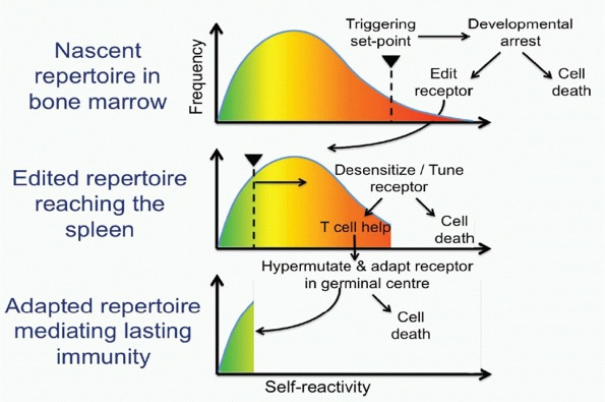

FIG. 32.5. Gradual Evolution of Antibodies with Minimal Self-Reactivity. Self-reactive B cells are eliminated in a series of steps that balances the need for self-tolerance against the need to maintain clones for immunity. (*Top*) Hypothetical distribution of clones are plotted by degree of autoreactivity (x axis) against clone frequency (y axis). The degree of autoreactivity is a function of the amount of autoantigen presented and the avidity with which it is bound by the clone. Most newly formed B-cell clones have low but appreciable self-reactivity, but only a subset appear to exceed an inherited set point and trigger either elimination in the bone marrow or editing to lower self-reactivity. Clones with less autoreactivity are exported to the periphery, illustrated by the hypothetical distribution of clones in the *middle*. By this time, repeated binding of autoantigens has tuned down surface immunoglobulin signaling in the more self-reactive end of the spectrum, illustrated by *orange shading*. Binding of autoantigen and competition for follicular niches also trigger exclusion and death of the more self-reactive clones in the T-cell zones, although these cells can potentially be rescued by T cells if they bind foreign antigens with much higher avidity than they bind to self. As a result of follicular competition, together with hypermutation and further selection in germinal centers, the B-cell repertoire that recirculates for weeks or months among lymphoid tissues is skewed toward a small subset of B cells with the least autoreactivity (*bottom*). A much larger range of newly produced clones is nevertheless available in the T-cell zones of the spleen (*middle*) to be tested for its fit against microbial antigens and potentially recruited for transient antibody responses or remodeling in germinal centers. (Adapted from Goodnow[405]).

Indeed, a large fraction of the preimmune antibody repertoire does exhibit polyspecificity that includes binding to a variety of self-antigens.[22,23,24,25,26,27,28] This may reflect conformational flexibility in the binding sites of germline antibodies, which then become locked into a monospecific shape by point mutations arising during germinal center selection.[411] Allowing many B cells bearing antibodies with self-reactivity to reach the peripheral lymphoid tissue may enable gradual refinement of these antibodies in germinal centers by hypermutation and the twin forces of purifying selection to “breed out” the negative trait of self-reactivity and positive selection for better binding to foreign microbes.[405,406]

B-Cell Receptor Editing in the Bone Marrow

Nemazee's analysis of Ig-transgenic mice expressing an antibody to the MHC I protein, $H2K^k$, initially suggested the B cells were deleted as soon as they expressed this antibody and bound the self-antigen on neighboring bone marrow cells, because no cells with surface IgM could be detected.[403,404] However, more sensitive staining and cell mixing experiments in membrane lysozyme transgenic mice revealed that the immature B cells did not initiate apoptosis in the first day or two after binding the self-antigen but instead they actively downregulated their surface IgM to very low levels and arrested their maturation at a stage that was intermediate between immature B cells and small pre-B cells.[412] This response was reversible if self-antigen ceased to bind to the arrested B cells before the onset of apoptosis: when removed from membrane lysozyme, the B cells regained high surface IgM and matured to the IgD positive stage. This seemed an oddly precarious way to eliminate forbidden clones of B cells.

Nemazee[413] and Weigert[414] independently recognized that the transgenic mice had illuminated an entirely new mechanism for actively acquired tolerance: instead of clonal selection as envisaged by Burnet, this was a system for *receptor selection*. Nemazee showed the B cells that had downregulated their surface IgM had also increased their expression of *Rag2* mRNA, encoding the Ig-gene recombinase, and contained abundant circular DNA excision products from rearrangements of the endogenous lambda light chain.[413] He proposed that strong binding of self-antigens actively induced “receptor editing”: by initiating another round of light-chain rearrangement, the self-reactive antibody could be replaced by one that was less self-reactive. Indeed, a subset of the B cells with the self-reactive antibody to H2K or to double-stranded DNA in Weigert's experiments were salvaged from clonal deletion and matured by expressing less self-reactive antibodies comprised of the transgenic heavy chain paired with an “editor” light chain derived from an endogenous light chain gene rearrangement. The latter were highly selected and did not bind MHC I or double-stranded DNA.

In the transgenic experiments, receptor editing was nevertheless inefficient because the transgenic light chain gene was located at a random chromosomal site where it was not flanked by upstream Vκ elements that could be joined to downstream Jκ elements. Second generation Ig-transgenic mice were then generated with the rearranged light chain VJκ exons integrated into the endogenous light chain locus flanked by upstream Vκ and downstream Jκ elements.[415,416,417] In these “knock-in” Ig-transgenic animals, self-antigen binding

triggered efficient replacement of the offending light chain by joining an upstream Vκ element to a downstream Jκ element. Indeed, when competitive bone marrow chimeras were established, bone marrow B cells that started out with prerearranged but self-reactive receptors nevertheless produced edited mature B cells as efficiently as competing B cells that needed to rearrange their H and L chain genes de novo.[418] The efficiency with which a self-reactive antibody can be edited is likely to vary depending on what fraction of the light chain repertoire can serve as "editors" and exhibit sufficiently lower binding to self. Some H-chains have such a strong propensity to bind self-antigens like DNA, (for example, binding to DNA due to long CDR3 loops and multiple charged arginines in their binding site) that a very small minority of oppositely charged light chains can salvage these H-chains.[419,420]

Analyses of mice with normal antibody genes indicate that 20% to 50% of productive light chain rearrangements are edited by a second light chain rearrangement.[421,422,423] This is likely to be driven primarily by editing of self-reactivity because 55% of the antibodies produced by immature B cells with undetectably low surface IgM are poly-specific for self-antigens whereas only 7% of the antibodies in surface IgM+ immature B cells are poly-specific. The downregulation of surface IgM that is induced by self-antigen binding[412] is comparable to the downregulation of non-self-reactive H-chain that occurs when they pair with surrogate light chains in pre-B cells that have yet to rearrange their light chain genes.[424] When a light chain displaces surrogate light chain and IgM accumulates on the B cell surface, the receptor complex spontaneously signals through the PI3-kinase pathway and inactivates the Foxo1 transcription factor, which in turn is required for *Rag1* and *Rag2* gene expression. Downregulation of surface IgM by self-antigen allows Foxo1 to accumulate, reactivate *Rag1* and *Rag2*, and induce a second round of light chain recombination.[425,426,427]

Dramatic downregulation of surface IgM, developmental arrest at the pre-B/immature B cell transition, followed by receptor editing or deletion, has been demonstrated in Igtransgenic mice expressing many different antibodies (see Table 32.2). These include damaging antibodies to the blood group surface antigens alpha-Gal[428] and sialyl-Lewis X,[429] antibody with high affinity for IgG2a,[430] a bispecific antibody that binds DNA and the foreign hapten TNP,[431] antibody against membrane phosphatidylserine with low affinity for DNA,[432] a demyelinating antibody to myelin oligodendrocyte glycoprotein that cross-reacts with an additional unknown selfantigen,[433] nephrotoxic antibodies to glomerular basement collagen or laminin—the latter bispecific for DNA[434,435]—and a broadly neutralizing antibody to human immunodeficiency virus (HIV) that is also polyspecific for cardiolipin, histones, cytoplasmic, and nuclear antigens.[420] The last example analyzing the 2F5 antibody to HIV provides a compelling clinical example of why the immune system cannot afford to discard antibodies with self-reactivity: in this case, it appears that cross-reactivity between a conserved epitope on the virus and multiple self-antigens stands in the way of developing broadly neutralizing immunity.

Anergy and Peripheral Deletion of Self-Reactive B Cells

Depending on their affinity and specificity, self-reactive B cells that escape or fall below the threshold required to induce developmental arrest and editing in the bone marrow follow two general fates in the spleen: 1) antigen/antibody pairs where the self-reactive B cells become mature follicular cells marked as IgD^{high} $CD24^{low}$ CD93- and L-selectin+, which recirculate to lymph nodes and may be relatively longlived; and 2) B cells that are very short-lived, mostly found in the spleen at the immature transitional stage marked as IgD^{low} $CD24^{high}$ CD93+ and L-selectin-, and few recirculate and reach the lymph nodes (see Table 32.2).

Anergy in Recirculating Immunoglobulin D^{high} B Cells

The longer-lived, recirculating self-reactive B cells are characterized by selective downregulation of surface IgM but high surface IgD. In Ig-transgenic mice with varying concentrations of soluble lysozyme, the extent of IgM downregulation is closely correlated with the fraction of antigen-engaged receptors and occurs after the cells have passed through an IgM^{high} IgD^{low} CD93+ $CD24^{hi}$ transitional stage.[395,398] This prompted the hypothesis that the broad range of surface IgM that exists from cell to cell among IgD^{high} L-selectin+ B cells in the normal repertoire reflects variable degrees of self-reactivity and that the 25% of IgD+ B cells with lowest surface IgM were anergic.[395] Recent analyses in humans confirm this is indeed the case.[436,437] The IgM^{low} IgD^{high} fate has been observed for B cells in Ig-transgenic mice with antibodies that have relatively low affinity to single-stranded DNA and potentially other autoantigens,[415,438,439] antibodies that are polyspecific for DNA and the foreign hapten arsonate,[440,441,442] a lupus antibody to the Smith ribonucleoprotein antigen,[443,444] and an antibody to insulin.[445,446] A similar fate

occurs in normal humans for the ~10% of naive B cells that use the VH4-34 heavy chain variable segment, which is almost invariably self-reactive to I/i glycolipids in the membrane of erythrocytes.[447]

Selective downregulation of IgM but not IgD on anergic cells is due to rapid recycling of internalized antigen-IgD complexes back to the cell surface[448] and to degradation of newly synthesized IgM in the endoplasmic reticulum.[449] The halt to IgM traffic probably results from being outcompeted for CD79 subunits with IgD, whose mRNA is increased in anergic cells,[450] and to changes in chaperone activity from depletion of endoplasmic reticulum calcium, due to constant release of calcium to the cytoplasm by inositol-3-phosphate. Selective downregulation of IgM occurs in the absence of antigen-binding when inositol-3-phosphate activity is not dampened by the enzyme inositol 1,4,5-trisphosphate 3-kinase B.[451]

The antigen receptors on the surface of anergic B cells are desensitized at a proximal point in their intracellular signaling cascade, activating less tyrosine phosphorylation of the immunoreceptor tyrosine-based activation motifs in CD79alpha and beta and Syk kinase, with a concomitant decrease in the magnitude of intracellular calcium.[440,452,453,454] Desensitization of antigen receptors on anergic cells depends upon normal function of the SHP-1 (PTP1C) tyrosine phosphatase[455] and the antigen receptor-activated tyrosine kinase Lyn.[456] Lyn initiates antigen receptor signaling but at the same time it activates SHP-1 as a negative feedback, by phosphorylating immunoreceptor tyrosine-based inhibitory motifs in inhibitory cell surface receptors such as CD22, Siglec-G, and CD72 that recruit SHP-1 to antigenbound receptors.[456,457,458,459,460,461]

Desensitization of the intracellular response to antigen in anergic B cells is nevertheless pathway specific. It selectively dampens intracellular signals that activate the NF-κB transcription factor and the c-jun N-terminal kinase.[462] Low magnitude (~200 nM) spikes of intracellular calcium are repeatedly induced as long as anergic B cells continue to be exposed to self-antigen.[462] While these are too low for NF-κB activation, they are sufficient to promote repeated cycles of calcineurin-mediated dephosphorylation of the NFATc1 and NFATc2 transcription factors, triggering their nuclear translocation and inducing a subset of NFAT-target genes.[450,462,463] Likewise, continuous activation of the MEK-ERK kinase pathway in anergic B cells induces target genes like *Egr1* and opposes induction of the plasma cell transcription factor Blimp-1.[450,462,464,465] Rather than making no response to antigen, the anergic B cells induce a unique pattern of mRNAs when they encounter antigen compared to B cells that encounter the same antigen as a foreign protein.[450]

These early events of continuous calcium spiking and Egr1 induction cease if the B-cell antigen receptors stop being exposed to self-antigen.[453,462] Recovery of the intracellular calcium flux in response to a new round of antigen-engagement occurred within minutes of removal from self-antigen in polyspecific DNA/TNP B cells,[453] whereas it had not recovered after 36 hours in lysozyme-anergic B cells.[452] In the latter, full recovery of surface IgM takes between 4 and 10 days, and the capacity to make a T-cell-dependent plasma cell response does not recover even 10 days after removal from antigen, as long as the B cells remain in a resting, follicular state and are not activated into cycle through other receptors such as TLRs or by primed helper T cells.[466] Thus both short-lived and long-lived inhibitory feedbacks are at work in anergic B cells, and the latter are still poorly understood.

Short-lived, Immunoglobulin M^{low} Immunoglobulin D^{low} Anergic B Cells

The short-lived splenic fate has been observed for self-reactive B cells bearing antibodies with intermediate affinity to double-stranded and single-stranded DNA,[441,467,468,469,470] ribonucleic acid,[471] high-affinity human rheumatoid factor antibody,[472,473,474] high-affinity arthritogenic antibodies to glucose-6-phosphate isomerase,[475] hemolytic antibody to erythrocytes,[476,477,478] very-low-affinity autoantibody to a glyco-epitope on the T-cell membrane protein Thy1,[479] membrane lysozyme or membrane H2K^b limited to 5% to 10% of blood cells,[480,481] and membrane H2K^b MHC molecule or a kappa light chain crosslinking "superantigen" limited to liver hepatocytes.[482,483,484]

In each of these examples, the self-reactive B cells develop in the bone marrow with little downregulation of IgM and hence most cells are not edited at that point. The B cells are found in the spleen primarily as transitional immature cells

with downregulated surface IgM and low IgD, low complement receptor CD21, little CD62L lymph node homing receptor, and high expression of CD24 and CD93. Anergic, self-reactive B cells with this phenotype represent ~5% of the peripheral B cell pool in normal mice.[485] The IgM^{low} B cells persist in the spleen for only 1 to 3 days before being eliminated by the

intrinsic, Bcl2-regulated apoptosis pathway[400] that reflects antigen-induced increase in the proapoptotic Bcl-2 inhibitor Bim.[486,487] Anergic B cells in the spleen require higher concentrations of the anti-apoptotic cytokine BAFF for their survival compared to B cells that are not selfreactive,[487] and their elimination can be delayed or blocked in animals that have increased BAFF.[484,488] This heightened dependence upon BAFF provides a basis for the selective clinical benefits of BAFF antagonists in some people with autoantibody-mediated diseases.[489]

During the time that short-lived anergic B cells remain in the spleen, they are excluded from the B-cell follicles and concentrate at the junction with the T-cell zones.[400,467,471,475] Concentration at the T-B junction is a general effect observed in B cells that have bound antigen, either self or foreign, and is due to BCR signals that increase CCR7 expression and enhance responsiveness to the CCL19 and CCL21 chemokines produced by stroma in the T zone.[490] When B cells that have acutely bound foreign antigen are attracted to this site, they are also triggered to express high levels of the T-cell costimulatory molecule CD86 and to enter G1 of cell cycle. By contrast, self-reactive B cells have already been exposed to the same antigen in the bone marrow,[398,445] and as a result have become desensitized and do not induce CD86 or enter cell cycle when antigen signals them to migrate towards the T zone in the spleen.[452,491] Although they can present antigen to unprimed T cells, this leads to active killing of the anergic B cells through the sequential action of T cell-derived CD40L and FasL.[284,492,493]

Salvaging Self-Reactive Antibodies from Anergic B Cells

A key point is that desensitization to antigen is relative and not absolute. Anergic B cells can activate high intracellular calcium flux, induce CD86, and collaborate with naïve T cells to proliferate and make antibody if their antigen receptors are stimulated by a much more potent agonist than the one to which they have grown accustomed. In other words, they are not unresponsive but have tuned down their responsiveness to antigen, similar to that suggested for selfreactive T cells (see previous discussion). This is illustrated by the calcium flux and plasma cell reaction generated when B cells anergic to monomeric soluble lysozyme are acutely stimulated by polymeric membrane lysozyme and provided with helper T cells that recognize foreign MHC II molecules on the B cells.[452] Similarly, biotin-streptavidin polymerized lysozyme, but not monomeric lysozyme, was able to transduce signals that block Fas-mediated apoptosis in lysozyme anergic B cells, whereas both agonists delivered the protective signal in naive B cells.[494]

Primed T follicular helper cells[278,279] may also salvage anergic B cells that are multispecific and also bind foreign antigen. As antigen-presenting cells, anergic B cells are poor inducers of IL-4 and OX40 from unprimed helper T cells and this is a result of their lack of CD86, because anergic B cells that express CD86 constitutively recover the capacity to induce these helper T cell proteins, to evade Fas-killing, and to mount T-cell-dependent antibody responses.[495] IL-4 is well documented to override Fas-mediated apoptosis in B cells.[494,496,497] Moreover, while anergic B cells make a muted proliferative response to CD40 stimulation alone, the combination of CD40 and IL-4 stimuli elicits heightened proliferation compared to naïve B cells.[452,468,498] This switching capacity of IL-4 may enable primed follicular helper T cells to salvage B cells with antibodies that cross-react with foreign and self-antigens and induce their proliferation in germinal center reactions, where their antibodies can be remodeled to eliminate self-reactivity but preserve or enhance binding to foreign antigens.[405]

T cell-independent stimuli, in the form of foreign antigens linked to ligands for TLRs, can also divert short-lived anergic B cells from death to proliferation. This is best exemplified by the short-lived anergic B cells that result from an encounter with the H-2K^b protein in the liver while en route to the spleen.[483] Potent cross-linking of their antigen receptors by bacteriophages bearing a mimotope of the K^b molecule rescued these anergic B cells from peripheral deletion in the spleen and stimulated them into autoantibody formation. Reversal from anergy in this instance may result from the absence of liver-specific antigen in the spleen. Continuous exposure to self-antigen in lysozyme anergic B cells resulted in the sustained activation of the ERK signaling pathway, which blocked plasma cell differentiation and antibody secretion even when the B cells were induced to divide with TLR9 or TLR4 stimulation.[464,465] In addition, some self-antigen/antibody pairs result in a state of anergy in the short-lived splenic B cells that blocks the proliferative response to TLR4 ligands.[468,471] Collectively, these experiments indicate that abnormal processing of endogenous TLR ligands like DNA or ribonucleic acid,[499,500,501,502,503] or an overactive response of TLRs, may cause aberrant rescue of selfreactive B cells.[471,504,505,506,507]

In several antigen/antibody pairs analyzed in transgenic mice, B cells bearing self-reactive

antibodies are anergic and short-lived in the spleen, yet become expanded in the peritoneal cavity as B1 cells where they secrete autoantibodies. In Ig-transgenic mice expressing an antibody against erythrocytes, expansion of B1 cells depends upon their relative shielding from erythrocytes in this compartment[476,477] and requires concurrent infection with pathogenic or commensal microorganisms.[478] It is not known whether the infectious microorganisms present a cross-reactive foreign antigen that stimulates the self-reactive B cells or if they simply provide potent TLR stimulation of B cells. In either case, the IgM antibody that is secreted binds with high avidity to erythrocytes and causes severe autoimmune hemolytic anemia.

A similar situation occurs in Ig-transgenic mice expressing a low-affinity germline antibody against a carbohydrate epitope on the T-cell protein, Thy1, where the B cells are arrested as anergic immature cells in the spleen, few reach the lymph nodes, but they accumulate as B1 cells in the peritoneal cavity and secrete anti-Thy1 IgM autoantibody.[479]

In this case, the antibody binds with insufficient affinity to Thy1 to cause any depletion of T cells. Remarkably, the induction of B1 cells and autoantibodies requires the Thy1 autoantigen and is abolished in Thy1-deficient mice. It is not yet known if this also requires infection with commensal or pathogenic microbes, like the antierythrocyte B1 cells. When Thy1 is restored at 10% of normal levels in the mice, it changes the fate of the self-reactive B cells again by inducing their maturation into marginal zone B cells that do not secrete autoantibody.[508] These experiments support the view that some low-affinity polyspecific antibodies may be positively selected into the plasma cell, B1, or marginal zone pool by their binding to self-antigens, because these antibodies are not harmful to self-tissues but represent protective antibodies against common microbial antigens.[27]

Clonal Ignorance in Self-Reactive B Cells

The fate of "clonal ignorance," where self-reactive B cells are not tolerized because they do not bind sufficient autoantigen, has also been observed for a number of antibodies expressed in Ig-transgenic mice. These include a low affinity rheumatoid factor antibody against IgG,[509,510] a polyspecific VH1-69 germline antibody from a chronic lymphocytic leukemia,[473,511] an antibody against the lupus and Sjögren syndrome antigen SSB/La,[512] and a low-affinity antibody against single-stranded DNA,[469] although in this case the B cells displayed some level of anergy.[415,438,439] In the case of the low-affinity rheumatoid factor antibody, careful analysis revealed that the self-reactive B cells were not ignorant per se, but a small number were actively stimulated by selfantigen to form short-lived, nonproductive germinal center reactions.[510] This has some parallels with the stimulation of autoantibody production by low-affinity binding of Thy-1 self-antigen, although in that case the B cells were excluded from the follicular/germinal center pathway and formed plasma cells via the B1 B-cell pathway.[479]

TOLERANCE FROM BENCH TO BEDSIDE—A PLAY IN THREE ACTS

This chapter summarizes the enormous progress that has been made in understanding immunologic tolerance and the long and winding road involved. But it is fair to say that we are only in the early parts of a play of three acts.

The first act has been to define the physiologic mechanisms of actively acquired tolerance. This has proved much more complex than any human mind could have dreamt, and while many mechanisms have been defined, the recent discoveries of Foxp3+ T^{reg}s and *AIRE* indicate that even this first act is still in full swing. There are likely to be entirely new mechanisms revealed in the future, and answers are yet to come about fundamental questions like how lymphocytes choose alternative fates of death, survival, or growth at a given tolerance checkpoint.

The second act is to define the root cause of spontaneous autoimmune disease. Rapid progress is currently occurring in this area, particularly in simpler, monogenic forms of autoimmunity following on from autoimmune lymphoproliferative syndrome, APS-1, and IPEX. In the more common sporadic autoimmune diseases, MHC is the largest shared genetic factor, yet we still do not understand why particular MHC haplotypes are so strongly associated with particular autoimmune diseases and not with particular infectious diseases. With respect to the non-MHC heritable elements, unanswered questions remain as to what proportion are common versus rare genetic variants. Currently, this is an area of great activity, through genome-wide association studies of unparalleled size and the dawn of an exciting era of whole exome and genome sequencing in patient cohorts.

The third act will be to use the knowledge gained in the first and second acts to develop specific agents that induce or restore physiologic mechanisms of actively acquired tolerance in autoimmunity, allergy, or transplantation, or agents that break tolerance to allow immune clearance of cancer cells or chronic infections like HIV. The success of bone marrow transplantation in children with primary immunodeficiency, where immunosuppressive agents

can be withdrawn within months, represents progress directly from Medawar's bench to the modern bedside. The induction of tolerance to foreign RhD erythrocyte alloantigens in primiparous RhD-negative mothers is the best present-day example of the ability to induce antigen-specific tolerance reliably, although in this case clinical development was empirical and we do not really understand why it works. Analysis of B- and T-cell anergy has revealed the limitations of cyclosporin and tacrolimus as blocking both lymphocyte activation and actively acquired tolerance,[236,450] and helped promote a shift to "tolerance sparing" immunosuppressive drugs like rapamycin and mycophenolate.

Perhaps the most exciting evidence for what is to come is the clinical approval in 2011 of two human antibodies that really begin to use the amassed knowledge of tolerance for rational therapeutics. One is a blocking antibody to BAFF, belimumab (Benlysta), which is supported by the principle that self-reactive B cells require more BAFF than non-self-reactive B cells.[400,484,487,488] This heightened dependence upon BAFF provides a basis for the selective clinical benefits of BAFF antagonists in some people with autoantibody-mediated diseases.[489]

The other milestone is the clinical approval for a blocking antibody to CTLA-4, ipilimumab (Yervoy),[513,514] which works on the principle that T cells that recognize melanoma antigens are not all deleted but are unable to mount a beneficial autoimmune response. Neither Yervoy nor Benlysta represent a "penicillin moment" for clinical therapy. They are a small step for most patients, but the clinical response that occurs in a subset represents a giant leap for mankind. These agents mark the start of the age when we understand immunologic tolerance sufficiently to induce, restore, or suspend it in practical ways.
