Live-attenuated and inactivated vaccines have been successful in preventing and, in some cases, eradicating infectious diseases in the last century. However, there is an increasing demand for subunit vaccines composed of highly purified antigens because they are generally better tolerated compared to vaccines made of inactivated or live-attenuated pathogens. The limitation of subunit vaccines is that they are in general poorly immunogenic and often require the addition of an adjuvant to achieve protective immune responses. The term vaccine adjuvant has been used to define several compounds that enhance the immunogenicity of a coadministered antigen in vivo. As a consequence of this functional and empirical definition, the vaccine adjuvants group is composed of diverse classes of molecules such as microbial products, emulsions, mineral salts, small molecules, microparticles, and liposomes that have different mechanisms of action.[60] In general, adjuvants are believed to boost vaccine response by increasing the persistency of the antigen in vivo or by targeting innate immune pathways normally associated with response to infection[60,61] (Box 43.1).

Several studies have linked the mechanism of action of known adjuvants to the upregulation of major histocompatibility complex proteins, costimulatory molecules, and cytokines in dendritic cells (DCs). All these events increase the potential of DCs to prime naive T cells, a central step in the activation of both humoral and cellular adaptive responses. Interestingly, DC activation following adjuvant injection can occur either directly, through the stimulation of innate immune receptors, or indirectly, through the stimulation of blood cells or stromal cells at the injection site.[62] It has been shown that various cell types can react to adjuvant injection by producing cytokines or danger-associated molecular patterns, such as endogenous DNA and uric acid crystals that in turn can activate DCs.

BOX 43.1. ACTIVITIES ASSOCIATED WITH VACCINE ADJUVANT MECHANISM OF ACTION

- Increase persistency of antigen at injection site
- Enhanced antigen uptake by APCs
- Production of cytokines and danger signals at injection site
- Activation of APCs and other cells of the innate immune system
- Increased cross-presentation by DCs
- Recruitment of DCs and other immune cells to the injection site
- Migration of antigen-positive APCs to draining lymph nodes
- More efficient B-cell receptor engagement by making antigen multivalent
- Activation of B-cell proliferation and differentiation into plasma cells

APC, antigen-presenting cell; DC, dendritic cell.

Many independent studies have suggested that although activation of DCs is probably required for all vaccine formulations, it is not sufficient for optimal adjuvanticity, which is achieved when an adjuvant able to activate DC (generally called immunopotentiator) is formulated with a second adjuvant that enhance antigen uptake (also known as antigen delivery systems).[63]

Examples of immunopotentiators are microbial compounds, small molecules, and nucleic acids that are able to activate pattern recognition receptors (PRRs) such as TLRs, nucleotide oligomerization domain-like receptors (NLRs), and C-type lectins receptors (CLRs); cytokines such as granulocyte macrophage-colony stimulating factor, interleukin (IL)-12, IL-2, and interferon (IFN)-α saponins and microbial compounds targeting invariant natural killer T cells (αGal-Cer and derivatives).

Examples of antigen delivery systems are mineral salts (alum), emulsions, microparticles (polylactide coglycolide), liposomes, and monoclonal antibodies targeting DC internalization receptors such as DEC-205. All these compounds are able to enhance antigen uptake by APCs in vitro. However, alum and oil-in-water emulsions can also induce the expression of cytokines and other innate immune mediators at the site of injection that may contribute to DC activation (described in detail in following paragraphs).

It has been shown that codelivery of antigen and an immunopotentiator in the same APC can greatly enhance adaptive responses to vaccination. In most studies, codelivery has been achieved by adsorbing the antigens (generally recombinant proteins or purified subunits) and immunopotentiators to the same antigen delivery system. However, codelivery can also be achieved by linking directly immunopotentiators such as flagellin, oligonucleotides, lipopeptides, and small molecules to the vaccine antigen.

As a consequence of the innate immune stimulation, adjuvants can have a strong impact on adaptive responses. In preclinical and clinical studies, it has been demonstrated that adjuvants can increase the amount, avidity, and the cross-reactivity of antigen-specific antibodies, potentiate T-cell responses, and modulate the immune response toward a targeted CD4+ T-cell phenotype adapted against defined pathogens. Finally, adjuvants can improve adaptive responses to vaccination in immunologically hyporesponsive populations including the elderly and infants and can allow for antigen dose sparing. Despite the importance of adjuvants, only very few compounds selected in preclinical studies have been licensed for human use (Table 43.2). Among them, alum has been widely used for more than 70 years; oil-in-water emulsions have been licensed for

adjuvanted influenza vaccines; and AS04, a combination adjuvant composed of the TLR4 agonist monophosphoryl lipid A (MPL) adsorbed to alum, has been approved for HBV and HPV vaccines. The identification and development of new adjuvants is necessary because the limited number of currently approved vaccine adjuvants do not always elicit the desired immune responses capable of preventing the targeted infection. In particular, there is a need for new adjuvants eliciting potent CD8+ T-cell and Th1 responses. A large number of compounds have demonstrated vaccine adjuvant activities in preclinical models, and it would be difficult to review all of them in this chapter. Therefore, we will focus only on the adjuvants that have been either licensed (Table 43.2) or already tested in human (see Table 43.3), with a special focus on their use with subunit vaccines targeting infectious diseases.

TABLE 43.2 Licensed Human Vaccine Adjuvants

Name	Class	Components	Vaccine	Reference
Alum[a]	Mineral salts	Aluminum phosphate, aluminum hydroxide	Diphtheria, tetanus, pneumococcus, HAV, HBV, anthrax, tick-borne encephalitis, MenC, HPV	64
MF59	Oil-in-	Squalene,	Seasonal and	84,85,88

	water emulsion	Tween 80, Span 85	pandemic influenza	
AS03	Oil-in-water emulsion	Squalene, Tween 80, α-tocopherol	Pandemic influenza	89
AF03[b]	Oil-in-water emulsion	Squalene, Montane 80, Eumulgin B1PH	Pandemic influenza	86
Virosomes	Liposomes	Phospholipids, cholesterol, HA	Seasonal influenza, HAV	115,360
AS04[a]	Alum-adsorbed TLR4 agonist	Aluminum hydroxide, MPL	HBV, HPV	111,361
RC-529[c]	Alum-adsorbed TLR4 agonist	Aluminum hydroxide, synthetic MPL	HBV	114

HAV, hepatitis A virus; HBV, hepatitis B virus; HPV, human papillomavirus; Men, meningococcus, MPL, monophosphoryl lipid A; TLR, toll-like receptor.

[a] Adjuvants approved by the U.S. Food and Drug Administration.

[b] Approved in Europe but not marketed.

[c] Licensed only in Argentina.

Licensed Vaccine Adjuvants

Alum

Numerous subunit vaccines in use today, including those against HAV, HBV, HPV, anthrax, diphtheria, tetanus, MenC, tick-borne encephalitis, and pneumococcal conjugate vaccines, are adsorbed to aluminum salts.[64] The most used aluminum salts for licensed vaccines are aluminum hydroxide and aluminum phosphate, and they are generically called “alum.” Alum adsorption enhances the antibody responses to the coadministered antigens and, in some cases, can also increase antigen stability allowing for more extended vaccine shelf life. Only recently has the mechanism of action of alum been deeply investigated.[65,66,67] Early work suggested that alum is able to form a depot with the antigen at injection site increasing antigen persistency and availability. However, in the last 20 years, the depot effect of alum has been challenged by several studies that reported a similar half-life of antigen formulated in the presence or absence of alum.[68,69,70] Alum absorption increases antigen uptake by DCs in vitro, suggesting that it acts as an antigen delivery system.[71] More recently, it has been shown that the interaction between alum and DCs requires membrane sphingomyelin and cholesterol.[72] Moreover, alum injection results in cell recruitment to the injection site,[73,74] especially local recruitment of monocytes, which migrate to the draining lymph nodes and differentiate into inflammatory DC capable of priming T cells.[75] Altogether, these

data suggest that alum has a dual function in promoting antigen uptake and a local proinflammatory environment at injection site. In vitro experiments conducted on mouse and human blood cells led to the identification of at least one of the molecular targets of alum inflammatory activity. Alum activates a cytoplasmic NLR protein called NLRP3, which associates with the adaptor protein ASC and the caspase-1 protease to form a protein complex called inflammasome.[76,77,78] Activation of NLRP3 ultimately results in the processing of pro-caspase-1 into its active form, which cleaves several proinflammatory cytokines including IL-1β and IL-18. It is still not clear how alum activates NLRP3; however, it has been proposed that phagosomal destabilization induced by aluminum and by other crystal structures (silica crystals) following phagocytosis plays an important role.[79]

In vivo studies conducted in NLRP3-deficient mice have shown that direct NLRP3 activation contributes to alum adjuvanticity.[75,77,80] However, the requirement of NALP3 for the adjuvant activity of alum has been challenged by other studies using alternative antigens or different immunization routes.[76,81,82] Probably, other proinflammatory pathways triggered by alum exist and are independent from inflammasome activation. Recently, it has been proposed that host DNA released from dying cells acts as a danger signal that mediates alum adjuvanticity through the activation of several innate immune pathways including interferon regulatory factor 3 (IRF3). In addition, it has been demonstrated that (IRF3) is required for immunoglobulin (Ig)E antibody response to alum adjuvanted vaccines.[83]

Oil-in-Water Emulsions

Oil-in-water emulsions are liquid dispersions of oil droplets stabilized by one or more surfactants. The first emulsion to be licensed for human use was MF59 composed of squalene

oil, emulsified with two surfactants (Tween 80 and Span 85). MF59 has been licensed in Europe since 1997 in an adjuvanted seasonal influenza vaccine for its capacity to increase flu immunogenicity in the elderly.[84] More recently, MF59 and a second squalene-based oil-in-water emulsion called AS03, composed of squalene, Tween 80 and α-tocopherol, have been licensed in Europe for pandemic influenza vaccines and have been widely used for the 2009 H1N1 pandemic flu campaign.[85] A third squalene-based oil-in-water emulsion called AF03 has been approved for pandemic influenza in Europe but has not been marketed yet.[86] Clinical trials demonstrated that avian H5 pandemic influenza vaccines containing oil-in-water emulsions are superior to alum-adjuvanted or nonadjuvanted H5 vaccines in the induction of protective antibody titers.[87] Both AS03 and MF59 allowed for antigen dose sparing and increased seroconversion and cross-protection.[88,89] It is important to notice that in the case of H5 avian flu, for which most of the population has not been previously exposed, nonadjuvanted vaccines did not reach the antibody titers considered to be the serologic correlate of protection, whereas emulsion-adjuvanted vaccines were able to elicit protective antibody titers after two doses. A phage display library approach demonstrated that MF59 can enhance the breadth and the affinity of the antibody responses to H1 and H5 pandemic influenza vaccines.[90,91,92] In particular, the addition of MF59 enhanced the recognition of the HA globular head region that contains most of the neutralizing epitopes. Two additional clinical trials have been conducted on individuals vaccinated several years before with H5 vaccines either nonadjuvanted or mixed with MF59 or AS03 by administering a new dose of oil-in-water emulsion-adjuvanted H5 vaccine (boost). These studies demonstrated that priming with avian H5 vaccines mixed with MF59 or AS03 allows for better and more rapid responses to a booster dose compared to individuals primed with nonadjuvanted vaccines.[93,94] Priming with adjuvanted vaccines was effective even when H5 antigens from different influenza clades were used for priming and boosting, inducing a rapid increase of cross-neutralizing antibody titers. These studies suggest that adjuvanted influenza vaccines may be used for a prepandemic vaccination strategy. Another recent study highlighting the strong impact that adjuvants can have on vaccine efficacy was recently performed on children between 6 and 72 months of age. The addition of MF59 to seasonal flu subunit vaccine increased the efficacy of the vaccine from 43% to 86% against polymerase chain reaction confirmed influenza-like illness.[95] Interestingly, in the age subgroup 6 to 24 months,

nonadjuvanted influenza vaccine was unable to protect, whereas the efficacy of MF59-adjuvanted vaccine was 77%.

Several studies using the mouse model and human blood cells have addressed the mechanism of action of oil-in-water emulsion. In contrast to alum, which physically binds antigens through an adsorption process, oil-in-water emulsions are simply mixed with antigens. MF59 neither increases antigen persistence at the injection site nor induce any depot effect.[96] However, MF59 can enhance antigen uptake by activated DCs in mouse muscle[97] and phagocytosis in vitro in human peripheral blood mononuclear cells.[98] These data suggest that MF59 can act as an antigen delivery system; however, other studies have shown that it has also immunostimulating properties. In vitro analysis of human blood cells showed that MF59 induces the differentiation of monocytes toward DCs and can stimulate chemokine secretion (CCL2, CCL3, CCL4, and CXCL8) in human macrophages, monocytes, and granulocytes.[98] Intramuscular administration of MF59 in mice induced the recruitment of mononuclear cells partially dependent on chemokine receptor 2 (CR2).[99] The local effect of MF59 at an injection site has been evaluated in detail by combining DNA microarray and immunofluorescence techniques. Transcriptome analysis showed that the injection of MF59 in mouse muscle induced the activation of several innate immune genes, including Ccr2 and its ligands (CCL2, CCL7, and CCL8), further supporting the data described previously on CR2-dependent cell recruitment.[100] In addition, MF59 promoted the upregulation of many proinflammatory cytokines and other innate immunity genes and genes involved in leukocyte migration.[100] Two of the early genes modulated by MF59, JunB and pentraxin 3, were upregulated in the muscle, suggesting that the activation of muscle cells by MF59 might play some role in its adjuvant activity.

Intramuscular injection of fluorescently labeled MF59 and antigen revealed that MF59 colocalizes with the antigen in APCs in the muscle and enhances the number of antigenpositive DCs and B cells in the draining lymph node.[101]

Similarly to MF59, AS03 induces transient cytokine activation at the injection site and triggers the secretion of cytokines in human monocytes and macrophages.[102] In addition, AS03 induces cytokine expression in the draining lymph node in a mechanism that is at least partially dependent on the presence of α-tocopherol in the formulation.

In summary, the data described previously suggest that squalene-based oil-in-water emulsion function by enhancing antigen uptake and migration of antigen-positive APCs in the draining lymph nodes and by inducing an immunostimulatory environment at the injection site. However, the innate immune pathways required for the mechanism of action of emulsions are not well characterized. Unlike alum, MF59 does not activate NLRP3 in vitro and is not dependent on NLRP3 or caspase-1 in mouse immunization studies.[82,103] Despite the fact that MF59 adjuvanticity is inflammasome independent, adaptive responses induced by an H5 influenza subunit vaccine adjuvanted with MF59 largely depend on the inflammasome component ASC. Therefore, it has been proposed that ASC plays an inflammasome-independent function required for MF59 adjuvanticity.[103] Surprisingly, MF59 adjuvanticity to a recombinant MenB subunit vaccine requires another adapter protein called MyD88, which plays an essential role in TLR and IL-1R signaling. However, MF59 does not have any TLR agonist activity and the MyD88-dependent pathway required for its adjuvanticity is still unknown.[82]

Monophosphoryl Lipid A and Derivatives

TLRs are key pathogen sensors that modulate the host immune system and play a fundamental role in response to microbial infection.[104] TLRs are PRRs expressed on innate immune cells including DCs that sense PAMPs. Upon pathogen recognition, DCs are activated and provide essential

signals for naive T-cell priming and development of an adaptive immune response. In addition to pathogen infection, microbial products from live-attenuated or heat-killed vaccines can also stimulate TLR pathways providing adjuvant activities.[105,106] For example, the yellow fever

vaccine activates DCs by signaling through TLR2, 7, 8, and 9.[107] Many preclinical and clinical studies using purified TLR agonists have been conducted and demonstrated that all TLRs examined can be exploited to enhance adaptive responses to vaccination. However, despite the large amount of work performed, so far, only the TLR4 agonist 3-O-desacyl-4′-MPL, a component of lipopolysaccharide (LPS) purified from *Salmonella minnesota* has been licensed for human use. MPL is approved for two vaccines against HPV and HBV. In both vaccines, MPL has been adsorbed to alum to form a combination adjuvant called AS04. The HBV vaccine formulated with AS04 was developed for patients with renal insufficiency and was tested in several immunocompromised individuals including the elderly and patients on hemodialysis. The incorporation of MPL allowed for a more rapid increase of antibody titers and enhanced seroprotection rates using fewer vaccine doses.[108] HPV vaccine formulated in AS04 induced higher neutralizing antibody titers and memory B-cell responses compared to the same vaccine formulated only with alum.[109] A head-to-head trial was conducted to compare the alum-MPL adjuvanted HPV vaccine versus another HPV licensed vaccine that is adjuvanted only by alum.[110,111] Both vaccines exploit VLP technologies for the production of antigens and are highly efficacious in preventing HPV16/18-associated cervical intraepithelial neoplasia in women. However, the AS04-adjuvanted vaccine produced significantly higher neutralizing antibody titers to HPV16 and HPV18, and higher frequencies of memory B cells compared to the other vaccine.

The molecular mechanism of action of AS04 is well understood. The MPL component activates directly the LPS sensor TLR4 that is expressed by human innate immune cells including DCs and macrophages. Adsorption of MPL to alum does not interfere with its ability to activate human immune cells including DC.[112] AS04 injection in the mouse muscle lead to a transient production of interferon and proinflammatory cytokines at injection site and to an increased number of antigen-loaded DCs in the draining lymph node.[112] TLR4 stimulation on the surface of conventional DCs induces the production of IL-12 and activates the expression of MHC class II and costimulatory molecules leading to efficient CD4+ T-cell priming and to strong Th1 adaptive responses.

Synthetic TLR4 agonists have the advantage over MPL to be more pure and less expensive. Several synthetic TLR4 agonists such as RC-529 and GLA have been developed and tested as vaccine adjuvants.[113] RC-529, a fully synthetic monosaccharide mimetic of MPL, is the most advanced and has been approved in Argentina for a vaccine against HBV.[114]

Virosomes and Liposomes

Virosomes were licensed for an influenza vaccine in 1994 and are composed of a mixture of phospholipids and cholesterol that are assembled in vitro with purified influenza HA and NA to form synthetic influenza viral-like structure. Influenza virosomes can be also used as adjuvants to incorporate additional antigens from other viruses or other pathogens in general. One formulation composed of H1N1 virosomes and inactivated HAV was licensed in 1997 to target HAV. The mechanism of action of virosomes is mainly linked to antigen delivery functions. Virosomes increase antigen uptake by APCs and display the antigen in draining lymph nodes in a multimeric form, facilitating B-cell-receptor engagement. The presence of preexisting immunity against influenza further enhance the adjuvant effect of virosomes probably through the formation of immune complexes that are rapidly internalized by APCs.[115]

Other liposome adjuvants made of phospholipid bilayers have been tested in preclinical models and in clinical trials in combination with various antigens and in some cases with other adjuvants, as described in the following paragraphs.

Vaccine Adjuvants in Clinical Development Phase

New Toll-Like Receptor Agonist Adjuvants

There is a great interest worldwide in exploiting TLRs as targets for vaccine adjuvants. Besides MPL, several additional TLR agonists are known to be effective adjuvants in preclinical studies.[116] Among them, agonists of TLR2 and TLR9 and novel TLR4 agonists have been extensively tested in human as vaccine adjuvants (Table 43.3). Clinical data are

also available for vaccine formulations including TLR5 and TLR7 agonists. Human data on TLR3 agonists are not yet published; however, clinical trials have already started.

***Toll-Like Receptor 2*.** Bacterial lipoproteins targeting TLR2/1 or TLR2/6 dimers are validated vaccine adjuvants in humans and multiple TLR2 ligands have undergone clinical evaluation. The most advanced TLR2 agonist is the lipopeptide moiety of OspA, the surface protein of *B. burgdorferi*, the major component of a vaccine preventing Lyme disease.[117] The vaccine was efficacious and licensed by the U.S. Food and Drug Administration (FDA) in 1998. However, despite the fact that the vaccine was safe and well tolerated, it was withdrawn by the manufacturer 3 years later following media coverage of possible autoimmune side effects.

***Toll-Like Receptor 3*.** Agonists of the double-stranded RNA sensor TLR3 have not been extensively tested in human yet. However, a synthetic analogue of double-stranded RNA called polyinosinic:polycytidylic acid (Poly I:C) has been tested in multiple animal models with various antigens. Poly I:C can activate TLR3 and a second double-stranded RNA sensor called MDA-5, both leading to the production of type I IFN. In mice, Poly I:C was as effective as other TLR agonists in boosting antibody responses to HIV gag antigen and more efficient than any other TLR agonist tested in inducing specific IFN-γ+ CD4+ T cells.[118] The same study showed that the adjuvanticity of Poly I:C depends on type I IFN. A study conducted with a *Plasmodium falciparum* antigen has shown that Poly I:C is effective in inducing specific antibodies and promoting multifunctional CD4+ T-cell responses in nonhuman primates.[119]

TABLE 43.3 Vaccine Adjuvants in Clinical Development

Name	Class	Components	Vaccine	Reference
CpG 7909	TLR9 agonist	CpG ODN	HBV, malaria, influenza, anthrax, cancer	116
CpG 1018	TLR9 agonist	CpG ODN	HBV, cancer	126
Imiquimod	TLR7 agonist	Small molecule formulated in a topical cream	Cancer	124
Pam3Cys[a]	TLR2 agonist	Lipopeptide	Lyme disease	117
Flagellin	TLR5 agonist	Bacterial flagellin fused to antigen	Influenza	121
Iscomatrix	Combination	Saponin, cholesterol, dipalmitoylphosphatidylcholine	HCV, influenza, HPV, cancer	133
AS01	Combination	Liposome, MPL, saponin (QS21)	Malaria	140,141
AS02	Combination	Oil-in-water emulsion, MPL, saponin (QS21)	Malaria, TB, cancer	131,139
IC31	TLR9	ODN, cationic peptides	TB	129

	agonists			
Montanide ISA 51	Water-in-oil emulsion	Mineral oil, surfactants	Malaria, HIV, cancer	23
Montanide ISA 720	Water-in-oil emulsion	Squalene, surfactants	Malaria, HIV, cancer	23
LT	Bacterial toxins	A subunit + B pentamer of *Escherichia coli* heat-labile enterotoxin	Influenza (intranasal), ETEC, pandemic influenza (Patch)	149,154,155
LTK63	Bacterial toxins	Genetically modified A subunit +B pentamer of *E. coli* heat-labile enterotoxin	Influenza, TB, HIV (intranasal)	152,153

ETEC, enterotoxigenic *Escherichia coli*; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HPV, human papillomavirus; MPL, monophosphoryl lipid A; ODN, oligodeoxynucleotide; TB, tuberculosis; TLR, toll-like receptor.

[a] Licensed and then withdrawn from market.

***Toll-Like Receptor 5*.** TLR5 recognizes bacterial flagellin and is a validated adjuvant target in animal models. A vaccine composed of a recombinant fusion protein consisting of flagellin and four tandem copies of the ectodomain of the conserved influenza matrix protein M2e protects mice from a lethal challenge with influenza A virus.[120] Furthermore, a recombinant fusion protein made of *S. typhimurium* flagellin type 2 and the globular head of influenza HA could increase HA inhibition (HAI) titers by 12-fold over baseline in subjects over 65 years old.[121] However, seasonal influenza vaccines are known to be immunogenic even in the absence of a coadministered adjuvant, and the absence of a control group in this vaccine trial makes it impossible to assess the real contribution of flagellin in HA responses.

***Toll-Like Receptor 7/8*.** Preclinical data in mice and in nonhuman primates showed that small molecules agonist of the single-stranded RNA sensors TLR7 and TLR8 can improve the immunogenicity of various vaccine antigens if adequately formulated or directly conjugated to protein antigens.[122,123] Agonists of TLR7/8 have not been used as adjuvant in human vaccine formulations. However, a cream formulation of the TLR7 agonist imiquimod, which is licensed for dermatologic diseases, has been applied at the site of injection of several tumor antigens.[116] The application of imiquimod-containing cream at the site of injection of recombinant human NYESO-1 protein antigen in melanoma patients induced measurable CD4+ T-cell and antibody responses in a subset of subjects. Unfortunately, the trial was designed without a control group that did not receive the adjuvant, and it is not possible to estimate the impact of imiquimod on the adaptive immune responses directed against NY-ESO-1.[124]

***Toll-Like Receptor 9*.** DNA oligodeoxynucleotides (ODNs) targeting TLR9 are in advanced development stage.[125] Two synthetic CpG-containing ODNs called 1018 and 7909 have been incorporated in various vaccine formulations and tested in humans. Both ODNs belongs to the B type CpG class; therefore, they are strong activators of B cells and induce large amounts of type I IFN by plasmacytoid DCs. ODN 1018 has been evaluated as an adjuvant to HBsAg vaccine and induced more rapid and sustained seroprotection in healthy adults and vaccine hyporesponsive populations.[126] The ODN 7909 has been tested with HBV, malaria, influenza, anthrax, and various cancer antigens.[116] Clinical data demonstrated that 7909 enhances antibody responses to vaccines directed against infectious diseases. In addition, in

some vaccine trials targeting cancer, 7909 had also a significant impact on CD8+ T-cell responses.[116] Another class of TLR9 agonist adjuvant called IC31 consists of a cationic peptide KLKL(5)KLK complexed with the immunostimulatory ODN1a sequence.[127] IC31 was found to promote highly efficient Th1 responses through a MyD88- and TLR9-dependent manner.[128] The complex between the cationic peptide and the immunostimulatory ODN results in a depot effect at the injection site. Furthermore, the presence of the peptide reduces the amount of ODN needed to elicit an immune response. IC31 has been combined to the

Mycobacterium tuberculosis (Mtb) antigens Ag85B-ESAT-6 and tested in a phase I clinical trial.[129] IC31 significantly boosted antigen-specific IFN-γ-producing T cells.

Saponins

Saponins are natural products extracted from plants, which have been known to exert adjuvant activities for more than 80 years. Most of the saponins used as vaccine adjuvants today are extracted from the bark of *Quillaja saponaria*. The QS21 is a fraction of *Quillaia saponaria* extract purified by reverse-phase chromatography.[130] QS21 is known to promote cross-presentation and stimulate specific CD8+ T-cell responses to subunit vaccines in preclinical models and has been formulated with liposomes, emulsions, MPL, and CpG to obtain various combination adjuvants that have been tested in human.[131] Two of these combinations, AS01 and AS02, have been successfully adopted for a vaccine preventing malaria transmission.

Saponins have also been formulated with cholesterol and phospholipids to obtain a particulate adjuvant called Iscomatrix® (CSL, Victoria, Australia).[132] Iscomatrix® has been formulated with several vaccine antigens and tested in various animal species including mice, guinea pigs, cattle, and nonhuman primates.[132] In addition, experimental vaccines containing Iscomatrix® targeting HCV, influenza, and HPV16 have been tested in humans.[133] More recently, a subunit vaccine composed of a recombinant NY-ESO-1 testis cancer antigen formulated with Iscomatrix was tested in a phase I trial.[134] In animal models, Iscomatrix® is an efficient adjuvant in boosting antibody and both CD4+ and CD8+ T-cell responses even to recombinant antigens.[133] Mechanism of action studies showed that Iscomatrix® increases antigen translocation from the endosome to the cytosol of DCs in vitro and can promote cross-presentation in both proteasome-dependent and tripeptidyl peptidase II-dependent pathways.[135] Accordingly, when Iscomatrix® was combined to ovalbumin and injected in mice, it potently enhanced the number of DCs in draining LN able to activate OT-I CD8+ T cells ex vivo.[136] More recently, it was shown that Iscomatrix® injection in mice induced cytokine expression and antigen-independent cell recruitment in draining lymph nodes and enhanced antigen uptake by CD8+ and CD8- DCs; however, CD8+ DCs were more efficient in cross-presenting ovalbumin peptides to CD8+ T cells.[137] Unfortunately, CD8+ T-cell responses induced in human by subunit vaccines are in general less strong compared to those induced in animal models, suggesting that cross-presentation in humans is more difficult to achieve. For example, the experimental vaccine using HCV core protein antigen formulated in Iscomatrix® induced high antibody titers in all patients and specific CD4+ T-cell responses in seven out of eight patients; however, in only two of eight patients with HCV could core-specific CD8+ T cells be detected.[138]

Water-in-Oil Emulsions

Water-in-oil emulsions were developed by Freund in 1937 and are still largely used in preclinical models. Incomplete Freund adjuvant is composed of mineral oil emulsified with mannide monooleate and is a potent adjuvant with a large number of antigens. However, when incomplete Freund adjuvant was tested in humans, it produced several local adverse reactions including sterile abscesses. Later, novel water-in-oil formulations were developed by using less reactogenic oils and surfactants. The most advanced are Montanide ISA 51 and ISA 720 (Seppic, Paris, France) that have been used in malaria, HIV, and cancer vaccine trials.[139] Montanide ISA 51 is composed of mineral oil and surfactants, whereas ISA 720 is

made of squalene oil emulsified in mannide monooleate to obtain droplets of 1 μm of diameter. The different oil composition affects the reactogenicity profiles of this class of adjuvants: Mineral oils persist at injection site for a long time, whereas squalene is more rapidly metabolized. The mechanism of action of water-inoil surfactants has been linked to their ability to 1) increase the persistence of the antigens that are slowly released at the injection site (depot effect), 2) increase antigen uptake by APCs like other antigen delivery systems, and 3) induce local inflammation that promotes blood cell recruitment at injection site. In a clinical trial, Montanide enhanced antibody and cellular adaptive responses to coadministered antigen. Cellular responses could be further enhanced by the inclusion of CpG ODNs.

Novel Adjuvant Combinations

In some cases, a single adjuvant may not be sufficient to achieve a protective immune response. For this reason, several combinations composed of various classes of adjuvants have been tested in preclinical and clinical settings. The most successful example of adjuvant combination is AS02 composed of MPL, QS21 saponin and an oil-in-water emulsion. When *P. falciparum* recombinant antigen RTS,S was formulated with AS02, a 37% reduction of malaria infection was observed in a clinical trial.[140] Recently, the same vaccine has been optimized with the adjuvant combination AS01, in which the oil-in-water emulsion is substituted with liposomes, further increasing the protection rate.[141] The AS02 combination has been also used for the non-small cell lung cancer antigen MAGE-A3. The vaccine gave a significant antibody and CD4+ T-cell responses. However, only a small subset of patients developed antigen-specific CD8+ T-cell responses.[142] In the future, adjuvant combinations may be further improved by using different TLR agonists. In vitro data on human cells showed that TLR3 and TLR4 agonists can synergize with TLR7, TLR8, and TLR9 inducers for cytokine production and DC activation.[143] Accordingly, preclinical data in mice showed that combining TLR3 with TLR9 or TLR2 agonists resulted in a synergistic effect on the development of antigen-specific CD8+ T cells.[144] Furthermore, the small molecule TLR7 agonist imiquimod/R837 synergized with the TLR4 agonist MPL in mice inducing more persistent germinal centers, increased antibody titers, and increased frequencies of antigen-specific CD4+ and CD8+ T cells and plasma cells.[145]

Mucosal Adjuvants LT and LTK63

Mucosal vaccines elicit protective immune responses at the site of pathogen infection and have the additional advantage to be needle free, thereby improving accessibility and

cost-effectiveness. Out of five licensed mucosal vaccines, four are live attenuated (intranasal flu, oral rotavirus, OPV, and typhoid) and one is made of killed *V. cholerae* given with cholera toxin (CT) B antigen. Notably, no subunit vaccine has been licensed for mucosal administration due mainly to the absence of safe and effective human mucosal adjuvants. In fact, the administration of antigens in the absence of adjuvants in respiratory or gastrointestinal tracts can induce tolerance. Mucosal adjuvants are required to 1) protect antigens from degradation by mucosal proteases, 2) enhance internalization of vaccine antigen by intraepithelial DCs or M cells, and 3) overcome regulatory mechanisms that prevent the development of effector B- and T-cell responses in the mucosal-associated lymphoid tissue. Mucosal immunity can protect from pathogen infection by various mechanisms including local production of IgA, IgG, and IgD antibodies by mucosal B cells; activation of mucosal CD4+ T cells producing IL-17 (Th17); and activation of mucosal CD8+ T cells.[146] A large number of animal studies showed that some TLR agonists such as CpG ODNs, MPL, and flagellin can act as mucosal adjuvants; however, they have not been tested in humans yet.[147] The most advanced mucosal adjuvants are CT and heat-labile toxin (LT) from *E. coli*. Both are adenosine diphosphate (ADP)-ribosyl tranferase enterotoxins composed of a pentameric B subunit and a catalytic A subunit. The B pentameric subunit binds the ganglioside GM1 expressed on the surface of several host cells including mucosal M cells. The binding of the B pentamer promotes internalization of LT and CT into target cells followed by processing of the complex and release of the A subunit into the cytosol, where it catalyzes the ADP-ribosylation of trimeric G proteins.[148] Both CT and LT induce potent

mucosal responses to coadministered antigens when administered intranasally in mice. However, the use of wild-type toxins as adjuvants in human has been prevented by a nonfavorable safety profile. LT was included in an inactivated virosome influenza intranasal vaccine licensed in Switzerland. After licensure, the vaccine was associated with a 19-fold greater risk of facial nerve paralysis (Bell palsy) compared to unvaccinated controls and therefore was withdrawn by the manufacturer.[149] In order to improve the safety profile of CT and LT, several nontoxic mutants have been designed. LTK63 and CTK63 have a single amino acid substitution in the nicotinamide adenine dinucleotide-binding site of the subunit A of LT and CT, respectively, which results in a complete loss of enzymatic activity. Both protein complexes assemble into a holotoxin and induce mucosal immune responses.[150,151] LTK63 was superior to CTK63 in inducing mucosal responses in mice and was selected for further investigation in human clinical trials. In a phase I clinical trial, LTK63 was tested as mucosal adjuvant with an intranasal trivalent inactivated influenza vaccine. LTK63 was simply coadministered with influenza HA antigens or formulated in a nanoparticle called biovector made of polysaccharide, phospholipids, and cholesterol. Both intranasal formulations were safe and enhanced IgA mucosal responses to HA in nasal secretions. The presence of the biovector enhanced both IgA responses and HAI titers.[152] Later, LTK63 was also administered intranasally with Mtb Ag85B-ESAT6 fusion protein or with HIV glycoprotein 140 in two phase I clinical trials. In both trials, one subject developed a transient form of Bell palsy, questioning further development of LTK63 in intranasal administration.[153] It is important to report that LT has been used also for transdermal immunization using a skin patch system. In a first approach, the LT patch has been used to induce anti-LT immune responses and protect from enterotoxigenic *E. coli* infection. In a phase II placebocontrolled field trial, the LT patch protected 75% from moderate-to-severe diarrhea and 84% from severe diarrhea.[154] The same patch has been used as an adjuvant to enhance immune responses to a coadministered intramuscular H5 influenza vaccine. The application of the LT patch to the vaccine injection site increased HAI titers and seroconversion.[155] The mechanism of action of CT and LT as mucosal adjuvants is not well characterized. However, the data on genetically modified toxins showed that the enzymatic activity is not required. Experiments conducted in mouse lungs demonstrated that LTK63 activated the expression of several innate immune genes that may be involved in adjuvanticity by activating mucosal APCs.[156] The same study demonstrated that LTK63 induced recruitment of DCs and activation of alveolar macrophages in the airways. These events may increase antigen capture and presentation in the lung. Recently, one study demonstrated that LT and LTK63 can have direct effects on DC in vitro. Mouse bone marrow -derived DC stimulated ex vivo with LT or LTK63, and antigen have an increased capacity to stimulate specific IL-17, IL-10, or IFN-γ-positive CD4+ T cells in recipient mice. The same study showed that LT and LTK63 can stimulate the production of MIP-2 by mouse DCs and synergize with TLR agonists for the production of other cytokines including IL-1α and IL-1β.[157] Similarly to what has been previously observed for alum (see previous paragraph), LT and LTK63 increased IL-1β production in vitro by activating the NLRP3 inflammasome complex. In agreement with in vitro data, IL-1R has been implicated in IL-17 and IFN-γ CD4+ T-cell responses elicited by parenteral immunization with LT, LTK63, and keyhole limpet hemocyanin antigens. It remains to be demonstrated if the same pathway is involved in mucosal adjuvanticity.

ROUTES OF ADMINISTRATION

Most vaccines are administered parenterally and stimulate systemic immune responses such as serum antibodies and in some cases effector T cells. Currently, the preferred immunization route is intramuscular, whereas the subcutaneous and intradermal routes are used less frequently. However, most pathogens enter the host through mucosal epithelia; thus, an ideal vaccine should induce protective immune responses in these tissues. Dimeric secretory IgA (sIgA) is the predominant Ig found in respiratory and gastrointestinal tract mucosal secretions, saliva, and breast milk. SIgA is concentrated within and on the apical side of the mucosal epithelium and functions by neutralizing toxins and preventing pathogen attachment to and translocation across epithelial cells. Parenteral vaccines are inefficient at stimulating primary mucosal immune responses such

as sIgA; therefore, the development of mucosal vaccines is actively being pursued.

Mucosal routes of administration include nasal, oral, rectal, and vaginal. Although all these routes are amenable to the application of vaccines, in practical terms, only nasal and oral administrations are suitable options for all ages, genders, and cultures. Intranasal administration of vaccines by spraying, nebulization, or aerosolization induces sIgA in the airway mucosa and in the genital tract but is rather inefficient at generating intestinal antibody responses. However, intranasal vaccine delivery has raised safety concerns after reports of Bell palsy adverse effects associated with retrograde passage of inhaled antigens or adjuvants through the olfactory epithelium. To date, the only licensed vaccine administered intranasally is a live-attenuated influenza vaccine. Conversely, the ingestion of antigens (orogastric route) can induce sIgA responses in the small intestine, proximal colon, and mammary and salivary glands but is poorly efficient for the distal segments of the gut and the respiratory and reproductive tracts. All licensed vaccines against enteric pathogens are given by the orogastric route (Sabin OPV, cholera, typhoid, and rotavirus). A promising alternative to intranasal and orogastric routes might be the sublingual route of vaccine delivery, which is gaining increased attention from recent studies indicating that sublingual immunization may induce broadly disseminated mucosal and systemic immune responses including sIgA and CTL.[158]

Finally, transcutaneous immunization, a technique that introduces vaccines onto the skin in the form of a patch or topical ointment, targets the numerous resident professional APCs known as Langerhans cells in the superficial layer of the skin epidermis. Vaccine delivery in the skin may offer advantages over the intramuscular route of immunization including dose sparing, broad mucosal and systemic antibody responses (gut, lung, saliva, oral and nasal cavity, and female reproductive tract), and CD4+ T helper and CTL. The major obstacle to transcutaneous immunization, however, resides in the stratum corneum, the outermost layer of the skin that provides a natural barrier against foreign materials. Gentle disruption of this outer layer is necessary to improve vaccine delivery in the skin epidermis and requires the usage of special devices.[154]

Needle-free delivery of vaccines remains a high priority for both the industrialized and developing world due to increasing aversion to injections; improper practices involving nonsterile needles and syringes causing abscesses and transmitting blood-borne pathogens such as HBV, HCV, and HIV; and safety risks of needlestick for health care providers. Sublingual and transcutaneous routes of delivery of vaccines are alternatives that bypass the need for needles and represent promising new venues.

LICENSED VACCINES

In this section, we will discuss some of the licensed vaccines that are more commonly used. Other vaccines are either licensed for emergency use (eg, anthrax vaccine) or are used in selected populations (eg, Japanese encephalitis or cholera vaccines, which are indicated for travelers in endemic area) and will not be discussed.

Viral Vaccines

Poliomyelitis

Development of a vaccine against poliomyelitis represents an important achievement in the history of vaccines. It demonstrated that two different approaches, based on inactivated or live-attenuated formulations, could be successfully applied to prevention of this disabling disease. Although generally associated with the names of Salk and Sabin, discovery of the polio vaccine benefited from several key findings that preceded their work. These were the isolation of the poliovirus in monkeys, the identification of three immunologic different serotypes of the virus, the demonstration that neutralizing antibodies against one serotype could not protect against the other two, and finally the propagation of the virus in vitro in human embryonic cells of nonneural origin. Indeed, early efforts in the 1930s to obtain a vaccine using inactivated poliovirus isolated from monkey spinal cord were unsuccessful, with induction of the disease at an unacceptable rate of 1 in 1000 vaccinated individuals. Application of all the discoveries on the biology of poliovirus allowed Salk to develop the first IPV, obtained using three serotypes grown on monkey primary kidney cells, inactivated by formalin and then formulated in a final trivalent vaccine. This vaccine was 80% to 90% efficacious in one of the biggest field trials in the history of vaccines,[159] and its introduction

in the United States resulted in a dramatic decline in the cases of poliomyelitis in few years. Unfortunately, the use of IPV is also associated with the most famous and dramatic case of adverse effects related to vaccine administration. In the summer of 1955, 204 cases of vaccine-associated poliomyelitis were reported a few months after IPV was licensed in the United States. The infections were caused by two lots of vaccine produced by Cutter Laboratories, in which the virus was not adequately inactivated, despite having passed safety controls. Although isolated, the Cutter case stimulated a revision of the production procedures for IPV with inclusion of more stringent safety controls, which on the other hand also resulted in a reduction of the immunogenicity of the vaccine preparations. Subsequent technical advances, in particular culturing of the virus in long-term cell lines such as Vero monkey kidney cells and concentration of the virus before inactivation, improved the potency of IPV that is currently used in all developed countries. The presence of neutralizing antibodies at levels above a 1:8 dilution in the serum of vaccinated subjects is considered a correlate of protection. Several studies showed that following four immunizations with IPV, protective antibodies titers were still present in at least 95% of the vaccinees up to 7 years after the priming dose, whereas another study demonstrated neutralizing titers 18 years later in 100% of the subjects.[160] The Cutter incident encouraged further research on development of an attenuated vaccine, which was finally obtained by Sabin in 1961. The efficacy of this vaccine depends on the capacity of the virus to infect and multiply in the gut of the vaccinated individuals.

Initially, the OPV was manufactured as three separate monovalent formulations and then as a single trivalent vaccine. The three strains, one for each serotype, contained in OPV were selected for their reduced neurotropism in monkeys, but they preserved the capacity to infect the human intestinal tract.[3] After three doses of OPV, more than 95% of the individuals showed seroconversion for all three serotypes of virus and developed a long-lasting immunity, similar to that induced by infection with a natural poliovirus. After licensing in the United States and Europe, OPV rapidly replaced IPV for polio vaccination in all countries because of its lower costs and because oral vaccination was easier to administer than an intramuscular injection. Moreover, revisions in the IPV production that followed the Cutter incident had reduced the immunogenicity of this vaccine, resulting in cases of paralytic polio in IPV-vaccinated persons that were related to vaccine failure and led to a diminished confidence in the IPV. However, one drawback of the OPV is a low risk of inducing vaccine-associated paralytic poliomyelitis because of reversion to neurovirulence for one of the vaccine strains, serotype 3 in particular. The incidence of vaccineassociated paralytic poliomyelitis can be estimated in one case per 1.4 million of doses in case of first administration of OPV, but it is higher in case of immunocompromised individuals. To reduce the incidence of vaccine-associated paralytic poliomyelitis in many developed countries, a sequential vaccination schedule was adopted in which IPV was administered for the first two doses followed by two doses of OPV. Today, in most developed countries, including the United States, Canada, and most of Europe, polio vaccination is based only on IPV, whereas a few other countries continue to use a sequential IPV/OPV schedule. The rest of the world, which includes all developing countries and therefore the majority of all newborns who need to be vaccinated, is using only OPV. Indeed, the international community relies solely on OPV-based vaccination programs to achieve polio eradication, which is the goal for the Polio Global Eradication initiative of the WHO.[161]

Influenza

Influenza is a systemic infection that is mainly manifested with respiratory symptoms. It is broadly diffuse around the world with epidemic outbreaks associated with the winter season in temperate climate regions, whereas it has no seasonal pattern in tropical regions. Although often asymptomatic or self-limited, seasonal influenza infection can be debilitating, resulting in the loss of many working days every year. Moreover, it can be associated with life-threatening complications, especially in some at-risk populations such as the very young, the elderly, and the chronically ill. Annual seasonal influenza epidemics result in about three to five million cases of severe illness and about 250,000 to 500,000 deaths worldwide. Periodically, the human population is affected by influenza pandemics, characterized by rapid global spread of this infection and an increase in morbidity and mortality compared to seasonal influenza. For years *H. influenzae* was erroneously believed to be the origin of this

disease, and the etiologic agent of influenza, the influenza virus, was identified only in 1933. Part of the *Orthomyxoviridae* family, influenza viruses are enveloped viruses with a genome made by eight separate negative strand RNA segments and can be differentiated in three major types named A, B, and C. Influenza types B and C viruses show low variability and infect mainly humans, but only virus B is responsible of epidemic episodes. On the other hand, type A virus can also infect mammals other than humans, such as pigs, dogs, and horses, and domestic or wild birds. Based on differences in the major envelope glycoproteins, HA, and NA, influenza type A virus can be further divided in many subtypes. Sixteen major variants for HA and nine types of NA exist, and type A viruses with many different combinations of these two proteins can be isolated. Whereas HA is the protein responsible for attachment to the receptor on the host cells, and is the major target of protective neutralizing antibodies, NA is required for maturation and egress of viral particles from infected cells, and anti-NA antibodies can reduce the spread of infection. Receptor specificity of the different HA subtypes influences the host specificity of the different subtypes. Indeed, HA of human influenza viruses preferentially binds to sialic acid 2,6 galactose residues, which are expressed by human upper respiratory tract, whereas that of avian virus has a preference for sialic acid 2,3 galactose residues expressed in birds. Influenza viruses are characterized by a great variability of HA and NA that complicates the production of a protective vaccine.

Point mutations are continuously introduced during influenza virus replication because the enzymes that replicate the viral genome have no proofreading activity. These mutations, which are called “antigenic drifts,” are responsible throughout the years of small changes in the antigens of the circulating viruses and can be observed in both types A and B viruses. These changes confer a selective advantage to the new virus, against which large segments of the population have insufficient immunity, requiring the preparation of a new vaccine every year to immunize the susceptible populations. The high genetic mutability of the influenza virus requires continuous monitoring of influenza cases by the WHO surveillance system in order to identify the prevalent virus antigens in the population. Following the recommendations of this surveillance system, yearly vaccines for active prophylaxis of influenza are produced ad hoc and distributed worldwide to protect against the new variants of the influenza virus that are predicted to be the most widely circulating. A second type of variations that is observed only in influenza virus A is called “antigenic shifts.” These depend on the reassortment of RNA segments from two different virus subtypes that occurs when both viruses infect the same host, ultimately resulting in the formation of a new subtype. This reassortment can take place when both avian-specific and human-specific subtypes infect pigs, which express both sialic acid 2,3 and 2,6 galactose and therefore are susceptible to both viruses. The exchange of genetic material can lead to the formation of a new subtype that is able to infect humans and will be very different from the previously circulating viruses. As no immunologic memory for this virus exists in the human population, the new virus will rapidly spread worldwide resulting in a global pandemic outbreak. The so-called Spanish flu in 1918, the

most severe pandemic flu in the modern era, was caused by a highly pathogenic virus A/H1N1 that is estimated to have resulted in 50 to 100 million deaths worldwide. The other two pandemics which occurred in the 20th century were the Asian flu in 1957 and the Hong Kong flu in 1968, which were caused by H2N2 and H3N2 viruses, respectively. In 1977, there was a reemergence of a H1N1 virus which, however, had a limited spread and did not cause a real pandemic but only several outbreaks. However, this H1N1 virus continued to circulate and therefore was added as a third strain in the yearly vaccine formulation. Indeed, H3N2 subtype was still responsible of seasonal influenza A outbreaks from 1968 to 2009 and therefore was kept in the yearly vaccine composition.

More recently, in April 2009, a new strain of H1N1 was isolated in Mexico and California and was associated with severe to fatal cases of flu. The new virus derived from the reassortment of a previous triple reassortment of bird, swine, and human flu viruses, which was circulating among pigs in North America, with a Eurasian pig flu virus; it was called “swine flu.” This new virus rapidly spread worldwide and by June 27,737 cases of influenza A/H1N1 2009 virus were confirmed across 74 countries with 141 deaths, inducing the WHO to declare a pandemic. The WHO and national health agencies agreed that a specific vaccine was needed due to the severity of human infections and due to the risk of more pathogenic new reassortment. Vaccine manufacturers initiated efforts to develop vaccines against the

pandemic strain, and different adjuvanted and nonadjuvanted monovalent pandemic vaccines were licensed and used in national vaccination campaigns.

Alternatively, a pandemic influenza can originate when an avian virus infects humans and can be easily transmitted from person to person. This is the fear of what might happen with a highly pathogenic strain of bird influenza, the A/H5N1 virus, which was isolated in humans for the first time in 1997 in Hong Kong. The infection has spread to wild birds and chickens in many countries in Asia, Africa, and Europe, directly causing the death of tens of million of birds and requiring the sacrifice of hundreds of million of domestic chickens in the attempt to contain spreading of the infection. The WHO has recorded 564 human infections by H5N1 with 330 deaths through August 2011. Although no transmission from human to human has been observed, the H5N1 virus has the potential of originating a new severe influenza pandemic.

The first vaccine against influenza was made available to the public in 1945 and was a formalin-inactivated whole virus vaccine from viruses grown in embryonated hen eggs. Most vaccines currently in use is still produced from virus cultured in eggs and then inactivated; however, additional steps in the production process have been added to obtain more purified viral preparations. A detergent treatment that eliminates the viral envelope and other purification steps are used in the production of "split" influenza vaccines, which contain only some viral components. Even cleaner vaccine preparations, called "subunits," are obtained by additional purification procedures and mainly contain the viral surface proteins. Nonetheless, two main reasons have convinced vaccine manufacturers to search for an alternative to eggs for growing influenza virus for vaccine production. First, the spreading of an avian infection caused by flu or other viruses could greatly reduce the availability of hens and thus the eggs required for vaccine manufacturing. Second, each new influenza virus has to be adapted to grow in eggs with the risk that antigenic mutations will rise in the egggrown virus compared to the virus that is circulating in the human population, ultimately negatively affecting the vaccine efficacy. Therefore, several cell lines such as Vero or MDCK have been evaluated for growing the influenza virus, and recently, the first vaccine using cell culture-derived virus has been licensed in Europe.[162] This cell-derived influenza vaccine offers a safe alternative for individuals with egg allergies. All seasonal influenza vaccines are currently trivalent containing one strain of B type and two subtypes of A virus according to WHO recommendations. Not all influenza virus strains grow well in eggs, and this can affect yield of vaccine production. During the 1970s, the influenza virus A Puerto Rico/8/34 (PR8) strain, which shows a high growth capacity in eggs, was isolated. PR8 strain can be used together with a wild-type virus to obtain in vitro a reassortant strain that contains only HA and NA from wild-type virus and all other genetic material from the PR8 strain, usually maintaining a high growth capacity in eggs. To increase yield in vaccine production, most of the influenza A vaccine strains are reassortant of PR8 with the wild-type seasonal strains. In the 1990s, the circulating B strain diverged into two separate subtypes, which in the last two decades circulated with a different prevalence during each season, but the vaccine contains only the strain that will most likely circulate. However, during some seasons, the vaccine strain did not match the most widely circulating strain, resulting in reduced efficacy for the vaccine, especially in children who are the population most affected by influenza B virus. For this reason, the proposal by the WHO and vaccine manufacturers to include in the seasonal vaccine both B subtypes is currently under discussion.

An adjuvanted vaccine containing the emulsion MF59 is licensed in Europe and many countries worldwide for use in the elderly. This adjuvanted vaccine shows increased immunogenicity and better clinical protection compared with the split conventional influenza vaccine in the elderly population.[163,164] A virosome-based formulation of the flu vaccine is also in use in Europe and is immunogenic in children.[165]

Several live attenuated strains of influenza virus have been obtained either by growing in nonhuman cells, the host range mutant strains, or by isolation of temperature-sensitive strains, which do not grow at 39°C. However, none of these strains was able to give a really attenuated strain to be used as vaccine. On the contrary, cold-adapted strains, which grow at 25°C, were used as master strains for reassortment to successfully obtain an attenuated virus containing HA and NA coding RNAs from wild-type virus and the other six RNAs from the master strain. A live-attenuated influenza vaccine can therefore be obtained each year

from two cold-adapted strains of A and B subtypes by reassortment with the seasonal wild-type viruses. The reassortant strains are attenuated and immunogenic but are not able to be transmitted by

the vaccinated person to other individuals.[166] A live-attenuated influenza vaccine has been licensed in the United States and is administered as an intranasal aerosol spray. This vaccine contains three attenuated reassortant strains that express the antigens from the seasonal recommended strains and are grown in pathogen-free eggs.

Neutralizing HA-specific serum antibodies are the main mechanism of protection against influenza, although mucosal sIgA antibodies and cell-mediated immune responses may also play a role. Therefore, titration of serum antibodies is used as a surrogate of protection to evaluate vaccine efficacy. Three serologic assays can be used for measuring the antibody response to influenza vaccination: hemagglutination inhibition (HAI), single radial hemolysis, and microneutralization. The HAI test is widely used to assess vaccine immunogenicity because of its reproducibility. Several studies of influenza infection suggested that HAI antibody titers ranging from 1:18 to 1:65 were associated with protection in 50% of adult individuals, and that protection directly correlated with HAI titers.[167,168] This finding led to the decision that a HAI titer ≥1:40 is accepted as a surrogate marker for protection in adult individuals, although a similar marker for children has not been established. However, the HAI test is not accurate to measure neutralizing antibodies against avian viruses, and a modified test is used for assessment of vaccination against avian strains. It is indeed accepted that the microneutralization assay is a more reliable method to specifically evaluate the antibody response against H5N1 virus in patients or vaccinated subjects.

As also observed during the 2009 pandemic, in case of the unexpected emergence of a new influenza pandemic strain, it may be difficult to produce within a short time frame sufficient quantities of the specific vaccine to block spreading of the emerging strain and reduce casualties. For this reason, one option of the pandemic preparedness strategy is the development and licensing of prepandemic vaccines against a strain that has the potential of becoming a pandemic strain. The H5N1 avian strain is still considered as a likely candidate for future pandemic influenza, and prepandemic vaccines for this virus have been produced and licensed. During the interpandemic period, these vaccines can be used to immunize individuals at high risk of both avian and human virus infection (eg, veterinarians, poultry workers, operators involved in the manufacturing of vaccines with pandemic-like strains, laboratory workers) to reduce the chance of an emergence of a reassortant pandemic strain. At the beginning of a pandemic caused by a strain that matches the vaccine strain, a rapid use of these vaccines can allow early protection of the human population. A pandemic by a not completely matched strain could still benefit from the use of such prepandemic vaccines if the prepandemic vaccine is able to elicit a crossreactive immune responses in the vaccinees. Indeed, it is calculated that even a vaccine with low efficacy can mitigate the effects of a pandemic.[169]

Hepatitis A and B

Described by Hippocrates as transmittable jaundice, infectious hepatitis has been responsible for epidemics throughout the centuries and has influenced military strategies in the past because of frequent outbreaks among soldiers. Only at the beginning of the 1950s was infectious hepatitis definitively differentiated from serum hepatitis, and these two diseases were classified as hepatitis A and B, respectively. Hepatitis A is caused by HAV, an enterovirus of the *Picornaviridae* family. HAV is transmitted by the fecal-oral route and has an incubation period of 2 to 6 weeks. As with many other infectious disease, key steps on the road to a vaccine were the identification of its etiologic agent[170] and the establishment of an infection animal model in the marmoset, which permitted isolation of the virus,[171] and testing of a prototype vaccine using formalin-killed virus.[172] Subsequent advancements in virus propagation in cell culture were then developed to obtain the first licensed vaccine for humans.[173] Currently, two vaccines are licensed in the United States, whereas four vaccines are registered in Europe, Canada, and other regions. HAV is grown in the human diploid lung fibroblast cell line MRC-5, purified from lysed cells and inactivated with formalin. However, the manufacturing process is characterized by low yields. The inactivated HAV vaccine

induces anti-HAV neutralizing antibody titers that are considered protective. Two immunizations are indicated for both children and adults and provide anti-HAV antibody levels that are predicted to persist for many years. Efficacy of the vaccine has been demonstrated by several studies showing a decline in disease occurrence in vaccinated communities.[174] The virus strains used for preparation of the inactivated vaccine are attenuated by cell culture passages, and a live-attenuated vaccine has been successfully tested in humans while a similar vaccine is registered and used in China. An attenuated vaccine would present no advantages over the inactivated formulation, as the high production costs due to the low yields are not addressed. On the contrary, a promising VLP-based vaccine could be a feasible cheaper alternative.[175]

Hepatitis B, which was known in the past as serum hepatitis, is transmitted by parenteral inoculation with infectious materials, particularly blood or blood-derived products, and has a long incubation period from 40 days to 6 months. Infection with HBV is a worldwide health problem, with more than two billion people presenting evidence of previous infection and more than 350 million who are carriers of the virus according to the WHO estimates. The age of the first encounter with HBV greatly influences the outcome of the disease; 90% of children infected when younger than 1 year of age develop a chronic disease. As 25% to 40% of these chronic infections progress to liver cirrhosis or cancer, HBV represents one of the major causes of mortality globally. HBV is a double-strand DNA virus of the *Hepadnaviridae* family that does not propagate in vitro. Vaccine development was facilitated by the following findings: 1) discovery of the so-called Australia antigen in the serum of people who had received blood transfusions, 2) recognition of HBsAg, and 3) identification of VLPs in the serum of patients with hepatitis that contained the Australia antigen. The first vaccine against HBV was prepared with formaldehyde-inactivated particles isolated from the serum of chronically infected people and was proven safe and efficacious.[176] However, as mentioned previously, cloning of the viral DNA allowed development of a new vaccine made

by recombinant HBsAg produced in yeast or mammalian cells, which self-assembles into VLPs and is as protective as the previous vaccine.[4] The recombinant vaccine is currently used in most countries worldwide and is able to induce anti-HBsAg antibodies above the protective concentration of 10 IU per mL after the standard three-dose schedule in more than 95% of normal children or adolescents. Although 90% of vaccinated adults younger than 40 years old achieved this protective level, this percentage declines with age with only 75% of 60-year-old vaccinees generating adequate levels of anti-HBsAg antibodies. Vaccine-induced antibodies tend to decline with time and, depending on the study, return to undetectable levels in up to 60% of vaccinees 10 years after the last immunization. The effectiveness of the vaccine has been demonstrated by reduction in the prevalence of HBV chronic infection following the implementation of routine vaccination programs. Because one of the long-term consequences of HBV infection is development of hepatocellular carcinoma, the HBV vaccine is considered the first licensed preventive human cancer vaccine. Indeed, infant HBV vaccination has been associated with a reduction of more than 50% in the incidence of hepatocellular carcinoma.[177]

Measles, Mumps, Rubella, and Varicella

Measles, mumps, rubella, and varicella are common childhood diseases that can be associated with complications and in rare cases may result in death. All these diseases can be prevented by live-attenuated vaccines.

Measles is still one of the leading causes of death among young children worldwide. It was responsible for 164,000 deaths globally in 2008, with 95% of them occurring in developing countries. One of the most severe complications of measles is subacute sclerosing panencephalitis, which is particularly frequent at those younger than 1 year of age and results in brain damage and death. Measles was mistaken with smallpox until the 17th century, and by the 18th century, it was considered an infectious disease, although the measles virus was only isolated in 1954 by Enders and Peebles in tissue culture from the blood of 13-year-old boy named Edmonston.[178] The Edmonston strain of measles virus was then attenuated by many passages in cell culture and adapted to grow in chicken embryos and finally used to develop the first measles vaccine in 1963 containing the Edmonston B

strain. However, coadministration with Igs was required to reduce the high frequency of side effects associated with this attenuated vaccine. Further passages in cell culture resulted in the isolation of more attenuated Edmonston strains, which were as efficacious as the original strain in inducing protective antibodies but were not associated with side effects and did not require coadministration of Igs.[179,180] Immunization with measles vaccine is able to induce specific IgG, IgM, and IgA in both serum and mucosal secretions of vaccinees, and seroconversion can be observed in more than 95% of individuals. The efficacy of this vaccine is demonstrated by the dramatic reduction in the incidence of measles cases in all populations after the implementation of vaccination and by a 78% drop in measles deaths between 2000 and 2008 worldwide.

Mumps is a highly infectious disease that was first described by Hippocrates. Parotitis is the classical symptom of mumps, which can be complicated by meningitis, pancreatitis, and orchitis in 20% to 30% of postpubertal males. Mumps virus, a negative-sense RNA virus of the genus *Rubulavirus* in the *Paramyxoviridae* family, was isolated in 1945 by growing on chick embryos and propagated in in vitro tissue culture, but attempts to attenuate this isolate for vaccine purposes were not successful. Hilleman's group then isolated the Jeryl Lynn strain which was attenuated by culturing on embryonated hens's eggs and chick embryos.[181] This vaccine induced seroconversion in 98% of the vaccinated subjects and demonstrated a 95% efficacy in protection.[161,182] Most of the mumps vaccines currently in use are still based on the Jeryl Lynn strain or its derivatives, whereas few other products are made with different attenuated strains.

Rubella is usually a benign and self-limiting disease in children characterized by maculopapular exanthema and is caused by a positive-strand RNA virus of the genus *Rubivirus* in the *Togavirus* family. However, infection of a pregnant woman can result in spreading of the virus to the fetus leading to fetal death or congenital rubella, which is associated with severe birth defects in many organs. In particular, infection during the first trimester of pregnancy results in developmental defects of the eyes and the heart, whereas deafness is the major consequence of infection in the second trimester. Between 1962 and 1965, a large outbreak of rubella spread throughout Europe and then to North America, infecting a billion people and tens of thousands of pregnant women, resulting in thousands of newborns with congenital defects. The rubella virus was isolated in 1962 by two different groups and different live-attenuated strains were then used to produce different vaccines, which were licensed in the United States, Europe, and other countries in 1969 and 1970.[183,184,185] Seroconversion rates ranging from 90% to 98% resulted in a remarkable reduction in the rate of both acquired and congenital rubella cases after introduction of the vaccine in many countries. However, as vaccines based on the RA27/3 attenuated strain have shown a better immunogenicity and a reduced incidence of side effects, these strains are currently used for the production of most rubella vaccines in use worldwide. Rubella virus can be detected in mucosal secretion of vaccinees starting 1 week after immunization and can persist for 2 weeks, but no spread of the virus to contacts could be observed, excluding the risk that the vaccine strain can pass to pregnant women causing congenital rubella.[186]

Varicella or chickenpox is caused by a double-strand DNA virus of the *Alphaherpesviridae* family, which is also the etiologic agent of herpes zoster and therefore has been named varicella-zoster virus. Similar to measles, varicella was clinically mistaken with smallpox until the 18th century and is characterized by a maculopapular rash rapidly transforming into vesicles, pustules, and crusts. Varicella-zoster virus was isolated in 1952, but no sufficiently attenuated strain suitable for vaccine purpose was derived for many years. Such a strain was indeed obtained in 1974 by Michiaki Takahashi in Japan with a virus isolated from a boy suffering from a mild form of varicella, which was passed several times in human embryo lung fibroblasts and then in guinea

pig fibroblasts, and was named the Oka strain.[187,188] This strain was used to prepare a vaccine that was shown to be efficacious in clinical trials and was first licensed for use in immunocompromised children and their healthy contacts in several European countries in 1984, followed by Japan and Korea. Ten years later, Oka-based varicella vaccines were approved for use in all children in Europe and North America. The immunogenicity of this vaccine has been evaluated in many clinical studies that showed that the Oka strain induced

seroconversion from 76% to 96% of vaccinated individuals,[189,190] although no clear correlation could be established between the levels of serum antibodies and protection from varicella infection. Varicella-zoster virus-specific antibodies tend to decrease with time but can still be detected many years after vaccination.[191]

Measles, mumps, and rubella vaccines have been combined in a trivalent vaccine, and more recently, a tetravalent formulation with addition of varicella Oka strain has been developed. The immunogenicity and the side effect rate of this combined vaccine are comparable to that obtained with administration of each single vaccine separately.

Rotavirus

Rotavirus infection is the leading cause of severe diarrhea in children younger than 5 years of age in all countries in the world, resulting in a large number of hospitalizations in developed nations and more than 500,000 deaths a year worldwide, most of them by dehydration in developing countries. Rotaviruses represent a genus of the *Reoviridae* family, containing many members that can infect humans or other animal species such as cows or nonhuman primates. Rotaviruses have a double-stranded DNA genome segmented in 11 fragments that can reassort during infection of a cell by more than one strain of virus, resulting in a novel virus type. Many strains of rotavirus can be identified based on differences in two surface proteins VP4 and VP7, which define, respectively, the P- and the G-types. Many combinations of VP4 and VP7 were isolated from humans, although most cases of gastroenteritis in children are associated with five strains, with the P1A[8]-type associated to the G1, G3, G4, or G9 serotypes, and the P1B[4]-type associated with the G9 serotype. Both VP4 and VP7 can induce typespecific neutralizing antibodies that can prevent infection by a specific serotype of rotavirus, although some level of crossreactivity can be observed.[192] Moreover, natural sequential infections are associated with a progressively reduced risk for subsequent rotavirus infection even if caused by another serotype,[193] suggesting that broad protective immunity may be stimulated by an attenuated oral vaccine.

The first attempts to develop an oral rotavirus vaccine followed Jenner's approach, using more easily attenuated nonhuman strains and relying on a potential protective effect from a live-attenuated heterologous strain. Two candidate vaccines used two different bovine rotavirus strains, whereas a third was based on a simian virus strain. All these vaccines were well tolerated and immunogenic, and induced serum-neutralizing antibodies against the vaccine strain. Although some clinical studies showed that each of these vaccines could induce protection against rotavirus-mediated gastroenteritis, efficacy data were not consistent. This suggested that animal strains do not induce efficient protection against human rotaviruses, and this approach was eventually abandoned.

An alternative approach has been the selection of reassortant strains expressing VP7 or VP4 protein from human rotavirus in a genetic background of a simian- or bovineattenuated strain. A first vaccine of this type contained three rhesus-human reassortants each expressing the human VP7 protein from one of the serotypes 1, 2, or 4, plus the parental simian strain that expressed a simian VP7 protein of serotype 3. Many clinical trials demonstrated that this tetravalent vaccine was immunogenic, inducing neutralizing antibodies in more than 90% of vaccinated children and had 69% to 100% efficacy against severe rotavirus-mediated gastroenteritis.[194] This vaccine was licensed in 1998, but after 1 year, in which more than 1.5 million of doses were administered, a small increase in the risk of intussusception (a rare bowel obstruction in which one segment of bowel prolapses into a more distal segment) in the vaccinated population was observed, leading to the withdrawal of the product. The incidence of intussusception attributed to this vaccine was 1 in 10,000 and was considered unacceptable for children in developed countries such as the United States where only 1 in 150,000 cases of rotavirus infection results in death. However, this tetravalent vaccine was still beneficial for young populations in developing countries where 1 in 250 children die because of rotavirus-induced gastroenteritis and where the use of this vaccine could have saved many more lives compared to the number of lives saved avoiding the adverse event associated with the vaccine.

Another rotavirus vaccine based on bovine-human reassortants was developed and contains five in vitro derived strains expressing either the human VP7 protein from one of the G1, G2, G3, or G4 serotypes, or the human VP4 protein of P1A[8] genotype in the genetic

background of a bovineattenuated strain. Because administration of the first licensed rotavirus vaccine had been associated with increased risk of intussusception, licensing of this pentavalent vaccine required an extensive phase III trial on nearly 70,000 young children worldwide. This, as well as subsequent studies, demonstrated that administration of three doses of this oral vaccine was not associated with an increase of any severe adverse event and was efficacious against severe gastroenteritis or any grade of disease due to rotavirus, reducing hospitalizations associated with rotavirus infection.[195] In 2006, this vaccine was approved for use in the United States and is now licensed in more than 95 countries.

Analysis of the immune response to natural infections has shown that although the first infection primarily induces serospecific neutralizing antibodies, subsequent infections are able to generate more broadly cross-reactive responses.[196] This observation has stimulated an alternative approach to rotavirus vaccine design, which consists of the use of a single human attenuated strain with a G1PA1[8] serotype. Similar to the pentavalent recombinant vaccine, this monovalent oral formulation has been evaluated in a large phase III trial on more than 70,000 subjects that showed that the vaccine was safe and efficacious in preventing

rotavirus-mediated gastroenteritis after two doses.[197] This vaccine is now licensed in Europe, the United States, and many other countries.

After introduction of these vaccines in the United States, a great reduction in rotavirus-mediated gastroenteritis was observed. Recently, the WHO recommended the inclusion of rotavirus vaccine for infants in all national immunization programs, particularly in countries where diarrhea is responsible for more than 10% of deaths among children younger than 5 years old. Implementation of the rotavirus vaccination in developing countries is expected to have a great impact on mortality rates among infants worldwide.

Human Papillomavirus

HPV is a nonenveloped virus with an icosahedral capsid made up of only two structural proteins, L1 and L2, which surround a double-stranded DNA genome. Each viral particle contains 72 pentamers of L1, the major capsid protein, and up to 72 monomers of the L2 protein. HPV can infect different types of human epithelial cells. Until the beginning of 1980s, HPV infection was not considered clinically relevant because most were asymptomatic or associated with benign cutaneous papillomatosis and genital warts. However, in the last 30 years, it has been clearly demonstrated that infection of the female genital tract by some types of HPV is associated with development of cervical cancer, and that 100% of these malignancies are caused by infection with one of the “high-risk” HPV types, so called for their capacity to induce a malignant transformation of the cervical cells. More than 100 genotypes of HPV have been identified, and at least 15 of them have been associated with cervical cancer. Two genotypes, HPV16 and HPV18, are responsible for 70% of these malignancies. After breast cancer, cervical cancer is the most frequent type of cancer in women around the world, affecting mostly young women in their 20s to 40s. Cancer of the cervix was responsible of 275,000 deaths worldwide in 2008, with most of them occurring in developing countries. The disease, therefore, represents a significant social and economic burden due to the costs for screening and treatment as well as the young age of the affected patients.

HPV specifically infects human cells, and no animal model of infection is available for testing potential vaccine efficacy. However, experiments with homologous bovine or canine papillomavirus showed that an inactivated virus preparation was able to induce neutralizing antibodies that protected cattle and dogs from infection.[198,199] This suggested that a preventive vaccine able to induce neutralizing antibodies to HPV was feasible. HPV replicates only in differentiated epithelial cells, and it is difficult to grow in culture, making propagation of this virus in order to prepare a live-attenuated or killed vaccine complicated. Early attempts to use a recombinant L1 protein of bovine papillomavirus as a vaccine against this virus were not successful. A breakthrough in the development of an HPV vaccine came from the demonstration that when expressed in insect cells using a baculovirus system, recombinant L1 capsid proteins were able to self-assemble in VLPs that induced neutralizing antibodies upon immunization.[200] However, these antibodies are genotype specific, suggesting that a broadly protective vaccine would need to include VLPs from multiple genotypes. Fifteen years of further research and clinical trials were required to develop the first licensed vaccine for

prevention of HPV infection in 2006. Two types of vaccines are currently available in the United States, Europe, and many other countries. One product contains VLPs produced in yeast cells adjuvanted with alum and protects from infection by the two oncogenic HPV16 and HPV18 and two other genotypes, HPV6 and HPV11, which are responsible of 90% of genital warts. VLPs from HPV16 and HPV18 produced in insect cells are present in the second vaccine, which also contains the AS04 adjuvant system. Both vaccines were efficacious in preventing infection by the HPV genotypes contained in the vaccine preparation and development of cervical intraepithelial neoplasia, an endpoint that was required by FDA in the efficacy trials.[201] Although no correlate of protection for HPV has been established, the observation that transfer of antibodies from VLP-immunized animals prevents infection by papillomaviruses in animal models indicates that the presence of serum-neutralizing antibodies could be considered as an indicator of vaccine efficacy. Although the current licensed HPV vaccines are administered intramuscularly, they are nevertheless able to protect from infection by HPV at the genital mucosa, probably by secretion of neutralizing IgG in the mucosa fluids. The high production costs of the licensed HPV vaccines are reflected in the relatively high cost of these products, limiting their use in developing countries where 80% of cases of cervical cancers occur. Alternative and less costly vaccines are therefore required to reduce the economic burden of broad HPV vaccine implementation in developing countries.

Bacterial Vaccines

Diphtheria, Tetanus, and Pertussis

The diphtheria-tetanus-pertussis (DTP) combination vaccine is the oldest but still the most used combination vaccine. Two types of this vaccine combination are available today: the classical DTwP, which contains the whole cell pertussis vaccine, and the DTaP in which the diphtheria and tetanus toxoids are combined with an acellular pertussis vaccine.

Tetanus is a nontransmissible disease caused by a toxin produced by *C. tetani*, a gram-positive bacterium that can grow in anaerobic conditions in infected tissues. Tetanus toxin is one of the most powerful neurotoxins that affects particularly inhibitory neurons, resulting in localized and generalized spasm of the muscles and leading to death in almost 100% of cases if left untreated. The identification of tetanus toxin and the demonstration that the toxin induced the production of protective neutralizing antibodies in animals when injected in small amounts led to the discovery that an inactivated toxin, anatoxin or toxoid, could induce protective immunity against tetanus, as described previously. The toxoid obtained by formaldehyde treatment became available at the end of the 1930s when it started to be widely used for tetanus prophylaxis. Although no formal study has been performed to directly evaluate the vaccine efficacy, the great reduction of tetanus cases in all vaccinated populations demonstrates the effectiveness of

toxoid immunization. Several studies have evaluated persistence of immunity following three immunizations with tetanus toxoid. Vaccine-induced antitoxin antibodies decline over the years. Therefore, after a three- to four-dose primary immunization series, a booster dose every 10 years is recommended to maintain protective levels of antibodies.

Diphtheria is a lethal infectious disease that was a major cause of childhood death in the prevaccination era. It is caused by *C. diphtheriae*, a gram-positive bacterium that infects the upper respiratory tract and secretes a potent toxin that induces cell death, producing local and systemic damages, and is responsible for diphtheria lethality. Identification of diphtheria toxin in 1888 was followed by the discovery that antisera produced in animals immunized with inactivated bacteria could protect other animals or humans from disease, which led to the use of antisera or antitoxin for the treatment of diphtheria. In 1907, a mixture of toxin-antitoxin was successfully used to immunize animals and humans, and its use became a common practice to prevent children disease. When in 1923 Ramon showed that a formaldehyde-inactivated toxin could induce protective antitoxins, a toxoid-based vaccine became available and widely used. Although no clinical trials to measure efficacy of this vaccine have been performed, the vaccine effectiveness has been demonstrated by the disappearance of diphtheria disease in the developed countries where routine vaccination is in place. After a three-dose schedule during the first year of life, serum antibodies reach a protective concentration but then diminish with time. Indeed, decreased immunity has probably been responsible for many

diphtheria outbreaks among adults observed in several states of the former Soviet Union in the 1990s. As with tetanus, a booster dose every 10 years is therefore recommended to maintain protective levels of antibodies. Finally, although a mutated inactive form of diphtheria toxin, called CRM197,[202] induces antitoxin protective antibodies, this has not been used alone as a diphtheria vaccine; rather, it has found application as a protein carrier in many glycoconjugate vaccines.

A whole-killed **pertussis** vaccine (wP) was the first of the three components of DTP to be licensed in 1914, a few years after the identification of *B. pertussis* as the etiologic agent of whooping cough or pertussis. It is obtained by a suspension of the *B. pertussis* killed by formaldehyde. Efficacy of the wP vaccine was demonstrated by early clinical trials during whooping cough epidemics on the Faroe Islands and by a rapid decline of pertussis in the United States after the introduction of the universal vaccination for children in the 1940s. Although efficacious, the wP vaccine is reactogenic, inducing sometimes serious although transient adverse events. However, several controlled studies have definitively excluded any causative relation between the wP vaccine and all particularly worrisome reactions such as encephalopathy, sudden infant death syndrome, and infantile spasms, which in the past were associated with this vaccine. Nevertheless, in the 1970s, the adverse events associated with DTwP vaccines containing the wP started to create alarm among parents and doctors in developed countries where pertussis had almost disappeared and where the benefits of the vaccination were becoming less appreciated. Public concerns for wP-mediated adverse reactions were so strong that vaccination rates declined leading in some countries to recurrence of pertussis outbreaks, which resulted in the death of hundreds of children. An example of the effects of the decline in pertussis vaccine coverage was observed in Japan, where the universal pertussis vaccination was initiated in 1947, leading to a remarkable reduction of whooping cough cases to such a low rate of 0.1/100,000 by 1971. In 1975, the vaccine-unrelated death of two vaccinated children increased fears for the vaccine-related side effects, leading to a dramatic decline of the vaccination rate in the following years, resulting in an increase of pertussis cases to 8.4/100,000 in 1979 with many associated deaths.[203] Reactogenicity of the wP vaccine encouraged the search for a better tolerated vaccine, leading to the development of the first acellular pertusis vaccine (aP), which was licensed in Japan in 1981 as a DTaP combination. Many DTaP vaccines have been developed during the years, leading to replacement of DTwP in all developed countries. All DTaP vaccines contain the inactivated pertussis toxin, a protein complex with ADP-ribosyl transferase enzymatic activity, which is the major pathogenetic component of *B. pertussis*, with the addition of one or more bacterial components such as filamentous HA, pertactin, and fimbrial proteins. One vaccine, which has been an important innovation in this field, was based on a genetically inactivated form of pertussis toxin, in which two amino acid substitutions in the catalytic site abolish toxin activity.[2] Many clinical trials have evaluated the efficacy of the different DTaP vaccines, some also comparing one or more DTaP vaccines to one DTwP vaccine. Differences in the execution of these trials render a comparative analysis complicated. However, a general conclusion that can be drawn is that DTaP vaccines are as efficacious as the DTwP vaccine in protecting from pertussis disease, with an efficacy from 71% to 96%, depending on the study. Evidence of efficacy for the DTaP vaccines is also the persistent reduction of pertussis cases in Japan after the introduction of this vaccine. More than 5000 cases were reported in this country in 1980, the year before licensing of the DTaP, whereas only 131 were reported in 1993. All clinical studies also showed fewer local and systemic adverse events for the different DTaP vaccines compared to the DTwP. Although a significant increase of serum antibodies against the different components of the aP vaccine can be detected in subjects immunized with both DTaP and DTwP vaccines, no clear correlate of protection could be established. Data from various trials conducted with DTaP and DTwP vaccines have also suggested that after a three-dose schedule, the immunity persists for 5 to 6 years, after which protection starts to decline, leading to the recommendation for a booster immunization at the age of 5 to 6 years old. An adolescent boost with diphtheria-tetanus or DTaP is also recommended, after which a boost every 10 years can help to maintain a protective immunity. Unfortunately, whooping cough is still a major cause of childhood mortality worldwide, in particular in countries with low vaccination coverage. The WHO estimates that in 2008, about 16 million cases of pertussis occurred worldwide, resulting in 195,000 deaths, 95% of which were in developing countries. The WHO currently recommends a primary three-dose course

of DTP within the first year of life, followed by a booster immunization in the second year of life. This first series should be able to confer protection for at least 6 years.

Haemophilus Influenzae Type b

Bacterial meningitis and septicemia are caused mainly by three capsulated pathogens, *H. influenzae*, *S. pneumoniae*, and *Neisseria meningitidis*. *H. influenzae* infection can also result in other clinical outcomes such as pneumonia, otitis media, sinusitis, epiglottitis, septic arthritis, and osteomyelitis. *H. influenzae* was originally described by Koch in 1883. Two major groups of *H. influenzae* can be identified: capsulated and uncapsulated. Bacteria in the first group are the most virulent types and contain a polysaccharide capsule that allows the identification of six antigenically different serotypes named from A to F. In the prevaccination era, capsulated Hib strains were responsible for more than 95% of severe infections caused by this species of pathogens. Uncapsulated or nontypeable strains (nontypeable *H. influenzae* [NTHi]) generally cause pneumonia, otitis media, and sinusitis. Hib capsular polysaccharide is made of polyribosylribitol phosphate (PRP) and is a major virulence factor, as it renders the bacteria particularly resistant to complement-mediated killing. A polysaccharide-based vaccine containing PRP was the first vaccine against Hib to be evaluated in the early 1980s. Efficacy trials showed that this vaccine was 90% effective in protecting children 18 months and older from Hib infection, although no efficacy could be observed in subjects below this age, who are most at risk for Hib invasive disease. These results stimulated the development of a DT glycoconjugated vaccine that was licensed in 1988. Efficacy of this vaccine, however, was inconsistent, in particular in very young children. Three other vaccines were developed, in which Hib PRP has been conjugated to CRM197, the outer membrane protein complex of *N. meningitidis* serogroup B, or TT, respectively. All these vaccines are highly immunogenic in all age groups after three doses, although the outer membrane protein complex conjugated vaccine induces higher antibody titers after the first or second immunization.[204] Many clinical trials have shown an overall efficacy ranging from 87% to 100% in prevention of Hib infection after a three-dose immunization schedule, although no study has compared all three vaccines in parallel. Efficacy of the conjugated Hib vaccines is also demonstrated by the reduction of more than 90% in the incidence of Hib disease in all countries where routine vaccination has been implemented. Several studies have shown that after a threedose primary immunization series, serum antibody levels tend to decrease to a concentration thought to be insufficient to confer protection, although a minimum protective antibody level has not been clearly established. However, a booster immunization is able to drastically increase serum antibodies that then decline to a concentration that is higher than the preboost concentration and remains constant with time.[205] Therefore, the WHO recommends a three-dose immunization schedule for Hib starting from 6 weeks of age and given at a 4-week intervals. In most developed countries, a booster dose at 12 to 18 months is also included in the routine schedule. The WHO has actively supported Hib routine vaccination in developing countries, but in 2009, vaccine coverage was still below 50% for the world population. Glycoconjugated Hib vaccines are currently combined with DTwP or DTaP vaccines, which may also include IPV and HBV vaccine.

Pneumococcus

S. pneumoniae is a major cause of diseases such as meningitis, pneumonia, sepsis, and otitis media. Children younger than 2 years of age and the elderly are the most susceptible populations. In 2005, the WHO estimated that pneumococcal infection is responsible for 1.6 million deaths every year and most of these occur in developing countries *(*http://www.who.int/nuvi/pneumococcus/en/*)*. Soon after its isolation in 1881, pneumococcus was identified as the major cause of pneumonia. *S. pneumoniae* are gram-positive bacteria coated by a polysaccharide capsule that protects them from the host immune system. Indeed, an antibody response against capsular polysaccharide is able to stimulate opsonophagocytosis and bacterial killing, resulting in protection from pneumococcus infection. Structural and antigenic differences in the capsular polysaccharide allow the identification of more than 90 serotypes, although the number of pathogenic serotypes is lower. As antibody to the capsular polysaccharide is protective but serotype specific, in order to induce broad protection against pathogenic serotypes, a pneumococcal vaccine needs to

contain different polysaccharides.

A first pneumococcal vaccine containing polysaccharides from six serotypes was successfully developed in the mid-1940s.[13] At that time, however, it was believed that pneumococcal infection could be easily cured by penicillin, and there was no interest in the use of this vaccine, which was therefore withdrawn soon after its licensure. In the 1970s, 6-valent, 12-valent, or 13-valent polysaccharide vaccines were tested in clinical trials performed in South Africa in adult gold miners, a population at high risk for pneumococcal pneumonia. These studies reported a vaccine efficacy between 76% and 92% against pneumonia caused by the pneumococcus serotypes contained in the vaccine[206,207] and supported licensure of a 14 serotype vaccine in 1977. This vaccine was then replaced in 1983 by a 23 polysaccharide vaccine that covered 85% of the serotypes causing invasive pneumococcal disease (IPD) at the time of vaccine introduction. These polysaccharide-based vaccines stimulate a T-cell-independent antibody response and therefore are able to induce an increase in serotype-specific antibodies in adults but not in children younger than 2 years of age. Indeed, no protection against otitis media was observed in clinical trials among children younger than 2 years of age. Results of several controlled clinical trials evaluating these vaccines in different adult populations were inconsistent and did not confirm efficacy for these polysaccharide-based vaccines against pneumococcal pneumonia as endpoint. However, the conclusions of these studies might have been negatively affected by the fact that pneumococcal infection with bacteremia is relatively rare in an adult population, that the clinical diagnosis of nonbacteremic pneumonia is based on not very specific and sensitive criteria, and that the sample size of

some trials was probably not adequate to correctly measure vaccine efficacy. On the contrary, many postlicensure observational studies have reported effectiveness for these vaccines against IPD in adult subjects, supporting the use of the currently licensed 23-valent vaccine in elderly and other adult subjects at risk of pneumococcal infection.

Induction of polysaccharide-specific antibodies in children younger than 2 years of age requires a T-cell-dependent response, which can be stimulated by a glycoconjugate vaccine. A 7-valent pneumococcal conjugate vaccine (PCV7) with CRM197 as carrier protein and polysaccharide from serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F was licensed in 2000 in the United States, then in Europe, and in many other countries for use in children younger than 2 years of age. When PCV7 was licensed, 65% to 80% of IPD in children from industrialized countries were associated with serotypes contained in this vaccine. In a large PCV7 clinical trial performed in California before licensure, 40 cases of IPD associated with the vaccine serotypes were identified with only one in the vaccinated population, resulting in an efficacy of 97%.[208] After the introduction of PCV7 in routine immunization schedule, a 95% reduction of IPD by vaccine serotype and a 75% decrease in all serotype IPD has been observed as well as an indirect effect on unvaccinated population as a reduced incidence was observed also in the adult population.[209] Similar observations have been made in other countries where PCV7 has been introduced. Several studies have documented that a wide use of PCV7 has resulted in carriage reduction for the vaccine serotypes, which is associated with a parallel increase in carriage of nonvaccine serotypes. The nonvaccine serotypes are more likely to produce a disease compared to the prevaccine era, resulting in a serotype replacement among disease-associated strains. Immunogenicity of pneumococcal glycoconjugate vaccines can be evaluated by measuring serum-specific antibodies against capsular polysaccharides using enzyme-linked immunosorbent assay or opsonophagocytic assay. This latter method detects functional antibodies that are able to kill bacteria in the presence of complement and phagocytic cells. Despite the lack of a clear correlate of protection for pneumococcal vaccines, WHO guidelines suggest the use of a concentration of 0.35 µg per mL for polysaccharide-specific IgG as a threshold when comparing immune responses to each serotype for a new PCV.

A high proportion of IPD in developing countries, particularly in Africa, are associated with serotypes 1 and 5, which are not included in this 7-valent vaccine formulation. A 9-valent CRM197 conjugated vaccine, which also includes serotypes 1 and 5, has been evaluated in two trials in South Africa and in The Gambia, where efficacy against IPD by vaccine serotypes was 85% and 77%, respectively, supporting the use of such type of vaccine for children in developing countries where the burden for pneumococcal infection is highest.

Two new glycoconjugate vaccines against pneumococcus have recently been licensed in the United States, Europe, and other countries. One is an evolution of the PCV7 and contains 13 serotype (PCV13), including serotypes 1, 3, 5, 6A, 7F, and 19A and has shown to meet the WHO criteria of immunogenicity and noninferiority compared to PCV7.[210] The other licensed product is a 10-valent vaccine that contains polysaccharides of the PCV7 serotypes plus serotypes 1, 5, and 7F but uses a different carrier protein than that of PCV7. One serotype is conjugated to TT, one to DT, and all other serotypes to protein D from NTHi.[211] The advantage of this last vaccine should be the capacity of protecting from otitis media induced by both pneumococcus and NTHi. With the inclusion of more serotypes, both these new vaccines should broaden coverage of protection, in particular including serotypes 1 and 5 which are most spread in many developing countries. Moreover, PCV13 has included invasive serotypes that have been increasingly causing severe disease both in the United States and Europe because of strain replacement following PCV7 introduction. Future epidemiologic observations will inform whether new pathogenic strains will continue to replace the vaccine strains after the introduction of these new vaccines. The need for a universal pneumococcal vaccine has stimulated research for a protein-based vaccine. Such a vaccine should not induce strain replacement; it should theoretically have a broader coverage compared to the glycoconjugate vaccines, and it should be cheaper to produce, helping the extension of vaccine use to less developed countries. Several protein-based vaccines are currently being evaluated in preclinical models.[212,213,214]

Meningococcus

N. meningitidis is the major cause of epidemics of bacterial meningitis and still represents a major worldwide threat to public health. Children younger than 2 years of age are at a higher risk of contracting the infection, although some protection seems to be provided by persisting maternal antibodies for up to 6 months of age. Incidence then declines with increasing age but increases again in the teenage years. In 10% to 20% of cases, meningococcal infection is associated with severe sepsis that rapidly progress to death 40% of the time. Today, the overall fatality rate for all meningococcal infections is 10% to 15%, whereas 10% to 20% of subjects who survive have lifelong disabling sequelae. Humans are the only natural reservoir of the bacterium that colonizes the nasopharynx and is transmitted by aerosol or secretions. This makes eradication feasible. It is estimated that 5% to 10% of the adult population in nonendemic areas are asymptomatic carriers. In only a small fraction of carriers the bacterium penetrates the mucosa entering the bloodstream, causing the systemic disease, although for most individuals bacterial carriage is associated with the acquisition of a protective antibody response.[215] The precise mechanism of progression from carriage of bacterium to invasive disease is still poorly understood.

N. meningitidis is a gram-negative aerobic encapsulated diplococcus. There are 13 known serogroups based on the immunologic reactivity of the capsular polysaccharides, of which the A, B, C, W-135, Y, and occasionally X account for virtually all meningococcal disease cases. Protection is usually group specific, and for serogroups A, C, Y, and W-135, protection appears largely to be due to antipolysaccharide antibodies.

Most cases in Europe and the Americas are due to MenB and MenC, whereas MenA and MenC are the most common in Asia and Africa. The major worldwide burden of the disease is, however, caused by MenA epidemics in Africa, in particular in “the meningitis belt,” which includes the sub-Saharan region extending from Senegal to Ethiopia. These epidemics occur at irregular cycles every 5 to 12 years, lasting for 2 to 3 years, and peaking for still unknown reasons at the end of the dry season. The burden of the epidemics is heavy, with case fatality rates of 10% to 20% and 75% of cases occurring in individuals younger than 15 years of age. MenB is the main cause of endemic meningococcal disease in the industrialized world and accounts for 30% to 40% of cases in North America and up to 80% of cases in some European countries. Incidence is highest in winter and in infants younger than 1 year of age, for which the fatality rate is also higher. MenB strains have also been the cause of severe persistent epidemics such as those in South American countries (Cuba, Colombia, Brazil, and Chile), in Norway, and in New Zealand. MenC is the cause of most of the remaining cases of disease in North America and Europe. MenW-135 accounts for only a small number of cases

in the United States but recently has caused outbreaks in Africa. MenY cases have recently increased in the United States, becoming a predominant cause of invasive infection in the elderly.[216]

The licensure of meningococcal vaccines has been based on a serological surrogate marker for protection, the serum bactericidal assay (SBA). This assay measures the level of antibodies that are capable of directing complement-mediated bacterial lysis. Based on the work by Goldschnider et al.,[217] the accepted correlate of protection from meningococcal disease is currently considered an SBA titer ≥4.

Initial vaccines against bacterial meningitis were based on heat-killed whole bacterial preparations; however, they had variable efficacy and caused severe adverse reactions probably due to the high endotoxin content. The first polysaccharide vaccines to be developed were those against MenA and MenC. They were developed in response to disease outbreaks in military recruits and proved to be a safe and effective preventive measure. Trials in army recruits during MenC outbreaks demonstrated an estimated 90% efficacy at 8 weeks following vaccination.[218,219] Meningococcal polysaccharide vaccines presently in clinical use are either bivalent, covering serogroups A and C, or tetravalent, covering serogroups A, C, W-135, and Y. These vaccines are currently used for the control of meningococcal disease epidemics in Africa.

The main disadvantage of polysaccharide vaccines is the poor immunogenicity in the young (younger than 2 years of age), who are at the highest risk for of infection, in addition to the short-lived protection induced in all age groups. Following the successful introduction of Hib conjugated vaccine, conjugation of the polysaccharide to a carrier protein has been exploited also for meningococcal vaccines. Monovalent glycoconjugated meningococcal vaccines against MenC were developed using CRM197 or TT as protein carrier. Three MenC vaccines were introduced in 1999 in the United Kingdom as additional vaccines in the routine infant immunization schedule at 2, 3, and 4 months of age, combined with a catch-up campaign for a single dose at 1 to 18 years of age in response to high rates of serogroup C infection. The immunization campaign has been a great success, resulting in a decrease >90% in the number of clinical cases and deaths, and a decrease of 66% in asymptomatic carriage The incidence of the disease also decreased by 70% among the nonvaccinated population, an effect probably due to reduced circulation of the bacterium and to the effect on nasopharyngeal colonization.[220]

The Meningitis Vaccine Project, a joint project between the WHO and PATH, was initiated in 2001 aiming at the development of affordable conjugated vaccines against MenA (MenAfriVac) for developing countries. The goal was to license a conjugate vaccine that is expected to be more effective than the existing polysaccharide vaccine currently in use and to cost only 40 cents per dose. A single dose in mass immunization campaigns in those 1 to 29 years old in the meningitis belt in Africa has been initially considered. At the end of 2010, MenAfriVac was introduced in Burkina Faso, Mali, and Niger, and after 6 months, these countries reported the lowest number of confirmed MenA cases ever recorded during an epidemic season.

Two slightly different tetravalent conjugate vaccines against serogroups ACW-135Y were developed in recent years. One vaccine, which uses DT as protein carrier, has been licensed in the United States in 2005 for use from 9 months to 55 years old. Licensure was exclusively based on the noninferiority to the PS vaccine, and no efficacy trial was conducted. In a trial in individuals aged 11 to 18 years old, both the polysaccharide and conjugated vaccines were able to elicit a fourfold or greater increase in SBA titers against the four serogroups (range 80% to 97%). However, in a 3-year follow-up, the persistence of bactericidal antibodies and booster response to a second dose was only measured in subjects who had received the glycoconjugate vaccine.[221] Studies in the 2-year-olds showed that a higher immune response against the four meningococcal serogroups was obtained with one dose of the tetravalent glycoconjugate vaccine than with the tetravalent polysaccharide vaccine.[222] Although antibodies persisted for 2 years for a large proportion of children, SBA titers were <1:4. This suggests that a booster dose might be needed in order to maintain long-lasting protection.[223]

CRM197 is the carrier for the second conjugate vaccine against serogroups ACW-135Y,

which has been licensed in both the United States and Europe, and is indicated for individuals 2 to 55 years of age, although an extension of the license for use in those younger than 2 years old has been filed with the FDA and the European Medicines Agency. Immunogenicity of this vaccine in children aged 2 to 10 years old is comparable to the other licensed tetravalent conjugated vaccine,[224] whereas in a higher proportion of vaccinated subjects, a persistence of bactericidal response could be observed.[225] Moreover, after three doses in infants, SBA titers ≥1:4 could be detected in 93% to 97% of subjects depending on the serogroup,[226] suggesting a good efficacy in this age group.

Currently, there is no vaccine available for broad protection against MenB disease. Classical approaches, such as those using polysaccharide-based vaccines, are not feasible because

MenB polysaccharide is structurally and antigenically identical to polysialosyl glycopeptides present in fetal and adult human neural tissue and, therefore, is poorly immunogenic and has the potential to trigger autoimmunity. Most vaccines developed against MenB are based on outer membrane vesicles (OMV) prepared by detergent extraction, which contain outer membrane proteins and lipooligosaccharides. These vaccines elicit functional bactericidal antibodies mainly directed against PorA, the most abundant protein component of these vaccines, and confer serosubtype-specific protection. Although PorA is almost ubiquitously expressed by meningococci, it has different antigenic specificities in the different strains, making it unlikely that a universal vaccine based exclusively on PorA could be generated. It has been estimated that 20 PorA proteins should be included in a MenB OMV vaccine in order to cover 80% of the prevalent circulating strains causing sporadic cases in the United States.[227] MenB vaccines based on OMV have been developed in response to disease outbreaks caused by a single strain in Cuba, Brazil, Chile, Norway, and New Zealand. The use of these OMV vaccines to combat MenB disease has been limited, however, due to the strain-specific nature of the protection.

A breakthrough in development of a MenB vaccine was the sequencing of the *N. meningitidis* genome, which opened the way to the identification of new potential antigens that could not have been characterized by conventional immunologic and microbiologic approaches. This approach, called “reverse vaccinology,” has led to the identification of 570 open reading frames encoding novel surface-exposed or exported proteins.[228] A total of 350 open reading frames were expressed as fusion proteins and tested in mice. Of these 350, 28 recombinant proteins were able to elicit serum bactericidal antibodies in the mouse. Five of the more conserved antigens (GNA2132, GNA1870, NadA, GNA1030, and GNA2091) were selected based on their function and used to prepare a multicomponent MenB vaccine, which was able to induce high SBA titers in mice. Bactericidal antibodies were obtained against 78% of a panel of 65 meningococcal strains representative of the global population, and protection was broadened by using adjuvants such as CpG and MF59.[229] A final vaccine formulation, containing three recombinant proteins and OMV from the New Zealand strain (rMenB+OMVnz), was shown to be immunogenic against strains expressing homologous proteins or homologous PorA.[230] This vaccine has progressed to phase III clinical trials, and a license authorization has been submitted to the European Medicines Agency. It could be the first vaccine to allow broad protection against the great majority of MenB strains responsible for invasive disease.

VACCINES IN DEVELOPMENT

In this section, we will review vaccines that have completed human studies and for which clinical data are available. Particular attention will be devoted to the big three: HIV, TB, and malaria. Interested readers will find more information on vaccines still in preclinical stages of development by consulting corresponding chapters in *New Generation Vaccines*, Fourth Edition.[231]

Human Immunodeficiency Virus

HIV-1 is the causative agent of the global AIDS epidemic, with about 7000 persons newly infected each day. The burden of the disease affects resource-poor countries where education, diagnosis, and treatment are most difficult to obtain. Therefore, the development of prophylaxis and/or therapeutic vaccines would have a profound impact on the spread of

this disease.

HIV-1 is naturally transmitted through sexual intercourse and from mother to infant during pregnancy. The virus infects predominantly CD4+ T cells, seeds in mucosaassociated lymphoid tissue, and reaches maximal viremia with up to 10^7 particles per mL of blood by week 3 after infection. By 2 to 6 months after infection, the viral load usually falls to reach a relatively stable level (the set point) due to the host immune response. A low set point has been shown to correlate positively with a slower progression to AIDS and with a greatly reduced risk of sexual and maternal-to-infant HIV transmission.[232,233,234,235] Eventually, the level of CD4+ T cells gets so low that resistance essentially disappears and the disease progresses to AIDS. The two pillars of the host immune response against HIV infection are envelope-specific neutralizing antibodies[236] and CTL and multifunctional CD8+ T cells.[237] Hence, it is natural that efforts at developing HIV vaccines have predominantly targeted these two arms of the immune response.

HIV-1 represents a formidable challenge to the host's immune system and to vaccine developers alike. The virus has evolved potent immunoevasion strategies that include the following: 1) high genetic diversity, 2) structural features of the envelope involved in infectivity that interfere with the induction of broadly neutralizing antibodies, 3) high rate of mutation of the envelope allowing the virus to escape neutralizing antibodies, 4) infection of and persistence in memory CD4+ T cells, 5) persistence of the virus out-of-reach of immune responses in extracellular spaces in lymph nodes and immunoprivileged sites such as the brain, and 6) destruction of CD4+ T cells. The efficacy of HIV-1 at escaping immune defenses is demonstrated by the failure in developing a vaccine for preventing HIV-1 infection to date, despite more than two decades of intense scientific research, more than 120 phase I, 7 phase II, and 3 phase III clinical trials (IAVI Database of AIDS Vaccines in Human Trials: www.iavireport.org).

Subunit Vaccines against Human Immunodeficiency Virus-1

Vaccine-induced envelope-specific neutralizing antibodies as a key to HIV-1 prophylaxis is supported by two observations: First, passive antibody administration to macaques can prevent infection with a simian immunodefeciency virus-HIV hybrid,[238] and second, at least a dozen broadly neutralizing antibodies have been isolated from HIV-1-infected individuals.[239] Early attempts to develop an HIV-1 vaccine followed the alum/subunit protein path. These subunit vaccines consisted in the most prominent antigens on the viral surface, namely, the envelope (*env*) glycoprotein gp160 and its products surface gp120 and transmembrane

gp41 because of their functional importance for virus attachment and entry into CD4+ T cells and as primary targets for neutralizing antibodies. The most advanced adjuvantedsubunit vaccine is **AIDSVAX** that consists in recombinant monomeric gp120 adjuvanted with alum (Table 43.4). AIDSVAX progressed to phase III efficacy evaluation in two large trials. The vaccines were safe and induced gp120-specific antibodies and CD4+ T-cell responses. However, the antibodies failed to neutralize commonly transmitted primary HIV-1 isolates, and there was no efficacy detected in either trial.[240,241]

DNA, deoxyribonucleic acid; NIH VRC, National Institutes of Health Vaccine Research Center.

Vectored Vaccines against Human Immunodeficiency Virus-1

Several gene delivery approaches of viral antigens have shown promises for inducing strong CD8+ T-cell responses, including CTL. The most advanced vector-based strategies involve replication-defective recombinant canarypox and rAd in prime-boost regimen. **ALVAC-vCP1521** is a canarypox-derived vector expressing clade E gp120, transmembrane gp41, gag, and protease. ALVAC-vCP1521 was tested in a prime-boost vaccine strategy followed by AIDSVAX (B/E) in an efficacy trial in persons at risk from heterosexual HIV-1 transmission and, for the first time for an HIV vaccine, demonstrated a 31% reduction in HIV-1 acquisition.[242] It remains to be determined which vaccineinduced immune responses correlate with this protection. Previous phase I and II trials showed that all vaccinees developed neutralizing antibodies, more than 80% of them developed antibody-dependent cell-mediated cytotoxicity, and 64% had measurable CD8+ CTL after the prime-boost strategy.[243,244] Two other HIV candidate vaccines based on multivalent rAd5 vectors have reached efficacy trials in humans. **MRKAd5** is a vaccine containing rAd5 vectors expressing clade B gag, pol, and nef (see Table 43.4) in two efficacy trials (STEP and Phambili) enrolling a total of 3801 persons. Despite the induction of HIV-1 gag- and pol-specific CD8+ T-cell responses in a majority of subjects, early viral loads were not decreased, and a trend to increased risk of acquisition in vaccine recipients was observed, leading to a premature termination of both trials in September 2007.[245] The National Institutes of Health is testing a DNA prime-rAd5 boost vaccine strategy (**VRC-HIVDNA016-00-VP/VRC-HIVADV014-00-VP**). Both gene delivery systems include HIV-1 modified env genes from clades A, B, and C, and *gag* and *pol* genes from clade B. Preliminary endpoint analysis is expected mid-2012. In previous phase I and II clinical trials, this heterologous prime-boost consisting of DNA followed by rAd5 showed increased antibody and T-cell responses and more polyfunctional T cells than for either vaccine modality given alone.[246] Preexisting immunity to Ad5 is high throughout the world and can reach 90% of adults in developing countries where an HIV-1 vaccine is the most needed. High titers against Ad5 have been associated with diminished T-cell responses induced by the rAd5-based vaccine[246,247]; therefore, Ad26 and Ad35, less common serotypes, and an Ad5/Ad48 chimera (resistant to anti-Ad5 neutralizing antibody) are being further developed.[247] In addition to canarypox and rAd5 vectors, new replication-defective viral vectors such as MVA and New York *Vaccinia* (a derivative from the Copenhagen vaccinia strain) evaluated with DNA priming have shown promising immunogenicity characterized by high levels of polyfunctional T-cell responses and are moving toward phase II testing.[248,249]

The results of two decades of intensive scientific research aimed at developing an HIV vaccine is quite sobering with most candidate vaccines failing in phase II and III evaluation. There is a glimmer of hope with the 31% efficacy observed with GenVax's canarypox prime-recombinant protein boost strategy, which might provide critical information on vaccine-induced correlates of protection.

Human Cytomegalovirus

HCMV is an enveloped double-stranded DNA virus member of the *Herpesviridae* family. It causes a spectrum of diseases in adults and children ranging from asymptomatic to a mononucleosis-like disease and can be fatal in immunocompromised individuals. HCMV is the most prevalent pathogen transmitted to the fetus by infected mothers resulting in severe neurologic sequelae in about 10% of

congenitally infected infants. Prevention of congenital disease is the main incentive for developing HCMV vaccines. A secondary objective would be to provide HCMV immunity to individuals prior to becoming immunosuppressed due to transplantation, HIV, or other reasons.

In vivo, epithelial cells, endothelial cells, fibroblasts, smooth muscle cells, and macrophages can support replication of the virus while latent virus can be found in macrophages and other myeloid cells. Protection against HCMV is multifactorial and involves innate immunity (natural killer cells); neutralizing antibodies primarily to glycoproteins gB, gH, and gM; and pp65-, IE1-, and gB-specific CD8+ T cells. Approaches to HCMV vaccines have included live-attenuated and whole-killed viruses, vectored, DNA, protein, and peptide-based subunit vaccines.[250] The live-attenuated Towne vaccine is the most widely evaluated HCMV vaccine. It was shown to be safe and well tolerated, induced seroconversion in healthy adults, and protected against challenge with the Toledo strain.[251,252] Furthermore, the Towne vaccine, albeit not preventing HCMV infection, reduced severe disease by 85% in renal transplant recipients,[253,254] although it failed to provide protection to women naturally exposed to HCMV from their infant.[255] Attempts were made at enhancing the immunogenicity of the Towne vaccine by adjuvanting it with IL-12[256] or by adding back gene regions from the more virulent Toledo strains that had been deleted in the Towne strain during the attenuation process. The recombinant Towne/Toledo appeared safe in seropositive adults.[257] Subunit HCMV vaccines tested in the clinic predominantly target gB, pp65, and IE1. The most advanced subunit vaccine in human studies is gB/MF59 (developed by Sanofi Pasteur MSD, Lyon, France), a recombinant glycoprotein gB formulated with MF59 adjuvant. In two large phase I studies in healthy adults, gB/MF59 was found safe and immunogenic and induced higher anti-gB titers compared with alum gB recipients.[258,259] A third study in toddlers revealed that immunization with gB/MF59 resulted in titers higher than found in vaccinated adults.[260] A phase II efficacy study in seronegative women within 1 year of giving birth revealed a significant increase in the number of vaccine recipients that remained uninfected during the follow-up period.[261]

Another vaccine strategy used alphavirus-like replicon particles from Venezuelan equine encephalitis virus to express HCMV antigens. Alphavirus-like replicon particles have been shown to specifically target DCs in vivo and induce broad immune responses including neutralizing antibodies and CTLs. AVX601, a bivalent alphavirus replicon vaccine expressing three HCMV proteins (gB, pp65, and IE1) (developed by AlphaVax Inc., Research Triangle Park, NC, U.S.A.), was found safe and induced neutralizing antibody and multifunctional CD4+ and CD8+ T-cell responses.[262] The bivalent DNA vaccine, VCL-CB01 (developed by Vical Inc., San Diego, CA, U.S.A.), consisting of plasmids encoding for gB and pp65 formulated with poloxamer CRL1005 and benzalkonium chloride to enhance immune responses, was evaluated in HCMV-seropositive and -seronegative adults.[263] VCL-CB01 was immunogenic as measured by IFN-γ ELISpot in 45.5% of seronegative and 25% of seropositive vaccine recipients. VCL-CB01 boosted pp65-specific T-cell responses but not anti-gB antibodies in seropositive individuals, suggesting that this vaccine is more effective at inducing T-cell than gB-specific antibodies.

Finally, prime-boost strategies have been also evaluated. Trivalent HCMV DNA vaccine VCL-CT02 (developed by Vical Inc.), encoding gB, pp65, and IE1, was evaluated in three phase I studies using a DNA prime/Towne liveattenuated boost approach.[264] HCMV-specific memory T-cells were detected by IFN-γ ELISpot in 20% and 60% of unprimed and primed subjects, respectively. The median time to first pp65 T-cell and gB antibody response after Towne was 14 days for DNA-primed subjects versus 28 days for controls administered Towne only. Similar observations were made with a canarypox gB prime/Towne live-attenuated boost.[265]

Tuberculosis

TB caused by Mtb complex bacilli is one of the leading causes of death worldwide. The WHO has declared TB a global public health emergency and predicts that almost one billion people will be infected, with 35 million dying from the disease, by 2020. TB is prevalent in developing regions of the world such as sub-Saharan Africa and Southeast Asia, where it is often associated with the HIV epidemic. Upon exposure to Mtb, 30% to 40% of close contacts will develop TB infection, of whom 5% would be expected to develop active disease within a 24-month period, whereas the other 95% enter a state of controlled latent TB infection (LTBI), which can reactivate later in life following decreased immunocompetence of the host.

Despite the availability of drugs against Mtb and the directly observed therapy short-course campaign initiated by the WHO, TB persists as a global health concern in part because infected individuals do not have access to point of care and/or are often noncompliant with the 6-month or longer drug treatment. This is particularly true in the developing world where more than 95% of infections occur. Treatment noncompliance has contributed to the current TB pandemic by increasing the probability of transmission and sustaining the development of multidrug-resistant strains of Mtb. Multidrug-resistant strains are resistant to the two most powerful first-line drugs: rifampicin and isoniazid. Since the discovery of multidrug-resistant TB in the 1990s, the resistance pattern of TB has continued to evolve, and isolates resistant to both first- and second-line drugs have been identified. Therefore, development of safe, effective, and affordable prophylactic vaccines that also provides long-lasting protection in BCG-immunized people is a critical step toward controlling TB.

Promptly after inhalation, Mtb is engulfed by lung alveolar macrophages in an attempt by the host to destroy the invader. Mtb, however, has adapted to survive in macrophages by preventing phagosome acidification and fusion with lysosomes. T cells, both CD4+ Th1 and CD8+, and IFN-γ and tumor necrosis factor (TNF) cytokines play important roles in the prevention of active disease and the control of LTBI, as demonstrated by gene-knockout animal models and

human subjects with mutations affecting the expression of these two cytokines.[266] As a result of macrophage activation by these inflammatory cytokines, Mtb bacilli stop multiplying and enter a state of dormancy.[267] Once the activation status of macrophages is lowered, however, mycobacteria can resuscitate, leading to disease reactivation. Current vaccine design strategies focuses on stimulation of a highly potent T-cell response in an attempt to contain or even eradicate Mtb after it has established itself in the phagosome of macrophages.

BCG, the only licensed vaccine currently available against TB, is likely the most widely used vaccine in the world with more than four billion doses administered. BCG is a live-attenuated strain of *Mycobacterium bovis* that was developed by Albert Calmette and Camille Guérin by serial passage on media.[268] During the attenuation process, BCG lost a large number of genes clustered in numerous regions of difference.[269] The BCG vaccine strain was introduced in 1921 and was further distributed to numerous institutions all over the world. Today, due to differences in culture conditions over decades, the BCG vaccine exists in more than one genetic background, possibly resulting in differences in efficacy. BCG is administered to newborns and is effective in preventing severe childhood forms of TB such as miliary TB and TB meningitis, whereas its efficacy in adults against pulmonary TB has been highly variable and ranged from 0% to 80% protection.[270] In adults, the lowest BCG efficacy was found in countries with the highest incidence of tuberculin skin test positivity due to prior exposure to Mtb or other environmental bacteria, suggesting that preexisting immune responses to mycobacterial antigens shared in BCG prevent necessary bacterial replication and vaccine take. Therefore, although safe in all immunocompetent individuals, BCG was efficacious only in the skin test negative population, primarily children.[271] As a consequence, vaccine protection against adult pulmonary TB, the most common form of TB, in high-endemic countries is very limited[272] and demonstrates the urgency of developing novel TB vaccines. Other drawbacks of BCG include waning efficacy over time and interference with the tuberculin skin test diagnosis of TB.

Novel TB vaccines currently in development target different needs and individuals. Some efforts are made at improving the current BCG vaccine for newborns and nonimmunized tuberculin skin test-negative adults. In addition, a heterologous booster vaccine, consisting of an adjuvanted or vectored subunit vaccine, is a high priority for individuals who have already received BCG, as BCG efficacy wanes after 10 to 15 years and boosting with BCG has proven ineffective in both preclinical and clinical studies.[273,274,275,276,277,278] Ideally, this booster vaccine would be given during adolescence and possibly repeated during adulthood as necessary. In theory, such a booster vaccine could also boost the immunity of individuals already exposed to Mtb. Finally, a therapeutic vaccine as an adjunct to antibiotics in the therapy of TB has been considered with the hope of reducing the overall duration of drug treatment. All novel TB vaccines that are being tested in humans or are about to enter clinical trials demonstrated immunogenicity and protective efficacy in mouse, guinea pig, and/or nonhuman primate models of TB.[279]

Vaccines Replacing Bacille Calmette-Guérin

Due to the long history of BCG's safety and efficacy in children, it is likely to remain on the WHO Expanded Program on Immunization vaccination schedule. Therefore, a line of improved BCG vaccines was developed and showed superior efficacy compared to BCG in different animal models of TB, including the stringent guinea pig infection model.

The first two such vaccines to complete phase I clinical trials were rBCG30, a recombinant BCG overexpressing Mtb extracellular Ag85B antigen (developed by Dr. Horwitz's group at the University of California Los Angeles, CA, U.S.A.), and VPM1002, a urease-deficient BCG expressing listeriolysin (rBCGδureC::Hly+::Hyg+) that delivers mycobacterial antigens to the cytosol for enhanced presentation to T cells (developed by Dr. Kaufmann's group at the Max Plank Institute, Berlin, Germany) (Table 43.5). rBCG30 was as safe as nonrecombinant BCG and significantly enhanced the population of Ag85B-specific CD4+ and CD8+ T cells capable of proliferation and IFN-γ secretion.[280] Similarly, no safety concerns were reported for VPM1002 in studies including individuals with or without preexposure to BCG (Germany) and with preexposure to BCG in endemic areas (South Africa). Furthermore, VPM1002 induced antigenspecific multifunctional CD4+ and CD8+ T cells and showed a trend of superiority compared to BCG at equivalent dosage (for more information, see www.vakzine-manager.de/en/resources/Produkte/VPM1002_en.pdf).

Another approach still in preclinical evaluation is worth mentioning and consists of an attenuated Mtb strain resulting from the inactivation of the phoP virulence factor and has extensively been tested for safety and efficacy, including in the guinea pig model of TB.[281,282]

Subunit Tuberculosis Vaccines

Hundreds of Mtb proteins have been screened in experimental animal models of TB, including systematic functional genomic antigen discovery and prioritization.[283,284,285] Combinations of one or more among six protective Mtb antigens (Ag85A, Ag85B, ESAT-6, TB10.4, Rv0125, and Rv1196) comprise the subunit vaccines currently in human studies. Ag85A and 85B are major secreted Mtb proteins; ESAT-6 and TB10.4 are virulence factors belonging to the Esx family of proteins; Rv0125 is a serine protease; and Rv1196 belongs to the PE/PPE family of proteins. All but ESAT-6 antigens are present in BCG vaccine strains, allowing for heterologous prime-boost vaccination strategy using BCG as the prime and subunit as the boost.

Three adjuvanted recombinant subunit TB vaccines have been tested in human studies. Mtb72F, a fusion protein made of Rv0125 and Rv1196 formulated with the AS02A adjuvant system has completed phase I. The Mtb72F/AS02A subunit vaccine was found safe and well tolerated in purified protein derivative-negative adults, with some mild reactogenicity. It induced good production of IL-2 and IFN-γ in the ELISpot assay, and polyfunctional CD4+ T cells expressing CD40L, IL-2, TNF, and/or IFN-γ were observed with intra-cellular staining while no CD8+ T-cell responses were detected.[286,287] Mtb72F is currently being evaluated in phase II studies. H1, a fusion protein consisting of Ag85B and ESAT-6, has been

tested with IC31 adjuvant in different cohorts including negative tuberculin skin test, BCG

vaccinated, and subjects with LTBI in phase I clinical trials. Vaccination with H1/IC31 did not cause local or systemic adverse effects besides transient soreness at the injection site, but it elicited strong antigenspecific T-cell responses against H1 and both the Ag85B and the ESAT-6 components.[129]

TABLE 43.5 Most Advanced Tuberculosis Vaccine Candidates

Category	Candidate	Trial Phase	Key Investigator
Genetically engineered BCG	**rBCG30**: BCG overexpressing *Mycobacterium tuberculosis* antigen Ag85B	I	University of California Los Angeles, Aeras
	VPM1002: Urease-deficient BCG expressing listeriolysin	I	Vakzine Projekt Management GmbH
	AERAS-422: Urease-deficient recombinant BCG, overexpressing *Mycobacterium tuberculosis* antigens Ag85A, Ag85B, and TB10.4 as well as listeriolysin	I	Aeras
Adjuvanted subunit vaccine	**Hybrid-1 (H1):** Fusion protein of Ag85B and ESAT-6 administered with IC31 adjuvant	I	Statens Serum Institute and TBVAC
	Hybrid-1 (H1): Fusion protein of Ag85B and ESAT-6 administered with LTK63 adjuvant	I	Statens Serum Institute, Novartis Vaccines, MUVAPRED
	Mtb72F: Fusion protein of Rv1196 and Rv0125 administered with AS02 adjuvant	II	GSK and Aeras
	HyVac4 (**AERAS-404**): Fusion protein of Ag85B and TB10.4 administered with IC31 adjuvant	I	Statens Serum Institute, Intercell, Aeras
Vectored vaccine	**MVA85A**, a modified vaccinia virus Ankara expressing *Mycobacterium tuberculosis* antigen Ag85A, as booster of BCG-priming or naturally acquired TB immunity	IIb	Oxford University
	FP85A, a recombinant fowlpox virus 9 expressing *Mycobacterium tuberculosis* antigen Ag85A, as booster of BCG-	I	Oxford University

	priming or naturally acquired TB immunity		
	AERAS-402: Replication-incompetent adenovirus 35 vector expressing *Mycobacterium tuberculosis* antigens Ag85A, Ag85B and TB10.4	IIb	Crucell Holland B.V. and Aeras

BCG, Bacille Calmette-Guérin; TB, tuberculosis.

Two additional vaccines ready to enter clinical evaluation are worth mentioning:

1. *ID93*, a fusion protein comprising Rv3619 (Esx Mtb protein family), Rv1813 (involved in Mtb latency), Rv3620 (Esx Mtb protein family), and Rv2608 (PE/PPE Mtb protein family). Rv2608 formulated with the adjuvant system GLA-SE was found immunogenic in mice, guinea pigs, and nonhuman primates. ID93/GLA-SE boosted BCG-primed immune responses and increased protective efficacy in the stringent guinea pig TB challenge model.[288]
2. *H56*, a fusion protein based on H1 and further including Rv2660c (Mtb latency antigen) (developed by P. Andersen and colleagues at the Statens Serum Institute, Copenhagen, Denmark) adjuvanted with CAF01 induced polyfunctional CD4+ T-cell responses in vaccinated mice, was associated with more efficient containment of late-stage TB infection than the H1 and BCG, controlled reactivation, and significantly lowered the bacterial load in two postexposure mouse models.[289]

Vectored Tuberculosis Vaccines

MVA85A, a MVA expressing the extracellular Mtb antigen Ag85A, and AERAS-402, a modified adenovirus 35 expressing Mtb antigens Ag85A, Ag85B, and TB10.4, are in phase IIb efficacy trials and the most clinically advanced novel TB vaccines (see Table 43.5). MVA85A is the first vector-based TB vaccine tested in humans, and it was found safe and well tolerated in multiple phase I studies with BCG-naive and BCG-vaccinated healthy adults[290,291,292,293]; in adults with LTBI[294]; and in BCG-vaccinated adolescents, children, and infants in an endemic area.[295,296] In all studies, immunization with MVA85A induced high levels of Ag85A-specific polyfunctional CD4+ T cells producing IFN-γ, TNF, and IL-2 with additional subsets secreting IL-17 or granulocyte macrophage-colony stimulating factor. Surface staining showed the responding CD4+ T cells to be relatively immature ($CD45RO+CD27^{int}CD57-$); this observation was supported by the robust proliferative responses observed following antigenic stimulation.[297] AERAS-402 was found safe and well tolerated in healthy Mtb-uninfected BCG-vaccinated adults from a TB-endemic region of South Africa.[298] The vaccine induced a robust polyfunctional CD4+ T-cell response dominated by cells coexpressing IFN-γ, TNF, and IL-2. AERAS-402 also induced a potent CD8+ T-cell response, characterized by cells expressing IFN-γ and/or TNF, which persisted for the duration of the study.

Therapeutic Tuberculosis Vaccines

Therapeutic vaccines have a potential role as adjunctive therapy during or after completion of antibiotic treatment against active TB as well as LTBI. Heat-killed *Mycobacterium vaccae* has been extensively studied in humans as an immunotherapeutic vaccine for active TB with variable success.[299,300,301] In a recent clinical trial, patient treated with *M. vaccae* regimen showed faster and more complete clinical improvement than patients administered with placebo.[300] In contrast, RUTI, a therapeutic vaccine made from virulent Mtb grown in stressful conditions, fragmented, detoxified, heat inactivated, and formulated in liposomes has been designed to be used against LTBI after one month of chemotherapeutic treatment. In a phase I study, RUTI induced T-cell responses to purified protein derivative and a number of Mtb antigens in healthy adults.[302] In conclusion, TB vaccine research, development, and testing has become an active area in the recent years; thanks to the increasing investment

from public funds such as the European Union, National Institutes of Health, and the Bill & Melinda Gates Foundation. Several vaccines have entered human clinical trials and there is hope for new and better TB vaccines soon.

Staphylococcus aureus

Staphylococcus aureus (SA) are mostly capsulated grampositive extracellular bacteria that exist as human commensals in the nares and on the skin of about one-third of individuals. A breach in natural barriers (skin epithelium and mucosal membranes) predisposes the host to SA invasion of the tissues and associated disease manifestations. In addition to skin and soft-tissue infection, SA can also cause pneumonia, osteomyelitis, endocarditis, and septicemia. Historically, significant SA infections were most often nosocomial, as hospitalized patients have weakened natural immunity and are more vulnerable.

There are no vaccines currently licensed against SA, and antibiotics are the only treatment to fight off SA infection. Penicillin, introduced in the 1940s, and semisynthetic methicillin in the 1960s were potent antistaphylococcal drugs; however, SA quickly developed resistance, and today, more than 60% of hospital-acquired strains are methicillin resistant.[303] Over the past decade, more virulent methicillin-resistant SA strains developed outside the hospital environment, frequently transmitted among otherwise healthy individuals, and designated as community-acquired methicillin-resistant SA. Antimicrobial resistance and the emergence of more virulent strains call for the development of vaccines that are capable of inducing protection against a wide array of diseases caused by SA infection in the population at large.

Vaccine targets against SA are multiple and include capsular polysaccharides type 5 and type 8 (expressed by 80% of all strains), surface poly-*N*-acetylglucosamine polysaccharide, microbial surface components recognizing adhesive matrix molecules such as fibrinogen- and fibronectin-binding proteins (ClfA, ClfB and FnbA, FnbB, respectively), collagen adhesin (Cna) and matrix-binding proteins (Sdr), iron-regulated surface determinants (IsdA, IsdB), Ess secretion system (EsxA, EsxB), exotoxins, and a collection of proteases. In addition, targeting molecules from SA involved in immunoevasion, including protein A (SpA) that binds the Fc portion of host IgG; CHIPS, a modulator of phagocyte chemotaxis; and SCIN, a modulator of the complement, are alternative vaccine strategies. SA has developed a myriad of molecules to escape host immunity; therefore, it is likely that vaccines targeting more than one factor will have improved chances of success. Based on experimental evidences such as passive immunization, it is believed that protection against SA is largely mediated by bioactive antibodies.

Human studies of SA vaccines have been mostly disappointing to date. In the 1940s, intramuscular vaccination with 3 to 4 hour cultures of **live SA** in individuals suffering from chronic ocular staphylococcal infection resulted in improvement in two-thirds of the patients.[304] However, further controlled human studies have not been carried out since. Vaccine-induced protection with live-attenuated strain in multiple animal models highlights the potential of this approach against SA. In the 1960s, protein-based vaccination strategies with phage- or enzyme-induced **lysates of SA** strains were evaluated for efficacy in the treatment of human skin infection with some success[305,306,307] but were not developed further. An attempt with **SA whole-killed** bacteria plus **toxoids** in patient receiving kidney replacement therapy induced an increase in antistaphylococcal antibodies but failed to demonstrate efficacy against peritonitis.[308] IsdB protein-based subunit vaccine **V710** was well tolerated and immunogenic in healthy adults in a phase I studies with and without alum.[309] V710 was further tested in a phase II and in a phase II/III study, but data are not available yet. Finally, **StaphVAX** (developed by Nabi Biopharmaceuticals, Rockville, MD, U.S.A.) consists of types 5 and 8 capsular polysaccharides coupled to a nontoxic recombinant form of *Pseudomonas aeruginosa* exotoxin A as protein carrier. In phase III clinical trials, StaphVAX was found to be safe, induced protective levels of SA-specific IgG in more than 70% of the individuals, and conferred approximately 60% protection for 10 months against bacteremia caused by SA in patients on hemodialysis.[310,311] From 2004 to 2006, StaphVAX has completed three phase III human studies in. Despite its immunogenicity, StaphVAX development was dropped when a large multicenter phase III study failed to demonstrate reduction in SA infections among kidney transplant patients in the 1-year follow-up period.

In summary, no SA vaccine has resisted the efficacy test in human studies yet, and

researchers are back to the drawing board with a handful of promising candidates still in preclinical development.

Malaria

Malaria is the most prevalent vector-borne disease in the world with 2 billion people at risk of contracting this disease, 500 to 600 million cases each year, and 1 to 2 million deaths per year, mostly in children younger than 5 years old. Malaria is caused by protozoa of four species of *Plasmodium* among which *P. falciparum*, responsible for deadly cerebral malaria, and *Plasmodium vivax* are the most prominent and dangerous.

The feasibility of a vaccine against malaria is supported by two observations: People living in endemic regions

eventually become relatively immune to the disease, although this immunity is not sterilizing and disappears when individuals move to a malaria-free region, and antibodies can be therapeutic. The challenges facing those trying to develop a malaria vaccine are daunting and reflected by the considerable amount of research that has been done and the absence of a licensed vaccine. *Plasmodium* protozoa are exceedingly complex pathogens that 1) consist of 5300 genes among which to select vaccine candidates,[312] 2) have a multistage life cycle characterized by stage-specific protein expression, and 3) display extensive allelic polymorphism of candidate antigens. To further complicate the task of vaccine developers, both *P. falciparum* and *P. vivax* are difficult to grow in vitro, and no animal model truly reflects the human disease. On the positive side and unlike HIV and TB, controlled *P. falciparum* challenges are possible in humans to test vaccines for efficacy.

Malaria candidate vaccines targeting each of the four stages of the parasite life cycle are being developed. These include vaccines against the sporozoites, the infected hepatocytes (liver stage), the merozoites (blood stage), and the gametocytes (transmission-blocking vaccines). Preerythrocytic malaria vaccines target sporozoites and hepatic stages to completely prevent blood-stage infection and thus manifestations of the disease, whereas bloodstage vaccines aim at reducing parasite burden, therefore decreasing the severity and resulting complications of the disease. Finally, transmission-blocking malaria vaccines are designed to arrest the development of sexual stages inside mosquitoes through passive ingestion of specific antibodies during the insect's blood meal.

Four preerythrocytic stage antigens have reached clinical testing: the circumsporozoite protein (CSP), thrombospondin-related adhesive protein (TRAP/SSP2), and liver-associated antigen 1 and 3 (LSA1, LSA3); seven blood-stage antigens: merozoite surface proteins 1 to 3 (MSP1, MSP2, MSP3), apical membrane antigen 1 (AMA-1), serine-repeat antigen 5 (SERA/P126), glutamate-rich protein (GLURP), and erythrocyte-binding antigen^{175} (EBA175); and one sexual-stage antigen: Pfs^{25}. From animal models and human naturally acquired immunity to malaria, it is assumed that immune responses required for protection against sporozoites, merozoites, and gametocytes are mostly antibody dependent, whereas protection against liver-stage likely requires CD8+ T-cell-mediated immune responses for clearance.[313] There is evidence that all of these immune mechanisms are involved in protecting against malaria.[314] Therefore, choosing the proper antigen delivery system is a key element in determining protective-efficacy of candidate malaria vaccines. Wholekilled or live attenuated parasites, gene-based approaches, and adjuvanted recombinant proteins and peptides (Table 43.6) will be discussed.

Whole-Organism Malaria Vaccines

Immunization of volunteers with radiation-attenuated *P. falciparum* sporozoites (PfSPZ), a candidate malaria vaccine targeting preerythrocytic stage, resulted in sterile immunity and completely prevented infection upon challenge with fully virulent sporozoites.[315,316,317,318] High levels of antibodies to sporozoites and CSP-specific antibody and T-cell responses were observed in individuals receiving the PfSPZ vaccine.[316,319] Since 2003, scientists at Sanaria Inc. (Rockville, MD, U.S.A.) have made significant progress in developing manufacturing processes that are scalable and meet regulatory requirements for producing irradiated sporozoites. Clinical lots of PfSPZ have been made and are currently tested in

phase I/II clinical trials (NCT01001650, NCT01441167).

Adjuvanted Malaria Subunit Vaccines

A variety of preerythrocytic and blood-stage recombinant proteins and long synthetic peptides have been evaluated with alum, emulsions, and liposomal adjuvant formulations in numerous phase I/II studies. The only candidate malaria vaccine with a proven track record of protecting people against sporozoite challenge in clinical settings and in the field is **RTS/S** developed by GSK and WRAIR (see Table 43.6). RTS/S includes hepatitis B surface antigen, which promotes assembly into VLPs, and a portion of the CSP molecule consisting of 1) the immunodominant repeat region that is a target for neutralizing antibodies against sporozoites and 2) a protein domain that contains CD4+ and CD8+ T-cell epitopes. RTS/S formulated in AS02A and AS01B is safe and immunogenic, and has consistently shown 30% to 50% protection on immunized individuals against experimental sporozoite challenge.[320,321,322] Meta-analyses of 11 human clinical trials concluded that in semiimmune children, RTS/S reduced clinical malaria episodes by 26% and severe malaria by 58% for up to 18 months with no severe adverse events.[323] Furthermore, RTS/S in AS02D and in AS01E reduced the new onset of parasitemia in infants by 66% over a 6-month observation period[324] and 61.6% over a 19-month follow-up period, respectively.[325,326] Strong multifunctional CD4+ T-cell responses were detected in RTS/S immunized infants.[327] Two malaria vaccine candidates against LSA1 and LSA3 have been tested in phase I/II trials. LSA-NRC formulated in AS02A and AS01B induced high levels of LSA1-specific antibodies and IFN-γ producing T-cells but failed to protect against sporozoite challenge.[328] Malaria blood-stage AMA1-C1 candidate vaccine formulated with alhydrogel and alhydrogel plus CpG 7909 reached phase IIb clinical trials. AMA1-C1 consists of two forms of AMA-1 and was developed to reduce the effect of antigen polymorphism. AMA1-C1 in alhydrogel was safe and immunogenic; however, the antibodies only moderately inhibited merozoite growth in vitro and the vaccine later failed to show efficacy in a phase IIb field trial.[329] Addition of CpG 7909 to the vaccine greatly increased levels of functional antibodies but failed to protect immunized volunteers against a controlled challenge with *P. falciparum*-infected erythrocytes.[330] In a phase II study in Mali, FMP2.1, another AMA-1-based vaccine, in AS02A, did not provide significant protection (20%) against clinical malaria on the basis of the primary end point, but on the basis of secondary results, it may have strain-specific efficacy (64%).[331] Several vaccine candidates targeting the 42-kDa C-terminal region of MSP-1 (MSP-1_{42}) and MSP-3 formulated with AS02A, ISA720, and alhydrogel

± CpG 7909 were safe and immunogenic but failed to induce high levels of functional antibodies and were not efficacious against clinical outcomes. Finally, transmission-blocking vaccines, Pfs25 and Pvs25, formulated with Montanide ISA 51 induced functional antibodies, but the vaccines were too reactogenic,[332] requiring new vaccine formulations to be developed.

TABLE 43.6 Most Advanced Malaria Vaccine Candidates

Category	Candidate	Stage	Trial Phase	Key Investigator
Live-attenuated vaccine	**PfSPZ**, live radiation-attenuated sporozoites	PE	I/II	Sanaria Inc./NIAID
Adjuvanted subunit vaccine	**RTS,S:** fusion protein of CSP repeat region (R), T-cell epitopes region (T), and hepatitis B surface antigen (S), formulated with **AS02A**	PE	IIb/III	GSK

	and **AS02D** oil-in-water emulsion or **AS01B** and **AS01E** liposomal adjuvant formulations			
	LSA-NRC, N- and C-terminal regions of LSA1 flanking two 17-aa repeats formulated with **AS01B** or **AS02A** adjuvants	PE	I/II	U.S. Army Medical Research
	PfLSA-3rec formulated with alum or Montanide ISA 720	PE	I/II	Radboud University
	AMA1-C1, FVO and 3D7 forms of AMA-1 formulated with **alhydrogel ± CpG7909**	Blood	IIb	NIAID/University of Oxford
	FMP2.1, 3D7 form of AMA-1 formulated with **AS02A**	Blood	II	NIAID
	FMP1, 3D7 form of MSP-1_{42} formulated with AS02A	Blood	IIb	U.S. Army Medical Research
	MSP1_{42}-C1, FVO and 3D7 forms of MSP-1_{42} formulated with **alhydrogel ± CpG7909**	Blood	I/II	NIAID
	MSP-3 LSP formulated with **alum**	Multiple	IIb	Vac4All
	Pfs25, Pvs25, formulated with Montanide **ISA 51**	Transmission	I	NIAID

CSP, circumsporozoite protein; DNA, deoxyribonucleic acid; GSK, GlaxoSmithKline; MVA, modified *Vaccinia* Ankara; NIAID, National Institute of Allergy and Infectious Diseases; PE, preerythrocytic-stage antigens.

Vectored Malaria Vaccines

Gene-based malaria vaccines can be divided in three groups: DNA, poxvirus, and adenovirus vectors. In human studies, DNA malaria vaccines consisting of single antigens or mixtures of plasmids showed minimal antibody, modest T-cell responses, and no evidence of protective efficacy.[333,334] A DNA prime-MVA boost vaccination strategy targeting the ME-TRAP preerythrocytic antigen showed good immunogenicity and some level of efficacy in sporozoite-challenged volunteers with an approximately 80% reduction in parasite load but later failed in a phase IIb field efficacy trial (11% efficacy).[335,336] Despite higher METRAP-specific T-cell responses obtained with fowlpox FP9 prime-MVA boost than previously observed with the DNA/MVA vaccination strategy,[337] no efficacy was observed in field trials.[338,339] In humans, DNA, MVA, and FP9 coding for the CSP antigen were poorly immunogenic. Finally, adenovirus (Ad5, Ad26, Ad35, and AdCh63) vectors expressing preerythrocytic stage CSP and ME-TRAP, and blood-stage AMA-1 and MSP-1 antigens are being evaluated in phase I/II for efficacy against sporozoites challenge by different groups (see Table 43.6).

In summary, with the exception of RTS/S, most malaria vaccine candidates failed to show efficacy despite good safety and immunogenicity in humans. Novel combinations of antigens targeting multiple life stages of the parasite and heterologous prime-boost vaccination strategies are being pursued.

Leishmania

Leishmania species are protozoan parasites causing a wide range of disease manifestations from simple self-healing cutaneous leishmaniasis (CL) lesions to highly disfiguring mucosal leishmaniasis (ML) and lethal visceral leishmaniasis (VL). All species of *Leishmania* are naturally transmitted by the bite of female sandflies that inoculate low numbers (100 to 1000) of flagellated metacyclic promastigotes during a blood meal. Infected humans (anthroponotic leishmaniasis) and animals (zoonotic leishmaniasis) represent reservoirs for the parasites. Once in its mammalian host, *Leishmania* becomes an obligate intracellular pathogen that resides and replicates as nonflagellated amastigotes in the host's macrophages. Acquired resistance to leishmaniasis is mediated by CD4+ Th1 cells and CD8+ T cells, but like for TB, surrogate markers of protection are not fully identified.

There is currently no effective prophylactic immunization available against *Leishmania*, outside the cutaneous inoculation of live virulent *Leishmania major*, a practice known as “Leishmanization,” to produce a self-healing lesion that induces lifelong immunity due to the chronic persistence of low levels of parasites in the host. Leishmanization was mostly practiced in the military from the 1960s to the 1980s, but stopped after the Iran-Iraq war mostly due to unwanted side effects, prolonged duration of lesions, and a few nonhealing

cases that were difficult to treat.[340,341] In school-aged children and migrants in a high endemic region in Uzbekistan, a mixture of dead and live *L. major* continues to be given.

First-generation *Leishmania* vaccines consisted of wholekilled parasites (from one to five different *Leishmania*) with or without BCG as an adjuvant. In absence of adjuvant, New World (Americas) vaccines were found safe albeit weakly immunogenic[342] but failed to afford protection against CL.[343] Inclusion of BCG as an adjuvant increased both immunogenicity and protective efficacy of the vaccine[344]; however, in another trial, volunteers refused to take the last vaccine dose because of side effects (active lesion and scarring due to live BCG).[345] Interestingly, three doses of whole-killed parasites + BCG vaccine given a month apart as immunotherapeutic might be a safer (less serious side effects) and more costeffective than drug treatment against CL, ML, and early diffuse CL.[346,347,348,349] A similar approach, using autoclaved *L. major* + BCG in single or multiple injections was initially applied with Old World vaccines against homologous or heterologous leishmaniasis. The vaccine was found safe and induced *Leishmania* skin test conversion in up to 36% of the individuals; however, it failed to demonstrate protective efficacy superior to BCG-alone control groups.[350,351,352,353] A meta-analysis of all clinical trial data available confirmed the lack of protective efficacy of whole-killed vaccine.[354] More recently, a new formulation of alum-precipitated autoclaved *L. major* + BCG demonstrated enhanced immunogenicity with 25% to 56% *Leishmania* skin test conversion.[355,356] More than 20 second-generation *Leishmania* vaccines, consisting of adjuvanted-protein or DNA subunit vaccines that demonstrated protective efficacy against CL and/or VL in animal models of leishmaniasis, are currently in preclinical development.[357] The most advanced one to enter human clinical trials is a fusion protein made of *L. major* stress-inducible protein 1, thiol-specific antioxidant, and *Leishmania* elongation/initiation factor, called LEISH-F1 and LEISH-F2 (modified-F1 version lacking histidine (His) tag and including a single amino acid mutation to reduce protein breakdown), formulated with MPL-SE adjuvant. Phase I studies completed in healthy LTS-negative and LTS-positive individuals living in *Leishmania* nonendemic and endemic regions demonstrated that the vaccine was well tolerated and immunogenic.[358] In addition, the vaccine was safe and well tolerated when administered as an adjunct to drug treatment in CL- and MLinfected individuals,[359,360] although data in post Kala-azar dermal leishmaniasis (a complication of VL) patients are not yet available.

To date, the best efficacy data with first- or second-generation *Leishmania* vaccines were obtained in therapeutic rather than prophylactic immunization strategies.

CHALLENGES FOR THE FUTURE

During the recorded history, infectious diseases had profound influence on the human population. From 1347 to 1351, the Black Death or bubonic plague caused by *Yersinia pestis* killed approximately 30% of the European population. During the 18th century, it is calculated that smallpox used to kill approximately 0.7% of the total European population (1 person per 140) every year. The 1918 pandemic influenza killed approximately 1% of the global population. In the United States, at the beginning of the 20th century, there were at least 1.7 million cases of infectious diseases with an average mortality rate of 1%. Today, most of these infectious diseases have been eliminated at least from highincome countries, mostly thanks to the availability of clean water and vaccination. In low-income countries, infectious disease are still a major problem, and it is estimated that at least 8 million people die annually from infectious diseases for which vaccines already exist, and >10 million die from infectious diseases for which vaccines do not exist such as HIV, TB, malaria, *Salmonella*, and *E. coli*.

Our children are routinely vaccinated against approximately 10 infectious diseases, and we have forgotten that it was not a long time ago that infectious diseases used to be one of the major problems of mankind. Given the great success that vaccines already had in eliminating infectious diseases, a question that is often asked is whether there is a role for vaccines in the 21st century.

During the last 30 years, we have experienced several waves of innovation that made possible vaccines that were previously impossible. Examples are recombinant DNA that made possible the hepatitis B vaccine; conjugate vaccines that made possible vaccines against

Hib, pneumococcus, and meningococcus; and reverse vaccinology that allowed the discovery of new antigens for MenB, adjuvants to improve the efficacy of influenza vaccines. Novel technologies are emerging every day, and it is likely that in a few years we will be able to do things that are still impossible today. These technologies will allow the development

of novel vaccines that will be used for the following purposes: 1) eliminate the remaining infant infectious diseases such as meningococcus, respiratory syncytial virus, group B streptococcus, and influenza; 2) develop vaccines against cytomegalovirus, Epstein-Barr virus, and herpes simplex virus; 3) develop vaccines against antibiotic-resistant bacteria such as *S. aureus, Clostridium difficile*, *E. coli*, and *P. aeruginosa*; 4) develop vaccines able to prevent or delay cancer; 5) develop vaccines against HIV, TB, malaria, and other infections of developing countries such as typhoid and nontyphoidal *Salmonella* and *E. coli*; 6) prepare better vaccines against emerging infectious diseases such as pandemic influenza; 7) improve therapy of cancer, chronic infectious diseases, and allergies; and 8) treat metabolic diseases such as diabetes, obesity, etc.

In conclusion, we expect that in the 21st century, vaccines will be able to 1) take care of the remaining infant infectious diseases; 2) provide vaccines for all ages, including adolescents, adults, the elderly, and special groups such as travelers and patients with chronic diseases; 3) mitigate the effect of emerging infectious diseases; and 4) help to eliminate poverty from low-income countries by providing the vaccines that will eliminate the burden of disease and help to develop an healthy economy.

Autoimmunity and Autoimmune Diseases

Ken T. Coppieters

Matthias G. von Herrath

Dirk Homann

INTRODUCTION

The concept of autoimmunity (ie, the phenomenon of immune reactivity directed against an organism's constituent organs, tissues, cells, and/or extracellular factors) comprises both physiologic and pathophysiologic components that attain practical relevance in the context of autoimmune diseases, a collection of more than 80 disorders with circumscribed pathologic features that are thought to result primarily from the induction and perpetuation of aberrant immune reponses. The precise etiopathology for most human autoimmune diseases remains incompletely defined but appears to be promoted by the complex interplay of genetic predispositions, environmental insults such as viral infections and, in an acknowledgment of the many questions yet to be answered, bad luck. However, a role for immune-mediated processes and pathologies has by now been documented in at times compelling detail and provides important direction for novel and improved diagnostic, prophylactic, and therapeutic modalities. Herein, we discuss the evolution of major conceptual and practical advances and challenges in autoimmunity and autoimmune diseases in general, and consider individual autoimmune disorders regarding the contribution of genetic and environmental components, specific pathology and autoimmune features, experimental models and ongoing research efforts, as well as current and potential future therapeutics.

GENERAL CONCEPTS IN AUTOIMMUNITY

Immunity and Autoimmunity

> *"… weil, so schliesst er messerscharf, nicht sein kann, was nicht sein darf"*
>
> *("… for, he reasons pointedly, that which must not, can not be")*

—Christian Morgenstern, *The Impossible Fact* (1910)

Autoimmunity is "the Other"[1] of immunity. And in true dialectical fashion, immunity's inception as a scientific discipline encapsulates the conceptual problem that was to shape the immunologic debates in the first 15 and last 50 years of the past century. As much as the prefix *auto* assigns a specific place apart from immunity proper, the idea of immunity is not

conceivable, for better or worse, without the notion of the self.[2] Immunity's distinct association with the individual self stretches from its etymologic roots in the Roman legal concept of an *individual's* exemption from duty, service, or tax; to its official induction into the canon of medical terminology (defined as “idiosyncratic condition” in the 1878 edition of Littré's Dictionnaire de Médecine[3]); and beyond. However, with the dawn of a new century, in the wake of the seminal discoveries of immune protection by active immunization with attenuated pathogens[4] or passive transfer of convalescent serum[5] and the seemingly unstoppable success of the “New Immunology,” the notion of the immunologic self underwent a dramatic reconfiguration. The price for immunity, it appeared, was autoimmunity, a concept so problematic that its existence had to be relegated to the realm of the almost unspeakable, that is, the Greco-Latin neologism of a “horror autotoxicus.”[6] Paradoxically, the time that witnessed the concept of horror autotoxicus acquire quasi-dogmatic status as the “law of immunity research”[7] also became what A. Silverstein[8] has termed the “classical period” of autoimmunity research. Though declared anathema, autoimmune phenomena were reported in a quick succession of widely publicized observations. In 1902, Portier and Richet[9] reported the phenomenon of anaphylaxis (as opposed to *pro*-phylaxis); Maurice Arthus[10] characterized the local inflammatory response that was to bear his name in 1903. Donath and Landsteiner[11] described the first human autoimmune disease (paroxysmal cold hemoglobinuria) in 1904, and the term *allergy* (“altered reactivity”) was coined by von Pirquet and Schick[12] in their analysis of serum sickness in 1905. The

idea that tissue destruction may lead to expanded immunopathology (nowadays referred to as “determinant spreading”) was proposed by Weil and Braun in 1907: In the course of an infectious disease, “tissue destruction results in the generation of antibodies that […] will be directed not only against the degraded products of the destroyed cells but also against human cell products as such. […] These autoantibodies could attack cells, [and] liberate antigen which in turn could induce the generation of autoantibodies.”[13] Even the concepts of organ specificity,[14] immunoprivilege, and a breakdown of regulatory mechanisms as a cause for autoimmunity[7] were developed in the early days of autoimmunity research.

This period of extraordinary productivity was followed by an almost 40-year hiatus, “the dark ages of autoimmunity research.”[8] The reasons for a generalized disinterest in autoimmune phenomena are manifold and include political reconfigurations after World War I, the death of both Ehrlich (1915) and Metchnikoff (1916), a misconception of horror autotoxicus as the immune system's *inability* to generate responses against “self,” as well as a paradigm shift in the field of immunology in favor of immunochemical approaches.[8] The renaissance of autoimmunity research had to await observations about immunologic tolerance of mice congenitally infected with lymphocytic choriomeningitis virus (LCMV),[15] description of tolerance in chimeric cattle twins,[16] and Peter Medawar's work on skin transplant rejection,[17,18,19,20] as well as the integration of these findings into a conceptual framework of self and nonself as determinants for immunologic reactivity.[21] Burnet subsequently developed and extended these ideas into the “clonal selection theory of antibody formation, ”[22] thereby establishing the conceptual centrality of self, nonself, and immunologic tolerance.

Although the dogmatic reading of horror autotoxicus was still prevalent (Ernest Witebsky delayed his publication about thyroid antibodies[23] for several years assuming an experimental error[8]), Ehrlich's original conception as “regulatory contrivances” that prevent autoimmunity was now validated within the context of the clonal selection theory.

Again, however, the usefulness of self and nonself as distinguishing parameters was challenged at the very time they began their rise to prominence. Ludwik Fleck, in his singular study *Genesis and Development of a Scientific Fact* , questioned the capacity of an immune system that only interacts with structures that are strictly nonself: “… it is very doubtful whether an invasion in the old sense is possible, involving as it does an inference by completely foreign organisms in natural conditions. A completely foreign organism could find no receptors capable of reaction and thus could not generate a biological process.”[24] This view is echoed and elaborated upon in the work of Jerne[25] and Coutinho et al.,[26] and even the possibility of a beneficial role for autoimmune processes was postulated by concepts such as “physiologic autoimmunity,”[27] “positive autoimmunity,”[28] and “protective autoimmunity.”[29] The importance of autoreactivity as an integral aspect of immunity is furthermore demonstrated by the process of “positive selection” of developing T cells in the thymus and the T cell-mediated destruction of transformed or infected tissues that is based on the recognition of “foreign” (eg, viral peptides or even self as in the case of some tumorderived antigens) in the context of self (major histocompatibility complexes [MHCs]). In fact, events associated with “danger” or the preservation of “tissue integrity” rather than the discrimination between “self/nonself” have been postulated as a primary driving force that engages the immune system.[30,31] More recently, the notion that immune reactivity is generated by the introduction of strong antigenic discontinuities (“criterion of continuity”) has been proposed and may offer an elegant solution to some of the conceptual problems outlined previously.[32,33] Still, the idea of “recognition”[2,34,35] remains a central element common to all these models as the immune system's principal task is cast as a differentiation between organismal states (self vs nonself, safety vs danger, integrity vs damage, continuity vs discontinuity, etc.). Such operational distinction is indeed a powerful tool to conceptualize, with both impressive success and some obvious shortcomings, the functions of the immune system. Yet, it may also insinuate a proximity of logical and functional categories that can culminate in the postulate of a principal objective, a veritable raison d'être for the immune system, and thus reintroduces a tinge of teleology. Rather, we favor an evolutionary perspective that conceives of the immune system, devoid of a particular purpose,[36] as “the cause of its own necessity.”[37]

The notion of autoimmunity as an aberrant phenomenon has informed much of our current understanding about the immune system and its functions, and there appears to be a growing awareness that immunity and autoimmunity are both historically and conceptually inextricably intertwined. An emerging consensus indicates that the anthropomorphisms of “self” and “non-self” should be overcome (eg, as suggested in the respective forewords to two major autoimmunity textbooks[38,39]), and that autoimmunity is likely a universal phenomenon in the evolution of the vertebrate immune system. As part of the evolving organism, the immune system processes antigen stimuli in a deterministic fashion restricted by genetics, previous antigenic experience of the host, nature of the antigen, and the conditions of its

presentation.[38] However, imbuing the immune system's function with an overriding purpose, no matter how important for our conceptualization and experimentation, has to consider that evolution is ignorant to teleology. In this respect, the remark by the Darwinist Paul Ehrlich that production of autoantibodies is “dysteleological in the extreme”[6] may be extended to the functionality of the immune system as a whole: There is no teleology in autoimmunity nor immunity, just the workings of a complex system under evolutionary constraints. The rules that inform immunity are the same ones that govern autoimmunity.

The Burden of Autoimmune Diseases

The existence of autoimmune diseases in humans has been known for 100 years. By now, autoimmune pathogenesis has been attributed to more than 80 human diseases,[40] yet it is still far from clear which features can conclusively prove an underlying autoimmune pathogenesis. It has been suggested, somewhat provocatively, that with knowledge about

an infectious origin, diseases are called immunopathologically mediated, whereas lack of such knowledge results in reference to such diseases as autoimmune.[41] While this argument is akin to the medical taxonomy where diseases of unknown origin are assigned to the domain of the “endogenous,” “idiotypic,” “essential,” or “primary,” a “positive” definition for autoimmune diseases is needed to provide a specific diagnostic framework that allows for unequivocal identification of distinct autoimmune disorders, yet remains flexible enough to accommodate new insights in etiologic and symptomatologic processes. A first attempt to provide such a basis for the establishment of the autoimmune origin of human diseases was formulated by Witebsky et al.[42] who modeled their postulates on those of Koch: recognition of an autoimmune response (autoantibody or cell mediated), identification of a corresponding autoantigen, as well as induction of an analogous autoimmune response and disease in experimental animals. A timely update for these criteria has been proposed by Rose and Bona,[43] who suggested a combination of direct evidence (transfer of pathogenic antibodies or T cells), indirect evidence (reproduction of disease in experimental animals), and circumstantial evidence (clinical clues) to determine an underlying autoimmune etiology for human diseases. However, it is important to note that any specific guidelines have to be tailored to individual autoimmune disorders. An example for a catalog of diagnostic criteria to be evaluated in a scoring system for identification of patients with a specific autoimmune disease is the report of the International Autoimmune Hepatitis Group.[44] This report also illustrates the importance of distinguishing between an autoimmune and infectious origin for hepatitis[44]: Immunosuppressive therapy has a beneficial effect on the course of autoimmune hepatitis (AIH); responsiveness to such therapy is in fact one of the diagnostic criteria for AIH but may be detrimental when employed for treatment of virus-induced hepatitis.

As a first of its kind, a meta-study by Jacobson et al.[45] provided the comprehensive evaluation of prevalence and incidence studies conducted for 24 autoimmune diseases between 1965 and 1995. Overall, 1 in 31 Americans (˜8.5 million people, 3.2% prevalence) were estimated to be afflicted by autoimmune diseases, and the most common disorders, divided into organ specific and systemic conditions, and ranked in order of prevalence, are listed in Table 44.1. More recent epidemiologic studies have provided even higher estimates for the comtemporary burden of autoimmune diseases. Eaton et al.,[46] using national

hospitalization registry data in Denmark from 1977 to 2001, arrived at a prevalence of 5.3%, and Cooper et al.[47] calculated a global prevalence rate of 7.6% to 9.4% for the period from 1989 to 2008. Although clearly only approximations, it therefore appears that autoimmune diseases are much more frequent than previously thought. Walsh and Rau[48] approached this subject in a different manner by

determining the relative ranking of autoimmune diseases in terms of mortality risk among women under the ages of 65. Remarkably, the collection of 24 autoimmune diseases specified by Jacobson et al. ranked within the top 10 causes of death.[48] Thus, autoimmune conditions not only decrease the quality of life among afflicted individuals but also due to their high prevalence constitute a major public health burden. In addition, a trend toward rising incidence rates among most autoimmune disease has been noticed over the past few decades. For example, the incidence of multiple sclerosis (MS) in Italy has doubled between 1981 and 2002,[49] and in the United States, the incidence of celiac disease increased fivefold in 15 years.[50] These trends are not likely to abate, and predictions for the number of new type 1 diabetes (T1D) cases in Europe are as high as 24,400 by 2020, whereas while the prevalence under the age of 15 years is estimated to rise from 94,000 in 2005 to 160,000 in 2020[51]; in Finland, the country with the highest incidence of T1D, the number of new cases diagnosed at or before the age of 14 years will likely double in the next 15 years.[52] The economic challenges associated with these developments are indeed staggering as shown by the health care-related expenses in the United States and provided by the American Autoimmune Related Diseases Association for Crohn disease ($10.9 to $15.5 billion in 2008), rheumatoid arthritis (RA; $19.3 billion in 2005), or psoriasis ($11.2 in 2010). Treatment costs are expected to increase even further due to the nature of some of the more succesful therapeutic modalities developed for chronic autoimmune conditions, for example, the introduction of antitumor necrosis factor (TNF) biologics. While clearly an important advance and of great benefit to patients, these drugs do not promote a cure for the underlying disease, and the need for continuous treatment will exacerbate associated health care costs.

TABLE 44.1 Prevalence of Autoimmune Diseases

Autoimmune Disease	Organ	Weighted Mean Prevalence Rate/100,000	Weighted Mean Incidence Rate/100,000
Thyroiditis/hypothyroidism	**Thyroid**	**1323.8**	**21.8**
Grave disease/hyperthyroidism	**Thyroid**	**1151.5**	**13.9**
Rheumatoid arthritis	Joints, lung, heart, other	**860.0**	**23.7**

Vitiligo	**Skin**	**400.2**	
Type 1 diabetes	**Pancreatic B cells**	**192.0**	**12.2**
Pernicious anemia	**Stomach**	**150.9**	__a
Multiple sclerosis	**Brain/spinal cord**	**58.3**	**3.2**
Glomerulonephritis (primary)	**Kidney**	**40.0**	**3.6**
Systemic lupus erythematosus	Skin, joints, kidney, brain, lung, heart, other	**23.8**	**7.3**
Glomerulonephritis (immunoglobulin A)	**Kidney**	**23.2**	**2.4**
Sjögren syndrome		14.4	__a
Addison disease	**Adrenal**	**5.0**	__a
Myasthenia gravis	**Muscle**	**5.1**	**0.4**
Polymyositis/dermatomyositis	Muscle, lung, heart, joints, other	**5.1**	**1.8**
Scleroderma	Skin	**4.4**	**0.8**
Primary biliary cirrhosis	**Liver bile ducts**	**3.5**	**0.9**
Uveitis	**Eye**	**1.7**	**18.9**
Chronic active hepatitis	**Liver**	**0.4**	**0.7**

Data taken from Jacobson et al.45

Organ-specific autoimmune diseases in **bold**, systemic autoimmune diseases are in regular type face.

The prevalence/incidence rate from each study within a disease category contributed proportionately to the mean prevalence/incidence rate based on the population size of that study. The proportion or weight was calculated by dividing the study population denominator by the total of all the study population denominators for each disease.

For details see Jacobson et al.45

[a] No studies on disease incidence available.

These epidemiologic studies also permit several additional, if not entirely unexpected, conclusions. Many autoimmune conditions are clearly understudied, and some of the most frequently studied diseases exhibit comparatively low prevalence rates. The cause for the seeming imbalance between the public health burden posed by some autoimmune disorders and their attraction as objects for scientific study remains to be elucidated but will likely include the presence or absence of effective therapy. Pernicious anemia, the sixth most common autoimmune disease in the United States, can be effectively managed, and therefore elicits only limited epidemiologic interest. In contrast, some rare conditions may pose a pronounced burden to afflicted individuals and thus warrant continued efforts to develop more effective prophylactic and therapeutic interventions. Further, the availability of certain models for autoimmune diseases, again not necessarily a reflection of the epidemiologic importance of the corresponding human autoimmune disease, will have an impact on choices made by researchers charting their field of study. Additionally, as in other areas of research or clinical medicine, the funds and resources available are the result of multiple factors that may or may not include the public health burden exerted by a particular autoimmune disease. Balancing these aspects to appropriately appreciate and address the burden of autoimmune diseases, based on both the afflicted individual and society at large, is a challenge that will require our continued efforts to identify, investigate, inform, and, hopefully, improve the therapies for many autoimmune diseases.

Spectra and Continua: Organ-Specific and Systemic Autoimmune Disorders, Autoinflammatory Diseases, and the Challenges of Taxonomy

A perennial approach in our quest to make sense of the complex phenomena we encounter is the establishment of dichotomies, however, fraught with shortcomings, inconsistencies, and exceptions to the rule. Steeped in clinical traditions and immediately intelligible, the distinction between systemic and organ-specific autoimmune diseases is as useful as it is inadequate. Given that our evolving understanding of autoimmune diseases requires a constant reevaluation of our concepts pertaining to etiopathogenesis and effective treatment modalities, it would be premature to abandon such a simple and still useful classification. Rather, that porous juncture between systemic and organ-specific disorders may reveal hitherto unappreciated aspects of pathogenesis. On the surface, the patterns of pathology result from the distribution of anatomic niches that provide a suitable environment to

“interface” antigens and immune effectors. Leaving for the moment aside the difficulties pertaining to the identification of initiating autoantigens in many human autoimmune diseases and the challenging task to correlate markers of immunologic activity (eg, autoantibodies) with cause or consequence of tissue destruction, a particularly puzzling phenomenon is the seeming organ specificity of some disorders in the face of autoimmune responses that target ubiquitous antigens. For instance, the ribonucleoprotein antigens implicated in Sjögren syndrome or the transfer ribonucleic acid (RNA) synthetases targeted in polymyositis are widely expressed intracellular antigens, yet the pathology of these diseases is relatively circumscribed. Another intriguing example is the K/BxN arthritis model in which pathogenic antibodies recognize the ubiquitous cytoplasmic enzyme glucose-6-phosphate isomerase. Here, the preferential involvement of the joints apparently results from unique properties of the regional vasculature that allow for an antibody-mediated increase of vasopermeability and amplification of pathology by extracellular glucose-6-phosphate isomerase deposition in the articular cavities.[53,54] The observation that autoimmune damage is critically dependent on aspects of the local microanatomy emphasizes the importance to consider autoimmune processes in the larger context of interdependent organ systems.

In addition, an examination of some animal models used for the study of particular organ-specific autoimmune disorders further challenges the simple notion of restricted pathology and may provide clues about etiologic commonalities of ostensibly disparate clinical autoimmune syndromes. The nonobese diabetic (NOD) mouse is the most widely used animal model for the study of T1D, a severe condition caused by autoimmune destruction of

the insulin-producing β cells in the pancreas.[55,56] However, NOD mice also exhibit aspects of type 2 diabetes[57] and are prone to autoimmune sialitis, thyroiditis, peripheral neuropathy, prostatitis, a lupus erythematosus-like syndrome that develops after exposure to killed mycobacteria, as well as, under certain circumstances, exocrine pancreatitis.[56] Similar to the etiology of T1D, specific T cells are involved in the pathogenesis of all these disorders, although antigenic targets and requirements for costimulatory interactions are distinct. Thus, as in human T1D, the NOD mouse combines a generalized genetic susceptibility to multiorgan autoimmunity that is focused on pancreatic β cells but not limited to endocrine organs.

While the preceding considerations argue against a rigorous opposition of systemic versus organ-specific autoimmune diseases and rather support the notion of a spectrum of clinicopathologic features that variously emphasize prominent organ-specific and systemic features, even the conceptual distinction of autoimmune disorders at large is suffused with certain limitations (eg, absence of MHCs or autoantibody associations with some diseases tentatively labeled “autoimmune”) that have prompted new taxonomic proposals for immunologic diseases in general. Perhaps most prominently, McGonagle and McDermott introduced the concept of autoinflammation defined as “self-directed tissue inflammation, where local factors at disease-prone sites determine the activation of the innate immune system.”[58] Accordingly, a continuum of immunologic diseases is demarcated by rare monogenic disorders that are purely autoimmune and demonstrate preferential involvement of adaptive immune responses (eg, autoimmune polyendocrine syndrome-1 resulting from mutations of the AIRE gene), and purely autoinflammatory conditions defined by mutations in cells or molecules of the innate immune system and localized pathologies that escape the

traditional purview of “classical” autoimmune mechanisms (eg, TNF receptor-associated periodic syndrome). Between these boundaries, the vast majority of other immunologic disorders can be organized along a continuum of pathologies that range from classic polygenic autoimmune diseases to mixed pattern diseases and to polygenic autoinflammatory diseases.[58] The major appeal of this expanded notion of autoimmunity lies in the recognition of innate immune mechanisms as an important component of autoimmune disorders (with inevitable echoes of the Ehrlich-Metchnikoff rivalry informing the current discussions) and in the provision of an inclusive classification of immunologic diseases.

Central and Peripheral Tolerance: Implementing an Operational Concept

A detailed historical discussion of the concept of tolerance is beyond the scope of this chapter, but some aspects of the usage of the term tolerance require clarification at the outset. Tolerance in adaptive immunity, sensu stricto, is the absence of specific lymphocyte activity, the consequence of physical deletion, or functional silencing of specific T and B cells. Some researchers refer to these tolerance mechanisms as “passive” or “recessive” tolerance to explicitly distinguish them from “active” or “dominant” tolerance. While the latter mechanisms constitute bona fide immune responses (therefore, other researchers do not categorize them as a mode of tolerance), their particular nature results in a phenotype that is comparable to that achieved by means of passive/recessive tolerance. Distinct effector mechanisms (eg, immunosuppressive cytokines) and possibly dedicated classes of immune cells (eg, “regulatory T” [T_{reg}] cells) assure that local or systemic autoimmunity is avoided.

The concept of T-cell suppressors, first proposed in the early 1970s by Gershon and Kondo,[59] was resurrected in the form of “professional” cluster of differentiation (CD)25+FoxP3+CD4+ and “adaptive” T_{reg}s cells (TR1 and other T_{reg}s) and has since attracted considerable attention. However, while there is indeed a CD25+ lineage of T cells committed to regulatory activity in naive, nonimmunized mice, we wish to underscore that regulatory functions, including those that limit autoimmunity, are a feature of the immune system as a whole and can be exercised by other classes of immune cells as well (eg, CD8+ T cells, γδT-cell receptor (TCR) T cells, natural killer T cells, etc.). Thus, while CD25+CD4+ T_{reg} cells occupy a distinct and important niche in the complex dynamic network of immune functions, not all T-cell regulators are CD25+CD4+ nor do all CD25+CD4+ T cells function as suppressors. Indeed, novel markers might characterize regulatory function better; among these are expression of the transcription factor FoxP3[60,61,62,63,64,65,66] and secretion of cytokines with regulatory function such as interleukin (IL)-10[67,68] or transforming growth factor (TGF)-β.[69] The multiplicity of current efforts to understand the nature of CD25+CD4+ T_{reg} cells has been expertly reviewed elsewhere,[70,71] and we note in particular more recent observations on the transcriptional, phenotypic, and functional instability of T_{reg} population.[72,73] This has important repercussions in the context of autoimmunity, as T_{reg}s can lose their regulatory capacities when exposed to local conditions of autoimmune inflammation. On the one hand, these results suggest that aberrant conversion from regulatory to effector phenotype may partly underlie progression to overt autoimmune disease in susceptible individuals. On the other hand, such propensity may jeopardize the long-term efficacy of therapeutic strategies based on the induction or adoptive transfer of autoantigen-specific T_{reg}, as these cells could potentially convert to effectors once they

arrive in the inflamed tissue. Therefore, these recent insights clearly warrant caution regarding the popular endeavor of assigning T cells to defined subpopulations based on their "signature" transcription factors and functionalities and emphasize the importance of plasticity and mutability the mechanistic foundation and relevance of which remains to be explored in further detail. Lastly, we emphasize that changes in T_{reg} functionality rather than a mere numerical decrease appear to constitute a correlate for some human autoimmune diseases.[74] Thus, the simple quantification of peripheral T_{reg} numbers as a measure of risk in autoimmunity-prone indviduals or as a biomarker in clinical studies will have to be complemented with functional assays to generate relevant data.

T-Cell Tolerance

Autoreactivity, by definition, designates a specific immune response to self-antigens. Antigen nonspecific responses such as inflammatory and innate immune processes should not be considered autoimmune in the strict sense, although they may accompany, enhance, or even trigger autoimmune processes proper. Thus, antigen-specific T- or B-cell immunity will have to underlie a genuine autoimmune disorder. Furthermore, for organ-specific autoimmune diseases, antigen specificity of primary effector lymphocytes must be largely restricted to autoantigens derived from defined organs or tissues. Once initiated, specific responses that precipitate or "drive" the localized autoimmune reaction may diversify to comprise additional specificities (determinant spreading) and pathogenic mechanisms.

How does the adaptive immune system restrict generation and activation of autoreactive lymphocytes? The central process by which the generation of TCR diversity is limited is called thymic selection. Thymic selection is a developmental process that selects T cells with a biased repertoire for export into the periphery.[75,76,77,78,79] T cells that interact at least weakly with self-peptides presented in the context of MHC molecules are chosen in the course of positive selection,[80,81] while those that do not effectively interact with MHC/peptide complexes die "by neglect." However, interactions above a certain avidity threshold result in elimination by negative selection and constitute the basis for "central tolerance."[75,79] Thus, central tolerance prevents widespread autoimmunity as a function of lymphocyte/antigen-complex avidity and preferentially selects T cells with specificity for antigens not expressed in thymic epithelium for export into the periphery. However, central tolerance is not a complete mechanism, and a sizable pool of T cells with intermediate avidity can escape negative selection and constitutes most autoreactive T cells found in the peripheral immune system. The presence of these autoreactive T cells can be considered physiologic, and they are not noxious for two reasons: either they are usually not activated and exhibit a "naive" phenotype or they exhibit regulatory effector functions and act as adaptive T_{reg}s following activation. Thus, not all self-reactive lymphocytes need to necessarily exhibit an aggressive phenotype. Depending on their specific effector functions, autoreactive T cells may exhibit regulatory functions and may critically modulate or even abort local autoimmune processes. Such autoreactive regulators might occur physiologically and constitute most autoimmune responses present in healthy individuals. Only an encounter under appropriate stimulatory conditions (ie, presentation of autoantigen-derived peptides presented in the context of MHC class I or II molecules accompanied by antigen-nonspecific costimulatory interactions and strong inflammatory signals) can lead to their full activation and

detrimental effector functions in the periphery. As such “armed effectors,” autoreactive T cells are now potentially very dangerous and may initiate specific autoimmunity, if they recognize the autoantigens or closely related proteins in a defined tissue. It is thought that a few autoaggressive “driver clones” with highly detrimental effector function can sustain a localized autoimmune process. High receptor/MHC/self-peptide avidity likely, but not necessarily, predisposes to this phenotype.[82,83,84]

The presence of autoreactive T cells in the periphery might suggest that detrimental autoimmunity should occur quite frequently if organ-specific autoantigens are not expressed in the thymus, or alternatively or in addition, such physiologically occurring autoimmunity is not of a regulatory nature. Yet, there are several additional mechanisms that maintain tolerance in the periphery. “Peripheral tolerance” involves a set of mechanisms that ensures that autoreactive T lymphocytes are not activated in the periphery. It should be noted that these mechanisms pertain to both autoreactive and “heteroreactive” T cells and involve the following pathways. First, it has been observed that naive T cells triggered by a strong signal through the TCR alone may lose the ability to proliferate, and some but not all effector functions become “anergic.”[85,86,87] Presence of certain cytokines or costimulatory interactions can avoid the induction of anergy or may reverse an anergic state. Second, highly activated T cells will eventually undergo activationinduced cell death (AICD).[88] AICD is thought to be essential for the downmodulation of immune responses and the reestablishment of immune homeostasis. Impairment of AICD may lead to continued immune activation and generalized autoreactivity. For CD4 lymphocytes, AICD is FAS/FAS-L dependent[89,90]; it is not clear which interactions precisely control AICD in CD8 cells. Third, molecules that can deliver specific negative signals, such as the B7-binding cytotoxic T-lymphocyte antigen (CTLA)-4 are involved in “turning off” of antigen-specific T cells.[91,92] Finally, other factors such as regulatory lymphocytes and regulatory antigen-presenting cells (APCs) might play important roles in maintaining peripheral tolerance.[59,70,93]

B-Cell Tolerance

Although they are not selected in the thymus, similar paradigms as those for T cells apply to autoreactive B lymphocytes. Clonal selection occurs after recognizing antigens, is avidity dependent, and allows the B cells to undergo further receptor editing. Both central (ie, bone marrow) as well as peripheral tolerance mechanisms are in place to avoid generating mature B cells with specificity for self-antigens. After B cells mature in the bone marrow, they clonally expand after recognizing antigens in the periphery. T-helper (Th) lymphocytes are needed for this process in response to most protein antigens, and these B-cell responses are therefore termed “thymus dependent” or, in other words, require T cells with specificity linked to an epitope on the antigen they are reacting with. Th cell-independent B-cell responses occur mostly to bacterial and lipid antigens, for example, to lipopolysaccharide, and are therefore rarely autoaggressive. Thus, T-cell tolerance directly controls B-cell reactivity to autoantigens. In general, systemic autoimmune disorders such as systemic lupus erythematosus (SLE) are B-cell dependent, and organ-specific diseases such as MS and T1D are less dependent on autoantibodies, although

B cells can play important roles as APCs, and antibodies can possibly enhance disease pathogenesis. In both diabetes and MS, autoantibodies correlate with disease progression. In

thyroiditis, autoantibodies are instrumental for causing disease and in AIH, their role is thought to be crucial.

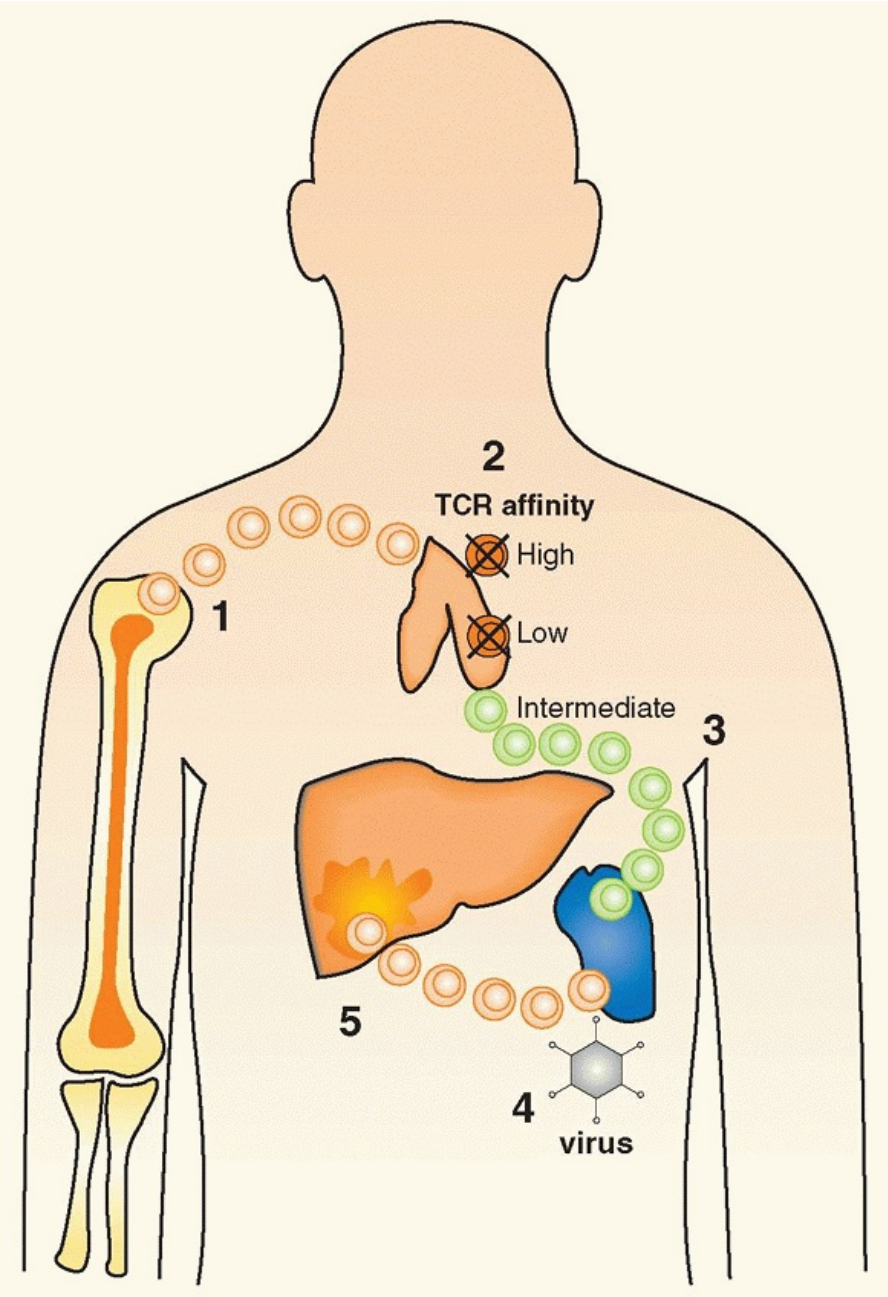

FIG. 44.1 Events Important for the Pathogenesis of Autoimmunity. 1: Lymphocyte precursors migrate from the bone marrow to the thymus to undergo maturation. **2:** In the thymus of susceptible individuals, autoreactive lymphocytes can escape thymic selection. Whereas cells with high or low T-cell receptor affinity are generally deleted; "intermediate" lymphocytes fail to undergo negative selection. **3:** Such initially naive cells migrate to peripheral organs such as the spleen and may remain unresponsive for many years. **4:** Certain environmental triggers have the ability to activate these naive cells by bystander activation, molecular mimicry, or antigenpresenting cell cross-presentation. **5:** As a consequence, activated autoreactive lymphocytes migrate to target organs such as the liver and mediate inflammation and tissue damage, leading to clinical autoimmune disease symptoms.

In conclusion, central (thymic) and peripheral tolerance mechanisms will effectively control the vast majority of autoreactive lymphocytes, which assures that autoaggressive immune responses are relatively rare (< 5% overall population). Some of the considerations described in this paragraph are illustrated in Figure 44.1.

Organ-Specific Tuning—Regulatory and Destructive Autoimmunity

As indicated previously, while autoimmune disorders must conform with a set of general criteria, organ-specific autoimmunity must be considered in the context of the target organ affected. Certain effector functions exerted by autoreactive lymphocytes will be detrimental only to particular cells or tissues. For example, the pancreatic β cells are more sensitive to the damaging effect of inflammatory cytokines than neighboring α cells (both cell types are part of the islets of Langerhans) and other cells in their vicinity (eg, fibroblasts or acinar tissue of the pancreas).[94] On the other hand, some organs provide a microenvironment that suppresses inflammatory responses. For example, both the gut and the central nervous system (CNS) contain relatively large amounts of TGF-β, which can have direct anti-inflammatory effector functions on T cells and APCs, and activate T_{reg}s, unless IL-6 is present.[69,95,96,97,98] Also, certain large organs such as the liver may better tolerize lymphocyte responses directed toward them because they contain a high number of cells that are incapable of costimulation (eg, hepatocytes) and will, therefore, more likely shut down naive autoreactive lymphocytes that stimulate them.[30] Finally, the precise activation state, phenotype, and effector function of an autoreactive cell is critical in determining their impact on tissues expressing their cognate antigen. Some molecules will exert beneficial functions, for example, IL-4 and probably IL-10 and TGF-β in T1D.[99,100,101] Antigen-specific adaptive and professional regulatory cells are likely participants of every local autoimmune process and can therefore be essential for delay or prevention of clinical disease altogether. While their induction is a clearly therapeutic goal, phenotype and mechanistic aspects essential for regulatory function are not yet understood in complete detail. Likely, professional and adaptive T_{reg}s may exert their function by targeted alteration of APC function. Recent evidence even suggests that T_{reg}s may safeguard against autoimmunity by specifically killing APCs that present autoantigens to effector T cells.[102] They may also act as true bystander processors if their suppressive action via APC modulation is extended to aggressive immune responses regardless of specificity found in the microenvironment of the affected organ (Fig. 44.2). Indeed, such cells have been found in several animal models,[100,103,104,105] but their existence and function in humans is not well defined. Alternatively, regulatory lymphocytes may directly affect activated or naive aggressive lymphocytes and induce anergy or apoptosis. Lastly, by changing the overall cytokine milieu of a given inflammatory process, the number and function of aggressive cells and cytokines/chemokines may be dampened in a localized area.[106] Probably, the best understood balancing circuit employed by autoreactive adaptive T_{reg}s are the T_H1/T_H2 paradigm[107,108,109] and signaling by IL-10[68] and/or TGF-β.[69] In light of these observations, autoreactivity is not necessarily detrimental and maybe even essential in the sense of T_{reg}s.

Last, it might be difficult or even impossible to define a general phenotype of autoaggressive lymphocytes that will cause damage at any site or organ. Rather, autoaggression has to be defined in relation to the target organ or cell that is under

attack, and lymphocytes detrimental in one organ/disease will not necessarily be detrimental to other organs, and ubiquitous autoimmunity will therefore occur very rarely.

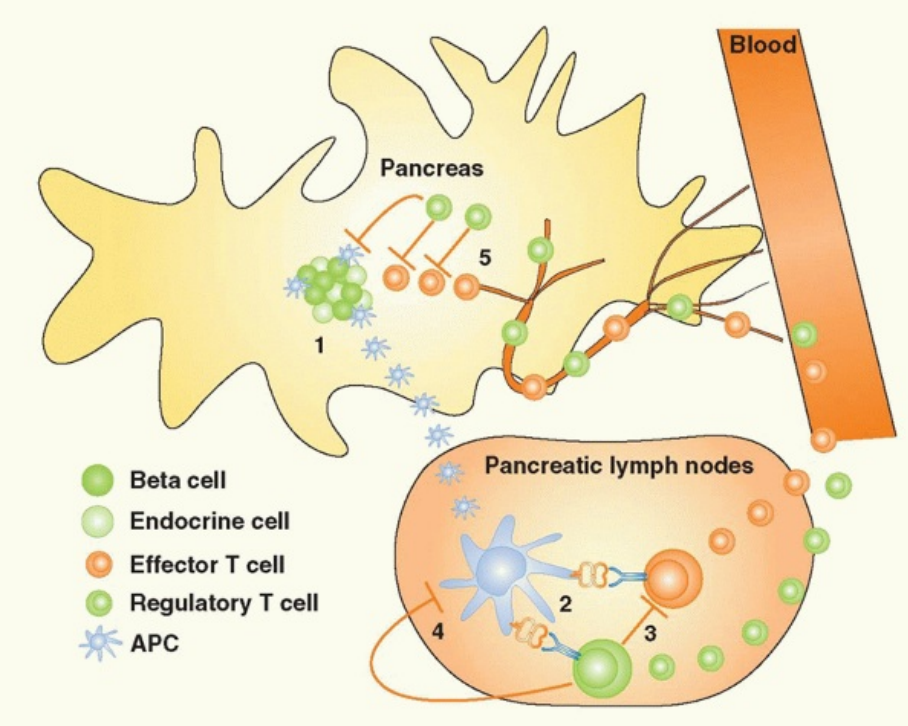

FIG. 44.2. The Concepts of Bystander Suppression and Infectious Tolerance. 1: Autoantigens are taken up by professional antigen-presenting cells (APCs) in the target organ, here depicted as the pancreas in type 1 diabetes. Upon maturation, APCs migrate to the draining lymph nodes. **2:** In the lymph nodes, lymphocytes specific for distinct β cell antigens are activated by the APCs. **3:** As a consequence, aggressive T cells directed toward one antigen could be regulated by regulatory T (T_{reg}) cells specific for another autoantigen, a process termed “bystander suppression” by Howard Weiner.[561] **4:** In theory, T_{reg}s could also modulate APC function and foster induction of more T_{reg}s to the same or other antigens, a process termed “infectious tolerance” by Hermann Waldman.[562] **5:** Identical mechanisms may then regulate autoimmune responses in the target organ, after both effector cells and T_{reg}s gain access via the circulation.

Initiating Autoimmunity: Antigens, Genes, and Environment

Antigens

A central challenge in most human autoimmune disorders is the identification of an initiating autoantigen or autoantigens. For example, several candidate autoantigens have been identified in T1D. However, to date, it remains unclear and controversial whether any are

actually involved in initiation of the disease. Similar situations exist for multiple sclerosis and arthritis. Thus, distinguishing features that constitute an ideal candidate autoantigen and parameters by which potential candidates can be searched for and identified as the initiating autoantigen antigen for a given organ-specific disease must be determined with much greater precision to yield insights applicable to preventative or therapeutic interventions.

The concept that "processing of antigens determines the self" has been introduced by Sercarz.[110,111] Autoantigens that are not expressed in the thymus or are of cryptic nature[110,112,113] may encounter a more extensive T-cell repertoire that is likely of higher avidity. Such antigens appear to be better targets. Low levels of thymic antigen expression or limited numbers of thymic medullary cells may lead to partial tolerance.[114,115] In addition, the precise timing of antigen expression during embryonic development may play a major role for the establishment of tolerance. Antigens that are cryptic or not expressed during early embryonic development might become better targets later because more autoreactive T cells will be present in the periphery. It should be considered that certain "embryonic antigens" are involved in initiating autoimmune diseases.[116]

Of further importance are the constraints with which particular antigens can be presented to the immune system in a given target organ. Exogenous uptake of soluble antigens usually results in processing via the MHC class II presentation pathway. Such antigens may also be processed through the MHC class I pathway by dendritic cells, a mechanism termed *cross-presentation*, if the antigen itself was originally expressed by a cell different from the APC.[117,118] Cross-presentation appears to be less efficient than direct endogenous presentation of antigens through the MHC class I pathway. At this point, it is not clear which properties will make an antigen a more efficient candidate for cross-presentation. The class I pathway may be important in the effector phase for many autoimmune disorders because CD8+ T cells with cytotoxic function (cytotoxic T lymphocyte [CTL]) can be induced in this fashion, and CTLs have profound detrimental effector functions (interferon [IFN]γ and TNF-α secretion, lysis of target cells).[119] Clearly, cross-presentation can lead to immunity, as well as tolerance, and in this way propagates or, alternatively, halts autoimmune disease.[117,120] It is less likely that autoantigens that are not presented by professional APCs or within lymphoid organs after their release from target cells/organs can initiate autoimmunity. Only under special circumstances (ie, extremely high-density presentation of an antigen on a target cell or highly inflammatory conditions including chemotaxis) would this appear possible. This might occur during localized or systemic viral infections and could also be an important event in lymphocyte entry into target organs, especially if chemotaxis is involved and endothelial cells present autoantigens.[121] In addition, experienced or primed autoaggressive lymphocytes will be capable of becoming activated after seeing antigen in the absence of costimulation; thus, accumulating a memory pool of autoaggressive T cells might be inherently dangerous to an organism.

Thus, the type of autoantigen will define its own potential "candidacy" in an autoimmune process. Autoantigens

that are not expressed during development, or were cryptic for an extended period of time, as well as antigens secreted and cross-presented in lymphoid organs by APCs, appear to be better suited for assuming the role as primary culprits.

Genes

An abundance of empiric evidence indicates the association of many organ specific autoimmune diseases with certain human leukocyte antigen (HLA) haplotypes as well as other susceptibility or protective genes. The principal specific genetic linkages will be discussed separately for each condition in part II. In general, MHC class I (such as HLA-B27)[122,123] or class II (such as DR4) genes might predispose to a certain disease by enhanced presentation of pathogenic peptides in the periphery or inefficacious presentation of autoantigenderived peptides in the thymus. For example, the human HLA-DQ8 molecule has a striking structural similarity to mouse I-A^{g7} class II that predisposes NOD mice to spontaneous autoimmune diabetes.[124,125] However, the link to disease appears not to be as simple as reasoned previously, and more complex mechanisms might be in place. Presentation of the pathogenic peptide in gluten-induced celiac disease involves acidic modification of the protein to generate the peptide ultimately presented by MHC class II,[126] and other chemical modifications can be expected to alter peptide binding to MHC and the resulting conformation of the peptide/MHC complex.

Other genes that encode immunoregulatory or inflammatory proteins may be involved in the disease process, and, finally, genes that support tissue or wound repair (eg, islet cell regeneration in T1D) may be of help in preventing disease development.[127] For most autoimmune disorders, the genetic links are complex, not absolute, and many susceptibility and resistance genes act in concert to modulate the clinical phenotype. Noteworthy, newly emerging themes in the genetics of autoimmunity are the fact that small nucleotide polymorphisms might result in alternate forms of the same gene and the fact that the character of the full array of MHC region genes is becoming understood.[128] A striking example for the former is the existence of an alternate spliced form of the inhibitor of cellular function, CTLA-4. Kuchroo and colleagues discovered that the presence of a secondary CTLA-4 lacking the B7.1/B7.2 binding motif can be instrumental in the genetic penetrance of diabetes pathogenesis.[129] An important area still largely unexplored is the nature of genes responsible for transcriptional control of other proteins. Experimental models indicate that transcription factors can have profound effects on the development of autoimmune disease, and variations in expression and activity levels may be found between susceptible and protected individuals. In summary, a complex interplay of many genes will predispose for a certain autoimmune disease, but the concordance of clinical manifestation is frequently not higher than 30% to 40% in monozygotic twins.[130,131,132,133,134,135,136] For this reason, other factors are to be considered in triggering or propagating the pathogenic autoimmune process.

Our understanding of the genetic component to autoimmunity has greatly benefited from the arrival of a first wave of so-called genome-wide association studies (GWAS) in the past 5 years. Prior to the use of this technology, genetic contribution was analyzed by two different approaches: linkage analysis and association studies. Linkage analysis tests for correlation between a genomic region and phenotype in families, whereas association analysis searches for correlations in the entire population.[137] In a genetic association study of autoimmune disease, sequence variants are genotyped in patients, and controls and the frequencies of these genotypes are compared. It is then evaluated whether certain alleles are significantly

more associated with patients than with controls. Most autoimmune conditions are polygenic diseases, meaning that they are caused by (a range of) combinations of polymorphisms within different genes. As mentioned previously, HLA-associated risk was discovered early in many autoimmune disorders and turned out to be reproducable because of its highly significant association. The vast majority of common genetic variants in autoimmunity, however, display modest effects. Even extremely large linkage studies have usually been unsuccessful in discovering susceptibility genes for polygenic diseases that met stringent statistical thresholds. Likewise, most common variants require large association studies for reliable detection. Advances in the development of high-throughput genotyping, statistical correlation methods, and better insight into the organization of the genome offered the opportunity to design approaches for the unbiased interrogation of the entire genome.[138] Sufficiently large case-control GWAS thus have the potential of identifying disease-associated mutations, even if the contribution of that polymorphism is minor. It should be noted here that GWAS often cannot unequivocally identify gene associations (at best "candidate genes"), as risk loci contain multiple genes, and, therefore, follow-up fine mapping or functional studies are generally required. Although GWAS have rapidly increased the list of known risk loci for many autoimmune disorders, some have questioned whether this knowledge substantially aids our understanding of their etiology and offers clues for rational intervention. It could be argued that all associations are often eclipsed by the major contributing factor, HLA polymorphisms, and essentially pinpoint genes with key roles in the immune system that could be expected to be involved to some degree. In T1D, for instance, minor associations with important genes encoding molecules involved in immunity such as CTLA-4 and IL-2 were discovered. From a therapeutic perspective, such findings may be hard to translate as, based on the relatively small association rates, these genes and their products may not necessarily represent pivotal targets in a diverse human patient population. In summary, it can be concluded that most likely all major susceptibility genes associated with the most common autoimmune disorders as discussed in the following text are currently known. Future years will tell whether this comprehensive genetic dataset translates to a better understanding of the origins of autoimmunity and if this will open new avenues toward better treatements.

Environment

***Viral Infections*.** For many years, viral infections have been discussed as potential candidates to trigger autoimmunity in susceptible individuals because of their capacity to directly

infect target tissues and induce strong inflammatory responses and immune activation. While the association between viral infections and organ-specific autoimmune disorders is an intriguing possibility, it has been exceedingly difficult to demonstrate a causative role for specific viruses in human autoimmune diseases. Among the many obstacles are the fact that 1) all individuals undergo a multitude of viral infections during their lifetime; 2) one has to assume that viruses are frequently cleared at the time of diagnosis and viral footprints can be difficult to find in individuals affected by an autoimmune disease ("hit and run" event); 3) the precise viral strain, infection kinetics, and number of T cells and type of effector functions induced may play an instrumental role in determining its effect in an individual genetically at risk, necessitating a very detailed immunologic profiling[139]; 4) due to MHC polymorphism,

there is a significant variation in specificity of the antiviral response; 5) viral infections might not, per se, trigger autoimmunity but affect an ongoing autoimmune process in a detrimental way; and 6) there now is increasing evidence that viral and other[140] infections may rather prevent than enhance ongoing autoimmune responses, either by apoptosing aggressive T cells or by augmenting the T_{reg} pool.[141,142] Thus, a successful approach should be to first explore the underlying mechanisms in virally induced autoimmunity and then apply the precise insight and paradigms developed specifically to the human situation.

The most important mechanisms to be considered are listed here and are summarized in Figure 44.3.

1. Molecular mimicry, which implies the cross-reactivity between viral and self-determinants as a principle cause or mechanism to enhance autoimmunity[143,144]
2. Bystander activation, which postulates that APCs and autoreactive lymphocytes will become activated indirectly as a consequence of the cytokine/chemokine by virus infection of a particular organ[145]
3. Virally induced determinant spreading, which involves the presentation of autoantigens (possibly previously cryptic) by virus-activated APCs[146,147,148]

The experimental evidence for all of these three scenarios obtained in different mouse models in vivo is well documented. However, none of these have been proven for any human autoimmune disorder due to the large size of human trials and the invasive nature of in vivo diagnostics required at the present stage. Thus, in the near future, we will continue to depend on animal models until noninvasive human in vivo diagnostic strategies have advanced and allow for imaging of trafficking of antigen-specific lymphocytes and high-resolution definition of immune process present in a specific organ. A final remark should be made for the existence of a negative association between viral infections and autoimmune disease found in several experimental models.[149] These observations are in support of epidemiologic findings that the incidence of many autoimmune disorders is decreased in equatorial countries, where the presence of certain infectious diseases is significantly increased. However, no firm associations have been established to date.

Other Environmental Causes. Similar to viral infections, other inflammatory stimuli may trigger or enhance autoimmunity. The gut deserves particular attention in this respect. At this site, each individual harbors thousands of different bacterial strains, and viral infections are common. Furthermore, the mucosal lining is permeable for nutrients and constitutes a very large interactive surface with the environment. Again, the complete absence of all bacteria results in severe immune dysfunction and possibly autoimmunity. However, it would be incorrect to conclude that infections are therefore always protective. Indeed, the commensal flora appears crucial in maintaining proper immune activation and function, but certain pathogens could definitely elicit strong gut immune responses that lead to autoimmune disease.[150,151]

Regulatory Circuits in Autoimmune Processes

Cytokines

Cytokines and chemokines are essential regulators of cellular and humoral immune

responses and lymphocyte trafficking.[152,153,154] They play a central role in orchestrating autoimmune processes and constitute a multitude of positive as well as negative feedback loops.[155] It is well established that certain cytokines can negatively or positively influence the production of other cytokines (ie, the Th1/Th2/Th17 paradigm) and thus determine the balance between proinflammatory and anti-inflammatory factors in the local environment. Furthermore, autocrine production feedback can augment or shut down production of a given cytokine by one cell. Cytokine networks operate with a fair amount of redundancy, and many cytokines and chemokines share common receptors. They are the most likely mediators of "bystander activation" and "suppression" processes and also offer an effective and versatile therapeutic target via the temporally restricted use of cytokine- or chemokine-blocking antibodies. Their precise function can vary quite dramatically in respect to the autoimmune disease under investigation and will be discussed in the section on Individual Autoimmune Disorders. Further, their level and timing of expression during an ongoing disease process will determine whether they have a positive or negative effect (or any at all; see the following discussion).

Many autoimmune disorders have traditionally been classified as "Th1-" or "Th2"-driven disorders based on, among other factors, the pathogenic role of cytokines such as IFNγ and IL-4.[107] Recent years have challenged this perspective with of the description the Th17 helper subset, characterized by the production of IL-17.[156,157,158] This class of T cells is considered highly proinflammatory, and its discovery was found to be of importance in several autoimmune disorders in both animal models and humans.[159] One example of an autoimmune disease where Th17 cells have taken center stage is RA. The disease's principal animal model was long referred to as a Th1 driven, but the field struggled with the observation that mice treated with neutralizing antibodies to IFNγ- and IFNγ receptor-deficient mice developed more severe arthritis.[160,161] Dominance of Th17-directed immunity was put forward when IL-17 knockout mice were found

to develop less arthritis,[162] and treatment with neutralizing antibodies to IL-17 or soluble IL-17 receptor alleviated joint inflammation.[163] In humans, it was found that IL-17 is increased in RA sera and synovial fluid and is present in the T-cell rich areas of the synovium.[164] Furthermore, IL-17 has profound inflammatory effects on a range of cell types within the joint. Several clinical trials are underway to either block IL-17 or the cytokines that govern the generation of Th17 cells such as IL-6.

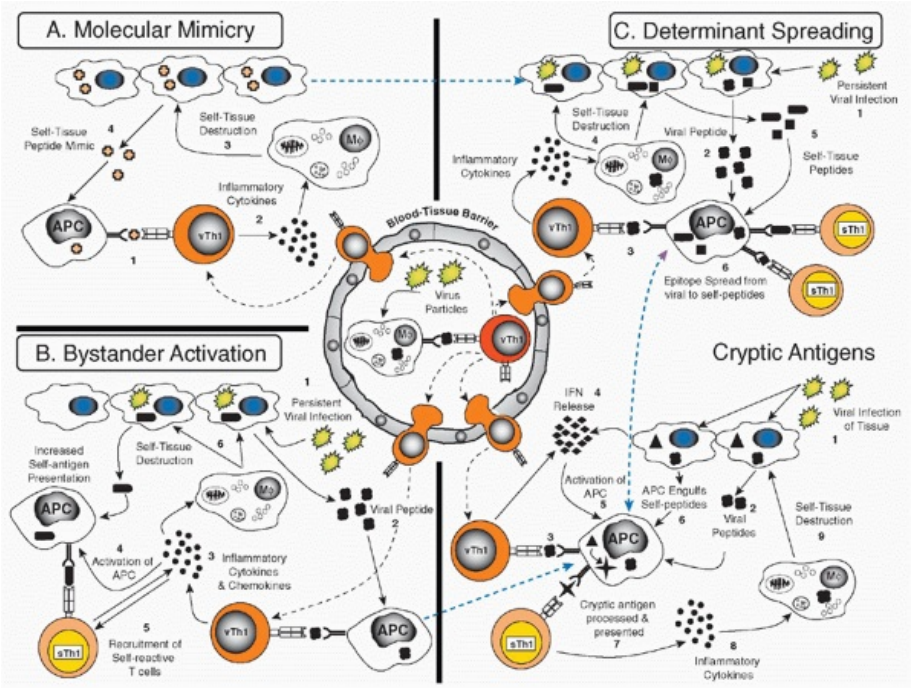

FIG. 44.3. Potential Mechanisms of Autoimmune Disease Induction. After a viral infection, activated virus specific T-helper cells (vTH1) and cluster of differentiation 8 cytotoxic T lymphocytes will migrate more readily through blood-tissue barriers to infected and noninfected organs. **A:** Molecular mimicry describes the activation of cross-reactive lymphocytes that recognize the original viral epitope and a self-epitope *(1)*, which leads to the release of cytokines and chemokines *(2)*, which enhance local inflammation, activate antigen-presenting cells (APCs), and indirectly or directly cause tissue destruction *(3)* and spreading of the autoimmune process *(4)*. **B:** In the epitope spread model, persistent viral infections *(1)* could result in the activation of virus-specific T cells *(2,3)*, which cause tissue damage by killing virally infected cells *(4)*, leading to the release *(5)* and (cross-)presentation of more autoantigens *(6)*. **C:** The bystander activation model describes the nonantigenspecific activation of autoreactive T cells. Infiltration by virally specific T cells *(1,2)* leads to inflammation and upregulation of immunity throughout the tissue *(3,4)*, involving the activation of APCs, which now differentially process autoantigens (also de novo or previously cryptoic antigens). This can lead to activation of lymphocytes by T-cell receptor (TCR)-specific or TCR-independent mechanisms *(5)*, which can then cause tissue damage *(6)*. The cryptic antigen model describes the initiation of autoimmunity by differential processing of self-antigen/peptides, which can occur under inflammatory conditions. After viral infections, interferons *(1)* are secreted by antiviral T cells and infected cells *(2-4)*. APCs are activated in this way (5), which enables them to engulf self-peptides *(6, triangle)* or to differentially process endogenous autoantigens. Cytokines can activate proteases more strongly, which might result in the presentation and processing of previously cryptic autoantigens *(7-9)*. These displayed pathways are not mutually exclusive and are probably operational at different levels in many autoimmune responses. Currently of high interest is the presentation of neoantigens and strategies to define them. Courtesy of Steve Miller and Ludovich Croxford, Northwestern University, Chicago, IL.

Apoptosis

It appears to be a general paradigm of great functional consequence that activation of the immune system is followed by a process that reverses the activation and reestablishes

homeostatic baseline levels of immunity.[88,90] In the absence of such regulatory mechanisms, immune responses will overshoot their goals and excessive immunopathology will occur. Thus, AICD is believed to play an important role in regulating autoimmunity. Apoptotic lymphocytes, for example, are easily detected in islet infiltrates in T1D,[165] and targeted induction of limited apoptosis may even prevent onset of autoimmune disease.[166] While increased apoptosis of aggressive lymphocytes that exceeds the "supply" of newly activated cells may directly limit an ongoing autoimmune process, limited apoptosis of target tissues may indirectly facilitate induction of protective regulatory responses. On the other hand, while apoptosis of target cells should at best be limited, decreased apoptosis of autoreactive aggressive lymphocytes will propagate autoimmunity. In RA, for instance, insufficient apoptosis of synovial macrophages, fibroblasts, and lymphocytes is one mechanism that might contribute to persistence of the disease and lead to synovial lining hyperplasia.[167] It is therefore important to consider precisely which cells undergo apoptosis in order to predict the possible outcome.

- If too many target cells die by apoptosis, organ destruction occurs more rapidly; however, at the same time, antigens releases from apoptotic cells appear to propagate tolerance rather than immunity.[166,168]
- If T_{reg} cells die by apoptosis, autoimmunity will be enhanced.[169]
- If aggressive lymphocytes die by apoptosis, disease should be ameliorated. However, because they have to first be activated, they might induce organ damage during their activation phase.

Thus, an ongoing autoimmune process can be viewed as a rather fine-tuned and fragile equilibrium of aggressive and regulatory components, and the precise activation kinetics and survival times of all lymphocyte types implicated in the process will determine the outcome. We are, at present, unable to delineate the precise in vivo cellular kinetics, and a more thorough understanding will require improved noninvasive diagnostic techniques.

Kinetics

One of the most important emerging areas for an improved understanding of the pathogenesis of autoimmunity is concerned with the kinetics of immune responses. The pathophysiologic or therapeutic effect of a given lymphocyte population depends not only on specificity, activation state, and effector functions but is also a function of the timing during which phase of an ongoing disease process it is present. Indeed, inflammatory cytokines such as IFNγ or TNF-α exhibit opposing effects in T1D depending on the precise time point of generation.[170] Early expression enhances islet destruction and disease development, whereas late expression ameliorates disease by inducing apoptosis of autoaggressive cells. These kinetic issues constitute a major obstacle for successful immune intervention because they preclude the use of specific blocking agents or administration of cytokines without

precise knowledge of their kinetically differential role in the disease process. Figure 44.4 illustrates these kinetic considerations in relation to target cell destruction. A better understanding of the underlying “autoimmune kinetics” is essential and treatments will likely have to be individualized, in particular for antigen-specific immune-based interventions.

Therapeutic Considerations

Efficacy, Specificity, and Undesired Effects

Treatment of autoimmune disorders is not that different conceptually from cancer therapy. A fine balance must be found between efficacy of the intervention and acceptable undesired effects. The main goal of autoimmune disorder therapy is suppression of the pathologic autoimmune response. Therapeutic options range in principle from continuous immunosuppression of the entire immune system to specific, targeted, temporally limited, and local immunosuppression. Systemic immunomodulation or anti-inflammatory therapy will affect the entire immune system and may compromise the immune status of the individual. One of the more succesful examples for effective systemic treatments is the blockade of TNF-α to ameliorate RA.[171,172] This new class of drugs is especially valuable because TNF blockade effects inflammatory pathways distinct from the targets of conventional anti-inflammatory therapy with corticosteroids or nonsteroidal anti-inflammatory drugs. TNF inhibitors can thus be used in patients that are refractory to the latter treatments with the added advantage of considerably improved outcome in terms of structural bone erosions. The remarkable therapeutic success of these drugs has since been replicated in other autoimmune conditions such as Crohn disease, ulcerative colitis, ankylosing spondylitis, and psoriasis. Whereas these diseases target different organs, common therapeutic improvements upon TNF blockade thus indicate shared mechanisms in terms of cytokine signaling. While undesired effects are relatively low, SLE-like symptoms have been observed in a few patients, as has the enhanced susceptibility to tuberculosis. Another important disadvantage, in addition to the high cost of these biologics, is that not all patients respond to TNF blockade. This has spurred a search for more potent blockers of inflammation, with the most promising developments stemming from the design of Janus kinase inhibitors for treatment of RA.[173] This class of small molecular drugs that interrupt signaling downstream of multiple rather than individual cytokines has recently cleared phase III trials in RA and is expected to revolutionarize the therapeutic landscape. While indications exist that this approach is at least safe in the short-term and that it outperforms anti-TNF biologics, long-term safety profiles obviously remain to be determined.

Autoantigen-specific immune interventions, in contrast, bear the promise of lower systemic side effects, as they can be targeted to antigens that are exclusively expressed in the diseased organ.[174,175] However, the efficacy might be lower and suitable target antigens have to be chosen carefully, because enhancement of autoimmunity is an important concern. The goal is either deletion of aggressive autoreactive T cells or induction of regulatory cells.[176] To achieve the latter, response modifiers are probably required at the time

of immunization in order to skew the resulting immune response to exert regulatory effector functions. Deletion of autoaggressive lymphocytes or anergy induction is even more risky, as only suboptimal immunization (ie, in the absence of costimulators) will result in this outcome. To control this in vivo is rather difficult. Ultimately, antigen-specific therapy will likely have to

be individualized due to MHC polymorphism and distinct T-cell repertoires between individual patients and should be combined with other systemically acting agents, for example, antibodies against CD3 or CD4 or costimulation blockade. Indeed, there is intriguing evidence along these lines in animal models: Combination of a non-Fc-binding anti-CD3 antibody with mucosal immunization of insulin or insulin-derived peptides exhibited clear synergy and enhanced efficacy in reversing recent-onset diabetes in the NOD.[177] In this case, induction of insulin specific adaptive T_{reg}s and their effector function were enhanced and protection by these T_{reg}s was transferable and highly effective in that it reversed recent-onset T1D.

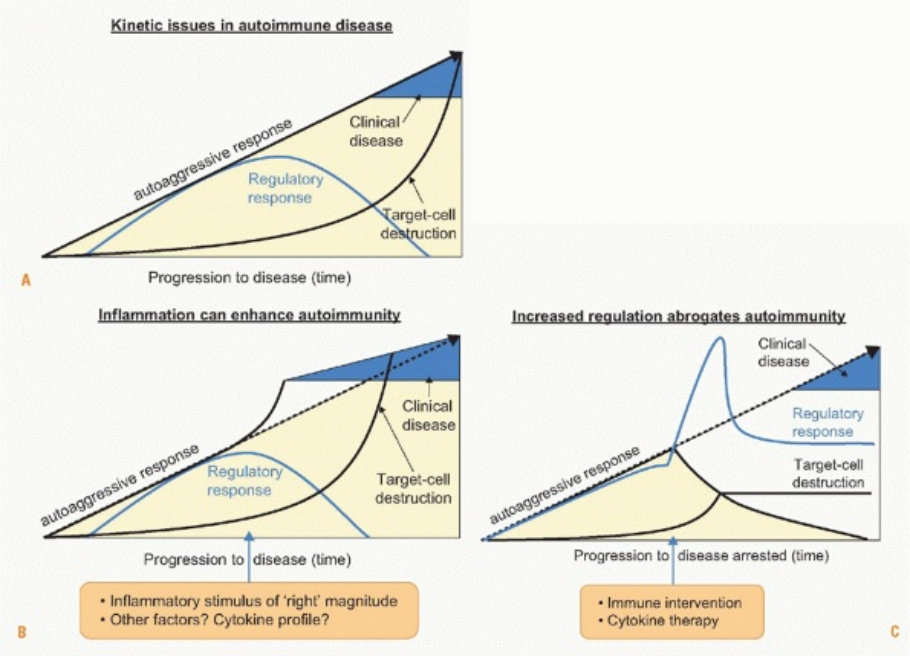

FIG. 44.4. Kinetic Issues in Autoimmune Diseases. A: Clinical manifestation of autoimmunity is the consequence of a dysequilibrium between protective (regulatory) and aggressive (effector) responses. An important consideration is that the destruction of the target cell or organ will usually lag somewhat behind the peak of the aggressive responses, because organ regeneration is common. **B:** Inflammatory stimuli will augment the effector arm of the autoreactoive response resulting in more rapid disease development. **C:** In contrast, induction of regulatory T cells can delay or dampen organ destruction.

Promising Targets

For anti-inflammatory interventions, the factor to be targeted should be as disease specific as possible. Therefore, blockade of TNF works well for RA but not for diabetes or MS.[178] Experimental evidence supports this observation because TNF is a crucial mediator found to be elevated in affected joints,[172] but has clearly positive, as well as negative effector functions in murine models of MS and diabetes.[179,180] Targeting ubiquitously present chemokines or cytokines will likely not bear much success because of the resultant

generalized immune modulation or suppression.

For antigen-specific interventions, antigens that are already targeted by regulatory autoreactivity are likely to constitute good targets to augment such a preexisting response.[181] In contrast, these antigens should not be selected to delete autoreactive cells, which results in a loss of regulation. For anergy or apoptosis induction, antigens targeted by a primarily aggressive response will be better suited. The fact that autoantigenic and epitope spreading occurs during each ongoing autoreactive process makes such interventions difficult to design, and individualization will likely be necessary.

Reestablishment of Tissue-Specific Immune Regulation

One of the factors that pose a challenge to understanding the pathogenesis of distinct autoimmune diseases may also hold a clue to developing effective and specific treatment strategies. Each target cell, tissue, or organ exhibits specific features that distinguish it from other sites of the body. These site-specific features of autoimmunity will

likely offer unique target sites for interventions with lower systemic side effects. However, one concern is that reestablishing proper immune homeostasis and regulation in one organ may still affect homeostasis systemically or at another site. Therefore, thorough preclinical evaluation and careful monitoring of undesired effects is urgently needed. Ideally, treatments have to be administered before complete organ destruction has occurred in patients identified by genetic or other screening to be at risk to develop full-blown clinical disease. During the preclinical state, frequently regulatory autoreactive responses are still strong and their augmentation can result in protection (Fig. 44.5). During advanced stages of autoimmunity, T_{reg} function or susceptibility of effector T cells to regulation might decrease.[182] The goal to reestablish homeostasis and proper regulation after an initial insult that caused organ-specific inflammation appears a natural countermeasure to which the specific immune system may be successfully harnessed. An intriguing example is the emerging concept of organ repair that can potentially be enhanced by drug therapy. In T1D, regeneration and replication of β cells can possibly occur after giving exenatide, a GLP-1 agonist, which is an established intervention in type 2 diabetes and under investigation in combination with other drugs such as anti-CD3 in T1D.

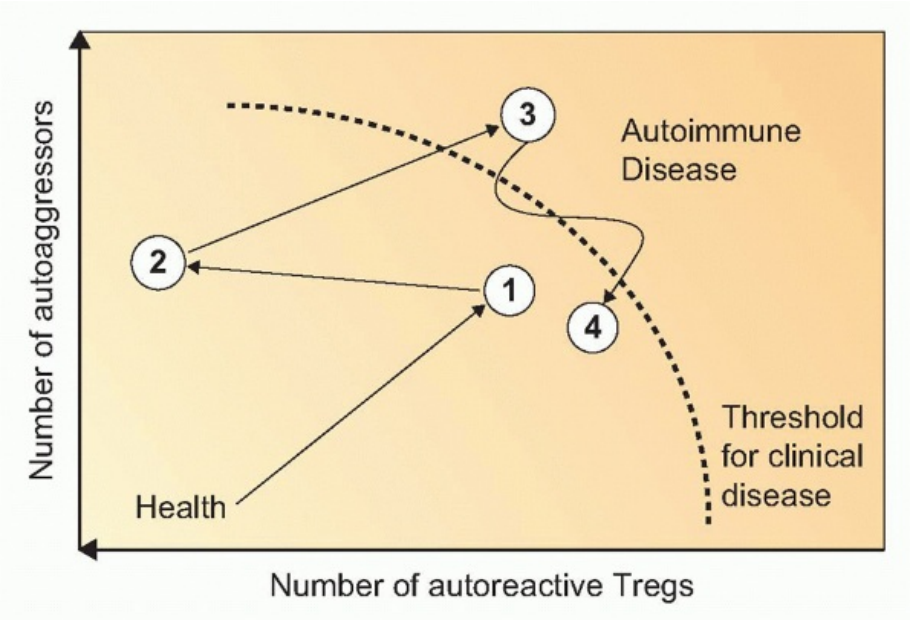

FIG. 44.5. Development of Autoimmune Disease as a Function of Aggression versus Regulation. Following induction of disease **(1)**, distinct numbers of autoaggressive and autoreactive regulatory T cells will be generated and activated. Undulations between protective states and diseases states follow **(2, 3)** (ie, the so-called honeymoon phase in T1D), which can eventually lead to an irreversible state of clinical manifestation of disease **(4)**. An additional important component to factor in is the ability of the target organ to regenerate.

INDIVIDUAL AUTOIMMUNE DISORDERS

A comprehensive and balanced discussion of autoimmune and autoinflammatory diseases at large is well beyond the scope of this chapter. Our choice of individual diseases for this section of this chapter was guided by their relevance to human health (ie, disease prevalence and severity), recent insights into pathogenetic mechanisms, as well as the development of novel treatment modalities. Given these limitations, we extend our apologies to all those scientists and clinicians whose work on autoimmune disorders is not mentioned in our discussion.

Endocrine Autoimmune Diseases

Thyroid: Graves Disease and Hashimoto Thyroiditis

***Introduction and Disease Description*.** The year 1956 was a seminal year for the field of human autoimmunity given the discoveries of Hashimoto thyroiditis as an autoimmune disease and of Graves disease as caused by an autoantibody. These discoveries have prompted some straightforward and relatively uncomplicated treatments.[183,184] In Graves disease, autoantibodies directed against the thyroid-stimulating hormone receptor on thyroid cells stimulate excessive production of thyroid hormone, which is normally controlled by feedback regulation. In contrast, in Hashimoto thyroiditis, autoantibodies to thyroid peroxidase and thyroglobulin are present over years and likely able to fix sublytic doses of complement to cells of the thyroid. The result is an inflammatory reaction, which is also

associated with T cell-mediated cytotoxicity. Thyroid damage due to painful Hashimoto thyroiditis may be associated with the development of Graves disease, indicating that there is a tendency for spreading of the autoimmune reaction in humans. Treatment of thyroiditis is relatively straightforward with antithyroid drugs (methimazole) and radioactive iodine.

Autoimmune Features. Autoantigens targeted in thyroiditis are thyroid peroxidase, a cell surface protein (Hashimoto thyroiditis), and the thyroid-stimulating hormone receptor (Graves disease). Autoimmune responses to thyroglobulin are also seen in animal models. The B-cell epitopes to these autoantigens have been mapped relatively well; however, as it is the case for other human autoimmune disorders, T-cell responses, their tracking and specificity, as well as their eliciting antigens in humans have remained largely elusive.[183] An interesting genetic link has been established to the CTLA-4 region, which is supported by the finding that NOD mice that also exhibit a link to this gene may present with thyroiditis. The usual suspects (ie, APC dysfunction, autoaggressive lymphocytes, and links to viral infections) have been examined, but no conclusive etiologic or mechanistic evidence has been obtained to date. It is noteworthy that a role for T_{reg} cells has been established in Mason's animal model for thyroiditis.[185]

Genetic Features and Environmental Factors. Interestingly, numerous viruses have been implicated in the pathogenesis of different thyroid diseases, but firm evidence for a direct involvement of viruses or virus-induced immune responses leading to clinically manifest disease is scarce. Subacute thyroiditis is a clinical and pathologic form of thyroid involvement that appears after infection with viruses such as measles, influenza, adenovirus, Epstein-Barr virus, and Coxsackie virus.[186] Again, however, a causative role in vivo has not been shown for any single infectious agent.[187] Presence of viral material in the thyroid and elevated virus-specific antibody titers were found to correlate with subacute thyroiditis.

In other instances, direct virally induced thyroiditis has been documented epidemiologically with thyroid or parathyroid disease.

Retrovirus, in particular human immunodeficiency virus (HIV) infections have generated much interest. Although HIV infection and acquired immunodeficiency syndrome (AIDS) may affect multiple endocrine organ systems,[188,189,190,191] thyroid dysfunction usually reflects weight loss, anorexia, and cachexia of advanced HIV disease, rather than a direct viral effect on the thyroid.[192,193] Thus, direct involvement of the thyroid by HIV or by opportunistic infections is uncommon and may include subclinical hypothyroidism and “euthyroid sick syndrome.” The clinical relevance is probably limited, as overt hyperthyroidism or hypothyroidism does not occur with greater frequency in patients with HIV and AIDS as compared to patients with other nonthyroidal illnesses (HIV and the thyroid gland have been reviewed in Heufelder and Hofbauer[192]). Involvement of the parathyroid in patients with AIDS could be shown by reduced basal and maximal parathyroid hormone levels, but the mechanisms underlying these findings have not yet been elucidated.[194] To account for a possible role of HIV in thyroid autoimmunity, a 66% homology between the HIV-1 nef protein and the human thyroid-stimulating hormone receptor has been noted. However, reactivity of sera of patients with Graves disease against a nef peptide showed no significant differences as compared to normal controls.[195] This does not rule out the presence conformationally shared T- or B-cell

epitopes with HIV proteins. In analyzing mechanisms of molecular mimicry, studies of potential antigenic surfaces have emerged as an important supplement to analysis of sequence similarity.[196]

In addition, antibodies from a patient with Graves disease showed reactivity to the gag proteins of another retrovirus, human foamy virus.[196] The association of human foamy virus with Graves disease or subacute thyroiditis is controversial. Whereas one study demonstrated human foamy virus-related sequences in the deoxyribonucleic acid (DNA) of peripheral blood in two-thirds of patients with Graves disease but none in normal controls,[197] another study could not confirm these findings.[198]

In other studies, an association between human T-lymphotropic virus I and II and the occurrence of autoimmune thyroiditis or Graves disease was reported.[198,199,200,201] Further, as in the case of HIV, hepatitis C virus was shown to lead to a wide variety of autoimmune disorders including involvement of the thyroid gland.[202,203,204,205,206] Moreover, treatment of chronic hepatitis B and C with IFNα leads to induction or enhancement of autoimmune disease.[207,208,209] For congenital rubella infection, which has been associated with diabetes mellitus, Addison disease, growth hormone deficiencies, as well as thyroid disorders,[210] it is not clear whether thyroid involvement is the result of a direct viral effect or a more generalized dysfunction of the immune system.[187]

***Animal Models*.** Animal models in mice and chicken have been used to study virus-induced thyroiditis.[187] Mice persistently infected with LCMV showed reductions of thyroglobulin messenger RNA and circulating thyroid hormones in the absence of thyroid cell destruction.[211] Thyroiditis characterized by focal destruction of the follicular structures, inflammatory infiltration, and generation of antibodies against thyroglobulin and thyroid peroxidase was observed in a reovirus type 1 mouse model of thyroiditis.[212] The reovirus gene responsible for autoantibody induction was identified and the encoded polypeptide shown to bind to tissue-specific surface receptors.[213] Spontaneous lymphocytic infiltration of the thyroid is observed in the obese strain of chickens. Such chickens express an endogenous retrovirus, avian leukosis virus (ev22), not found in healthy normal inbred strains.[214] Although ev22 appears to be a genetic marker rather than cause for thyroiditis, infection of normal chicken embryos with avian leukosis virus can cause hypothyroidism.[215] Moreover, aberrant MHC class II expression is demonstrated in obese strain chickens and elevated levels of 2.5-oligoadenylate synthetase as well as 2,5 oligoadenylate-polymer levels in the cytosol of thyroid epithelial cells occur, suggesting viral involvement.[216] Again, not all cross-reactivities with self-ligands need to increase autoimmunity,[217] and regulatory cells also play a major role in modulating autoimmune thyroiditis.[185]

Endocrine Pancreas: Type 1 Diabetes

***Introduction and Disease Description*.** While the distinct symptoms of diabetes mellitus have been known since antiquity, the underlying pathophysiologic processes were only identified in the late 19th and early 20th centuries. The proof of the involvement of the pancreas in diabetes etiology was conducted by von Mering and Minkowski,[218] who

demonstrated in 1890 that extirpation of the canine pancreas results in the classic symptomatology of hyperglycemia, abnormal hunger, increased thirst, polyuria, and glycosuria. Subsequently, inflammatory changes in the endocrine pancreas (ie, the islets of Langerhans) were correlated with diabetes by Schmidt[219] in 1902; two decades later, Banting and Best[220] identified insulin as a pancreatic hormone, thereby providing the basis for insulin substitution therapy, which remains to this day the cornerstone for T1D management. In a classic 1965 paper, Gepts[221] noted the histopathologic similarity between thyroiditis and insulitis and suggested an immune basis for the disease. By 1974, the concept of T1D as an autoimmune syndrome was firmly established by the discovery of islet cell antibodies and an association between T1D and certain HLA genes.[222,223,224]

Autoimmune Features. Today, a quarter century later, the possible autoimmune origin of T1D is understood in much greater detail. However, the lymphocytic infiltration of the islets of Langerhans (Fig. 44.6) and the presence of antibodies specific for β-cell antigens associated with the progressive destruction of insulin-producing β cells[225,226] still constitute the cardinal evidence for an autoimmune etiology. While there is a reasonably strong genetic linkage to certain HLA molecules, the disease has to be considered polygenic in nature,[130] and a significant discordance of disease among monozygotic twins suggests that environmental factors contribute to trigger and/or exacerbate the disease. Furthermore, it remains unclear which islet antigens are the

primary targets. The earliest islet cell-specifc antibodies in human individuals at risk are directed to insulin,[227,228] and evidence from relevant animal models and human studies points toward insulin as a primary antigenic target,[229] islet-specific glucose-6-phosphatase catalytic subunit related protein,[230,231] and possibly glutamic acid decarboxylase (GAD),[232] but definitive proof for a pathogenic role has only been ascertained in the NOD mouse model and not yet in humans.[233] The cellular infiltrates found in the islets contain both CD4+ and CD8+ T lymphocytes and their irreducible role in β-cell destruction has been documented in several animal models.[234,235,236] CD8+ T cells can exert direct cytotoxic effects toward MHC class I-expressing β cells, while CD4+ T cells secreting inflammatory cytokines and can provide help to CD8+ T cells as well as B cells. Ultimately, it is important to consider that β cells constitute about 60% of the islets, which in turn contribute only ~2% to the pancreas mass and demonstrate, unlike many other tissues targeted in autoimmune disorders, an exquisite sensitivity to cytokines such as IL-1, TNF, and IFNs that will result in their apoptotic cell death after prolonged exposure.[94]

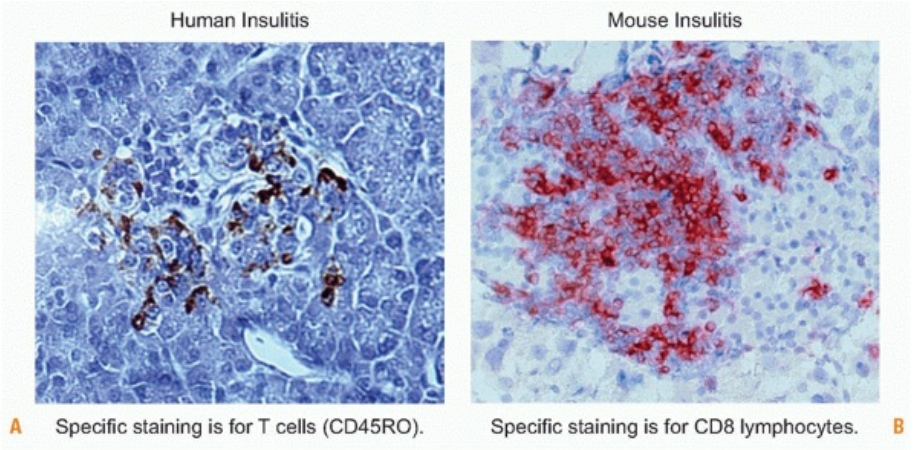

FIG. 44.6. Human and Mouse Insulitic Lesions. Comparison of human insulitis *(Left)*, courtesy of Francesco Dotta (University La Sapienzia, Rome, Italy), and mouse insulitis *(Right)*, from a rat insulin promoter-lymphocytic choriomeningitis virus mouse 14 days postinfection with lymphocytic choriomeningitis virus (von Herrath laboratory, La Jolla Institute for Allergy and Immunology, La Jolla, CA).

The detection of islet antigen-specific antibodies remains an essential tool in identifying prediabetic subjects and monitoring the progression of subclinical and clinical disease. Procedures for autoantibody determination have been substantially refined and standardized worldwide. Emerging data from clinical studies support the notion that with progression of the prediabetic phase, generation of islet antibodies also is increased.[237,238,239] Usually, antibodies to insulin become discernible first, then to GAD, thereafter to insulinoma antigen 2. Individuals with islet antibodies to three or more distinct antigens have a greater than 90% risk of developing T1D.[136] Thus, islet antibodies are an excellent marker for disease risk. However, they appear not to play a role pathogenetically, as transfer of antibodies from mothers to children does not increase the risk for T1D, and B cells are not needed for human diabetes.[240,241,242] In this crucial respect, the NOD mouse appears to provide a paradigm that might not be applicable to human diabetes, as maternal antibodies are an essential factor for diabetes development in NOD offspring.[243]

Measurements of human T-cell responses to islet antigens are not yet standardized and can vary considerably between different laboratories. One reason for this may be the source of T cells that are generally subjected to specificity analyses: blood-borne CD4+ or CD8+ T cells may not reflect the specificity distribution and frequencies of isletspecific T cells found in the target organ (ie, pancreas and its draining lymph nodes). Even the study of spleen-derived islet-specific T cells readily obtained from NOD mice and analyzed in standardized proliferation assays has shown variations between different NOD colonies.[244] Therefore, measurement of multiple effector functions (ie, cytokine production, etc.) in highly standardized assays will likely be required to assess T-cell autoreactivity on a routine basis.[245] A recent study shows that while techniques such as enzyme-linked immunosorbent spot can discriminate between patients and controls, difficulties in detection of low-frequency antigen-specific T cells probably leads to the limited reproducibility of such

measurements.[246] Another complicating fact is that T-cell responses between individuals are expected to vary and depend on the HLA haplotype and individual trigger(s) that precipitate T1D. An emerging technology that may improve specificity and sensitivity is through the use of combinatorial HLA multimers loaded with multiple disease-associated epitopes.[247] A remarkable paper[248] has shown that tracking of immune responses to naturally processed peptide epitopes can discern between healthy individuals and those afflicted with T1D: Whereas the number of overall T cells reacting with the naturally

processed peptide epitopes was similar, individuals with T1D produced more IFNγ relative to IL-10, whereas the ratio was the opposite in healthy individuals.

***Genetic Features and Environmental Factors*.** Recent data show that concordance rates among monozygotic twins are higher than previously thought.[249] Still, the remaining discordance and particularly the major temporal differences in clinical onset indicate that environmental factors have to act in concert with diabetes susceptibility genes to orchestrate the autoimmune destruction of β cells. The initial hope that only a few genes would contribute to disease pathogenesis and that genetic links would help to directly understand the mechanistic aspects of T1D pathogenesis has been progressively eroded. Instead, a complex network of susceptibility and resistance genes in both humans and animals (eg, the NOD mouse) has slowly taken shape. The recent publication of three GWAS has extended the list of gene associations in T1D. So far,[16] robust T1D-associated loci were discovered, some of which encompass important immunity genes (eg, IL-2, IL-2Rα [CD25], CTLA-4) or β cell-specific products (insulin), while other candidate genes do not have an apparent link to immune functions and/or β cells. The implications of this enhanced genetic characterization have so far not led to the identification of monogenic pathways that directly lead to disease. Rather, consensus is growing that disease susceptibility is the consequence of a global problem of immune regulation, with many genes involved in a variety of combinations in individual patients.[250]

Many of these genes exhibit direct parallels to NOD diabetes susceptibility genes.[251]

The association between particular HLA/MHC class II haplotypes and the occurrence of human diabetes has been of particular interest. The DRB1/04-DQA1/0301/B1 and DRB1/03-DQA1/0501/0201 strongly predispose to T1D, and more than 80% of patients carry either one or both alleles.[252] In contrast, other MHC class II haplotypes can protect from disease, as evidenced by the sixfold reduced risk to T1D in DRB1/15-DQA1/B1/0602-bearing individuals. Considerable evidence indicates that other genes in the MHC region likely contribute significantly to T1D risk.[128]

An intriguing mechanistic hypothesis was put forth by McDevitt's observation that predisposing HLA class II alleles appear to express small neutral amino acids at position 57 of the DQ allele of Caucasoid populations, whereas an aspartic acid is found in resistant alleles at the same position. Because position 57 is part of the peptide-anchoring pocket, amino acid substitutions in this area will affect peptide binding. Indeed, the susceptibility alleles prefer different peptides, but the contribution to T1D development is not yet clear and a mechanistic link has to be established. Both central and peripheral tolerance mechanisms have been implicated but no direct proof has been obtained. It is important to realize that the

human susceptibility MHC class II alleles share amino acids at position 57 with the I-A^{g7} alleles expressed in the NOD mouse and are required for NOD T1D predisposition. However, as previously mentioned, polymorphisms in the MHC class II coding region alone cannot explain diabetes pathogenesis. The amount of complexity involved in the immunogenetics of T1D has been well described by Serreze[253]:

> Many genes contributing to T1D may contribute to dysregulation of different biochemical steps in a common developmental or metabolic pathway. For example, sequential expression of hundreds, if not thousands, of genes would be expected in the developmental and functional maturation of a macrophage or dendritic cell from stem cell precursors. This process does not occur in a vacuum, but is contingent upon cues provided by the physical environment. In the case for APC development, the microfloral and dietary environments are crucial.

Thus, diabetes susceptibility and resistance genes contribute to disease in a polygenetic/multifactorial fashion that appears to gain in complexity as it is being unraveled. The link to environmental factors will be defined to shape gene expression and disease development. Major contributors in this respect appear to be the gut and viral infections.

With more than 400 m^2 of mucosal epithelium, the gut constitutes the largest interactive surface area of the human body connecting us with the environment and its pathogens.[150] Therefore, exposure to antigens or pathogens through the gut, mediated by the largest outpost of the immune system, the gut-associated lymphoid tissue, will strongly affect specific and general immune functions. It is intriguing that immune tolerance to the numerous foreign protein antigens found in food, as well as bacterial antigens derived from the commensal flora, is generally well maintained.[254] This may be attributable to the high levels of immunoglobulin (Ig)A and TGF-β in the gut and to the phenomenon of "oral tolerance."[255] Oral tolerance has been observed in animal models and humans and is characterized by tolerance induction to protein antigens present in the gut. It occurs via two principal mechanisms: Low amounts of antigens will induce a nonaggressive immunoregulatory response while high amounts of antigen can lead to lymphocyte anergy or deletion,[256,257,258] which is likely achieved via APC modulation. In addition, the profound immune dysregulation found in the absence of a bacterial flora in both animals and humans points to an important physiologic role that foreign antigens play in immune homeostasis in the gut.[259] Furthermore, NOD mice only exhibit high levels of autoimmunity when kept in a clean, specific pathogen-free environment; they do not develop T1D when housed under "dirty" conditions.[260] A seminal paper by Wen et al.[261] highlighted the pivotal role of the mucosal immune compartment by showing that host recognition of the digestive flora is essential in preventing T1D through engagement of a myeloid differentiation primary response gene 88-independent signaling pathway. Thus, changes in the intestinal microbiome, integrity of the mucosal barrier, infections of the gut, or certain dietary components may play a role in T1D pathogenesis.

Several reports and studies have attempted to establish a link between the introduction of

cow's milk and development of T1D in young infants. This link was not observed in the German, Australian, and American baby diabetes studies but was in a Finnish epidemiologic study.[262,263] The Finnish study differed from most of the others by an

extended observation time involving infant as well as childhood consumption of cow's milk. Therefore, a dietary link between milk feeding and T1D can be considered unlikely but not excluded after long-term exposure to cow albumin or other milk proteins. Similarly, wheat-derived gluten and milk-derived insulin have been implicated as a cause for childhood diabetes. The evidence, however, is not convincing at this point, and no firm links have been established.

Some intriguing observations have been published more recently supporting the concept of a viral etiology for T1D. The mechanistic links between viral infections and autoimmunity can be manifold and have been discussed in detail in the introductory section of this chapter. A significant association between rotavirus infection in young infants and the first occurrence of islet autoantibodies was established by Harrison's group in Australia[264] but not in Finnish populations.[265] Rotavirus is a double-stranded RNA virus, infects the intestinal mucosa, and is a common cause for seasonal childhood diarrhea. It can polyclonally activate T and B lymphocytes, and might possibly harbor antigens that could immunologically mimic islet cell-derived self-proteins. However, it is not clear whether it infects the pancreas or islets directly. The most convincing case can be made for enteroviruses, and there is now robust evidence for a significant association with T1D.[266] Coxsackie B4 virus has been isolated from islets of a child with acute-onset T1D,[267,268,269] and Coxsackie B3 and 4 strains commonly infect the gut, pancreas, and heart.[270] They lead to profound pancreatitis if they replicate at high enough titers and might harbor a mimicry antigen (P2C protein)[226] cross-reactive on the T-cell level with a human GAD epitope. However, this evidence could not be replicated by other laboratories and is still controversial. It has become apparent, however, that Coxsackie B3 viral strains can effectively trigger[271] or prevent[142] T1D in the NOD mouse, depending on the timing of infection. Thus, diabetogenicity of a viral infection may critically depend on the preexistence of insulitis and may either act as an initiating factor or by aggravating ongoing inflammatory processes. Clinical studies have recently provided indirect support for both of these scenarios.[272,273] The finding that infections under certain conditions confer protection might support the “hygiene hypothesis,” which suggests that infections protect from rather than enhance autoimmunity. It is still uncertain whether enteroviruses routinely infect or persist in pancreatic islets, although recent reports indicate that viral particles are found more frequently in islets of patients with T1D around the time of disease onset.[274] Similar to Coxsackie, other enteroviruses such as polio or echoviruses have been detected in the pancreas and might therefore at least have enhancing effects on ongoing islet destruction in prediabetic individuals at risk.[267] The establishment of a firm association between viral infections and T1D is difficult because the underlying mechanistic links established in several animal models allow for the virus to be cleared before autoimmunity develops (ie, in the rat insulin promoter [RIP]-LCMV model); viruses need not necessarily directly induce islet-reactive T-cell responses but can act as bystander activators and, in many cases, viral infections have been found capable of preventing autoimmunity.

Exciting new data suggest that the genetic constitution may (co-)determine whether viral infections will provoke islet autoimmunity in certain individuals. It was found that certain rare polymorphisms in the IFIH1 gene are associated with protection against T1D,[275] while others confer disease risk.[276] This gene encodes a helicase enzyme, IFIH1 (also known as MDA5), which triggers the secretion of IFNs in response to viral infection. Most, if not all, viral infections trigger the production of IFN by the host immune system. Being an IFN-response gene, IFIH1 allows the infected cell to sense the RNA genome of enteroviruses and increase IFN production. IFNs then primarily limit viral replication to prevent damage to the infected cell. They also, however, increase the visibility of the infected cell to the immune system by enhancing the expression of MHC molecules. A scenario could be envisioned where mutations leading to decreased IFIH1 activity are associated with milder responses against diabetogenic viruses and thus disease protection. Conversely, mutations leading to IFIH1 hyperactivity could induce inappropriate, exaggerated IFN responses and localized immunity against the infected β cells. Altogether, such a mechanism would explain why viruses that have presumed diabetogenic effects do not necessarily trigger diabetes in all infected individuals.[277]

***Animal Models*.** Because the pancreas and its draining lymphoid organs are notoriously difficult to access, many important insights about diabetes immunology have been gained from suitable animal models that continue to refine our understanding of the pathogenesis and the development of potential prophylactic and therapeutic strategies. There are a multiplicity of animal models for T1D. The most commonly employed models take advantage of natural mutations that give rise to spontaneous diabetes onset or antigen-specific induction of disease using transgenic technology. Other models make use of β-cell damage initiated by treatment with specific chemicals (eg, streptozodozin) or virus infection. Encephalomyocarditis virus is diabetogeneic in mice; the incidence of disease is dependent on both virus and mouse strains used.[144,268,269,278,279,280,281,282,283] Similarly, Coxsackie virus, associated with diabetes development in humans, causes extensive pancreatic tissue damage and release of sequestered autoantigens that lead to rapid diabetes development in some mouse strains.[284]

Models of Spontaneous Diabetes Onset. There are several animal models of spontaneous T1D.[285] The two most extensively used are the biobreeding rat, introduced in 1974 at the Bio Breeding Laboratories in Canada, and the NOD mouse strain established 1974 in Osaka, Japan.[285] Because the biobreeding rat is associated with leukopenia and other abnormalities,[285] the NOD mouse has been the model of choice due to its genetic linkages that are reminiscent of human T1D.[285] In both models, adoptive transfer of T cells can induce disease.[286] Interestingly, viral infections, first shown with LCMV, can prevent insulindependent diabetes mellitus in both biobreeding rats and NOD mice.[287,288] This occurs in the absence of a general immune suppression. While the mechanism involved is unclear, the generation of suppresser T cells has been suggested.[288,289]

Models of Antigen-Specific Diabetes Induction. Expression of influenza virus hemagglutinin (HA) under control of the RIP resulted in a low incidence (10% to 20%) of spontaneous T1D, but and no significant enhancement of disease occurred after infection of such RIP-HA mice

with influenza virus. However, in RIP-HA mice expressing a transgenic TCR specific for a determinant of the influenza virus HA, the incidence of spontaneous T1D increased to 100%.[290] These studies clearly demonstrate the importance of autoreactive T cells present at sufficient numbers for induction of autoimmune disease. Thus, the inability of influenza strain PR8 to cause T1D in RIP-HA mice likely reflects the low precursor frequency of self-reactive CD8+ T cells. Interestingly, studies from the Sherman laboratory have demonstrated that spontaneous disease in this model is associated with cross-presentation of HA. It has been postulated that crosspresentation constitutes an important mechanism for unmasking of islet-specific antigens to autoaggressive CD8+ T cells. When the model antigen ovalbumin was expressed as a self-antigen in β cells using the RIP, similar observations were made underscoring the likely importance of crosspresentation in autoimmune diabetes. These studies also demonstrated that the clinical outcome correlated with the number of autoreactive CD4+ and CD8+ cells generated and determined a "cut off level" below, which the autoimmune reaction would not take hold of the pancreas.[291,292,293]

Similar to RIP-HA and RIP-ovalbumin mice, the RIP was also used to express the nucleoprotein or glycoprotein of LCMV in the insulin producing β cells.[234,294,295] Diabetes develops 2 to 4 weeks after infection with LCMV due to a strong CD8+ or combined CD8+/CD4+ T-cell response directed to the viral/self-glycoprotein or nucleoprotein in the β cells. Insulitis is initiated only at a time when the systemic antiviral response reaches its peak and continues well after the LCMV infection has been eliminated.[130,296] Therefore, the localized, islet-specific autoimmune process, although initiated by a response to the viral/self-transgene, can be regarded as an autoimmune process that follows kinetics distinctly different from systemic antiviral immunity. Indeed, antigenic spreading to insulin and GAD is observed during the prediabetic phase.[237] Destruction of β-cells requires activation of APCs[297] in the islets and is mediated by both perforin and inflammatory cytokines, predominantly IFNγ.[298] Thus, the RIP-LCMV model reproduces many features found in human diabetes as well as other mouse models. A distinct advantage of RIP-LCMV mice is that the time point for induction of the autoaggressive LCMV nucleoprotein specific response can be chosen experimentally, and that virus-specific, destructive CD4+ and CD8+ T cells can be enumerated, functionally evaluated, and localized using limiting dilution analyses, MHC tetramers, or intracellular cytokine stains.[299,300] These aspects constituted an advantage in our studies demonstrating that feeding of insulin during the prediabetic period induces insulin β-chain specific CD4+ regulatory lymphocytes that act as bystander suppressors and can locally downregulate the autoaggressive dibetogenic response in the pancreatic draining lymph node and the islets.[300] Other studies in the RIP-LCMV model have underlined the role of thymic selection in allowing sufficient numbers of low-avidity autoaggressive T cells to emerge in the periphery,[301] the role of non-MHC-linked genes in influencing the kinetics and severity of T1D even in the presence of high numbers of autoaggressive T cells,[300] and the importance of APCs in breaking tolerance and sustaining autoaggressive T-cell responses.[302,303,304]

Under some conditions, CD4+ or CD8+ T cells can induce T1D by adoptive immunization.[286,305] In general, T1D develops more slowly or not at all in the absence of

CD8+ CTL, MHC class I, or perforin.[94,306] Similar considerations are true for MHC class II and costimulatory molecules, unless their elimination affects the generation of regulatory lymphocytes.[307,308] Cytokines, however, frequently play dual roles in T1D pathogenesis in animal models. IFNγ, in general known as a proinflammatory mediator that upregulates MHC molecules, not only can "unmask" β cells for immune recognition by induction of MHC class I expression but also exert direct antiviral effects and might be beneficial by increasing apoptosis of aggressive T lymphocytes later in the disease.[94] A similar dual role is true for TNF-α. that appears to enhance early disease (possibly by directly causing β-cell death in conjunction with other cytokines) but ameliorates advanced autoimmunity just prior to onset of clinical disease.[170,309] For these reasons, blockade of such inflammatory mediators might be problematic in T1D. Dual roles were also described for IFNα,[310,311,312] IL-2,[313] and IL-10.[314,315] In some of these studies, the level of the cytokine might play as important a role as the precise timing of expression. The only cytokine with largely beneficial effects has been IL-4, which ameliorates the disease and therefore might be a good candidate for treating or preventing T1D.[316] Figure 44.7 illustrates the pathogenetic hypotheses generated through research in multiple animal models.

***Treatment and Prevention*.** Despite intensive research, no effective prophylaxis, therapy, or cure of T1D is available to date. However, even under optimal disease management with insulin substitution therapy, T1D significantly shortens life expectancy due to eventual vascular complications in multiple organs. Currently, all strategies that look promising have either been evaluated in animal models or are in early clinical trials in humans (see following paragraphs). Part of the problem in devising such prophylactic or interventive immune-based approaches is that the only end points in human trials are disease prevention and insulin requirements as well as remaining insulin production (C-peptide levels). No precise interim staging is yet possible, which makes efficient clinical evaluation very difficult compared to MS or RA, where access to the target organ either visually by magnetic resonance imaging or directly by sampling fluids is much easier to achieve. Animal models have provided interesting ideas and evidence for a variety of antigen-specific and systemic interventions that bear promise for human diabetes.

Antigen-specific Immunoregulation. Immunization with DNA plasmids that express islet self-antigens, with or without cytokines, which act as response modifiers, can induce autoreactive regulatory CD4+ T cells. These cells are able to

suppress autoaggressive CD4 and CD8 cells locally in the pancreatic draining lymph node where they act as bystander suppressors. Phenotypically, they behave very similarly to the Th2-like regulators[181,317,318,319,320] induced after oral antigen administration. In treated mice (using several distinct diabetes models), insulitis is permanently reduced, and progression to clinical diabetes can be prevented in 50% to 80% of the animals.[175,181,317,318] To bring this approach to the clinic as a preventive therapy, a suitable marker will be needed that can predict early outcome, for example, levels and isotypes of autoantibodies. Like other antigen-specific interventions, this strategy will not likely be effective in late stages of the prediabetic phase and should therefore be thought of and tested as an early preventive therapy. The important advantage of this and other antigen-specific approaches is that the risk for systemic side effects is low, as the effector

cells will act antigen specifically only in the area, where autoimmune destruction is ongoing and their cognate antigen (eg, GAD, insulin, or heat shock protein) is presented. Discouraging results from recent clinical trials indicate that, while highly effective in animal models, translation of antigen-specific approaches to the clinic remains a challenge.[321] It may thus be possible that successful antigen-specific therapy will require a combination with systemic immune modulators. For example, we have demonstrated that a combination treatment with intranasal proinsulin peptide and anti-CD3-specific antibody can reverse recent-onset diabetes in two murine diabetes models with much higher efficacy as compared to monotherapy with anti-CD3 or antigen alone.[177] Despite the strong rationale to tackle the disease from different angles, drug companies are generally reluctant to include successful drugs in a combinatorial regimen.[322] A specific subtype of antigen-specific approaches is the design of altered peptide ligands: Modified insulin peptides that favor a Th2-like deviation of responder cells have been developed by Neurocrine (San Diego, CA) and showed great promise in the NOD mouse model. These succesfully passed preclinical safety studies,[323,324,325] but efficacy outcomes in the first clinical trial were disappointing.[326]

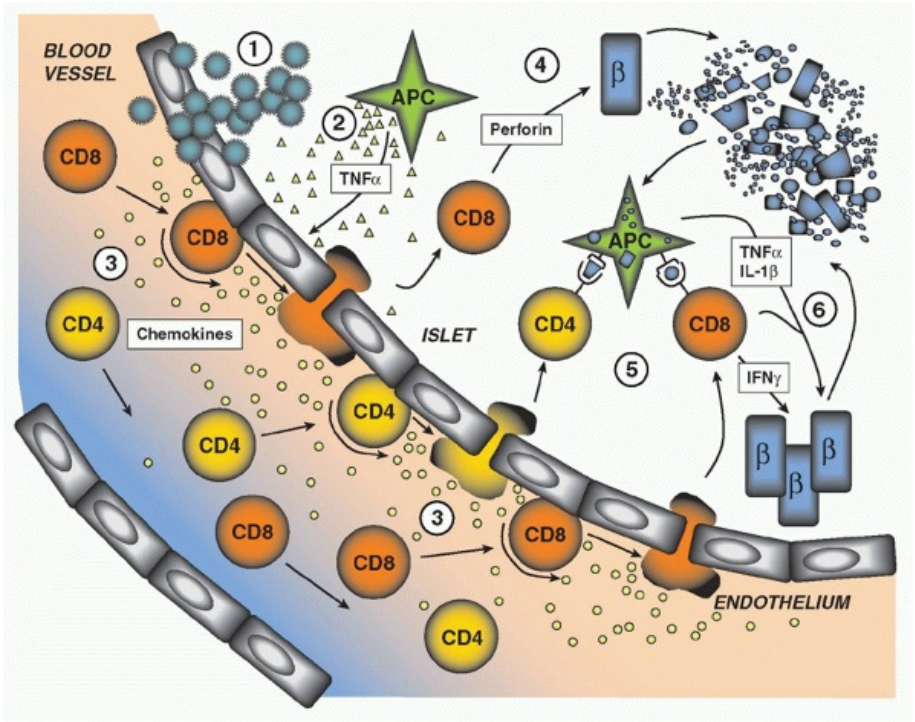

FIG. 44.7. Immunopathogenesis of Type 1 Diabetes. Viral infections and other inflammatory stimuli **(1)** can activate antigen-presenting cells (APCs) **(2)**, which secrete chemotactic mediators that entice lymphocytes in blood vessels to “rolling” and entry into the pancreatic islet tissue **(3).** Entering lymphocytes might directly destroy β cells **(4)** or activate APCs locally **(5)** and also propagate inflammation by secreting proinflammatory cytoines **(6)**. Recent intravital imaging data suggest that effectors may remain in a given islet for hours while inducing β-cell death.[559] Courtesy of Urs Christen, University of Frankfurt, Frankfurt, Germany.

Finally, induction of oral tolerance can be seen as a form of mucosally targeted antigen-

specific therapy. As for MS and RA, oral antigen trials have failed so far for T1D, except for in a distinct subgroup of patients,[327] spurring repeat investigations that are currently ongoing. The reasons for these failures after initially promising animal data have become increasingly clear from follow-up animal experimentation.

Likely, the dose of antigen was significantly too low (presumably by a factor of 10 to 100). This problem may be overcome by coupling the orally administered proteins to gut response modifiers such as the cholera toxin B subunit. Second, the choice of antigen is important, and even minor amino acid changes can modify the dose-response curves. Without a reliable preclinical marker, it will be very difficult to tune this treatment to the human situation.[259]

Therapeutic Failures and Future Perspectives

1. Anti-CD3 treatment: One of the more promising drug candidates from the past decade in terms of immune modulation in T1D was anti-CD3. The effector mechanism in mice is systemic and is likely relying on the induction of antigen nonspecific regulators[307] that are $CD62L^{hi}$ and $CD25^{hi}$ as well as anergy or deletion of activated aggressive lymphocytes. From data in animal models and humans, systemic immune suppression is not too profound, indicating reasonable safety for this strategy. Two independent randomized controlled phase III trials, however, showed minimal effectiveness of this approach for treatment of individuals recently diagnosed with T1D.[328] These notable and discouraging failures have raised questions concerning the trials' accuracy of dosing, choice of appropriate end points, and timing of administration. Finally, the inability to translate a therapy that is so potent in mice to humans may indicate that we have in the past relied too heavily on animal models to prioritize drug candidates.
2. CTLA-4Ig, anti-CD20, and anticytokine therapy: Encouraging data in mice, likely in combination with the availability of commercial compounds, have triggered a series of trials aimed at tackling islet autoimmunity from diverse angles. CTLA-4Ig (abatacept) modulates costimulation and prevents full T-cell activation. A recent trial shows that the drug initially induces a beneficial effect but also that continued administration did not offer lasting protection. The authors therefore speculated that T-cell activation in T1D may lessen with time.[329] Another study found that anti-CD20 therapy (rituximab; depletes B cells) partially preserved β-cell function over a period of 1 year in patients with T1D.[330] While the outcome was relatively modest, the finding that B lymphocytes contribute to the pathogenesis of T1D is of scientific value. Finally, clinical studies are underway to block cytokines such as TNF-α or IL-1β in order to eliminate their known deleterious effects on β-cell viability. It can be concluded from these modest successes that immunomodulatory regimens may hold potential (ie, that tackling the immune component from T1D is indeed a viable option). It is clear, however, that more potent or complementary strategies need to be evaluated in order to achieve significant and lasting protection.
3. Islet transplants: A promising therapeutic advance was made by developing a specific protocol for gentle isolation and purification of human islets (“Edmonton protocol”) that appear less prone to rejection after intraportal implantation into diabetic subjects.[331] However, continued immune suppressive treatment is still necessary in recipients of such transplants to prevent renewed autoimmune destruction of islet transplants emphasizing

the need for effective immune-based strategies of T1D prevention. A potential improvement was developed by the company Viacyte (San Diego, CA, USA) in the form of proprietary capsules that are designed to shield islet transplants from the deleterious effects of the immune system. The approach also encompasses a detailed procedure for the generation of viable β cells from human embryonic stem cells.[332,333] It is hoped that these advanced technologies will one day allow for the safe and lasting transfer of functional islets into patients with T1D.

***Perspective and Conclusion*.** No single animal model accurately reflects all aspects of human T1D. Consequently, translating the successful T1D prevention and reversion strategies developed in a variety of animal models into clinical applications faces significant obstacles, as is evident from failures in recent clinical trials. For example, to date, more than 140 therapeutic options have been developed to prevent T1D in the NOD mouse,[225] but not a single one that was tested in clinical trials is as effective in humans. To improve this situation, there is a dire need for preclinical markers that accurately predict the potential success of an intervention being evaluated by a clinical trial. Better tracking reagents for blood autoreactive T cells such as tetramers, noninvasive high-resolution in vivo imaging systems, and perhaps isotype profiles of islet antigen autoantibodies and their change after a given preclinical intervention are good candidates.[334] Similar considerations apply to the maintenance of longterm tolerance after islet transplantation, where prolonged systemic immunosuppression might not be feasible.[335,336,337,338] In addition, treatment modalities will likely have to be tailored to the specific needs of individual patients. Lastly, one could argue based on clinical studies using cyclosporine or nonmyeloablative stem cell transfer that a robust cure for T1D already exists, be it at a high cost in terms of patient safety and associated side effects. Future progress should therefore be aimed at walking the fine line between profound efficacy and optimal tolerability in order to favorably compare against lifelong insulin replacement therapy.

Central Nervous System and Occular Autoimmune Diseases

Multiple Sclerosis

***Introduction and Disease Description*.** MS is the most predominant human demyelinating disease of the CNS. An autoimmune etiology is suggested by elevated frequencies of myelin basic protein (MBP)-specific T cells documented in several independent studies of individuals diagnosed with MS.[339,340,341,342] Further, demonstrations that adoptive transfer of T cells specific for myelin or other CNS antigens can cause a CNS autoimmune syndrome in experimental animals resembling human MS support the concept of a direct T cell-mediated pathogenesis. In addition, myelin-specific and lipid-specific antibodies have been found in MS cerebrospinal fluid.[343] These antibodies are able to complement-fix

and induce antibody-dependent cellular cytotoxicity and may be involved in the demyelinating process. Despite these clues, the etiology of MS remains unclear, and a complex interplay of genetic and environmental factors (similar to T1D etiology) has to be postulated.

MS is a rather heterogeneous disease. However, we are only beginning to understand how clinical and pathologic differences may point toward distinct etiologies and, potentially, treatment strategies of differential applicability and efficacy. Different subtypes of MS are

somewhat better histologically defined (eg, the distinction between T cell-rich and macrophage-rich lesions as well as the balance between demyelination and remyelination, which can vary dramatically) than those of T1D as many tissues from patients with clinically active disease are available postmortem, whereas pancreatic islets are mostly destroyed in T1D and no immunologic correlates can be established at the end stage.[344,345] MS predominantly affects younger women, and its frequency, dependent on geographic location, may approach up to 3 in 1000.[346] Clinically, the disease can take a mild or very debilitating course, and, intriguingly, neuritis of the optical nerve is frequently the first sign for a beginning MS. Diagnosis is usually obtained by electroencephalogram and direct imaging that allows for identification of individual lesions, their development over time, and the success of therapeutic interventions. Immunebased approaches such as the use of IFNβ or Copaxone® (Teva Pharmaceutical Industries Ltd., Petach Tikva, Israel) combined with systemic immunomodulatory agents has brought some limited success for certain forms of MS. Thus, a cure for MS appears possibly a little closer than for T1D.

Autoimmune Features. Although MBP-lipoprotein and proteolipoprotein (PLP)-specific T cells have been documented in patients with MS, some follow-up studies have reported similar frequencies in normal individuals.[347] More recent studies have found increased numbers of MBP-specific T cells in patients with MS reactive to six different MBP epitopes, supporting the concept of determinant spreading as a potential pathogenetic factor. Furthermore, their activation appears to be increased selectively in patients with MS, and they are less dependent on costimulation.[348] Thus, it appears plausible that resting T cells specific for CNS antigens are present in both healthy and affected individuals, but their activation is selectively increased under conditions of disease and their epitope/antigen recognition repertoire is expanded. In addition to cellular infiltrations, MS is usually marked by edema and inflammatory signs such as MHC upregulation and cytokine and chemokine induction. A breakdown of the blood-brain barrier facilitates antibody access to the CNS. Antibodies specific for myelin structures and lipid components[349] are commonly found in patients with MS, and some studies indicate fluctuations similar to T-cell responses of antibody titers in parallel to exacerbations and remissions of disease. These findings still await confirmation in larger patient cohorts. It is important to note that such antibodies can be directed to MBP, myelin oligodendrocyte-associated protein, and other myelin constituents.[350] The fact that they can fix complement and enhance complement-mediated cytotoxicity implicates them as possible agents of demyelination.

***Genetic Features and Environmental Factors*.** There is a definite genetic link between progressive (HLA-DR3) as well as remitting relapsing MS (DR2) and human MHC class II alleles. However, similar to T1D, there is a significant discordance among monozygotic twins (>55%). A pronounced geographic gradient (higher incidence in northern as compared to southern regions) argues for additional environmental triggers or modulators.[346] Many viruses have been implicated in the pathogenesis of MS, but a causal link has not been established. For example, human herpesvirus 6 was discovered around MS lesions, but follow-up studies did not discover any differences comparing healthy, Alzheimer, or Parkinson tissues with MS lesions.[351] Furthermore, antibodies to corona virus have been detected in serum of patients with MS, which indicates that demyelination might occur similarly to the mouse hepatitis virus model. Mechanistically, the same paradigms as for diabetes might apply

(described in the introductory section), but a persistent viral infection might be more likely the culprit, based on similar observations in some mouse models (see the Theiler murine encephalitis virus [TMEV] model, for example). The difficulty in establishing conclusive proof is the multiplicity of infections during the course of a lifetime and the manifold viral traces that can usually be detected in healthy as well as diseased individuals. Even if the same levels of viral antigen, RNA, or DNA are found comparing healthy patients with patients with MS, this still does not rule out the possibility that a certain virus will only induce CNS disease in conjunction with a distinct MHC haplotype. Indeed, animal models indicate that this is in fact the case. With the advent of improved vaccination and antiviral treatment protocols for multiple infectious agents, we may be able to infer a causal relationship if the incidence of MS should recede after introduction of such an intervention.

***Animal Models*.** Experimental allergic encephalitis (EAE) is one of the oldest and most widely studied animal models for a human autoimmune disease.[111,352,353] EAE, a primarily CD4+ T cell-mediated disease, can be induced in susceptible mouse strains (SJL, PL/J) by immunization with MBP, PLP, myelin oligodendrocyte-associated protein, or respective MHC class II restricted epitopes together with complete Freund adjuvant and pertussis toxin. More recently, a role for CD8+ T cells has also been documented. The clinical picture resembles that of a relapsing/remitting disease with profound neurologic symptoms. CNS histologic findings include T-cell infiltration (mainly CD4+ T cells; Fig. 44.8), APCs and microglia activation, as well as disruption of the blood-brain barrier. Some demyelination occurs, and histologic changes can undergo periods of remission that are accompanied by remyelination. The predominant cytokine profile is Th1 like, and Th2 cytokines have protective function.[354] Epitope spreading occurs, and activated APCs take a central role as “drivers” of the autoimmune process.[355] A shortcoming of this model is the major extent of external manipulation required to break tolerance (adjuvant, pertussis). These might be necessary to affect the blood-brain barrier, skew the systemic cytokine profile to the Th1 phenotype, and support prolonged inflammation.

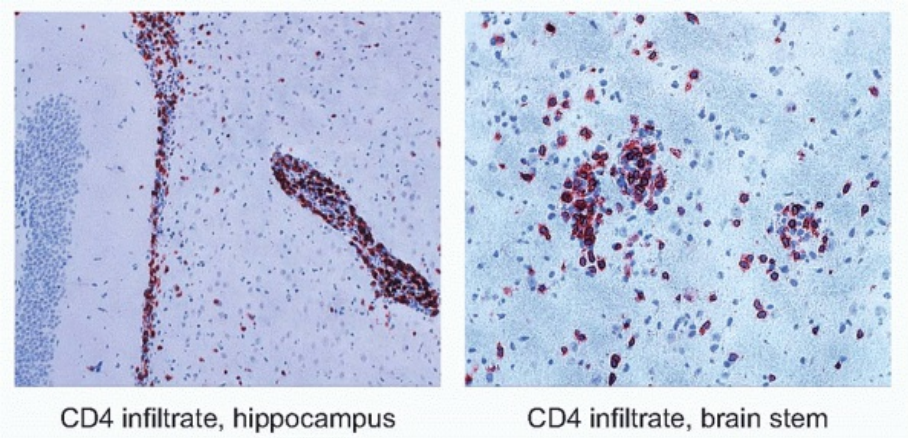

FIG. 44.8. Induction of Experimental Allergic Encephalitis in SJL Mice with PLP Peptide 139-151 and Adjuvant. Courtesy of Andreas Holz, Max Planck Institute for Neurobiology, Munich, Germany.

A lesser degree of additional nonspecific inflammatory conditions is required for some virus-induced animal models for MS. Infection with TMEV, which replicates predominantly in neurons (particularly motor neurons during initial stages of infection), results in a poliomyelitis-like syndrome including flaccid paralysis. Certain strains of mice that survive the primary infection become persistently infected and develop a chronic progressive inflammatory demyelinating disease.[355] Demyelination is the consequence of the CD4+ T-cell response to persisting TMEV and involves determinant spreading as a consequence of infection and local inflammatory processes.[355] Studies from Miller's laboratory have shown that APCs in the CNS are crucial for diversification/epitope-spreading of the initiating anti-TMEV response to other brain self-antigens such as MBP and PLP. Furthermore, when recombinant TMEV expressing PLP epitopes or modified mimic epitopes were employed, infection resulted in enhanced disease. These experiments provided in vivo evidence for a possible role of molecular mimicry in CNS autoimmune disease.[356]

Somewhat similar to TMEV, infection with neurotropic strains of mouse hepatitis virus induces neurologic disease accompanied by demyelination.[357] An interesting difference is that mouse hepatitis virus will not persist, and therefore allows for easier differentiation between the antiviral and the autoimmune response. CD4+ as well as CD8+ lymphocytes accompanied by inflammatory cytokines are needed for destruction. These virus-induced models of demyelination suggest that a transient or persisting presence of virus in the CNS may be needed in conjunction with a nontolerized antiviral response for disease induction and/or propagation.[357] Indeed, another animal model of virally induced CNS disease, the transgenic MBP-LCMV model developed in analogy to the RIP-LCMV model for T1D, only exhibits mild motor dysfunction despite good lymphocytic infiltration.[358] It is possible that activation of APCs is insufficient in this model to locally propagate systemically induced autoaggressive lymphocytes once they have entered the parenchyma of the CNS. These considerations are depicted in Figure 44.9.

Treatment and prevention. Similar to observations in the diabetes models,[319] DNA vaccines that aim to skew the autoreactive response to MBP or PLP from a Th1 to a Th2 phenotype have shown some success in the EAE model. A clinical phase II trial conducted by Bayhill Therapeutics (Palo Alto, CA) indicates that these results, at least to some extent, can be translated to humans.[359] At least for MS, there are preclinical markers that can noninvasively and continuously track the size and appearance of current lesions and in this way indicate success or failure of a given therapy in a

more immediate way as compared to T1D.[360,361] Oral tolerance induction had shown much promise in EAE models, but failed in a human trial.[362] Strong placebo effects were observed after feeding irrelevant protein versus MBP and the outcome was therefore not conclusive, leaving a smaller readout window. Blockade of TNF-α has shown promise in animal models but not in humans.[178] The antidepressive agent Rolipram® is currently under clinical evaluation after it exhibited anti-TNF effects in animal models for MS.

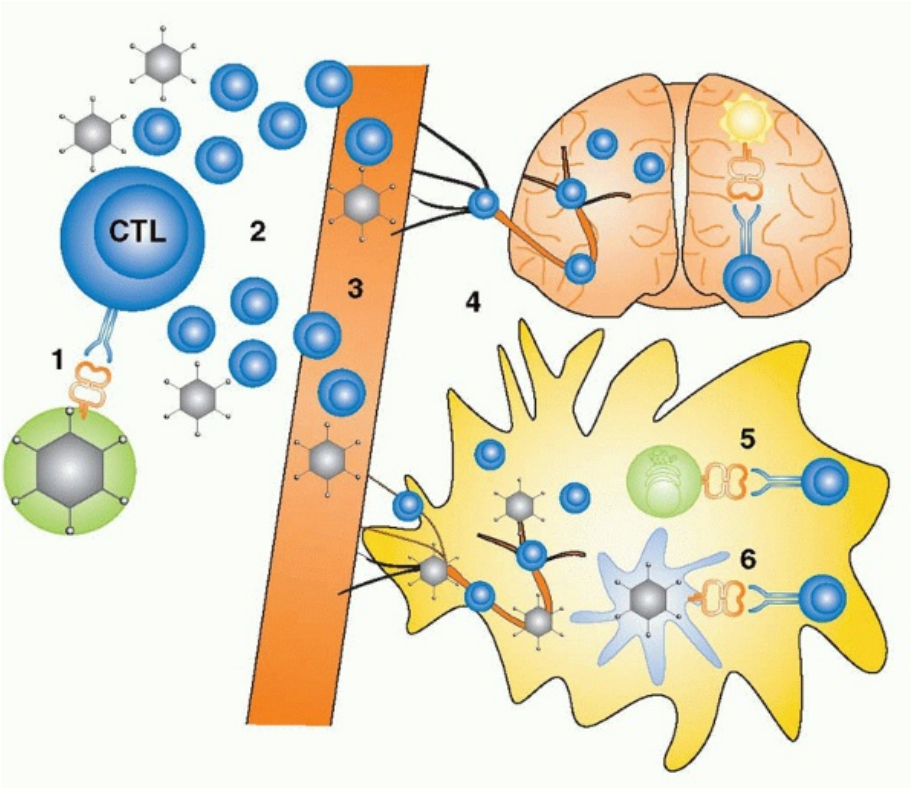

FIG. 44.9. Activated Antigen-Presenting Cells (APCs) Might Be a Crucial Local Driver Once an Autoimmune Process Has Been Initiated. Induction of profound autoimmune disease of the islets but only mild autoimmune infiltration in the central nervous system in rat insulin-promoter versus myelin basic protein-promoter lymphocytic choriomeningitis virus (LCMV) transgenic mice. **1:** In both systems, LCMV infects many peripheral organs, which leads to **(2)** activation and expansion of cytotoxic T lymphocytes (CTLs). **3:** Both virus and CTL are able to traffic via the bloodstream, but **(4)** only CTLs can cross the blood-brain barrier. In the pancreas, both transgenic β cells **(5)** and infected APCs **(6)** drive CTL activation and killing, whereas in the brain only the transgenic oligodendrocytes present antigen. The observation that clinical disease only develops in the pancreas but not the brain indicates that APCs might be crucial local drivers once an autoimmune process has been initiated.

Treatment of MS is, from the immunologic point of view, further advanced than treatment of T1D. It should be noted that life expectancy in MS is more reduced because no therapy comparable to insulin substitution is possible. Of the current regimens, IFNβ has shown strong therapeutic efficacy in phase III clinical trials; at present, more than 135,000 patients are on Avonex® (Biogen Idec, Weston, MA, USA) worldwide.[363] Interestingly, IFNγ, in contrast, has aggravated MS.[364] Furthermore, Copaxone® (Teva Pharmaceutical Industries Ltd., Petach Tikva, Israel) might act as a mixture of altered peptide ligands (as a polymer MBP analog) and in this way may skew immune responses systemically to a less aggressive phenotype, which has shown promise for certain forms of early MS.[365] Lastly, phosphodiesterase inhibitors might induce Th2 skewing, as demonstrated in a small-scale trial.[366] Finally, generalized immunosuppressive therapy with corticosteroids that are given in

conjunction with relapses, and thereafter slowly phased out, still remain an important backbone for MS treatment. Azathioprine, cyclophosphamide, and plasmapheresis are not effective. Cyclosporine A is helpful but has profound side effects. Altered peptide ligands to human MBP epitopes have shown strong allergic side effects and have worsened disease in one study indicating that APLs might activate in vivo aggressive, as well as regulatory, lymphocytes, and that the success can therefore vary from individual to individual.[326,367] Some setbacks have been encountered with monoclonal antibodies. Noteworthy is that anti-CD40L exhibited some efficacy but lead to coagulation disturbances in humans[368] and is currently on halt. In addition, integrin blockers have shown promise and are back in clinical trials, after they were on hold, because combination with IFNβ had led to reemergence of CNS viral infection in three patients.

***Perspective and Conclusion*.** Therapeutic interventions in MS are becoming more effective but will likely have to be individualized and fine-tuned in respect to the subtype of MS in a given patient. Antigen-specific therapy is still in development, but better understanding of the role of T cells in MS will be needed to translate experimental findings into clinical applications. One particularly promising strategy that is currently in clinical trials involves the intravenous administration of chemically fixed, autologous PBLs coupled with five immunodominant myelin peptides.[369] There is also interest in evaluating other therapeutic agents such as CTLA-4Ig with validated benefits in other autoimmune diseases.[370] Combination of systemically acting antibodies shows good promise and will have to be further developed and fine-tuned.

Ocular Autoimmune Diseases

Various inflammatory diseases of the eye accompany other systemic or organ-specific autoimmune disorders and are displayed in Figure 44.10. Some of these immune disorders will be discussed only briefly as they are described in more detail in other sections of this chapter or elsewhere in this book.

***Morbus Bechterew/Spondylarthoropathies*.** Iridocyclitis is frequently associated with Bechterew disease (ankylosing spondylitis) that is characterized by a chronic spondylarthrosis of the ileosacral joints resulting in profound kyphosis and is associated in 30% to 50% of cases with the HLA-B27 allele.[371,372,373] Interestingly, mucosal inflammation, ulcers, and vasculitis are frequently associated with this disease group.

The immunologic pathogenesis is not clearly known, but cross-reactive antibodies to bacterial proteins are frequently found in sera of patients with spondarthopathies such as Bechterew disease, Reiter syndrome, psoriasis, Crohn disease, or ulcerative colitis. Therefore, molecular mimicry has been hypothesized as a cause for these disorders, but proof has been difficult to obtain. Several animal models have been developed, the most intriguing of which is probably a HLA-B27 transgenic rat that develops joint diseases, genital ulcers, and eye diseases. Systemic immunosuppressive interventions are not effective and the treatment of choice is nonsteroidal anti-inflammatory drugs. Local steroids are frequently administered for symptoms affecting the eye.

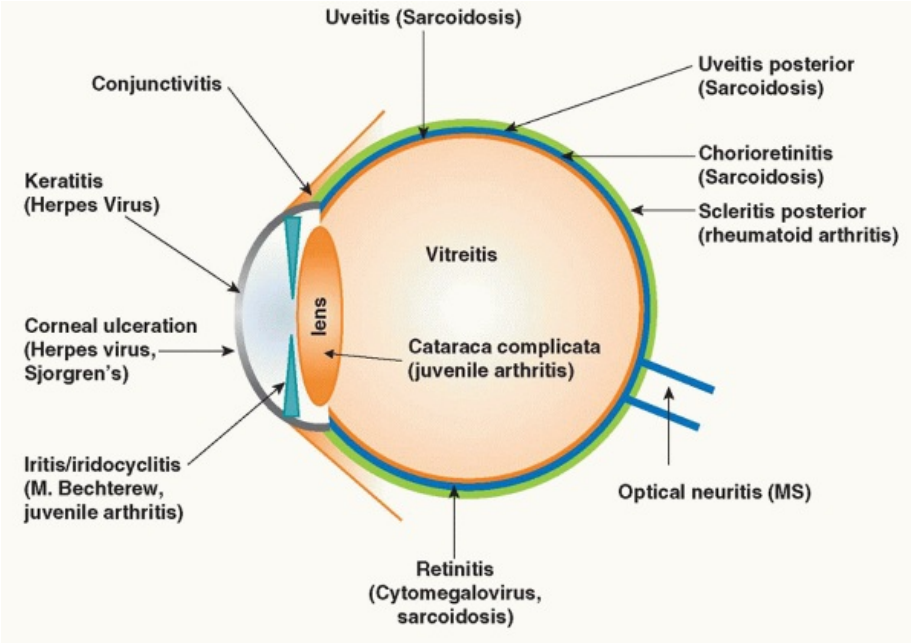

FIG. 44.10. Overview of the Structure of the Eye and Some of Its Inflammatory Diseases and Their Association with Other Systemic Disorders.

***Rheumatoid Arthritis*.** RA is an autoimmune joint disease (see following discussion) that is frequently associated with scleritis and episcleritis. Inflammatory infiltrates can be found in the peripheral cornea leading to ulcerations. Local treatments are usually without effect, and symptoms are ameliorated in conjunction with systemic immunosuppressive therapy. In contrast, juvenile arthritis is accompanied in about 20% of patients with cataracts and iridocyclitis, and ocular symptoms are often sensitive to local and systemic immunosuppression.

***Sarcoidosis*.** Sarcoidosis is a chronic, systemic granulomatous inflammatory disease that involves the eye (uveitis in 20% of cases) and constitutes the cause for uveitis in about 10% of patients. Multiple organs, in particular the lungs, are affected. The etiology is unclear, an autoimmune pathogenesis is suspected, and multiple other inflammatory changes can occur in the eye (see Fig. 44.10). Local therapy with steroids is usually helpful, and systemic immunosuppression can be considered.

***Idiopathic Uveitis*.** About half of the cases of uveitis are not associated with a known primary syndrome, and in young adults, the association (50%) with HLA B27 is striking. Only few of these patients will ultimately develop Bechterew disease. Again, the etiology is quite unclear, but some evidence suggests that molecular mimicry between ocular and viral antigens (eg, herpesvirus) could play a role. Peptide therapy is currently being evaluated; otherwise, steroids are the only effective choice.

A summary of the eye structures and some of the systemic diseases that are associated with a putative autoimmune affectation of the eye are listed in Figure 44.10.

***Animal Models*.** Small rodent models for autoimmune uveitis and herpesvirus keratitis have been very useful for understanding the underlying immunopathology of inflammatory eye disorders.

Experimental Autoimmune Uveoretinitis. Experimental autoimmune uveoretinitis (EAU) is induced, similar to EAE, by immunizing susceptible rodent strains with retinal proteins such as the receptor retinoid binding protein (IRBP).[374] Extensive studies by Tarrant et al.[375] have revealed that EAU follows similar autoimmune paradigms as other experimental autoimmune diseases including EAE and induced forms of diabetes. For example, a Th1-like response drives the aggressive EAU process,[375] whereas IL-10 in synergy with IL-4 has a pronounced protective function.[376,377,378] Similarly, diseaseresistant mice exhibit a predominantly Th2-like response to IRBP. Experimental evidence indicates that sequestration and local immune privilege of IRBP and possibly other retinal antigens leads to a lack of systemic tolerance to these proteins and, as a consequence, destructive autoimmune responses can be readily induced. Conversely, tolerance can be reestablished by application of tolerizing retinal-Ag/Ig fusion proteins or by inducing peripheral tolerance by systemic expression under an MHC class II promoter in transgenic mice. Interestingly, peptide therapy using an HLA-B27-restricted peptide appears to be effective in humans. The immunopathology of this EAU model in comparison to human uveitis, as found in sarcoidosis, is displayed in Figure 44.11. Recent evidence from the Fathman laboratory on the role of Deaf1 has revealed that multiple isoforms of this protein regulate the expression of peripheral tissue antigens, much like the gene AIRE controls antigen expression in the thymus.[379] Remarkably, the only phenotypic defect observed in Deaf1-deficient mice was the development of retina-reactive autoantibodies, which are also found in AIRE knockout mice. These data indicate that somehow the expression of an appropriate range of peripheral tissue antigens is important to maintain tolerance against retinal components.

Herpesvirus-Induced keratitis. Herpesvirus-induced keratitis has been explored in several animal models. The most intriguing studies come have come from the laboratory of Cantor. Inoculation of a genetically susceptible mouse strain with herpes simplex virus (HSV)-1 results in a viral infection of the eye and cornea that is accompanied by an immune response to HSV-1.[143] Interestingly, damage to the eye is only initiated by the virus and strongly depends on CD4 T cells that can cross-react with a self-protein. This animal model is one of the few that strongly indicate a direct immunopathologic role for molecular mimicry in an in vivo model for autoimmune disease. Studies by Gangappa et al.[380] have focused on the role of inflammatory bystander effects in the HSV keratitis model. In these studies, inflammatory cytokines were shown to play a major role in mediating local damage, and administration of DNA vaccine constructs expressing certain beneficial cytokines such as IL-10 ameliorated disease.[381] It is important to point out that these studies were performed using a different HSV strain, and that the precise immunopathogenic process (mimicry vs bystander effects) indeed depends on the strain of HSV used.[382] Additional observations have underscored the importance of regulatory cells in downmodulating a virally induced autoimmune disease. It is worthwhile mentioning that Kosiewicz et al. and Takeuchi et al.[383,384] have previously demonstrated regulatory cells in ocular autoimmune disease and found an important role for tolerizing APCs.

***Treatment and Prevention*.** Due to the associated side effects, it is desirable to avoid systemic immunosuppressive interventions as well as the local application of corticosteroids. A Munich group has identified a HLA-B27-derived peptide that can function as a mimic to the retinal S antigen

and induce EAU in Lewis rats.[385] Using this mimic peptide as an orally administered antigen has produced promising results in two human pilot trials in Germany. Thus, antigen-specific immune modulation using retinal self-antigens or their peptide mimics may be developed as an effective therapeutic choice. It remains to be seen whether combination of such a treatment with cytokine-DNA vaccines, as demonstrated by Gangappa's group for HSV keratitis or by Tarrant's group for EAU, both in mouse models, might enhance efficacy. In addition, systemic immunomodulation bears promise. Also, trials using anti-CD25 monoclonal antibody (daclizumab) for the treatment of recalcitrant ocular inflammatory disease demonstrated beneficial effects as they permitted the reduction of conventional immunosuppressive regimens.[386,387] It is noteworthy that in this case, the dampening of effector cells rather than any effects on CD25+ T_{reg}s appears to explain the efficacy.

Gastrointestinal Autoimmune Diseases

The gut constitutes a unique immunologic environment given its large interactive mucosal surface area and the need to maintain tolerance toward food antigens and bacteria normally present within the gut flora. The gut-associated immune system has an important regulatory and barrier function. Immune responses are usually initiated within the Peyer patches that obtain a significant amount of antigens via the M cells located within the mucosa and specialized in antigen uptake and transport.[151,388,389] Lymphocytes from the bone marrow

will circulate through the Peyer patches, where B- or T-cell responses can be initiated. Interestingly, the B-cell responses are characteristically IgA high. After antigen encounter, these cells will circulate to the mesenteric lymph nodes and enter the systemic circulation from there. Specifically for the gut, there are other extralymphoid locations where immune cells are found and where immune responses (aggressive or regulatory) can be initiated. One is the intestinal lamina propria, where MHC class II is expressed and bacterial products can be presented. Predominantly CD4+ T and B cells may assume regulatory functions, and IgA is secreted with the mucus into the gut lumen. The second are intraepithelial lymphocytes. A significant proportion of intraepithelial lymphocytes expresses the γδ TCR and they have cytotoxic as well as immunoregulatory functions.[390,391] Certain studies after oral or intranasal feeding of autoantigens have attributed regulatory function to γ/δ lymphocytes. Overall, the hypothesis that the gut environment is ideally suited to induce a tolerizing or regulatory immune response to antigens present in the gut lumen is of high interest and well supported by evidence from animal models (eg, "oral tolerance").[392] The rationale is that the immune system must have evolved to put some unique mechanisms into place to deal with the multitude of "foreign" antigens present in the gut and needed as nutrients

and for digestive purposes. Indeed, mice housed within a sterile environment have a shorter life span and multiple immune defects, indicating that the gut's immune system is vital for regular immune development and functions.[261]

Pernicious Anemia and Autoimmune Gastritis

Pernicious anemia is the end stage of autoimmune gastritis observed in about 10% to 20% of patients[393] and represents the most common cause of vitamin B_{12} deficiency.[394] Autoimmune gastritis is associated with autoantibody production to parietal cells and to its secreted product, intrinsic factor. In addition, a role for CD8 and CD4 T cells has been demonstrated.[395] Animal models have been developed.[396] Standard therapy is paternal B_{12} administration. Interestingly, this disease also develops in mice after thymectomy and is characterized by a relative lack of CD25+ regulatory CD4+ T cells.[176,397,398]

Ulcerative Colitis. Ulcerative colitis is a chronic inflammatory disease of the gut that affects men somewhat more frequently than women. It usually begins in the distal colon and rectum and will spread proximally resulting in severe cases in pancolitis. The hallmark is bloody mucoid diarrhea. The etiology is unclear; evidence points toward a certain genetic predisposition that has to meet triggering environmental factors. Unlike Crohn disease, the inflammatory foci are not granulomatous and not discontinuous. Overall, inflammatory mediators are increased, but systemic symptoms are rare. Treatment is usually achieved by corticosteroids; in severe cases, ulcerative colitis may require removal of the colon.

Crohn Disease. As opposed to ulcerative colitis, Crohn disease begins as a discontinuous, granulomatous inflammation of the proximal ileum. Ulcerations are frequent, and the disease is more severe than ulcerative colitis. The permeability of the mucosal epithelium is enhanced, which leads to a local breakdown of barrier functions and upregulation of TNF, IL-1, IL-6, and other cytokines. The immune reaction involves the whole mucosa and regional

lymph nodes. Interestingly, in addition to standard immunosuppressive treatments, blockade of TNF is highly efficacious and has been approved as a therapeutic strategy in Crohn disease.[399]

Hepatic Autoimmune Diseases

As an anatomic site for the induction and perpetuation of immune responses, the liver exhibits distinctive immunologic features that appear to favor an overall "tolerogenic" microenvironment. This perspective is supported by the apparent absence of liver pathology despite the continuous exposure to nutritional antigens and components of commensal gut flora,[400] the ability of viral (hepatitis B and C) and parasitic (malaria falciparum) pathogens to establish persistence and chronic hepatitis,[401,402] as well as the ready acceptance of liver allografts without immunosuppression in experimental models.[403] Moreover, successful liver transplants in humans require comparatively less immunosuppressive therapy,[404] and in some cases, complete weaning of immunosuppressive drugs has been achieved without compromising the functionality of the transplant.[405] The prevailing notion that the liver preferentially promotes abortive immune responses and tolerance was recently challenged in a meticulous study by Klein and Crispe.[406] Having optimized the considerable surgical feat of orthotopic liver transplants in mice, the authors conclusively demonstrated that the liver effectively initiates the bona fide activation and differentiation of specific T-cell responses.[406] Thus, the mechanisms operative in "liver tolerance" are not the consequence of altered antigen presentation, maturation failure, or premature T-cell death but rather appear to rely on the activation of poorly defined regulatory circuits by persisting antigens.

Conversely, a breakdown of such tolerance mechanisms, presciently postulated almost 100 years ago as a cause for autoimmune diseases at large,[7] may contribute to pathogenesis of hepatic autoimmune disorders. Here, we will discuss the three major autoimmune diseases of the liver: AIH,[407,408,409] which primarily targets hepatocytes; primary biliary cirrhosis (PBC),[410,411,412] in which small bile ducts are destroyed; and primary sclerosing cholangitis (PSC),[413,414] in which the damage is mainly focused on medium to large bile ducts. In addition, we have included "halothane hepatitis" as a paradigm for an immune-mediated adverse drug reaction.[415]

Autoimmune Hepatitis

***Introduction and Disease Description*.** Autoimmunity was invoked as a cause for hepatitis in the early 1950s,[416,417,418] and based on the association of AIH and antinuclear antibodies (ANAs), the term lupoid hepatitis was proposed.[419] AIH preferentially affects women but is observed worldwide in children and adults of both sexes in diverse ethnic groups; it contributes an estimated 10% to 20% to all cases of chronic hepatitis (which for the most part are due to infections with hepatitis viruses B, C, and D).[407,408] Clinical symptoms range from inapparent to fulminant disease courses, and differential diagnosis is guided by an exemplary scoring system developed by the International Autoimmune Hepatitis Group.[44,420] The presence of autoantibodies targeting different subcellular components is commonly used to differentiate two types of AIH. The etiology of AIH remains undefined, but a

contribution of environmental/microbial factors and genetic predisposition, as in so many other autoimmune diseases, is invoked as a trigger for T cell-mediated, destructive autoimmunity. Finally, it is also possible that as of today, unidentified hepatitis viruses or other chronic viral infections contribute to some AIH cases.[206,421]

***Autoimmune Features*.** The presence of specific autoantibodies in AIH is a key feature in the diagnostic scoring system and the foundation for the clinical distinction of type 1 and 2 AIH (Table 44.2). Type 1 AIH is characterized by ANAs, a class of antibodies also observed in PBC, PSC, and other forms of chronic hepatitis. Smooth muscle and antiactin antibodies, atypical perinuclear antineutrophilic antibodies and antibodies directed against soluble liver antigen and liver-pancreas antigen. None of these antibodies are specific for type 1 AIH, but their combined measurements allow for a reasonable distinction from type 2 AIH and, to a certain extent, other chronic liver diseases.

Anti-liver-kidney microsomal (LKM) antibodies are a serologic marker for type 2 AIH, with the majority binding the LKM1 antigen identified as cytochrome monooxygenase P450 IID6 (CYP2D6). In addition, <20% of patients with type 2 AIH also carry autoantibodies specific for uridine diphosphate glucoronosyltransferase, designated as LKM3, while 30% to 50% of patients generate antibody responses against formiminotransferase cyclodeaminase. Of all these targets in AIH, only one, the hepatocyte-specific asialoglycoprotein receptor, is cell surface expressed and may thus function as a direct immunogen for antibody-mediated hepatocyte damage. Hepatocyte-specific asialoglycoprotein receptor-reactive antibodies, also not disease specific, are found in 50% to 75% of all patients with AIH.[407,408,422] As the generation of these autoantibodies are Th-cell dependent, it is not surprising that loss of tolerance also occurs on the T-cell level and lymphocytes isolated from livers of patients with AIH type 2 can react in vitro and expand after exposure to P4502D6 antigen. This finding supports the concept of a lymphocyte-driven autoaggression and might underlie pathogenesis. Furthermore, mononuclear infiltration of the periportal areas and liver parenchyma is usually present when the disease progresses and causes the AIH-typical “piecemeal” appearance of the liver. Although evidence from animal models and human studies gives some indication that cytotoxic killing of hepatocytes could play a role, further analysis is still hampered by the fact that intrahepatic lymphocytes are difficult to access in humans. The notion that defective suppressor T-cell activity contributes to AIH pathogenesis, proposed more than two decades ago, is supported by the finding of reduced frequencies of peripheral CD4+CD25+ T_{reg} in patients with AIH as compared to healthy controls.[423] Cytokines also appear to play an important role in human AIH. Administration of type I IFN led to strong exacerbation of AIH, showing that it likely plays a central role in liver destruction.[424] IFNs upregulate MHC class I and II molecules, enhance inflammation, and have strong antiviral effects. The outcome of these studies therefore argues against a role of an ongoing chronic (or acute) viral infection in patients with AIH who test negative for hepatitis virus antigen or antibodies. A negative regulatory role can possibly be attributed to IL-6 and TNF-α. These two cytokines are reduced in livers of patients with AIH and have a negative effect on cytochrome P450 regulation.[425] As a consequence, the lower levels of IL-6 and TNF might enhance CYP2D6 expression and in this way support autoimmunity directed to CYP2D6 in patients with type 2 AIH. Lastly, AIH pathogenesis is not necessarily controlled by the Th1/Th2 paradigm: CD4+ T cells expressing Th1 cytokines are elevated in type 1 AIH,

whereas Th2 cytokines are augmented in type 2 AIH in agreement with the high levels of CYP2D6-specific antibodies present in these patients.

TABLE 44.2 Autoantibodies and Autoantigens in Autoimmune Liver Disease

	Type I AIH	Type II AIH	PBC	PSC
Auto-Abs	ANA: centromere, ribonucleoprotein, cyclin A, histone SMA: F actin, anti-ASGPR anti-SLA/LP pANCA: myeloid-specific nuclear envelop protein	Anti-LKM-1: CYP450, 2D6 Anti-LC-1: formiminotransferase cyclodeaminase	AMA: PDC-E2, BCOADC-E2, OGDC-E2, PDC-ERBP, PDC-E1a ANA: nuclear pore complex, anti-gp210, anti-p62, nuclear dot pattern, anti-Sp100, anti-PML, anti-SUMOs	pANCA: myeloid-specific nuclear envelope protein ANA: anticardiolipin, thyroperoxidase, rheumatic factor, *Helicobacter pylori* IgG
B cell infiltrate in liver	+ with plasma cells	+ with plasma cells	+ with plasma cells	+/-

AIH, autoimmune hepatitis; ANA, antinuclear antibody; ASGPR, hepatocyte-specific asialoglycoprotein receptor; BCOADC, branched chain 2-oxo-acid dehydrogenase complex; PDCERBP, ER binding protein of the pyruvate dehydrogenase complex; Ig, immunoglobulin; LC, liver cytosol (antigen type 1); LKM, liver-kidney mircosomal; OGDC, 2-oxo-glutarate dehydrogenase complex; pANCA, perinuclear antineutrophilic antibodies; PDC, pyruvate dehydrogenase complex; PML, promyelocytic leukemia protein; SLA/LP, soluble liver antigen and liver-pancreas antigen; SMA, smooth muscle antibody; SUMO, small ubiquitin-like modifier.

From Moriotki et al.422

Is production of autoantibodies important for AIH pathogenesis, or is it just an epiphenomenon signifying the breaking of tolerance to self-antigens? Evidence suggests that autoantibodies in AIH play a role that can be situated somewhere in between T1D, where autoantibodies and B lymphocytes likely play no pathogenetically important role in humans, and SLE, where autoantibodies are complement-fixing and enhance organ destruction. LKM antibodies found in AIH, for example, can inhibit cytochrome P450 function in vitro but not in vivo, and may participate in hepatocyte dysfunction or destruction. Epitope mapping of the CYP2D6 antigen in type 2 AIH revealed two immunodominant regions spanning aa 256-269 and aa 181-245 that are recognized by most of the sera of the patient with type 2 AIH. Because there is a significant genetic polymorphism in humans for the CYP2D6 antigen, it is possible that patients with AIH target CYP2D6 protein selectively (LKM1 antibodies), whereas cytochrome P4502D9 (LKM2) is targeted in patients with drug-induced hepatitis, disulfide isomerase in halothane-induced hepatitis, or UDP-glycosyltransferases in hepatitis D virus-associated autoimmunity. Identification of the major target antigens, clearly a decisive step toward a better understanding of the underlying disease process, has so far not yielded compelling hypotheses as to the precise pathogenetic mechanisms.

***Genetic Features and Environmental Factors*.** No single genetic locus capable of explaining AIH etiology has been identified. HLA-DR3 and HLA-DR4 are associated with type 1 AIH, and the HLA-A1-B8-DR3 haplotype exhibits

a particularly strong association with early disease onset, relapse, and the eventual necessity of liver transplantation. In contrast, type 2 AIH is associated with carriage of HLA-DR7. Genes outside the HLA loci potentially conferring disease susceptibility include complement component C4, CTLA-4, vitamin D receptor, Fas receptor, and others.[407,408,422]

The association with hepatitis C, D, and E virus-induced hepatitis and autoimmunity remains very intriguing. However, at this point, the prevalence of hepatitis C virus, for example, exhibits drastic variations between studies performed in different countries, and autoantibody titers appear much higher in patients with hepatitis C virus-negative AIH. In a more recent study, it was found that sera of 38% of patients with chronic hepatitis C reacted specifically with CYP2D6, whereas none of the sera obtained from patients with chronic hepatitis B showed CYP2D6 reactivity.[424] Furthermore, it was found that hepatitis C virus has the potential to induce autoreactive CD8+ T cells that crossreactively recognize the cytochrome P450 isoforms 2A6 and 2A7 that contain sequence homology to hepatitis C virus aa 178-187. In this context, it may be important to emphasize that molecular mimicry also seems to be an important factor in other immune-mediated diseases of the liver. Hence, trifluoroacetyl (TFA)-protein adducts, as generated during the metabolism of halothane by CYP2E1, confer molecular mimicry to the lipoic acid prosthetic group of the pyruvate dehydrogenase complex (PDC) and other members of the 2-oxoacid dehydrogenase family,[82,234,295,426] which in turn are major autoantigens in PBC.[115] Consequently, halothane hepatitis and PBC may be linked on the level of cross-reactive autoantibodies that recognize similar target antigens. It remains to be seen whether novel subtypes of hepatitis viruses can be found in patients with AIH and whether further studies will corroborate such an association. It is likely, however, that

viruses play a mutifactorial role in AIH pathogenesis (similar to T1D), and that no single virus will be identified as a specific cause for liver autoimmunity.

***Animal Models*.** Over the past 30 years, many attempts have been made to develop animal models for AIH; however, to date, no reliable model is available that reproduces the spontaneously relapsing chronic disease course of type 1 AIH.[427,428]

In the hepatitis B virus surface antigen-transgenic mouse, the hepatitis B virus surface antigen is expressed in hepatocytes under control of the mouse albumin promoter. Induction of transient hepatitis is possible after adoptive transfer of activated T cells from hepatitis B virus surface antigen-primed donor mice.[429,430] Although not designed to reproduce features of AIH, this model has been extraordinarily helpful in understanding the role of IFNs in inducing liver damage as well as clearing hepatitis B virus from the liver. Results have shown that IFNs, in the absence of cytotoxicity, can purge virus from infected hepatocytes. Furthermore, induction of hepatitis B virus-specific CD4+ and CD8+ T-cell responses can be evaluated in this model. The transgenic mice exhibit profound liver damage and infiltration after transfer of hepatitis B virus-specific T lymphocytes.

In another model system, the MHC class I molecule H-2K^b is transgenically expressed in the liver of mice that also carry transgenic T cells specific for H-2K^b. Hepatitis induction was only successful when such mice were infected with a liver-specific pathogen, indicating that bystander activation within the liver microenvironment can be very potent in causing autoimmune damage.[431] A similar approach was chosen in yet another model that combines liver-specific expression of a transgene (here, the immunodominant LCMV glycoprotein epitope [GP_{33}]) and transgenic T cells specific for the transgene.[432] These mice remain tolerant to the transgene even in the presence of transferred GP_{33}-specific T cells. However, under conditions of LCMV infection and TCR-transgenic T-cell transfer, these mice develop a transient form of hepatitis as evidenced by elevated alanine aminotransferase levels.[432] Together, these findings emphasize the importance of both autoreactive T cells and generalized inflammatory alterations in the wake of microbial infection.

The potential pathogenic contribution of autoantibodies was demonstrated in a new mouse model. Injection of a monoclonal antibody, derived from a patient with type 1 AIH and specific for an undefined 190 kDa cell surface protein, promotes predominantly perivenular hepatocellular necrosis in mice.[433] However, the validity of this model remains to be critically evaluated as the pathology does not appear to closely resemble that of type 1 AIH.

Arguably, more compelling models have been developed for the study of type 2 AIH. DNA immunization of mice with human CYPD6 and formiminotransferase cyclodeaminase antigens leads to the generation of LMK1 and LC1 autoantibodies (targeting CYPD6 and formiminotransferase cyclodeaminase, respectively) and specific cytotoxic T cells, pronounced lymphocytic infiltration of the liver, and an elevation of alanine aminotransferase levels indicative of liver damage.[434] Interestingly, work with this model has reproduced some aspects of the genetic predisposition exerted on disease development as C57BL/6 mice demonstrated more pronounced disease than 129/Sv mice, and no inflammation was found in BALB/c mice.[435] Lastly, adenoviral infection with recombinant expressing the 2D6 antigen can lead to focal and confluent liver necrosis in mice resembling that of AIH[436] (Fig. 44.12).

In summary, the success of most mouse models has only been partial, as hepatitis was transient and induction of chronic disease appeared difficult to achieve. Figure 44.13 illustrates the possible pathogenetic mechanisms implicated in AIH.

Treatment and Prevention. Immunosuppression is the therapy of choice for AIH. Since their introduction in 1968,[437] prednisolone and azathioprine have become standard treatment regimens.[408,438] The impressive success rate of this therapeutic approach (more than 85% of patients with AIH) may have, to a certain extent, removed the urgency to pursue basic AIH research.[428] Immunosuppressive therapy also improves survival of patients with severe AIH,[439] but no guidelines are available for individuals with minimal symptoms. End-stage AIH is an important indication for liver transplantation.[440] Recurrence of AIH has been reported after liver transplantation[441] but interestingly is not as frequent as observed for islet

transplants in patients with T1D. Therapeutic use of IFNs, effective for treatment of viral hepatitis, can worsen autoimmune liver disease[424] and challenges the assumption that unknown chronic viral infections of the liver, while possible initiators, maintain the active disease process.

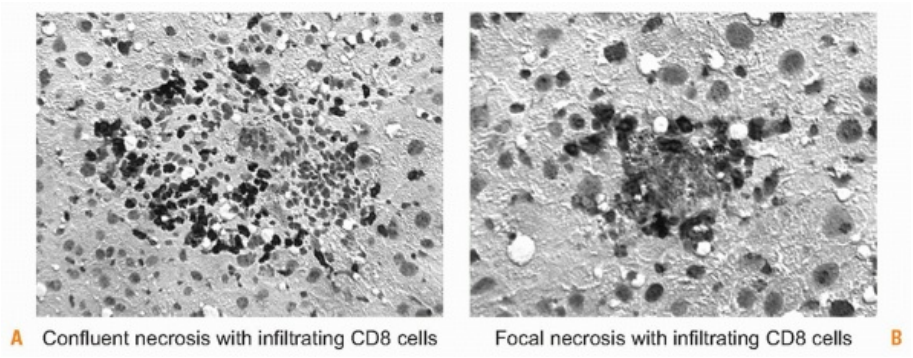

FIG. 44.12. Liver Necrosis in 2D6 Transgenic Mice Infected with an Adenoviral Recombinant Expressing 2D6. Courtesy of Urs Christen and Matthias von Herrath, University of Frankfurt, Germany, and La Jolla Institute for Allergy and Immunology, La Jolla, CA.

Primary Biliary Cirrhosis

Introduction and Disease Description. PBC is a slowly progressive hepatic autoimmune disorder that primarily affects women. The disease is typically associated with high titers of antimitochondrial antibodies (AMAs) that presage onset of clinical disease by 5 to 10 years; antinuclear antibodies (ANA) are found in about half of PBC patients. Histopathologic changes include portal inflammation and destruction of intrahepatic bile ducts that occur at various rates and degrees in different patients. The resulting decrease of bile secretion and retention of toxic substances within the liver leads to further hepatic damage, fibrosis, cirrhosis, and eventual liver failure.[410,411,412]

Autoimmune Features. Although speculation about the autoimmune pathogenesis of PBC

centers around the usual suspects of genetic and environmental/microbial factors, PBC may serve as an example how advanced knowledge about the targeted autoantigens can give rise to novel and intriguing hypotheses. The presence of AMA in PBC were first described in the 1950s, the autoantigens cloned in the 1980s and 1990s, and B cell, CD4+, and CD8+ T-cell epitopes of the major autoantigen PDC-E2 mapped in the 1990s and 2000s. More than 90% of patients with PBC have high titers of autoantibodies directed against the 2-oxoacid dehydrogenase complex E2 subunit, in particular the E2 component of the PDC. Mapping studies have identified determinants within the PDC-E2 lipoyl domains as a primary targets for antibody and T-cell reactivity, a motif that is also found in the E2 subunit of other 2-oxoacid dehydrogenase complex members (OGDC-E2, BCKD-E2; motif is also found in E3-BP).[411] Antibody reactivity to nuclear envelope proteins gp210 and p62 are found in 10% to 30% of patients and are apparently associated with more active disease. The obvious question emerging from the identification of these autoantigens pertains to the fact that they are 1) found in every cell type and 2) located on the inner surface of the inner mitochondrial membrane, thus separated

from immune effectors by three membranes. In addition, the existence of a clinical entity known as AMA-negative PBC, a disease very similar to PBC but without detectable AMAs, appears to further argue against a pathogenic role of these autoantibodies.[412] Yet, certain particularities of bile duct epithelial cells may predispose them as targets for humoral immune responses. These cells, just as salivary epithelial cells, express receptors involved in the transcytosis of IgA and high titers of PDC-E2-specific IgA are found in bile, saliva, and urine of patients with PBC. AMA IgA was shown to induce apoptosis, which in turn may lead to PDC accumulation in the cytoplasm and cell surface, as well as amplification of the immune response. Further speculation has focused on the possibility that failure of PDC glutathionylation specifically in epithelial cells may promote accumulation of immunogenic forms of PDC, a process that may be initiated by xenobiotic-modified PDC and molecular mimicry.[411] In the “determinant density model,”[442] potentially PDC-reactive T cells survive negative thymic selection due to low TCR avidity and remain “dormant” despite sporadic exposure to PDC-derived epitopes. However, strong inflammatory stimuli that allow for improved antigen presentation and activation of toll-like receptors (TLRs; monocytes from PBC patients exhibit enhanced sensitivity to TLR signals) (eg, through microbial molecular mimicry) may induce the breakdown of tolerance that precipitates the disease. It should be noted that the general validity of this hypothesis, including a key role for low-avidity T cells and TLRs, is fully supported by elegant studies in models for induction of autoimmune diabetes.[114,443] Finally, a model has been proposed in which a primary dysfunction of endothelial cells results in overproduction of endothelins, inflammatory alterations, and ischemic damage due to vasoconstriction and the generation of PDC-specific humoral and cellular responses as a secondary event.[412] These hypotheses are not mutually exclusive and may be critically evaluated in two animal models.

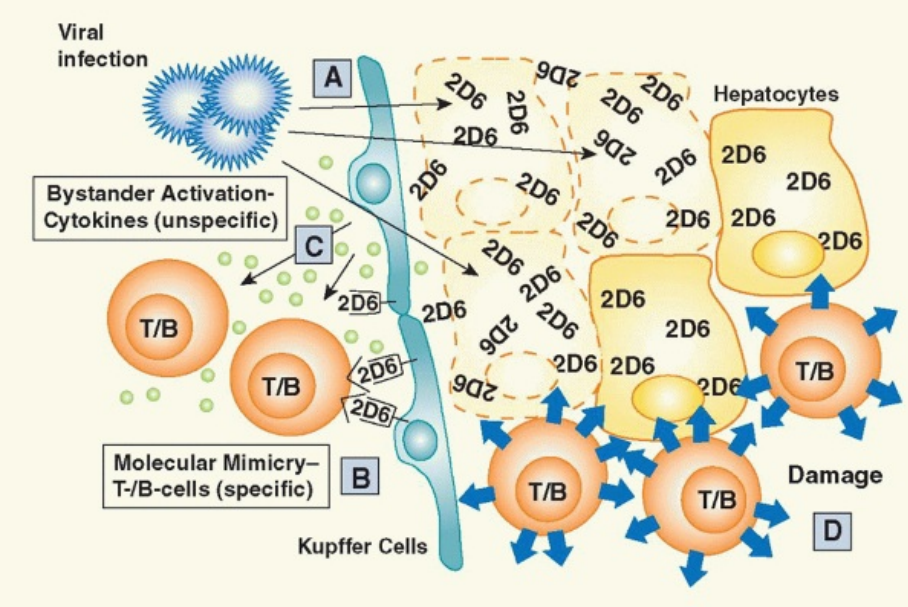

FIG. 44.13. Pathogenesis of Liver Autoimmunity after Viral Infection in the 2D6 Animal Model. A: Viral infection leads to expression of high cytokine levels in the liver. **B:** The infection will probably also activate resident macrophages (Kupffer cells). Antiviral T cells react against virally infected cells and destroy them. This leads to release of autoantigens fom hepatocytes, which can be (cross)-presented leading to pathogenic responses against autoantigens such as cytochrome P450 2D6. Chemokine and cytokine release **(C)** leads to enhanced inflammation and antigen presentation **(D).**

***Genetic Features and Environmental Factors*.** Familial clustering of PBC and a high concordance rate in monozygotic twins (63%) indicate a genetic component to PBC pathogenesis. A flurry of GWAS data has dramatically improved our insight into the genetics landscape of PBC. Before the implementation of GWAS technology, only class II HLA loci had been reproducibly shown to associate with disease. Non-HLA loci were reported on some occasions but replication often proved problematic. GWAS confirmed HLA as the strongest association and many additional non-HLA risk loci have been identified, with equivalent effect size to HLA, including IL-12A,[444] IL-12RB2,[444] STAT4,[445] IRF5-TNPO3,[446] 17q12.21,[446] MMEL1,[446] SPIB,[446] and CTLA-4.[444] As argued previously, the list of associated genes comprises many proteins with important roles in innate and adaptive immunity, and, thus, the existence of a monogenic pathway that leads to disease can be excluded. In correspondence with, for instance, T1D and RA, CTLA-4 also confers risk for this condition and many of the candidate genes signal though NF-κB, TLR, and TNF pathways, which are also important in many other autoimmune conditions. The future will tell whether this growing list of gene associations will be instumental in unraveling the immune pathology that underlies PBC.

***Animal Models*.** The absence of a suitable animal model has long been a serious obstacle to PBC research. However, two publications document important progress on this front by describing the spontaneous onset of a PBC-like disease in two mouse strains. NOD.c3c4 mice congenically derived from the NOD strain generate PDC-E2-specific autoantibodies and exhibit biliary pathology characterized by destructive cholangitis, granuloma formation, and eosinophilic infiltration. Importantly, T cells are found in affected areas of the biliary

epithelium, and transfer of splenocytes or CD4+ T cells induces disease in NOD.c3c4-scid recipients, suggesting a central role for T cells in pathogenesis.[447] In the second model, abolition of TGF-β signaling in T cells (achieved by T cell-specific expression of a dominant-negative TGF-βRII) results in production of AMAs directed at PDC-E2, BCOADC-E2, and OGDC-E2 as well as lymphocytic liver infiltration with periportal inflammation analogous to the histologic profile in human PBC. These observations implicate the TGF-β pathway in PBC pathogenesis and suggest that the activation of intrinsically self-reactive T cells is a consequence of impaired T_{reg} cell function rather than molecular mimicry.[448]

***Treatment and Prevention*.** It is noteworthy that despite its presumed autoimmune etiology, PBC is not ameliorated by immunosuppressive therapy. In the absence of optimized therapeutic protocols, treatment is tailored according to individual responsiveness of patients with PBC and includes management of disease symptoms (pruritus, osteoporosis, hyperlipidemia, portal hypertension) as well as therapy of the underlying disease by stepwise addition of ursodeoxycholic acid, colchicin, and methotrexate. Nevertheless, the use of colchicine and low-dose methotrexate, presumably acting as an immunomodulatory rather than antimetabolic agent, remains controversial. In cases of liver failure, orthotopic liver transplantation is the only effective treatment.[410]

Primary Sclerosing Cholangitis

***Introduction and Disease Description*.** PSC is a chronic cholestatic liver disease (cholestasis: suppression of biliary flow) frequently associated with inflammatory bowel disease (>75% of patients with PSC). It is characterized by fibrotic inflammation and destruction of large intrahepatic and extrahepatic bile ducts and may lead to the development of cholangiocarcinoma (in 10% to 30% of patients with PSC) and ultimately death by liver failure.

***Autoimmune Features*.** Although the etiology of PSC remains undefined, a complex multistep process has been delineated and involves cholangiocyte activation through bacterial pathogen-associated molecular patterns, production of proinflammatory cytokines in conjunction with aberrant chemokine expression and endothelial cell adhesion molecules, and the recruitment of T cells presumably specific for enterocyte antigens and primed in gut-associated lymphoid tissues.[414] The generation of autoantibodies is a common feature (see Table 44.2), but most antibodies are not specific for PSC and their contribution to disease pathogenesis remains at present unclear.[422]

***Genetic Features and Environmental Factors*.** The relative risk of PSC among first-degree relatives of patients with PSC is almost 100-fold increased as compared to the general population, indicating that there is a strong genetic component to the condition.[413] As in many other autoimmune conditions discussed here, GWAS have greatly contributed to our understanding of the array of genes that contribute to disease susceptibility. A first report revealed a similar genetic architecture as described in PBC, and it was confirmed that the association with HLA was even more pronounced.[449] The authors also found one non-HLA association at chromosome 13q31 (locus also associated with MS), and the next assayed 15 established inflammatory bowel disease (which affects 50% to 80% of patients with PSC) susceptibility loci. They were able to identify two additional non-HLA susceptibility loci

(chromosome 2q35 and chromosome 3p21) for which the G protein-coupled bile acid receptor 1 (TGR5) and macrophage-stimulating 1 (MST1) were proposed as the likely disease genes. A subsequent study from the same group added two more non-HLA loci, 2q13 and 10p15, with presumable candidate genes BCL2-like 11 (BCL2L11) and IL-2RA.[450] Interestingly, IL2ra-/- mice spontaneously develop intestinal and biliary inflammation.[451] Finally, three more inflammatory bowel disease susceptibility loci were found to be associated with PSC, encompassing the candidate genes REL, IL-2, and CARD9.[452] Collectively, these genetic data offer strong, albeit still indirect, support for an important role for innate and adaptive immune components in PSC. Moreover, the shared genetic patterns between PSC and inflammatory bowel disease indicate a certain degree of common immunopathogenesis and once again suggest the potentially shared origin of what first seemed to be distinct autoimmune disorders.

***Animal Models*.** None of the animal models developed to date reproduce all pertinent aspects of human PSC.[453] Rat models of small bowel bacterial overgrowth and administration of bacterial cell wall components have provided some support for an ethiopathogenetic role of pathogenassociated molecular patterns. Other models include injury of biliary epithelial or vascular endothelial cells (rodents, dog, monkey) and toxic, infectious, or intraluminal biliary injury (rodents) permitting the study of cytokines, chemokines, and inflammation in the development of diffuse bile duct sclerosis.[453]

***Treatment and Prevention*.** There is currently no effective medical therapy available for PSC.[454] Treatment with the hydrophilic bile acid ursodeoxycholic acid improves liver enzymes, but its effect on liver histology and prognosis remains inconclusive. Orthotopic liver transplant constitutes the only established long-term treatment for PSC with cumulative 5-year survival of about 70%.

Halothane Hepatitis

Halothane hepatitis is a severe, life-threatening form of hepatic damage that affects a small subset of individuals exposed to the anesthetic agent halothane[455] and is thought to have an immunologic basis. Sera of afflicted individuals contain autoantibodies directed against the native and the TFA form of hepatic proteins. TFA proteins are generated during the oxidative metabolism of halothane (2-bromo-2-chloro-1,1,1-trifluoroethane) and include cytochrome P450, protein disulfide isomerase, microsomal carboxylesterase, calreticulin, Erp72, GRP78 (BiP), and GRP94. Current evidence suggests that such TFA proteins arise in all individuals exposed to halothane. However, the vast majority of individuals appear to tolerate this covalent protein modification. The lack of immunologic responsiveness was suggested to occur due to tolerance induced through the presence of structures in the repertoire of self-determinants that immunochemically and structurally mimic TFA proteins very closely. In fact, lipoic acid, the prosthetic group of the constitutively expressed E2 subunits of members of the 2-oxoacid dehydrogenase complex family was demonstrated by immunochemical and molecular modeling analysis to perfectly mimic N^6-trifluoroacteyl-L-lysine, the major haptenic group of TFA proteins. Interestingly, a fraction of patients with halothane hepatitis exhibit irregularities in the hepatic expression levels of these cross-reactive proteins. Thus, molecular mimicry of TFA lysine by lipoic acid, or the impairment thereof, can be considered a susceptibility factor of individuals for the development of

halothane hepatitis.[456] A small animal model for chemically induced liver diseases has been described.[457]

***Perspective and Conclusion*.** The presence of autoantibodies in AIH, PBC, and PSC is indicative of autoimmune processes, but none of the antibodies described is liver specific and their contribution to pathogenesis remains unclear. While the complex role of T cells is subject to current investigations, the same caveats of specificity and pathogenicity discussed previously apply for autoimmune liver diseases.[458] Although the success of immunosuppressive therapy, in fact a criterion for the diagnostic scoring system for AIH,[44,420] further supports autoimmune etiology for AIH, it is conceivable that a viral infection might initiate disease as a "hit-and-run" event. Following elimination of viral antigens, disease may be perpetuated by immune-mediated processes and preclude the identification of a particular virus as causative agent at the time of liver disease diagnosis. Again, the role of "foreign antigens" and "self-antigens" becomes blurred and their interactions with the immune system in terms of immunity or autoimmunity conceptually problematic. Future investigations should seek to improve animal models and focus on human autoantigens and the application of contemporary tools for identification and isolation of specific lymphocytes. On the basis of such developments, future in vivo tracking of autoaggressive lymphocytes with noninvasive methods should substantially improve our insight into disease pathogenesis.

Renal Autoimmune Diseases

Glomerulonephritis (GN) is the major cause of chronic renal disease and kidney failure and exhibits a wide spectrum of histopathologic alterations, disease severity, and clinical outcomes. In most cases, evidence for an immunomediated pathogenesis, including humoral and cellular responses, has

been obtained.[459,460,461,462] The precise incidence of defined renal autoimmune disease is difficult to establish because definite diagnosis requires histologic evaluation of the kidneys. In this respect, the Italian Registry of Renal Biopsies provides a unique repository, and information about selected glomerular disease obtained from this resource is displayed in Table 44.3.[463,464] The identity of nephritogenic antigens targeted in most renal autoimmune diseases remain poorly defined, with the notable exception Goodpasture syndrome, a form of antiglomerular basement membrane disease in which autoantibodies bind to α3(IV) collagen in the glomerular basement membrane and are associated with rapidly progressive GN as well as pulmonary hemorrhage. Conformational epitomes have been mapped to two regions within the noncollagenous (NC1) domain of the α3(IV) chain.[465] A role for T cells, both in providing help for autoantibody production and exerting direct effector functions, has also emerged. Cast within the reigning concept of balanced Th1 and Th2 immunity, it appears that Th1 responses are associated with proliferative and crescentic forms of GN that cause severe injury while Th2 responses are associated with membranous patterns of injury.[459] These distinctions have also given rise to speculations that have harnessed the "hygiene hypothesis" as a potential explanation for the observation that proliferative GN have a relatively high incidence in developing countries, whereas minimal change disease and IgA nephropathy predominate in developed countries. Therapeutically, immunosuppression with

corticosteroids and in combination with cyclophosphamide and plasma exchange (to remove damaging antibodies) is employed to manage diseases. Based on the Th1/Th2 paradigm and its role in developing therapies for other autoimmune diseases that aim to target the Th1-Th2 balance, therapeutic approaches such as oral tolerance, cytokine-based immune modulation (anti-TNF-α and IL-12 p40 antibodies, recombinant IL-10), antiadhesion molecules, and chemokine receptor blockade are currently being evaluated for their potential use in the treatment of autoimmune renal diseases.[459]

TABLE 44.3 Incidence of Glomerular Diseases in 1993

Disease	Incidence per Million Population
Immunoglobulin A nephropathy	8.4
Membranous glomerulonephritis	4.9
Focal segmental glomerulonephritis	2.3
Minimal change disease	1.6
Mesangiocapillary glomerulonephritis	1.4
Poststreptococcal glomerulonephritis	0.7

Cutaneous Autoimmune Diseases

Cutaneous autoimmune disorders are commonly divided into nonorgan-specific and organ-specific diseases. The former group contains skin manifestations of systemic autoimmune disorders such as SLE, scleroderma, Crohn disease, and ulcerative colitis. The organ-specific autoimmune skin disorders discussed in this section include several autoimmune bullous dermatoses as well as pigmentation disorder vitiligo. Despite a relative paucity of animal models for human autoimmune skin disorders, the skin is one of the few organs that offers direct access to target antigens and effector cells; consequently, advanced insights into mechanisms of disease induction and perpetuation have been obtained.

Autoimmune Bullous Dermatoses

Autoimmune bullous dermatoses are a group of severe, possibly fatal skin disorders characterized by erosions and blisters of skin and/or mucous membranes (Table 44.4). The term “pemphigus” (from Greek/Latin: pustule, bubble), featured in the name of several of these diseases, dates back

to “pemphigoid fever” described by Hippocrates nearly 2400 years ago and has been used to describe chronic blistering skin conditions since the mid-18th century. All forms of pemphigus have distinctive characteristics but exhibit the common feature of epidermal cell-to-cell detachment known as acantholysis. On occasion, pemphigus syndromes are associated with other autoimmune diseases such as SLE, RA, myasthenia gravis, pernicious anemia, and Hashimoto thyroiditis.

TABLE 44.4 Autoimmune Bullous Dermatoses

Disorder	Acantholysis	Autoantigen	Autoantibody Class	T-Cell Subset
Pemphigus vulgaris	Suprabasilar	Desmoglein-3 > Desmoglein-1	IgG4, IgG1, IgA (occasionally)	Th1, Th2, Tr1, CD8+CD28- T_{reg}
Pemphigus foliaceus	Subcorneal	Desmoglein-1	IgG4, IgG1	Th1, Th2
Bullous pemphigoid	Subepidermal	BP180, BP230	IgG1, IgG4, IgA (occasionally)	Th1, Th2
Cicatricial pemphigoid	Subepidermal	BP180 > BP230, Laminin 5	IgG1, IgG4, IgA (occasionally)	Th1
Pemphigus gestationis	Subepidermal	BP180, BP230	IgG1, IgG3	Th1, Th2
Dermatitis herpetiformis (associated with glutensensitive enteropathy)	Subepidermal	Epidermal transglutaminase	IgA	Th2
Linear IgA disease	Subepidermal	BP180, BP230	IgA	Th1, Th2
Epidermolysis bullosa acquisita	Subepidermal	Collagen VII	IgG, IgA and IgM (occasionally)	Th1, Th2, no T_{reg} contribution

CD, cluster of differentiation; Ig, immunoglobulin; Th, helper T; T_{reg}, regulatory T.

***Pemphigus Vulgaris*.** Pemphigus vulgaris (PV) is the most common and severe form of pemphigus in the United States, constituting more than 80% of reported cases.[466,467] With a worldwide incidence of one to five cases per million per year in the general population, PV remains a rare disease and preferentially affects individuals in the fourth to sixth decade of life. Clinical features include flaccid, fragile, and noninflammatory bullae (from Latin: bubble) that arise on normal appearing skin. These lesions tend to coalesce and rupture, leaving larger areas of denuded skin that often heal poorly.[466,467,468] About half of the patients initially present with lesions confined to the oral mucosa, although any surface with squamous epithelial tissue may be affected. Blister formation begins with edema of epidermal intracellular spaces and progresses to complete loss of cohesion between epidermal cells. In PV, blisters occur in the suprabasilar region of the epidermis while leaving attachment of basal cells to the dermis largely intact.[466,467,468,469,470]

Autoimmune Features. The hallmark of PV are autoantibodies generated against the desmosomal glycoprotein desmoglein-3 (Dsg3) (Fig. 44.14). In fact, the unequivocal identification of this antigen makes PV one of just a few human autoimmune disease for which the relevant autoantigen has been defined. Although the pathogenic contribution of Dsg3 antibodies has been demonstrated in passive transfer experiments, more recent work has emphasized the importance of specific T cells.[471] TCR transgenic mice with autoreactive CD4+ T cells that are specific for Dsg3 were recently generated. It was found that these CD4+ T cells specific for a single skin-associated antigen could induce a pemphiguslike phenotype.[472]

Peripheral CD4+ and occasional CD8+ T-cell responses targeting Dsg3 with varying functional profiles (Th1 and Th2) have been described. These autoreactive CD4+ T cells may be involved in the coordination of specific B-cell responses as evidenced by Th1-regulated IgG1 and Th2-regulated Dsg3 antibodies in patient sera. Interestingly, IL-10-producing Dsg3-reactive T cells have also been identified in the majority of healthy individuals carrying PVassociated HLA alleles (see subsequent discussion) but were found in <20% of patients with PV.[473] Given these functional attributes reminiscent of the Tr1 T_{reg} cell subset as well as the documentation of CD8+CD28- T cells with potential regulatory function in patients with remittent PV,[471] it has been proposed that clinical disease may emerge as a consequence of an imbalance between autoreactive pathogenic and T_{reg} cells.[471]

Genetic Features and Environmental Factors. Although PV can affect anyone, an enhanced prevalence is observed in people of Mediterranean or Jewish ancestry. Associations with certain HLA alleles (HLA-26, HLA-B38, SC21, HLA-DR4) in Ashkenazy Jews and non-Ashkenazy Jews (HLA-DRW6) have been detected in patients with PV, and it has been suggested that the third hypervariable region of the β-1 chain of the DRB1 allele may constitute a susceptibility locus.[466,467,468] Recent studies indicate that the H-CDR3 region within anti-Dsg antibodies is critical for disease induction and even one amino acid change

can alter their pathogenicity.[474] It was concluded that mutations in these areas can uncouple pathogenicity and binding. Finally, while PV may be associated with other autoimmune diseases,[470] its occurrence with certain malignant diseases has been defined as a separate entity.[475]

Animal Models. The pathogenic role of autoantibodies has been demonstrated by passive transfer of PV patient sera into

neonatal mice.[476] More recent studies using Dsg3-deficient mice have established that loss of tolerance and induction of autoimmunity required the presence of both autoreactive B and T cells.[477,478,479] Finally, CD4 T cells from Dsg3-immunized HLA transgenic mice target Dsg3 epitopes identical to those identified in humans and thus constitute a promising model to further analyze the regulation of Dsg3-specific T cells and autoantibody production in vivo.[471]

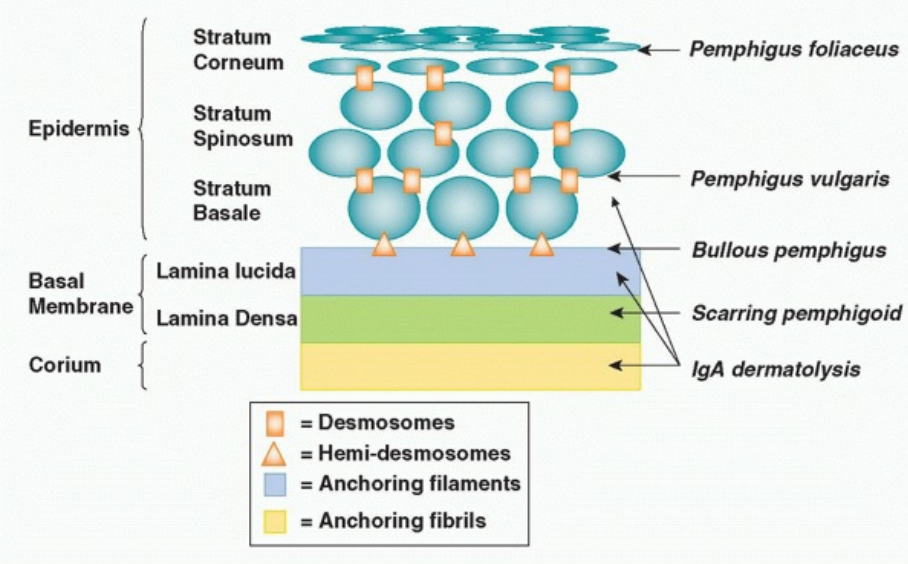

FIG. 44.14. Different Layers of the Skin and Their Involvement in Autoimmune Skin Syndromes.

Treatment and Prevention. Corticosteroids are the treatment of choice with supplementary immunosuppressive agents (cyclophosphamide, azathioprine, and methotrexate) commonly used to reduce the side effects of steroids. In severe cases, plasmapheresis may be of short-term benefit. Clinical data indicate that B-cell depletion, achieved by administrating anti-CD20 antibodies (rituximab), is an effective treatment for pemphigus, but it is generally acknowledged that, due to its potentially severe side effects, its use should be limited to the most severe types of the disease.[480]

Other Autoimmune Bullous Disorders. Other autoimmune bullous disorders include pemphigus foliaceus (PF), bullous pemphigoid (BP), cicatricial (scarring) pemphigoid, epidermolysis bullosa acquisita, dermatitis herpetiformis, and linear IgA disease (see Table 44.4). Two forms of PF are recognized: one affecting individuals irrespective of ethnic

background around the world and the other, PF fogo selvagem (Portuguese: savage fire), endemic to certain regions of Brazil. Antibodies found in the circulation of patients with PF preferentially target Dsg1, are of the IgG4 subclass, and similar to PV, can induce aspects of the disease in a neonatal mouse transfer model[466]; Th1 and Th2 T cells specific for the same antigen have also been described.[471] Information about genetic association remains incomplete due to the rarity of PF. However, PF fogo selvagem demonstrates associations with HLA-DR1 and HLA-DR4. Prior to the advent of corticosteroids, fewer than 10% of patients underwent spontaneous remission, and fatalities reached up to 40% within the first 2 years of disease. Compared to PV, patients with PF respond more rapidly and to smaller doses of corticosteroids.[466]

Together with PV, BP belongs to the best characterized bullous disorders with regard to pathogenesis. In BP, IgG autoantibodies are directed against components of the dermal-epidermal basement membrane such as BP antigens BP180 and BP230. Again, these antigens are also recognized by CD4+ T cells and comprise both Th1- and Th2-type subsets,[471] and systemic corticosteroids with facultative addition of other immunosuppressive agents are used for treatment. The principal autoimmune targets and basic pathologic features of the remaining bullous dermatoses are listed in Table 44.4.

Perspective and Conclusion. The identification of relevant autoantigens, a task that is far from complete in the majority of human autoimmune diseases, is usually considered to be a critical juncture in our understanding of pathogenetic mechanisms and an important step toward the development of targeted immunomodulatory therapies. However, the case of PV and BP is a telling reminder that even with established knowledge about such primary autoantigens, the development of specific immunotherapies faces continuing challenges.

Vitiligo

Introduction and Disease Description. Vitiligo is an acquired, noncontagious disorder of pigmentation resulting from melanocyte loss (reviewed in Passeron and Ortonne,[481] Spritz,[482] and Boissy,[482a] Theo Book). The disease is characterized by defined areas of depigmentation that range from limited numbers of macules (focal vitiligo) to bilateral, symmetric distribution of the lesions (generalized vitiligo, the most common type) to involvement of the complete body surface area (universal vitiligo). Vitiligo is arguably the most common pigmentary disorder affecting 0.5% to 2% of the population worldwide and demonstrates no predilection for gender or ethinicity. Although commonly regarded as a pathophysiologic entity with distinct clinical manifestations, the existence of a spectrum of vitiligo disorders with different etiologies was suggested. The potential autoimmune etiology of vitiligo has been discussed for some time and has gained traction through recent studies on genetic epidemiology. A combination of environmental, genetic, and immunologic factors is thought to contribute to autoimmune melanocyte destruction. This hypothesis is further strengthened by the reported association of vitiligo with other autoimmune diseases such as autoimmune thyroid disease, SLE, Addison disease, adult-onset T1D, and pernicious anemia.[483] Another interesting analogy with T1D was coined by Eisenbarth,[484] who noted that both diseases shared an unexplained focality of melanocytes or β cells. A lingering question in this regard is what differentiates one melanocyte or β cell from another in becoming a target for autoimmunity. Nevertheless, the specific causes of vitiligo remain

obscure and progress is limited due to lack of a clear definition of the disorder as well as a dearth of experimental animal models.[482]

Autoimmune Features. T-cell infiltrates have been reported in generalized vitiligo and exhibit molecular signatures indicative of CTL and Th1 responses (TNF-α and IFNγ).[485] CD8+ T cells tend to predominate in vitiligo lesions, and high frequencies of Melan-A-specific CD8+ T-cell subsets apparently correlate with severity of disease.[486,487] Additional infiltrating cells include macrophages and monocytes producing proinflammatory cytokines as well as dendritic cells. The role of dendritic cells in local immune reponses remains unclear, but the dendritic cell-mediated killing of melanocytes has been suggested as a mechanism for depigmentation.[488] Finally, circulating autoantibodies, including those specific for the melanocyte antigen TRP1, have been found in the sera of patients with vitiligo, and TRP1-specific antibodies can induce melanocyte loss in mice.[489] Nevertheless, there appears to be an emerging consensus that alterations of humoral immunity are secondary to T cell-mediated autoimmune destruction.

Genetic Features and Environmental Factors. Evidence for genetic factors contributing to onset of generalized vitiligo has been obtained in studies of the close relatives of patients with

vitiligo.[483,490] The largest vitiligo twin study to date has demonstrated concordance for generalized vitiligo in monozygotic twins of 23%, far greater than the risk for nonidentical siblings (6.3%) and the general population risk.[483] Vitiligo occurs with a frequency of 0.1-2.0% in various (general) populations.[483] At the same time, these data highlight the critical importance of environmental factors. Genetic association and linkage studies initially revealed an association between vitiligo and HLA-DRB1, HLA-DLRB4, and HLA-DQB1 alleles as well as other genes.[481,482] It is worth noting that the first vitiligo linkage data excluded a single candidate gene, the micro-ophtalmia-associated transcription factor. Microophtalmia -associated transcription factor appeared to be a relevant candidate due to numerous mutations at the mouse microphthalmia locus associated with reduced or absent pigmentation and with the mivit/vit mutation presenting postnatal depigmentation that resembles human vitiligo.[491] Many of the findings from early genetic studies were difficult to reproduce, and a recent study systematically tested the association of multiple previously reported candidate genes.[492] It was found that only HLA class I, HLA class II, and lymphoidspecific protein tyrosine phosphatase nonreceptor type 22 (PTNP22) were strongly associated, with weaker support for TSLP, XBP1, and forkhead box (FOX)D3. It can be concluded that most other previously reported associations most likely represent false-positives. One interesting finding came from association analyses that resulted in the identification of NALP1 (later renamed NLRP1) as a candidate gene.[493] This gene encodes an important regulator of the innate immune system that may monitor bacterial infection of the skin. Importantly, other reports have subsequently found genetic associations of NLRP1 with other autoimmune diseases such as T1D, Addison disease, celiac disease, and systemic sclerosis, pointing toward overlapping disease mechanisms.

The genetic basis of vitiligo was recently explored by a series of GWAS, which have drawn a more comprehensive and reliable picture of the potential disease genes in (generalized)

vitiligo. Almost all susceptibility genes that were found involve candidate genes functional in immune regulation and immune targeting of melanocytes, which has solidified the general consensus that vitiligo is a primary autoimmune disease.[494] The results from three large-scale GWAS have been reported, and major association signals in the MHC (both class I and II genes) and also numerous non-MHC associations were revealed.[495,496,497,498] The list is too long to summarize here (see Spritz[494]) but includes many important immunity genes such as *TYR* (tyrosinase), *PTPN22*, IL-2Rα (IL-2-receptor alpha chain), *GZMB* (granzyme B), and *FOXP3*. Most of these genes have been discussed in this chapter for other conditions, again highlighting potentially common immune pathways. It is estimated that the current set of known genes accounts for approximately 10% of vitiligo total risk, and it is thus expected that large GWAS in the near future will complete this picture.

Animal Models. The lack of a tractable experimental animal model has clearly hampered progress of vitiligo research. Nevertheless, the mutant Smyth line of chickens exhibits several relevant clinical features including melanocyte loss as a consequence of T-cell infiltration.[499] Furthermore, the potential contribution of herpesvirus infection to vitiligo induction in Smyth line chickens[500] emphasizes the role of environmental factors and warrants further investigations into this model.

Treatment and Prevention. Routine nonsurgical repigmentation strategies include phototherapy, topical steroids, and inhibitors of the calcineurin pathway. These treatment modalities, while interfering with a multitude of complex pathophysiologic pathways, modulate in particular the activity of local T-cell responses.

Perspective and Conclusion. In addition to genes involved in aberrant immune regulation, more than 120 genes are known to participate in the coordination of mammalian pigmentation. However, the identification of several candidate genes and genetic linkages associated with vitiligo will facilitate the elucidation of biologic pathways involved in vitiligo pathogenesis and allow for a better differentiation of the spectrum of vitiligo disorders. As a result, novel therapeutic and prophylactic approaches will likely be developed in the near future.

Cardiac Autoimmune Diseases

The etiology for primary myocarditis is unclear and an autoimmune cause has to be taken into account. The heart muscle is infiltrated mainly by CD4+ T cells and macrophages, and the infiltrates are usually diffuse and nonfocal. The infiltrating cells produce considerable amounts of INFγ and TNF-α. As a consequence of the inflammation, heart muscle cells can swell, the heart can dilate, and severe disturbances of the electrical conduction can occur. It is noteworthy that myocarditis can also occur in conjunction with certain systemic autoimmune diseases such as SLE, scleroderma, rheumatoid arthiritis, polymyositis, and polyarteritis nodosa. Two specific scenarios are noteworthy, as discussed in the following text.

The first is myocarditis occurring after Chagas disease. In this case, cross-reactivity between antigens presented by the parasite causing Chagas disease (*Trypanosoma cruzi*) and cardiac myosin has been found in patients with myocarditis (Kalil JCI). The scarcity of parasites in the chronic phase of the disease contrasts with the severe cardiac pathology observed in approximately 30% of chronic patients and suggested a role for autoimmunity as

the origin of the pathology. In these cases, various *T. cruzi* antigens, such as B13, cruzipain, and Cha, cross-react with host antigens at the B- or T-cell level, and their role in pathogenesis has been widely studied. Immunization with those antigens and/or passive transfer of autoreactive T lymphocytes in mice leads to clinical disturbances similar to those found in patients with Chagas disease. On the other hand, the parasite is becoming increasingly detected in chronically infected hosts and may also be the cause of pathology either directly or through parasite-specific mediated inflammatory responses. Thus, the issue of autoimmunity versus parasite persistence as the cause of Chagas disease pathology is hotly debated among many researchers in the field.

The second is coxsackie B virus-associated myocarditis. Also in this situation, immunopathology outlasts the direct presence of the virus in heart muscle. This disease has been extensively studied in experimental models by Rose et al.[500a] They developed two murine models of myocarditis, one elicited by cardiotropic coxsackie B3 virus infection and the other by cardiac myosin immunization, to better analyze the pathogenetic mechanisms responsible for immune-mediated heart-muscle disease. Both virus infection and myosin immunization produce myocardial inflammation and elicit heart-reactive antibodies that bind to the myocardium in vivo and which recognize the cardiac myosin heavy chain. Each model offers unique advantages. The virus-induced disease more closely resembles human myocarditis; myosin immunization isolates the autoimmune components of the disease because no virus infection is involved. They also distinguished strains of mice resistant to autoimmune myocarditis (such as B10.A) from those susceptible to the autoimmune phase of disease (such as A.CA and A/J). Mice from a resistant strain to virus- or myosin-induced autoimmune heart disease develop myocardial inflammation and myosin antibodies if cotreated with TNF-α or IL-1 when infected or immunized. Thus, cytokines can modulate the outcome of cardiotropic virus infection and enhance its autoimmune sequela. They also found that blocking IL-1R inhibits autoimmune myocarditis in genetically susceptible mice. Interestingly, there is no regulatory function of Th2 cytokines such as IL-4, illustrating that immune regulation is an organ specific concept rather than a global paradigm applicable to all autoimmune disease equally.

Rheumatoid Arthritis

Although RA is commonly classified as a systemic autoimmune disease (although it electively affects joints), we believe that RA offers insights and paradigms that are important for understanding organ-specific diseases such as T1D and MS. A particularly interesting aspect is that diagnostic or therapeutic access to the target organ is comparatively easily achieved facilitating comparatively, and that this has facilitated the development of rational and highly effective immunotherapies. In this case, high levels of TNF-α were detected in affected joints and TNF blockade has now proven to be a highly effective intervention in RA (see more detailed description in the following text).

Introduction and Disease Description

RA is a severe debilitating disease with unknown etiology. Epidemiologically, the prevalence is about 1% in the overall population, women are affected three times more frequently than men, and the peak of incidence is within the fourth and sixth decade of life.[172,501] Diagnostic criteria are the typical morning stiffness, joint swelling with fluid accumulation,

defined radiologic changes, subcutaneous rheumatic nodes, and positive rheumatoid factor (autoantibodies) (Fig. 44.15). The prognosis is worse in HLA-DR4-positive patients and, similar to diabetes and MS, there is genetic

linkage with certain MHC haplotypes. Recent advances by GWAS have added numerous non-HLA-associated disease genes, a list too long to include here (recently reviewed in Suzuki et al.[502]). Many important immunity genes, such as CTLA-4, PTPN22, and IL-2Rβ, were identified that have been found in other autoimmune conditions, in addition to genes involved in nonimmune-related pathways. One notable example in the latter category is PADI4, coding for a protein that converts the arginine residue (peptidyl arginine) to the citrulline residue (peptidyl citrulline) in a process called citrullination. Peptidyl citrulline is targeted by a class of autoantibodies in RA that have high diagnostic value, and this protein conversion is influenced by smoking. Interaction between PADI4 polymorphisms and smoking was repeatedly reported and thus offers a link between this important environmental determinant and genetic constitution of the host. Without systemic immunosuppressive or anti-inflammatory therapy, the disease will eventually result in destruction of many major joints and immobilize the patient. The major cause of death is infections that easily take a more severe course in immobile individuals.[172]

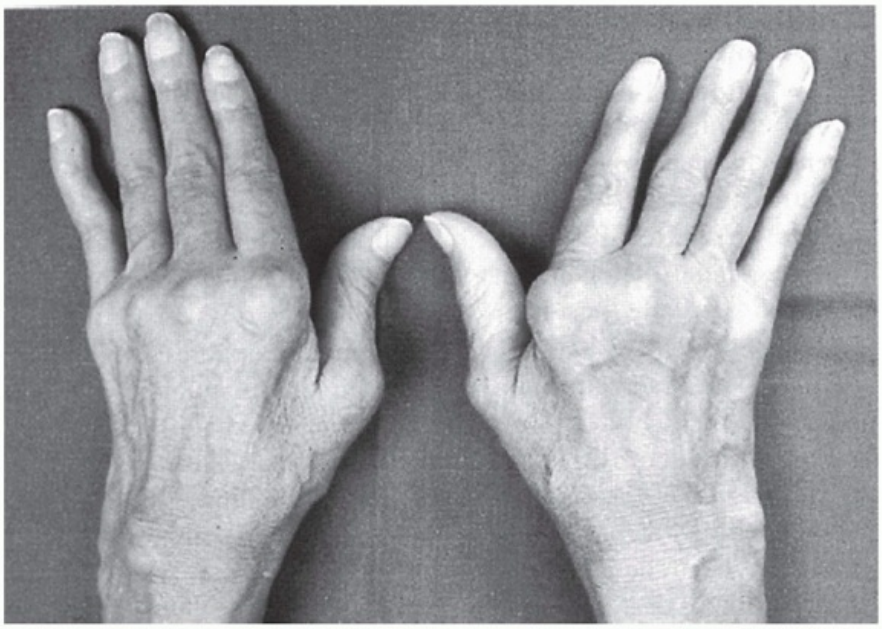

FIG. 44.15. Rheumatoid Arthritis. Typical ulnar deviation and swan's neck deformation of the hands in rheumatoid arthritis.

The etiology of RA remains ill-defined. As there is a possible overlap between infection-associated arthropathies (eg, Reiter syndrome), bacteria have always been good candidates as a cause for arthritis, and molecular mimicry has been suggested as a cause, as cross-reactivities of autoantibodies between self-protein and bacterial proteins have been detected.[123] However, while it is quite possible to demonstrate cross-reactive antibodies and T cells in human blood, proof of their pathogenetic involvement is exceedingly difficult to

obtain. The immune system is likely to have developed to tolerate a low level cross-reactivity, which might be necessary for its proper function, and it remains difficult to prove a mechanistic link between autoreactive cells and pathologic autoimmunity in humans.

Autoimmune Features

The evidence that RA is an autoimmune disease stems, as in the case of MS and T1D, from the observation that T lymphocytes in a patient's blood can react with joint-derived autoantigens and that IgM autoantibodies, as well as ANAs, are readily found in humans.[503] Inflammatory signs in the serum include complement activation and increased erythrocyte sedimentation rate, which indicates that the antibodies could possibly play a role in the disease process. Similarly, immunization with collagen can induce arthritis in susceptible mouse strains (Fig. 44.16). Figure 44.17 summarizes the major pathogenetic pathways leading to progressive joint destruction. As in many other autoimmune disease animal models, collagen-induced arthritis models require strong immunization with autoantigens and adjuvant, supporting the concept that breaking of self-tolerance, even on a genetically susceptible background, requires a rather pronounced inflammatory stimulus. In contrast, how disease is initiated in humans is unclear. The immunopathogenesis of RA has been redefined since the discovery of the Th17 lineage, which is now firmly established as a principal instigator of joint inflammation in animal models and has been repeatedly found in joints from affected patients. Current treatment modalities were generally developed based on the classification of RA as a prototypical Th1-driven condition. Potential future treatments, including anti-IL-17 and anti-IL-6 therapy, may be effective by dampening this Th17-driven disease component.

Treatment and Prevention

Treatment of RA was historically regarded as a difficult task because the medications that adequately suppress joint inflammation also had strong systemic side effects. Therefore, a delicate balance between different therapeutic approaches that target different stages of the inflammatory process needs to be established. Corticosteroids and nonsteroidal anti-inflammatory drugs can provide some baseline relief but are not able to halt progressive joint destruction. Gold compounds, methotrexate, and cyclophosphamide are more effective but also have profound systemic side effects. For this reason, progress with novel immunomodulatory interventions is of important benefit for patients with RA.

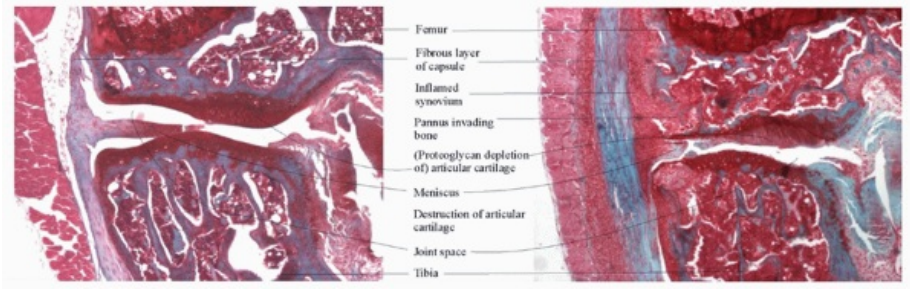

FIG. 44.16. Immunopathology of Collagen-Induced Arthritis in Mice. All features that are characteristic to rheumatoid arthritis can be found in sections from knee joints,

here stained for proteoglycans with Safranin O. *Left* is a joint from a healthy control animal, while *right* is from a mouse with full-blown arthritis. Both inflammation and structural damage to cartilage and bone are evident.

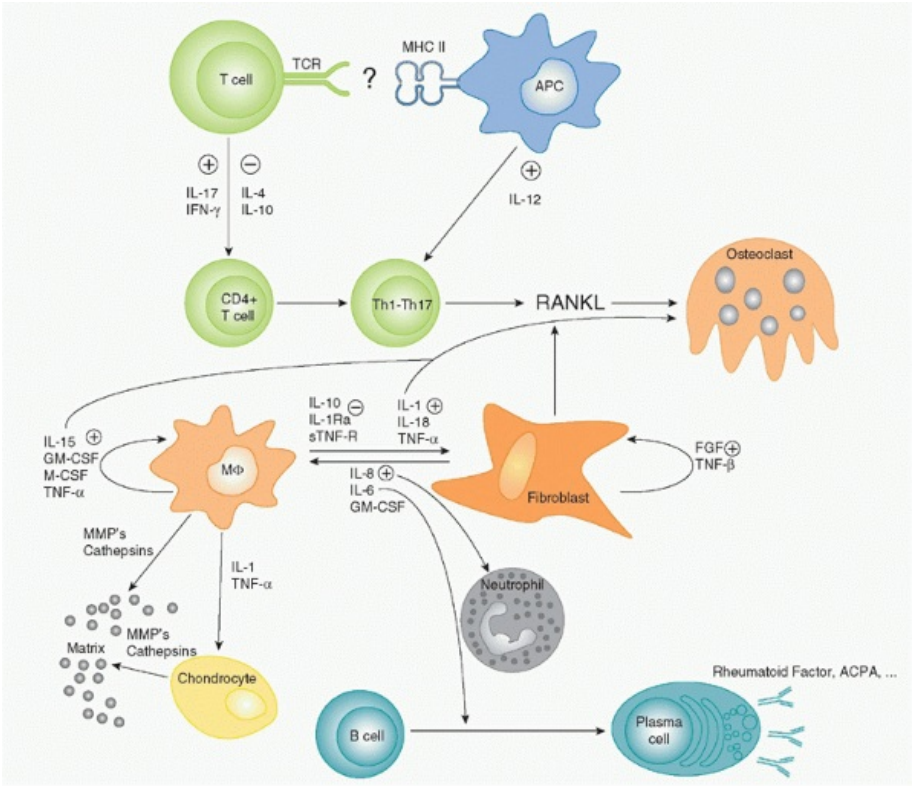

FIG. 44.17. Pathogenic Pathways Leading to Joint Destruction in Rheumatoid Arthritis (RA). T cells are thought to be essential in the etiology of RA, but it is unknown what triggers their activation. Once activated, T cells are skewed to a helper T (Th)1 or Th17 phenotype and release factors such as RANKL that activate bone resorption through osteoclasts. Macrophages are major effectors and are believed to account for the high levels of tumor necrosis factor (TNF) found in rheumatoid synovial tissue, resulting in cartilage destruction via effects on chondrocytes. Finally, pathogenic antibodies are produced such as rheumatoid factor as a consequence of B-cell activation. Note that the introduction of biologics such as anti-TNF, cytotoxic T-lymphocyte antigen-4Ig or anti-cluster of differentiation 20 intervene at distinct levels within the pathogenic process.

Application of cyclosporin A was shown to be effective by suppressing proliferation and activation of T lymphocytes. A more selective intervention has also been established based on research by Feldman et al.[171] TNF-α was found to play a key role in an in vitro model of synovial destruction using human cells, and numerous TNF-α blocking agents were subsequently developed. After promising preclinical results in animal models, this intervention was tested in clinical trials and is now licensed for treatment of RA and many other autoimmune conditions, as discussed previously. Although side effects do occur, as expected,

they appear tolerable and clinical improvement of disease is pronounced, although not all patients respond to treatment. In some patients, SLElike symptoms were observed, indicating that blocking a cytokine beneficial for one autoimmune disorder might be detrimental for another one. Indeed, TNF blockade appears to be less effective in MS because this cytokine exhibits complex dual functions depending on the disease stage. In T1D, a small trial did suggest some effectiveness, although animal models previously indicated that time of administration crucially dictated outcomes in terms of β cell preservation.[504] Based on the success story with TNF blockade in RA, and more particularly the approach of determining the dominant cytokine(s) locally at the target site, it may

be possible to find similar key cytokines for T1D or MS treatment. It should be stressed that the successful intervention was developed based on human cell cultures and not on animal models, underlining the need for direct research on human materials, if and when possible. Other strategies based on therapeutic antibody blockade such as CTLA-4Ig, anti-IL-1, and anti-CD20 adminstration have recently expanded the therapeutic arsenal for RA and in combination have led to dramatic improved life quality of patients with RA. It is also well established that anti-TNF biologics are the first to halt structural joint damage, a feat not achieved by any of the earlier generation disease-modifying antirheumatic drugs. Future improvements likely lie in this aspect of disease, which principally accounts for long-term disability in RA. Finally, high hopes were raised by the successful trials with Janus kinase inhibitors, which are small molecular compounds that can be orally administered and act at signaling pathways common to a variety of cytokines.

Scleroderma (Systemic Sclerosis)

Introduction and Disease Description

The term scleroderma, also known as systemic sclerosis (SSc), is derived from the Greek words *skleros* (hard) and *derma* (skin). Apart from thickening and tightening of the skin, this chronic condition often involves damage to internal body organs. The skin thickening in patients with SSc typically starts with the fingers and can proceed to affect the whole body. The thickening results from vasculopathy and sclerosis or stiffening of structures due to an increased collagen content of the connective tissue.[505] Depending on the degree of skin thickening, SSc can be divided into limited SSc (vascular and/or SSc-associated antibodies but no skin involvement), limited cutaneous SSc (typically involving forearms, hands, legs, feet, and face) or diffuse SSc (can affect almost any area of the body).[506,507] SSc is a relatively rare disorder—about 20 new cases are diagnosed annually per million in the Unites States—which primarily targets adult women.[508] While symptoms may initially be rather benign, serious complications can develop over time and may involve various organs such as the gastrointestinal tract, lung, kidney, heart, and musculoskeletal system.

Autoimmune Features

The pathophysiology of SSc is thought to have a vascular, immunologic, and fibrotic component.[505] A prominent diagnostic marker in SSc is the presence of ANAs while also nonnuclear antibodies such as antifibrillin and anti-MMP-1/3 are commonly found.[509] B cells in general seem to have a chronically activated phenotype,[510] while an oligoclonal T-cell

subset has also been found in skin lesions.[511] The fibrotic aspect is caused by the overproduction of cellular matrix by activated fibroblasts, which in turn induces contraction of the affected tissue.[512] The vascular component encompasses reversible vasospasms (as in Raynaud phenomenon) as well as structural changes in vessel architecture sometimes leading to obliteration of the vessel lumen. The elevation of endothelium-derived serum factors in SSc such as von Willebrand factor and endothelin-1 but also circulating endothelial cells point toward the existence of vascular abnormalities.[513,514,515] Moreover, vasculogenesis appears to be impaired in SSc.[516] It is still largely unresolved how these three mechanisms act in concert to culminate in the characteristic SSc disease phenotype.

Genetic Features and Environmental Factors

Family history constitutes a strong risk factor for SSc, although the low disease concordance rates in twin studies suggest that environmental factors play a role.[517] The advent of GWAS has offered more robust datasets in recent years and has added new susceptibility loci.[518,519] In accordance with our present understanding of the pathophysiology of SSc, the associated polymorphisms can be categorized in relation to either immunity, fibrosis, or vascular disease (Table 44.5). Possible environmental factors that may act in concert with a susceptible genetic constitution include viral or bacterial

agents,[520] vitamin D levels,[521] and a wide host of occupational factors.[522] The vast range of potential interactions between the many susceptibility genes and environmental factors may account for the disease's notable heterogeneity.

TABLE 44.5 Systemic Sclerosis Susceptibility Genes Organized According to Possible Involvement in One of Three Pathophysiologic Pillars of the Disease

Immunity	Vascular Disease	Fibrosis
Transcription factors	*Angiogenesis*	*Fibroblast proliferation, ECM production*
STAT4; TBX21; IRF5	CXCL12; VGEF	CTGF
Lymphocyte (co-)stimulation	*Vascular integrity, survival*	*Platelet aggregation*
CD247 (CD3ζ); CD226; TNFSF4 (OX40L)	CD105; HIF1A	Serotonin 5-HT2A receptor

Phospatases/kinases	*Vasoconstriction*	*Fibrogenic phenotype*
PTPN22; BLK	ACE; eNOS and iNOS; ET-1 and receptors	IL-1α/β
B cell-specific scaffold protein	*Voltage-gated K+ channel*	*ECM degradation*
BANK1	KCNA5	MMP
Ubiquitin-modifying enzyme	*GPI-anchored surface receptor*	
TNFAIP3	CD87	
Apoptosis	*Blood clotting*	
FAS	Fibrinogen	

CD, cluster of differentiation; CTGF, connective tissue growth factor; ECM, extracellular matrix; FAS, TNF receptor superfamily, member 6 or CD95; GPI, glucose-6-phosphate isomerase; IL, interleukin; MMP, matrix metalloproteinases; TNF, tumor necrosis factor; VGEF, vascular endothelial growth factor.

Principal gene type/function is listed but does not exclude other functions in systemic sclerosis. References to all original studies can be found in Romano et al.560

In italics: gene category according to function. Regular text: respective genes within this category related to sclerosis.

Animal Models

Multiple genetic and inducible animal models each cover some of the three aspects of SSc to a varying degree (see the excellent review in Beyer et al.[523]). We mention here three examples that demonstrate the partial spectrum of SSc characteristics mimicked by each model. A widely used inducible model is the bleomycin-induced skin fibrosis model. This

compound, originally isolated from *Streptomyces verticillus*, induces skin fibrosis localized to the injection area after repeated injections.[524] The model mimics the inflammatory changes in SSc that are thought to occur early in the disease course, usually before a patient seeks medical care. It is therefore useful for preclinical evaluation of therapeutics that target inflammation or early-stage cutaneous fibrosis. An obvious disadvantage is that fibrosis is restricted to the injection site, while SSc in humans typically presents as a systemic disease involving both skin and internal organs. Furthermore, vascular phenomena as seen in patients with SSc are absent, which is a serious shortcoming.

One of the genetically triggered models is the TSK-1 mouse,[525] where SSc-like skin tightening is caused by a tandem duplication of the fibrillin 1 gene (*Fbn1*).[526] Whereas the homozygous mouse dies before birth, heterozygous TSK-1 mice develop SSc-like disease, with skin fibrosis and autoimmunity. A remarkable parallel with human disease is the occurrence of autoantibodies against SSc-specific antigens (eg, topoisomerase I). The excessive release of extracellular matrix proteins by activated fibroblasts underlies the fibrosis seen in these animals. These mice do lack a vascular phenotype and are commonly used to study later stages of SSc associated with low inflammation.

One mouse model that does display characteristic SSclike microvasculopathy but lacks autoimmune phenomena is the *Fra2* (Fos-related AP1 transcription factor) transgenic mouse, which expresses Fra2 under the control of a class I MHC antigen promoter.[527] These examples serve to highlight the notion that a perfect SSc model does not exist, but rather that several models can be chosen to study one or more of the three pillars underlying the disease.

Treatment and Prevention

At present, most therapeutical approaches are organ-based, while systematic treatment modalities aimed at the vascular and inflammatory component may also be used. Drugs such as metothrexate (skin involvement[528]), cyclophosphamide (interstitial lung disease[529]), or dihydropyridine calcium blockers (Raynaud phenomenon[530]) have proven efficacy but clearly offer incomplete protection. No effective therapies, however, exist today that effectively block the fibrotic aspect.

Systemic Lupus Erythematosus

Introduction and Disease Description

SLE is a systemic autoimmune disease sometimes referred to as the “great imitator.” The wide array of clinical manifestations includes skin rashes, photosensitivity, oral ulcers, arthritis, pleuritis, pericarditis, kidney problems, neurologic symptoms, and hematologic abnormalities.[531] Clinical course is typically of the relapsing-remitting type. As a consequence, the disease is notoriously difficult to diagnose, and adequate treatment ideally involves a team approach due to the number of organ systems involved. SLE affects up to 10 times more women than men while estimated incidence ranges widely, likely due to inconsistencies in diagnosis, from 1.8 to 7.6 cases per 100,000 persons per year in the United States.[531a] Hormones are suspected to codetermine disease and thus account for the increased prevalence of SLE among women. Patients commonly present with general complaints such as malaise, fatigue, fever, or weight loss, and a correct diagnosis critically

depends on careful history and physical examination combined with appropriate laboratory testing.

One of the most characteristic skin manifestations is the “butterfly” rash, which shows a malar (across the cheeks) distribution and often develops in response to sunlight exposure. Arthritic symptoms are in fact the most common manifestation of SLE, affecting mostly the small joints of the hands, wrists, and knees but may involve any joint. Renal involvement is considered the single most common cause of morbidity and represents a major cause of mortality in SLE. Of particular diagnostic importance in SLE are autoantibodies against intranuclear nucleic acids, proteins and ribonucleoprotein complexes, commonly known as ANAs (see the next section). A general ANA test is performed by incubation of the patient's serum with a fixed, permeabilized cell line followed by fluorescently labeled antihuman IgG detection antibody. Specific autoantibodies that are associated with SLE and are used for diagnosis include anti-dsDNA, anti-Smith (part of small nuclear ribonucleoproteins), anti-U1-ribonucleoprotein, anti-Ro/SSA (largely unknown location and function), and anti-La/SSB (a nuclear phosphoprotein). This list is not exhaustive, and it has become clear that SLE sera contain antibodies against extranuclear components also, such as antiribosomal antibodies and various cell membrane components. None of these antibodies, however, represents a reliable diagnostic tool that covers the entire spectrum of SLE manifestations. Anti-Smith, for instance, is highly specific but is detected in only 10% of Caucasian patients with SLE.

Genetics

As expected from the heterogenous disease phenotype, genetic predisposition in SLE is extremely complex. Before the GWAS era, only a limited set of genes were known to be associated with SLE. As in most autoimmune diseases discussed here, HLA genes contained SLE-associated polymorphisms in addition to genes involved in the complement cascade (C2, C4), Fcγ receptors (FCGR2A, FCGR3A), B-cell differentiation (PDC1), a tyrosine phosphatase (PTPN22), and factors involved in cytokine signaling (TNF-α, IRF5).

At the time of writing, the combined results from seven GWAS are published, drastically adding to the number of SLE genes. While a complete summary of all associations is beyond the scope of this chapter (there is a full list in Sestak

et al.[532]), it can be concluded that many aspects of SLE genetics show overlap with other autoimmune diseases. For instance, the SLE susceptibility genes BANK1, BLK, IRF5, PTPN22, and STAT4 are all included in Table 44.5 detailing the genetic landscape of systemic sclerosis, while most are well-known autoimmune genes found in several other autoimmune conditions (eg, PTPN22, STAT4, and the HLA genes). Overall, the genetic data indicate that SLE results from interference with a diverse array of pathways such as antigen presentation, clearance of apoptotic material and immune complexes, immune cell function, innate immunity, cytokines, cellular energy machinery and leukocyte/endothelial adhesion, lymphocyte signaling, IFN response, complement activation, and apoptosis. Therefore, it remains to be seen to what extent this wealth of data will translate to conceptual and in particular translational insight. Although it is interesting to see that some of the usual suspects underlie SLE genetics, it is hoped that a thorough genetic understanding will explain which specific gene set provokes the SLE disease phenotype.

Autoimmune Features

A myriad of immunologic mechanisms is thought to underlie SLE, mirroring the disease's complex genetic and phenotypic profile (Fig. 44.18). How all these individual immune pathways culminate in clinical SLE is still unclear, and it is anticipated that different combinations of mechanisms might affect individual patients. As in many other autoimmune disorders, inadequate thymic selection is hypothesized to be responsible for the release of naive autoreactive T and B cells into the periphery.[533] What triggers their activation is still elusive, although support for some of the environmental factors mentioned before exists. The Epstein-Barr virus, for instance, has received a considerable degree of attention, and higher loads were found in patients with SLE in comparison with controls.[534] Molecular similarities between the Epstein-Barr virus nuclear antigen 1 and the common lupus autoantigen Ro were identified, fueling speculation about the role of mimicry in SLE.[535] A feature that further confounds our interpretation of the disease is the existence of autoantibodies up to 10 years prior to disease onset. Thus, whatever the inciting antigen may be, it is likely that the immune system generally encounters it long before presentation of clinical symptoms.[536]

Altered T-cell signaling of potentially autoreactive T cells may then lead to a lower activation threshold (ie, a relatively weak signal from presented self-antigen suffices to trigger activation). T cells are thought to be directly responsible for increased levels of proinflammatory cytokines, notably IL-17, which is found in the blood and kidneys of patients with SLE. Another notable feature is a reduced ability of the T cells to secrete IL-2, which could be the cause of an impaired T_{reg}-cell compartment or reduced activation-induced cell death followed by increased longevity of autoreactive effectors.

Increased turnover from B cells to plasma cells is a hallmark and is a consequence of their encounter with self-antigen in the presence of T-cell help.[537] Follicular Th cells are a specialized subset important in the formation of germinal centers and development of T cell-dependent B-cell responses. Emerging evidence underscores the potential pathogenic role in the germinal centers during SLE development. Plasma cells in turn produce autoantibodies that upon binding to self-molecules cause activation of the complement cascade. A first wave of apoptotic cell death is thought to be ineffectively cleared by macrophages leading to the presentation of intracellular self-antigens instead of the default pathway of “silent” removal. This process leads to variable patterns of “antigen spreading” and subsequent rounds of uncontrolled apoptosis. Other innate cell types such as dendritic cells further augment inflammation by type I IFN release and upregulation of activation markers. In addition, surface markers such as CD44 that are important in homing appear to be altered on T cells, leading to increased migration to sites of inflammation.

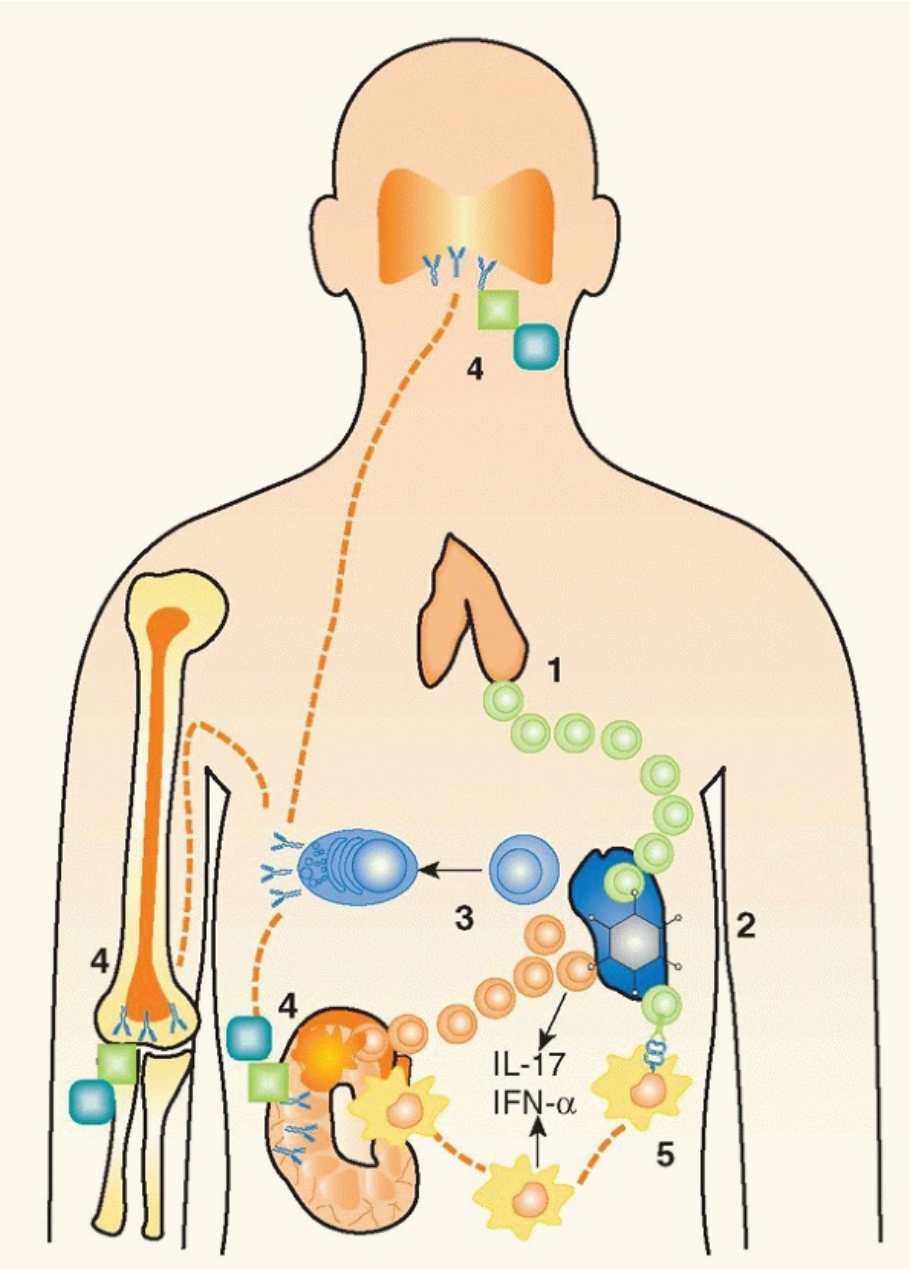

FIG. 44.18. Pathogenic Immune Mechanisms in Systemic Lupus Erythematosus. **1:** As in many autoimmune diseases, defective thymic selection is thought to contribute. **2:** Naive autoreactive cells reach the periphery and are activated by an unknown stimulus, possibly virus. **3:** These activated T helper cells in turn aid in generating plasma cells that produce copious amounts of autoantibodies. **4:** These autoantibodies bind components in various organs, here shown as joints, skin, and kidney. Complement activation and tissue inflammation initiates. T cells and other leukocytes may also infiltrate. **5:** Due to inadequate processing of apoptotic cells, a new round of autoimmunity is initiated by antigen presentation.

Animal Models

We will, without being exhaustive, discuss here two spontaneous and two induced mouse models that have been

instrumental in delineating SLE pathophysiology (see full reviews in Kippel and Dieppe,[531] and Perry et al.[538]). Numerous genetically modified strains were found to exhibit some SLE-like features and are thus informative in the identification of gene function but are not commonly used to study SLE per se.

One of the most widely adopted models is the New Zealand Black/White F1 mouse. This strain originates from a cross between the New Zealand Black and New Zealand White strains, of which only the former develops mild clinical signs of autoimmunity. The F1 hybrids, however, display a lupus-like phenotype including B-cell hyperactivity, development of ANA, and immune complex-mediated glomerulonephritis around 5 to 6 months of age. Mice typically suffer kidney failure and die around 10 to 12 months of age. As in humans, the disease develops more frequently in females and is hormone dependent. Extensive genetic analysis has been performed on related inbred strains that resulted from accidental backcrossing (New Zealand mixed strains) and led to the identification of multiple susceptibility loci. Several of these were also identified in human SLE subjects, including MHC class II alleles, Fcγ receptors, and components of the complement system.

The MRL lpr/lpr strain is another spontaneous model that develops massive lymphadenopathy, high concentrations of autoantibodies such as ANAs, anti-dsDNA and anti-Sm, and renal disease. In this strain, both males and females are equally affected. The *lpr* mutation interferes with expression of the Fas receptor (CD95), an important mediator of apoptosis. As discussed previously, defective apoptosis may in part underlie SLE in humans, and it is known that aberrant Fas signaling can lead to the development of autoimmune lymphoproliferative syndrome, which shares many symptoms with SLE.

SLE-like symptoms can be induced by the repeated injection of pristine, a compound found in mineral oil. These features include the development of ANAs, immune-complex deposition, and severe disease of the kidneys. This model can be reproduced in most mouse strains, although the extent of susceptibility varies. In strains such as the SJL/J mouse, females are more prone to disease development.

Alternatively, some aspects of SLE can be mimicked by the experimental induction of graft-versus-host disease. Disease aspects consist of lymphoid hyperplasia, formation of ANAs, and development lupus nephritis leading to severe kidney dysfunction and mortality. Only certain strains are prone to induction, once again illustrating the requirement for a genetic contribution in addition to an environmental stimulus. Disease severity can be tailored by adjusting the number of allografted cells, and onset occurs from a known starting point relative to injection. ANA sare usually detectable only 2 weeks after injection, which makes it a suitable model for the more rapid assessment of pathogenic pathways and experimental therapies.[539]

Therapy

The multiorgan nature of the condition and its course of relapses and remissions dictates that therapeutic management is in accordance with disease activity. In addition to diverse clinical scoring systems, active disease often correlates with altered levels of immune markers such as increased antidsDNA and decreased serum complement. Nonsteroidal anti-inflammatory drugs are prescribed to treat musculoskeletal symptoms or SLE-associated fever. Acute symptoms are generally treated by some form of corticosteroid treatment, either topical in

case of cutaneous flares or injected when major organ disease develops. Immunosuppressive agents such as azathioprine are used mostly when major organ disease threatens to considerably worsen the patient's condition. The antimalarial agent hydroxychloroquine is known to ameliorate disease by inhibiting the function of TLRs. It is thus clear that, in line with the disease's protean pattern, no disease-specific treatment options exist, and that the therapeutic goal often is to prevent where flares where possible (eg, avoid sun exposure) and tackle them in a symptomatic fashion as they occur. Since the approval of an antimalarial and corticosteroids for treatment of SLE in 1955, no new agents have been introduced.

After more than 50 years and many failed trials, the U.S. Food and Drug Administration finally approved a new drug for SLE. Belimumab (marketed as Benlysta® [GlaxoSmithKline, Brentford, UK]) is a fully human monoclonal antibody that binds to soluble human B-lymphocyte stimulator and inhibits its biologic activity.[540] B-lymphocyte stimulator was shown to be a key survival cytokine for B lymphocytes which, as argued previously, are a major pathogenic immune subset in SLE. In patients with SLE, B-lymphocyte stimulator concentrations reflect disease activity and correspond with anti-dsDNA antibody titers.[541,542] It was found that the drug selectively decreases B-cell numbers and shortlived plasma cells as well as SLE-associated anti-dsDNA antibody titers.[543] In two phase III trials that had enrolled patients with serologically active disease, a modest clinical effect was demonstrated combined with a safety profile similar to that of placebo.[544] It was argued that both inclusion criteria (patients with SLE activity that actually stands to be improved) and optimized disease-assessment indices contributed significantly to the successful outcome of these studies.[545] Initial studies with a humanized anti-CD22 monoclonal also had an encouraging initial outcome, further corroborating the idea of B cells as a suitable target cell in SLE.[546] The fact that not just any therapy that targets B cells has therapeutic potential was underscored by two recent phase III trials that failed to show efficacy of rituximab (anti-CD20) in SLE.[547,548] These recent advances, however, represent a glimmer of hope for patients affected by this particularly heterogenic and pathophysiologically complex condition.

CONCLUSION

A common trait among diverse animal models for autoimmune diseases and the human conditions they aim to model appears to be the difficulty with which experimental autoimmunity is achieved. Breaking of tolerance to self-antigens requires in most instances strong inflammatory (eg, pertussis toxin and adjuvant in EAE or collagen-induced arthritis) or infectious (eg, RIP-LCMV model for T1D or TMEV/mouse hepatitis virus models for MS) stimuli. In addition,

many animal models require a genetically susceptible background or have to rely on artificial autoantigen expression by means of transgenic technology. In contrast to the relatively easy detection of autoreactive lymphocytes in antigeninduced animal models, it has been a daunting endeavor in humans (as well as spontaneous disease models such as the NOD mouse) and data obtained frequently vary considerably between different patients as well as laboratories. What are the implications for our understanding of autoimmune diseases in humans given these challenges?

First, it is unlikely that strong inflammatory stimuli can be provided under natural conditions in the absence of infectious disease. Thus, viral and bacterial infections remain prime candidates for causing secondary autoimmunity (see Miller TMEV model of APC-mediated determinant spreading to autoantigens). Infectious pathogens can provide the "danger signals"[548a] needed for propagation of extended inflammation leading to clinical disease. Nevertheless, proof of a causal relationship is exquisitely difficult (if not impossible), as traces of pathogens detected may have no relation to the underlying disease process or may be cleared from the system by the time of secondary clinical disease. In addition, disease is likely dependent on individual pathogen strains, making a very detailed immunologic profiling in prospective clinical trials necessary. It is possible that the introduction of new antivirals might unmask such an association in the future. Finally, the importance of the gut microbiome has attracted some attention in the context of autoimmune disease.[549] This is not unexpected because the gut harbors the major part of our immune system, and immune tolerance can often be induced by passage of an antigen through the gastrointestinal system. We now have gained a more precise view on the vast diversity of commensals inside our bodies,[550,551] and it appears that this composition affects the likelihood of a genetically susceptible subject to develop autoummunity.[261] For instance, generation of the pathogenic Th17 subset described previously in many autoimmune conditions critically depends on the composition of microbiota.[552]

Second, a genetically susceptible background will likely be required to provide a "fertile field" for initiating a chronic inflammation involving autoantigens. This probably occurs via a multifaceted network of multiple susceptibility and protective genes, and it will be impossible to treat a respective disease just by analyzing the background genes involved. Last, autoreactive lymphocytes might predominantly be present in the affected organ or site and not in the peripheral blood, which makes their identification and characterization in humans rather difficult.

A word of caution should be devoted to our interpretation of specific findings obtained in individual animal models. Animal models should serve to teach us paradigms of how a disease *could* develop kinetically in vivo. The precise parameters, targeted antigens, susceptibility genes, and effector molecules may be considerably different in humans. Thus, for example, if there is indication that insulin is a primary antigen in the NOD mouse, this may or may not have direct relevance to the human disease. Some evidence exists that leads us to believe that insulin, indeed, maybe also a primary antigen in human autoimmune diabetes, but other antigens such as GAD might also play a role. The opportunities as well as limits of each animal model have to be delineated. Again, the NOD mouse appears to be prone toward multiorgan autoimmunity (induction of EAE,[553] neuritis,[554] arthritis, and hepatitis have all been observed in NOD or NOD-congenic mouse strains) and exhibits, in addition to diabetes, thyroiditis, sialitis, and orchitis. Thus, diabetes in the NOD mouse is clearly different from typical human T1D. Therefore, treatments capable of correcting the systemic immune dysregulation that predominates in the NOD model may not directly apply to human T1D where no such pronounced systemic dysregulation is present. Based on these considerations, it is not surprising that out of the more than 140 therapeutic strategies that prevent diabetes in the NOD mouse, only a handful have made it to phase I human trials. An appealing solution that has shown promise in T1D epitope discovery is the development of humanized NOD mice expressing HLA class I transgenic molecules for antigen presentation.

Remarkably, several of the islet epitopes that become targeted under these conditions correspond to the disease-associated specificities found in peripheral blood mononuclear cells from patients with T1D.[555] When those epitopes are administrated in a tolerogenic fashion, the disease course can be significantly altered.[556] While still animal data in principal, these results may have higher translational value when tolerogenic strategies are to be envisioned for humans. Experiments with human cells or materials should be undertaken in order to solidify the choice of molecules or target antigens. The successful story in respect to blockade of TNF-α to treat RA underlines the importance of this step. Employment of a multiplicity of models thus becomes imperative to evaluate potential candidate interventions, as does a careful proceeding, objective evaluation, and avoidance of premature conclusions. In addition to the researchers and clinicians, publishers as well as news media will have to share this responsibility. Continued research will undoubtedly provide us eventually with sufficient insight into the complexities of autoimmunity and autoimmune disorders, but patience and perseverance coupled with experimental objectivity will be required.

Therapeutic progress remains variable using monoclonal antibodies to dampen autoimmune processes in humans. Succesful examples include anti-TNF, CTLA-4Ig, anti-CD20, and anti-IL-1 treatments, while a highly anticipated non-Fc binding anti-CD3 antibody recently failed to clear phase III trials in recent-onset T1D.[557,558] As discussed previously, many of the successful therapies have also shown efficacy in a diverse array of other autoimmune diseases such as in psoriasis, Crohn disease, RA, MS, and uveitis. Thus, the road map to therapeutic success might lie in a well-tuned combination of such therapeutics, likely in conjunction with autoantigenspecific approaches that mediate more long-term and lasting tolerance. Augmentation of adaptive as well as intrinsic T_{reg}s might be, in the end, the key for achieving site-specific tolerance (involving bystander suppression of effector responses and “infectious” induction of more T_{reg}s) and is being explored with encouraging developments in many preclinical models.

Chapter 45

Immunologic Mechanisms of Allergic Disorders

Marsha Wills-Karp

Ian Lewkowich

INTRODUCTION

This chapter will provide an overview of our current understanding of diseases gathered under the rubric of "allergy." These diverse diseases (anaphylaxis, asthma, allergic rhinitis, atopic dermatitis, food allergy) are united at least superficially by the facts that a) these conditions all result from the expression of harmful immune responses; b) the implicated immune responses are all associated with the generation of immunoglobulin (Ig)E (whether or not IgE is integral to pathogenesis); and c) the antigens driving such immune responses are not derived from infectious pathogens. The basic cellular and molecular mechanisms that underlie the pathogenesis of allergic disorders, as well as the environmental and genetic substrates for their generation, will be closely considered. Although the study of allergic diseases has focused on the adaptive immune response in the last decade, in the period since the last edition of this book, the focus has shifted to dissecting the role of innate immune mechanisms in regulating susceptibility to the development of aberrant immune responses in allergic diseases. Thus, this edition will reflect this change in perspective when possible. Although much of our current understanding of mechanism in allergic disease has derived from the study of animal models, mechanistic data on human disease will be discussed wherever possible. The chapter finishes with a brief survey of the clinical and therapeutic characteristics of the major human allergic disorders. Readers are referred to clinically oriented texts for a fuller discussion of such issues.

HISTORICAL PERSPECTIVE

The term allergy was coined in 1906 by the astute pediatrician Clemens von Pirquet, who argued that antigenic stimuli led to two distinct categories or patterns of response: immunity and allergy.[1] The former, an old concept, referred to those responses leading to protection from infectious challenge. The latter, a novel theoretical construct, referred to "altered reactivity" that itself led to host damage. This idea of allergy, that is, the notion that the immune response can itself be a cause of disease, was a powerful conceptual advance that led to novel insights into the pathogenesis of a variety of diseases. Quite naturally, this concept of allergy initially included autoimmune diseases in addition to those conditions that find classification as allergic diseases today. As noted previously, current usage largely restricts allergy to diseases caused by the subset of harmful immune responses (to pathogen-unrelated antigens) that is associated with the generation of IgE. There is some artificiality to this. Very similar patterns of immune response can drive pathology in response

to infectious pathogens such as tissue helminths. Further, IgE may be more a marker of an underlying pattern of immune response than a mechanistic participant in the immunopathogenesis of at least some subtypes of allergic disease. As long as these caveats are kept in mind, however, this concept of allergic disease long enshrined by clinical subspecialists has considerable theoretical and practical utility.

The trail leading to the specific identification of IgE began with demonstration by Prausnitz and Kuster in 1921 that hypersensitivity to an antigen could be passively transferred in serum from one individual to another.[2] The instigating antigens (allergens in contemporary parlance) were known as atopens, and the mysterious plasma factor that conferred sensitivity was called atopic reagin. It was not until 1966 that Teruko and Kimishige Ishizaka demonstrated that reaginic activity was carried by a novel class of Ig, IgE.[3,4,5] The word atopy has since come to denote the propensity for developing allergic reactions to common environmental antigens (allergens), a propensity defined operationally by elevations in serum levels of IgE reactive with, or by skin test reactivity to, such antigens. Definitions of other key terms are given in Table 45.1.

General Features of Atopic Disorders

Allergic disorders are categorized by the anatomic site where disease is manifested: atopic dermatitis (skin), atopic rhinitis (nasal passages), atopic asthma (lung), food allergy (gut), and anaphylaxis (systemic) (Table 45.2). These clinical entities all involve a similar allergic effector cascade, at least superficially, with differences in presentation likely reflecting variation in the physiochemical characteristics of the allergen, the site of initial sensitization to the allergen, the route and dose of allergen exposure, and the programmed response of resident cells (eg, epithelial cells) to injury and inflammation. Anaphylaxis aside, there is often a stereotypical sequence in the development of allergic manifestations of disease in patients with atopy, with early expression of food sensitivities or atopic dermatitis and the subsequent development of either atopic rhinitis or asthma. Many individuals will have all three of the latter clinical entities, which form the “atopic triad.”

Atopic disorders represent a major health problem worldwide, affecting 5% to 30% of the population. The incidence of atopic diseases, including asthma, atopic rhinitis, and atopic dermatitis, has increased dramatically in recent

years in westernized countries.[6,7,8] In such countries, 30% of the population manifest some form of atopic disease at some time in their lives. Interestingly, the low baseline level of atopic diseases in developing countries has not changed over the same time period, suggesting that factors associated with the westernized lifestyle predispose to atopic disease. The widespread prevalence and morbidity of atopic diseases imposes a heavy burden on society.

TABLE 45.1 Definitions of Key Terms

Term	Definition
Allergen	An environmental antigen that typically elicits allergic responses in

	susceptible individuals. These antigens ordinarily have little or no intrinsic toxicity.
Allergy	Clinically adverse reactions to environmental antigens reflecting acquired immune responses that are marked phenotypically, by the presence of allergen-specific IgE, along with mast cell and eosinophil recruitment and/or activation. CD4+ T cells that produce a Th2 profile of cytokines (IL-4, IL-5, and IL-13) are thought to be central to the development of allergic responses.
Atopy	The propensity for developing immediate hypersensitivity reactions to common environmental allergens, defined operationally by elevations in serum levels of IgE reactive with allergens or by skin-test reactivity to allergens.
Allergic diseases	The group of clinical disorders (such as allergic asthma, allergic rhinitis [hay fever], and atopic dermatitis) in which IgE-associated immune responses, typically directed against otherwise innocuous environmental allergens, are thought to have a pathogenic role.

CD, cluster of differentiation; Ig, immunoglobullin; IL, interleukin.

The defining feature of atopy is the production of IgE in response to exposure (via muocosa or the skin) to a variety of ubiquitous, and otherwise innocuous, antigens. Such IgE production is a tightly regulated process, part of a complex network of cellular and molecular events necessary for the development of the allergic response. Initiation of this response appears to occur with presentation of the allergen by antigen-presenting cells (APCs) residing in the mucosa to cluster of differentiation (CD)4+ T cells in the draining lymph nodes (a process referred to as sensitization). In atopic individuals, responding allergen-specific T cells polarize to a Th2 pattern of production, with the elaboration of cytokines such as interleukin (IL)-4, IL-13, IL-5, and IL-9 (vide infra). Although T cells from nonatopic individuals clearly recognize these same environmental antigens, the expansion and differentiation of such T cells does not involve Th2-deviation. Instead, it is thought that nonatopic individuals develop “tolerance” to these innocuous environmental antigens. The mechanisms controlling allergen-associated Th2 polarization in atopic individuals or tolerance in nonaffected individuals are not completely understood. It appears likely that genetic and environmental factors impacting on the antigen-presenting process play a key role.

TABLE 45.2 Major Features of Allergic Immune Responses

1. Responses are elicited by certain groups of environmental allergens such as foods, drugs, and proteins derived from pollens, insects (house dust mite), and animal dander.

2. In susceptible individuals, allergens are sensed by a variety of pattern recognition receptors in the mucosal epithelium resulting in the elaboration of cytokines (TSLP, IL-15, IL-33) and chemokines that recruit, activate, and instruct antigenpresenting cells residing in the mucosa of the skin, gastrointestinal tract, or respiratory tract to drive naïve T cells to undergo differentiation to a Th2 cytokine producing pattern.

3. Elaboration of Th2 cytokines (IL-4, IL-5, IL-3, IL-9) initiates the allergic cascade via their combined ability to regulate IgE production, FcεRI expression, mast cell phenotype, and development, recruitment, and activation of eosinophils.

4. Under the control of Th2 cell-derived signals (IL-4, IL-13, and CD40L), B cells undergo class switching to production of the IgE subclass.

5. Upon reexposure to the offending allergen, acute responses occurring within minutes of allergen exposure result from release of preformed mediators (histamine, tryptase) from FcεRI-bearing cells via the cross-linking of allergen and IgE on their surface. Cells activated during the acute phase also release cytokines and mediators that perpetuate the Th2-driven response.

6. Late-phase responses are due to the combined effects of inflammatory cells (eosinophils and T cells) recruited to the tissues within 6 to 24 hours after the initial allergen exposure.

7. Repeated allergen exposures in the context of an already inflamed tissue results in structural changes (remodeling) such as smooth muscle thickening, tissue fibrosis, and mucus cell hyperplasia.

CD, cluster of differentiation; Ig, immunoglobulin; IL, interleukin; TSLP, thymic stromal lymphopoietin.

The elaboration of Th2 cytokines sets into motion a complex series of events leading to IgE production; the development, recruitment, and activation of effector cells such as mast cells, basophils, eosinophils, and effector T cells; and a variety of downstream effector cascades. Once an atopic individual is sensitized, the manifestations of allergy are readily induced upon reexposure to the allergen (the elicitation phase). Although the effector phases of IgE-associated atopic disorders generally appear as a continuum, it is useful to define three temporal patterns: 1) acute reactions (developing within seconds to minutes of allergen exposure), 2) delayed or late reactions (developing hours after allergen exposure), and 3) chronic reactions (developing over days to years). Acute reactions result from cross-linking of high-affinity FcεR (FcεRI) on the surface of mast cells/basophils, induced by the interaction of allergen with cell-bound IgE. Such cross-linking results in the release of vasoactive mediators, chemotactic factors, and cytokines that initiate the so-called allergic cascade. This early reaction may resolve within minutes but is often followed by late-phase responses that begin 3 to 6 hours after antigen challenge and

may persist for days in the absence of therapy. The pathophysiologic consequences of chronic reactions are associated with the migration of eosinophils and lymphocytes from the blood into affected tissues.

ALLERGENS

Definition and General Characteristics of Allergens

Allergens are, by definition, antigens that can elicit specific IgE responses in genetically susceptible individuals. The list of structures that have been identified as allergens represents a tiny subset of the antigenic universe to which humans are routinely exposed. Allergens are generally subdivided by route of exposure and source. Such allergens include aeroallergens (pollens, mold spores, animal dander, fecal material excreted by mites and cockroaches), food allergens, stinging insects, pharmaceuticals, and latex.

Allergen Classification

Purified allergens are named in accordance with guidelines published in 1994 by the World Health Organization International Union of Immunologic Societies Allergen Nomenclature Sub-Committee, based on their source and the order in which they were discovered.[9] The names incorporate the first three letters of the genus and the first letter of the species from which the allergen is derived, plus an Arabic numeral that is used to denote structurally homologous allergens from the same species. For example, the two major species of dust mite (*Dermatophagoides pteronyssinus* and *Dermatophagoides farinae*) are designated as Der p (Der p 1, Der p 2) and Der f (Der f 1, Der f 2). Other major allergens include Fel d 1 from the cat, Bet v 1, from birch pollen, Amb a 1 from ragweed pollen, Phl p 1 from the pollen of timothy grass, and Bla g 2 from cockroach.

Specific Allergens

Aeroallergens

Aeroallergens are airborne proteins or glycoproteins derived from a variety of different sources, including pollinating trees and grasses, mold spores, animal dander (cat, dog, and rodent), and particulates secreted by dust mites and cockroaches. Factors that affect the growth or accumulation of these latter organisms (high humidity, well-insulated homes, fitted carpets) increase the levels of these allergens in the indoor environment. Exposure to such indoor allergens is also dependent on a variety of geographical, climatic, and socioeconomic factors. Interestingly, whereas indoor allergens are more closely associated with development of asthma, outdoor allergens (eg, ragweed pollen) appear to be more important to the development of allergic rhinitis. The mechanisms underlying such associations remain obscure. Speculation has focussed on the physiochemical nature (size, chemical structure) and pattern of exposure (acute versus chronic).

Food Allergens

Although hundreds of different foods are ingested, only a small number account for the vast majority of food allergy. The most common foods responsible for childhood food allergy are milk, egg, peanut, soy, and wheat. Responses to food allergens are relatively common in children under the age of 2 but usually disappear as the child ages. In contrast, in adult food

allergy, the most common offending foods are peanuts, tree nuts, fish, and shellfish. Most food allergens have been found to be water-soluble glycoproteins ranging in size from 10 to 40 kD that are heat and acid stable and resistant to proteolytic degradation. Exceptions to this are fruit and vegetable allergens. Reactions to food allergens can be fatal, with one of the most severe food reactions occurring in response to peanut allergens.

Latex Allergens

A new class of antigens associated with immediate hypersensitivity reactions to latex rubber has been identified in the last few years. Latex allergy is frequently seen in health care workers, rubber industry workers, and subjects undergoing multiple surgical procedures in early infancy.[10,11] Symptoms manifest as contact urticaria, rhinoconjunctivitis, asthma, and mucosal swelling. However, severe reactions and death have occurred upon exposure of patients to latex balloons on the rectal mucosa, especially in children with spina bifida. Multiple individual latex allergens have been identified, eight of which have received an international nomenclature designation. These include Hev b1, rubber elongation factor; Hev b2, B-1,3-glucanase; Hev b3, homologous to Hev b1; Hev b4, a microhelix component; Hev b6, prohevein/hevein; and Hev b7, a patatin-like protein.[12] It has recently been appreciated that individuals with allergies to certain fruits such as banana, avocado, kiwi, and chestnut develop clinical symptoms upon initial contact with latex.[13] This phenomenon has been coined “the latex-fruit syndrome.” It is thought to occur as a result of the presence of IgE reactive to enzymes such as β-glucanase and chitinases that are present in both fruits and rubber. Interestingly, mammalian chitinases have been identified as inducible by Th2 cytokines such as IL-13.

Pharmaceuticals

Adverse drug reactions are relatively common clinical problems. Most conventional pharmaceutical agents are relatively low-molecular-weight compounds that become allergens only after their haptenization to endogenous proteins. The penicillins are classic instigators of allergic reactions. Penicillin is associated with a relatively high incidence of allergic reactions because of the chemical reactivity of penicillin and its metabolites. Although penicillin itself is the major allergen, its metabolic products, penicilloate and penilloate, are minor allergens but are responsible for a disproportionate share of severe, life-threatening reactions. Moreover, the drug is often administered parenterally, which greatly increases the probability that an adverse IgE-associated response will be fatal. Other agents, such as quaternary ammonium compounds (neuromuscular blocking agents) and sulfonamides (antibiotics) are relatively common stimuli of allergic reactions.

Insect Venom Allergens

Stinging insect hypersensitivity develops in both nonatopic and atopic individuals. Individuals are sensitized when

relatively high levels of proteins (approximately 50 µg) in venom are injected subcutaneously during a sting. The venom-associated allergens of several vespids (yellow jacket, wasp, fire-ants, and white faced hornet) are cross-reactive and include antigen 5, phospholipase, and hyaluronidase. The honeybee venom contains distinct allergens, including two major ones,

phospholipase A_2 and hyaluronidase, and a less important one, melittin. Many of these allergens have proteolytic activity.

Biological Properties of Allergens

The major allergens are a diverse group of proteins in which no one biologic property appears to be dominant. Allergens constitute a diverse range of molecules that derive from a variety of environmental sources, such as plants (trees, grasses), fungi (*Alternaria alternata*), arthropods (mites, cockroaches), and other mammals (cats, dogs, cows). As they are derived from complex living organisms, they serve a broad range of functions in their respective hosts, from structural to enzymatic. For example, the common house dust mite allergens include several cysteine proteases (Der p 1, Der p 3), serine proteases (Der p 3, Der p 6, Der p 9), chitinases (Der p 15, Der p 18), lipid-binding molecules (Der p 2), and structural molecules such as tropomyosin (Der p 10). Some are species specific; others are molecules with broad biochemical homology that are found in many species. The fact that there does not appear to be a common strucutural motif or conformational sequence associated with allergenic potential leaves open the possibility that proteins with allergenic potential exhibit a necessary commonality of biologic function. Indeed, it has been recently proposed that allergens are linked by their ability to activate the innate immune system at mucosal surfaces, triggering the activation of structural cells and initiating the influx of innate immune cells that subsequently promote Th2-polarized adaptive immune responses.

Recent studies suggest that allergens may activate the innate immune response either through their intrinsic enzymatic activity or through activation of pattern recognition receptors (PRRs) on mucosal epithelial cells or APCs directly. Allergens from diverse sources have enzymatic activity that may bias the immune response toward a Th2 phenotype. Several allergens have cysteine or serine protease activity, including diverse allergens from arthopods (eg, house dust mites[14,15]), German cockroaches,[16] fungi,[17] mammals (eg, *Felis domesticus*[18]), and plants (eg, pollens from ragweed[19]). In addition, many forms of occupational allergy are associated with encounters with proteolytic enzymes such as those used in the manufacture of detergents (alkaline detergents)[20] or in the food industry (papain).[21] Moreover, the potent peanut allergen, Ara h 2, is homologous to and functions as a trypsin inhibitor.[22] Other allergens, such as ragweed pollen, have been shown to contain intrinsic nicotinamide adenine dinucleotide phosphateoxidases. Pollen-derived nicotinamide adenine dinucleotide phosphate-oxidases have been shown to rapidly increase the levels of reactive oxygen species (ROS) in lung epithelium as well as the amount of oxidized glutathione and 4-hydroxynonenal in airway-lining fluid.[23] These oxidases, as well as products of oxidative stress (such as oxidized glutathione and 4-hydroxynonenal) generated by these enzymes, are thought to play a pivotal role in the development of lung inflammation.[24]

Alternatively, it has recently been recognized with the discovery of PRRs that allergens and their soluble components may contain pathogen-associated molecular patterns (PAMPs) that actively interact with innate recognition systems present in the mucosal layer of various tissues. Specifically, it has long been appreciated that allergens contain substances such as endotoxin, chitin, or β-glycans, which are recognized by PRRs (toll-like receptor [TLR]4, TLR2, dectin-1, mannose receptor) on cells lining mucosal surfaces such as the epithelium or

on underlying dendritic cells (DCs). Activation of these PRRs both directly and indirectly provides signals required for productive DC:T cell interactions at mucosal surfaces. The ability to provide these danger signals to DCs likely underlies the unique ability of allergens to initiate allergic responses. The best example of this comes from the recent observation that the house dust mite allergen Der p 2 has been shown to be a molecular and functional mimic of the TLR4 receptor adapter molecule MD-2[25] and to drive allergic inflammation through activation of the TLR4 complex directly in the absence of MD-2. Several other members of the MD-2-like lipid-binding family are major allergens, suggesting generality for these findings.

Many allergens also contain carbohydrate moieties that can stimulate the C-type lectin receptors that recognize complex carbohydrates. For example, the peanut allergen Ara h 1[26] and the dust mite allergen Der p 1[27] have both been shown to bind to C-type lectin receptors on DCs, thereby enhancing their uptake and activation of a Th2 immune response. Evidence for the importance of these biologic properties to allergenicity will be discussed further in the following. Nonetheless, although many of these allergens can potentially create a microenvironment conducive to Th2-cell differentiation and expansion, normal individuals do not mount Th2 responses when exposed to these allergens, which suggests that despite the nature of these antigens, other factors are necessary for the development of allergic outcomes in susceptible individuals.

TYPE 2 POLARIZED IMMUNE RESPONSES IN ATOPY

As the primary orchestrator of specific immune responses to foreign antigens, the T-lymphocyte has been implicated in the pathogenesis of allergic diseases. Several lines of evidence support a causal role for T-lymphocytes in allergic disorders. Increased numbers of T-lymphocytes are found in the bronchial mucosa, nasal mucosa, and skin of patients with allergic asthma, rhinitis, and dermatitis, respectively, when compared with nonatopic controls.[28,29,30] In asthma and allergic rhinitis, CD4+ T cells predominate. In atopic dermatitis, however, excess CD4+ and CD8+ T populations are both present in skin lesions.[30] Further, there is a generalized increase in T-cell activation in allergic individuals both at the site of disease and systemically. Experimental data support

a generalized increase in T-cell activation in all disorders of the atopic triad, with increased expression of the IL-2 receptor, class II histocompatibility antigens (human leukocyte antigen [HLA]-DR), and very late activation antigen-1.[28,30] These activated T cells have the capacity to rapidly expand in response to specific stimuli, and through the release of a variety of cytokines they recruit and activate other immune cells (B cells, CD8 T cells, macrophages, mast cells, neutrophils, eosinophils, basophils) thereby initiating a complex series of events resulting in the symptoms of allergic diseases. Following initial activation, CD4+ T cells remain in lymphoid tissues as memory cells. These memory cells retain the ability to respond to specific antigens upon reexposure throughout the lifetime of the individual.

As has been covered in detail in other sections of this text, functional subsets of CD4+ T cells have been distinguished at both clonal and population levels by the unique profiles of cytokines that they produce.[31,32] The differential presence of these cytokine phenotypes in a variety of allergic and infectious diseases both in mice and in humans has provided

descriptive power and theoretical insight into disease pathogenesis.[33,34] Th1 cells producing tumor necrosis factor (TNF)-β, and interferon (IFN)γ, are critical in the development of cell-mediated immunity, macrophage activation, and the production of complement fixing antibody isotypes. Th2 cells producing IL-4, IL-13, IL-5, IL-9, and IL-6 are important in the stimulation of IgE production, mucosal mastocytosis, eosinophilia, and macrophage deactivation. Another subpopulation of T cells, referred to as regulatory T (T_{reg}) cells,[35] have immunosuppressive functions and cytokine profiles distinct from either Th1 or Th2 cells. These cells are thought to play an important role in limiting immune responses to self- or exogenous antigens by preventing the activation and function of nonregulatory effector T cells through through cell-to-cell interactions or through elaboration of IL-10 and/or transforming growth factor (TGF)-β.

Until recently, the development of allergies has been thought to be due solely to an imbalance between allergenspecific Th1 and Th2 cells with a skew toward Th2 immune responses. Several lines of evidence suggest that allergic diseases may arise as a result of an imbalance between allergen-specific T_{reg}s and Th2 cells, resulting in a loss of tolerance mediated via T_{reg}s. Whether this imbalance occurs due to overzealous Th2 immune responses, to impaired T_{reg} responses, or a combination of both is an open question. Recent evidence also suggests a role for the Th17 subset, which uniquely produces IL-17A and IL-17F.[36] This subset has been generally shown to be important in neutrophil development, activation, and recruitment, and the induction of inflammatory mediators from a variety of tissue resident cells such as epithelial cells. In the context of allergic disorders, Th17 cells are likely to enhance Th2-dependent immune responses. Evidence for each will be discussed subsequently.

Type 2 Polarized Immune Responses in Atopy Disorders

Several lines of evidence support the involvement of Th2 cytokines in the pathogenesis of allergic disorders. Firstly, T cells at the site of disease (bronchoalveolar lavage, bronchial biopsies, nasal biopsies) in allergic individuals (allergic asthma, atopic rhinitis) express elevated levels of messenger ribonucleic acid (mRNA) for IL-4, IL-13, granulocyte macrophage-colony stimulating factor (GM-CSF), and IL-5.[37,38,39,40,41] In atopic dermatitis patients, elevated Th2 cytokines (IL-4, IL-13, IL-5) and their receptors (IL-4R, IL-5R) are found in skin lesions in acute disease,[38] while cytokine patterns in chronic lesions are mixed, with both Th2 cytokines (IL-5 and IL-13) and Th1 cytokines (IFNγ) being expressed.[39] Secondly, it has been shown that successful therapeutic treatment of these disorders is associated with a reduction in the Th2 cytokine pattern. For example, both steroid treatment and immunotherapeutic regimes result in reductions in Th2 cytokine levels in the nasal mucosa[40] of patients with allergic rhinitis and in bronchoalveolar lavage (BAL) of asthmatic patients.[41]

Although considerable descriptive evidence suggests that CD4+ T-lymphocytes and Th2 cytokines are important in the pathogenesis of atopic disorders in humans, definitive proof is, of course, difficult to obtain. As a result, experimental animal models have been extremely useful in mechanistic delineation of the role of CD4+ T cells and T cell-derived cytokines in the pathogenesis of allergic disorders. Murine models of antigen-driven asthma have

consistently revealed a causal role for CD4+ T cells in the development of the signs of allergic airway disease.[42,43] In these models, sensitization with various allergens (ovalbumin, house dust mite, ragweed, aspergillius) by either intraperitoneal injections or airway installation, followed by direct airway challenge, induces a phenotype closely resembling that observed in human asthmatics. Specifically, allergen sensitization and challenge results in airway hyperresponsiveness (AHR), eosinophilic inflammation, elevations in allergen-specific IgE levels, and mucus hypersecretion. Regardless of mouse strains or exposure protocols, an absolute requirement for CD4+ T cells for the development of allergic responses is clear in such models. A lack of CD4+ T cells, achieved either by antibody depletion[42] or gene targeting,[43] is associated with prevention of the development of allergen-induced airway responses. Furthermore, adoptive transfer of Th2 clones into the mouse lung is sufficient for the development of allergic airway symptoms.[44] On the other hand, transfer of Th1 clones[44] or administration of agents such as IL-12 and IFNγ that inhibit Th2 cytokine production and stimulate Th1 pathways prevent the development of allergen-induced AHR and eosinophilic inflammation in murine models.[45,46,47] Conversely, mice deficient in T-bet, a transcription factor important in IFNγ secretion, spontaneously develop Th2-mediated allergic airway responses.[48] Several studies have shown evidence of association between polymorphisms in the T-bet gene and asthma phenotypes in humans.[49] The involvement of each of the specific Th2 cytokines in atopic airway responses has been demonstrated in studies in which IL-4, IL-5, IL-13, and IL-9 have been manipulated through either antibody blockade[50,51] or gene targeting.[52,53,54] Similar roles for CD4+ T cells and Th2 cytokines have been demonstrated in experimental mouse models of each of the atopic disorders including atopic rhinitis,[55,56] food allergy,[57]

and atopic dermatitis.[58] Collectively, the Th2 cytokines orchestrate the elicitation of the allergic response via their ability to regulate IgE production and recruitment and activation of various effector cells (eg, mast cells, eosinophils). In particular, IL-4, through its critical role in Th2 differentiation, has been shown to be essential in the initiation of allergic airway responses.[59,60] IL-5 clearly plays a role in eosinophil development, recruitment, and activation at the site of Th2-inflammatory responses,[61] whereas IL-9 appears to be an important regulator of mast cell activation.[62] IL-13 has been shown to have a singular role in the effector phase of the allergic response.[63,64] Specifically, it is sufficient to induce many of the manifestations of allergic disease including airway inflammation, AHR, and mucus cell hypersecretion in allergic airway diseases.

ROLE OF NATURAL KILLER T CELLS IN ALLERGIC DISEASE

Although allergic diseases have clearly been associated with polarized Th2 cytokine production in tissues, the source of these Th2 cytokines has been recently debated. Specifically, studies have implicated invariant T-cell receptor (TCR)+ CD1d-restricted CD4+ natural killer (NK) T cells as one of the major sources of Th2 cytokines.[65,66,67] Akbari et al.[65] demonstrated that NKT-deficient mice do not develop AHR in response to systemic ovalbumin priming in the presence of adjuvants and subsequent allergen aerosol challenge.

The resistance of these mice to the development of allergen-specific AHR can be overcome by adoptive transfer of tetramer purified NKT cells producing IL-4 and IL-13 or by rIL-13 treatment. In support of a role for NKT cells, Morishima et al.[68] have shown that priming of mice with ovalbumin plus the NKT cell ligand α-GalCer overcomes the tolerance that is normally seen with airway exposure to ovalbumin (OVA) alone. In this model, the development of Th2-mediated AHR is CD1d+ dependent but it does not occur in mice deficient in major histocompatibility complex (MHC) class II, suggesting that NKT cells are necessary but not sufficient to induce Th2-mediated responses. Interestingly, a single administration of α-GalCer to the mouse airway induces AHR, suggesting that NKT cells may serve as effector cells in the absence of conventional Th2 responses through their ability to produce Th2 cytokines such as IL-13. The effect of NKT-cell activation appears to be dependent upon the timing and context of activation as other studies have shown that activation of NKT cells with α-GalCer + OVA in OVA-primed mice actually inhibits AHR, and Th2 cytokine production in a NKT cell and IFNγ-dependent manner.[69] In support of a role for NKT cells in human asthma, Akbari et al.[70] demonstrated that a large fraction of CD4+CD3+ cells in the lungs of allergic asthmatic individuals are not MHC class II-restricted, but rather NKT cells. Similarly, Sen et al.[71] found that Vα24+ invariant NKT cells in the blood of patients with asthma selectively expressed CCR9, and that large numbers of CCR9+ and Vα24+ cells were present in bronchial-biopsy samples from patients with asthma, but not from control subjects. They also showed that conventional CD3+α/β T cells could be polarized to a Th2 phenotype by cell-to-cell contact with Vα24+ invariant NKT cells, with enhanced expression of CCR9, from patients with asthma. The induction of Th2 cytokine production requires CCL25 and CCR9 to activate adjacent membrane signaling by CD226, a leukocyte-adhesion molecule, that is expressed on monocytes. CD226 appears to be critical for activating Vα24+ invariant NKT cells for the induction of a Th2 bias in conventional T cells. DCs and epithelial cells are major sources of CCL25. They also showed that the numbers of CCR9+Vα24+ NKT cells in the peripheral blood of symptomatic patients with asthma decreased after steroid treatment and when asthma was clinically silent. Taken together, these studies suggest that NKT cells play a prominent role in the development of some Th2 immune allergic responses; however, the exact nature of their role is dependent upon both the timing and dose of the activating ligand. Thus, NKT cells can function as an adjuvant when iNKT cells are activated during adminstration of a protein antigen, can direct induction of AHR when they are activated in the absence of other signals, or can function to prevent the development of AHR when they are activated by strong NKT cell activating agents once inflammation is established. Recent studies demonstrate that house dust extracts collected from different homes contain antigens capable of activating both mouse and human iNKT cells. These extracts enhanced OVA-induced AHR in an iNKT-dependent manner, suggesting that they have adjuvant properties. Interestingly, administration of these extracts together with OVA augmented the synthesis of cytokines from both Va14i NKT cells and conventional CD4+ T cells in the lung.[72] These results suggest a scenario in which NKT cells and conventional CD4+ T cells responding to their respective glycolipid and peptide antigens work in concert to mediate the development of allergic responses. Moreover, human CD1d-restricted T cells recognize lipids in pollens.[73] Interestingly, iNKT cells do not appear to be required for the development of another allergic disorder, namely atopic dermatitis.[74] Further studies will be required to determine the extent of the contribution of NKT cells in various allergic disorders and to define the specific

endogenous or exogenous glycoplipid antigens that are activating NKT cells in allergic patients.

TH17 CELLS IN ALLERGIC DISEASE

Although allergic diseases are typically thought to be Th2-dominated, recent studies suggest that certain forms of disease may also be associated with elevations in the cytokines IL-17A, IL-17F, IL-21, and IL-22 produced by the newly described Th17 subset.[75] These cytokines are strongly associated with neutrophil responses and protection from bacterial or fungal pathogens. Evidence for a pathogenic role for Th17 cells in severe forms of asthma include the observations that elevated levels of IL-17A in serum, sputum, or bronchial biopsy specimens,[76,77,78] and polymorphisms in the IL17A or IL17F promoters[79,80] are significant risk factors for the development of severe asthma. Similarly, single nucleotide polymorphisms (SNPs) in the gene that encodes the p40 subunit of IL-23 (also shared by IL-12) are associated with

severe asthma.[81,82] Interestingly, exposure to many known triggers of asthma exacerbations, including organic dust, inhaled particulate matter, and ozone, have been shown to trigger release of Th17 cytokines.[83,84,85]

Evidence from animal studies also supports a role for Th17 cells in more severe allergic disease. A number of studies demonstrate that mice lacking IL-17A (either through genetic manipulation, following anti-IL-17A treatment or pharmacologic intervention) display reduced airway inflammation and AHR.[86,87,88,89] Similarly, IL-23-deficient mice have decreased airway inflammation and Th2 immune responses.[90] Moreover, mouse strains that are genetically predisposed to mount a mixed Th2/Th17 response (A/J mice) demonstrate increased IL-23 production and more severe AHR than those that mount a pure Th2 response (C3H/HeJ mice).[76,91] Blockade of IL-17A reduced severity of AHR in A/J mice, while exogenous IL-17A exacerbated AHR in C3H/HeJ mice.[76] Similarly, simultaneous transfer of both Th2- and Th17-cytokine-producing T cells induces a significantly more intense AHR.[92,93,94]

Conflicting reports do exist however, with some reports arguing for either no role for IL-17A in promoting the development of allergic asthma, or a protective role for this cytokine.[95,96] While the reasons for these discrepancies remain unclear, a recent report by Besnard et al.[97] suggest that the pathogenicity of IL-17A may in turn be regulated by an additional cytokine, IL-22. In the presence of IL-22, the authors demonstrate that IL-17A is pathogenic, while in its absence, IL-17A appears to play a protective role. Thus, the presence of IL-22, a cytokine coproduced by Th17 cells, may regulate the pathogenicity of IL-17A. It is interesting that recent evidence suggests that different “subsets” of Th17 cells develop in the presence of different extrinsic signals,[98,99] suggesting the possibility that different Th17 cell subsets may play protective or pathogenic roles based on which signals they are exposed to during development.

While the role of Th17 cells has been studied most extensively in allergic asthma, there is also evidence that IL-17A plays a role in other allergic diseases. Increased IL-17A mRNA

expression is associated with the presence of nasal polyps in patients with both chronic rhinosinusitis and allergic rhinitis but not in those with allergic rhinitis alone.[100,101] These findings suggest that Th17 cells may be involved in particular subtypes of allergic rhinitis. In atopic dermatitis, increased IL-17A expression is found in biopsies of acute skin lesions, and there is a correlation between the number of Th17 cells found in the peripheral blood and the severity of acute atopic dermatitis (AD) lesions.[102,103] Filaggrin-deficient mice also display increased IL-17A expression in skin lesions after epicutaneous exposure to an allergen.[104] Interestingly, the association between IL-17A and AD lesions does not extend to chronic lesions, as very little IL-17A expression is detected in chronic lesions in patients with AD patients.[105,106] Rather, chronic AD lesions appear to be associated with infiltration of "Th22" cells—a subset of T cells that produce high levels of IL-22, but limited IL-4, IL-17A, or IFNγ.[106,107] Thus, the interplay of IL-17A and IL-22 may also play an important role in regulating pathogenicity of Th17 cells in AD.

While the mechanisms through which Th17 cells enhance the severity of allergic diseases remain unclear, a number of potential mechanisms have been proposed. The ability of IL-17A to regulate disease severity may be related to its capacity to support neutrophil accumulation, as asthma and allergic rhinitis in some patients are associated with neutrophilia.[108,109] Although the role of neutrophils in these diseases is not entirely clear, mice lacking neutrophils have been demonstrated to develop less severe allergen-induced AHR. However, enhancing neutrophil recruitment was not sufficient to trigger enhanced disease.[110] IL-17A also directly induces the production of the mucins Muc5AC and Muc5B by tracheal epithelial cells,[111] and overexpression of IL-17A by pulmonary epithelial cells is accompanied by increased mucus staining,[112] suggesting that IL-17A may be involved in mucus hypersecretion or goblet cell hyperplasia. Finally, of relevance for all models of allergic disease, IL-17A has also been shown to directly enhance IL-13-driven signaling both in vitro and in vivo,[76,113] suggesting that the presence of Th17 cytokines may serve to exacerbate Th2-driven immunopathology.

It has been recently postulated that Th17-derived cytokines may directly contribute to the steroid resistance observed in individuals with severe asthma. McKinley et al.[92] have reported that while in vitro culture of Th2 cells in the presence of the steroid dexamethasone completely abrogated Th2 cytokine production, culture of Th17 cells with dexamethasone failed to suppress their cytokine-producing capacity. Similarly, transfer of Th2 cells into naïve mice induced the development of steroid-sensitive AHR whereas transfer of Th17 cells triggered AHR that was resistant to steroid treatment. While the mechanisms of IL-17-driven steroid resistance are unclear, a recent report showed that IL-17-driven inhibition of histone deacetylase 2 activity was responsible for promoting steroid-insensitive production of IL-8 by human bronchial epithelial cells, suggesting that epigenetic mechanisms may be at play.[114]

IMPAIRED TREGULATORY CELL FUNCTION IN ATOPIC INDIVIDUALS

It has recently been hypothesized that under noninflammatory conditions, the outcome of immune responses to innocuous environmental allergens is the development of immunologic tolerance. Moreover, it is thought that a loss of tolerance results in Th2-biased immune responses at mucosal surfaces. Although the specific immunologic events that mediate

tolerance in this setting are not well understood, recent studies have suggested that T_{reg} cells protect against the development of allergic disease and that their function is impaired in genetically susceptible individuals. As is described in depth in other chapters within this text, T_{reg}s are cells that inhibit the development and function of other nonregulatory T cells. To date, two major categories of T_{reg} cells have been described. The first is the naturally occurring, thymically derived CD4+CD25+ T_{reg} cells that express high levels of the transcription factor Foxp3, which is essential for their development and function. The other major category is the antigen-specific T_{reg}, which can be induced in vitro and in vivo under particular conditions

of antigen stimulation. These antigen-specific T_{reg}s secrete anti-inflammatory cytokines such as IL-10 and TGF-β and regulate immune responses and inflammatory pathologies. Antigen-induced T_{reg}s that secrete IL-10 are often referred to as IL-10-T_{reg} cells, or Tr1 cells, whereas those that secrete TGF-β have been referred to as Th3 cells.

Several lines of evidence from both human and animal studies have suggested that alterations in T_{reg} populations and function may contribute to susceptibility to allergic disease. In animal models, several studies show that adoptive transfer of CD4+CD25+ T_{reg}s can reverse established airway inflammation through an IL-10-dependent process. Conversely, reduced expression of membrane-bound TGF-β exacerbates airway pathology in an asthma model.[115] Furthermore, environmental exposures to agents that induce T_{reg} cell expansion have been shown to ameliorate the development of asthma. In particular, exposure of mice early in life to lipopolysaccharide (LPS) resulted in the expansion of T cells expressing CD25 and IL-10 concomitant with reduced allergic manifestations upon sensitization and challenge as compared to those mice that were not exposed to LPS.[116] Treatment of mice with mycobacterium-induced allergen-specific T_{reg} cells producing IL-10 and TGF-β protected against airway inflammation.[117] Similarly, heat-killed *Listeria monocytogenes* treatment induced allergen-specific T_{reg}, producing IFN-γ and IL-10, which protected against food allergy in dogs.[118]

Although fewer conclusive studies have been conducted in humans, several support the hypothesis that impaired T_{reg} function may contribute to development of Th2-dependent pathologies in humans. For example, the frequency of allergen-specific IL-10-secreting cells was significantly decreased in allergic patients as compared to nonatopic individuals.[119] Whether the IL-10 is derived from T_{reg}s or activated effector T cells is unknown. In addition to a relative lack of T_{reg}s in atopic individuals, Ling et al.[120] have shown that CD4+CD25+ cells from atopic individuals have impaired ability to suppress effector T-cell cytokine production. Another interesting observation regarding the role of T_{reg}s in susceptibility to atopy is the finding that children who outgrew milk allergy had higher numbers of CD4+CD25+ cells in their blood.[121] Furthermore, therapies shown to be beneficial in the treatment of allergy and asthma, such as allergen immunotherapy or glucocorticoid therapy, have been shown to increase the induction of allergen-specific IL-10-secreting T_{reg} cells, concomitant with a reduction in allergen-specific Th2 responses.[122]

Although the mechanisms by which T_{reg}s regulate the development of allergic inflammation are not completely understood, they are thought to prevent allergic symptoms by suppression of Th2 cell effector function through the elaboration of the suppressive cytokines, IL-10 and TGF-β. However, recent studies now support the concept that T_{reg}s may alter sensitization and ongoing Th2 immune responses via regulating airway DC function. Mice lacking the transcription factor RunX3, which is involved in downstream TGF-β signaling, spontaneously develop symptoms of asthma concomitant with increased numbers of lung DCs displaying a mature phenotype with increased expression of MHC II, OX40 ligand, and CCR7.[123] In further support of a role for T_{reg} cell regulation of DCs, it has been shown that in mice (C3H/HeJ) that are resistant to house dust mite-induced asthma and ARH, T_{reg} depletion with the CD25-depleting antibody similarly led to increased numbers of pulmonary myeloid DCs with increased expression of MHC II, CD80, and CD86 and an increased capacity to stimulate T-cell proliferation and Th2 cytokine production.[124] In contrast, T_{reg}s from normally susceptible A/J mice do not suppress inflammation and AHR. These data suggest that resistance to allergen-driven AHR is mediated in part by CD4+CD25+ T_{reg} suppression of DC activation and that the absence of this regulatory pathway contributes to susceptibility.

The lack of allergen-specific tolerance in allergic individuals has been hypothesized to be related to improved hygiene in industrialized countries, possibly due to reduced infections, alterations in commensal microflora in the intestinal tract and/or reduced TLR signaling. This will be discussed in more detail in the following sections. Taken together, these studies suggest that T_{reg}s may induce tolerance to or provide protection against inhaled allergens in healthy individuals and that an imbalance between allergen-specific T_{reg}s and Th2 cytokine-producing cells may underlie susceptibility to the development of atopic diseases.

Determinants of Susceptibility to Type 2 Immune Responses in Atopic Individuals

Overview

Very little is known conclusively about the underlying causes of the aberrant expansion of Th2 cytokine-producing cells in atopic humans. However, the skewed Th2 immune responses in atopic disorders may be due to either overzealous Th2 immune responses, impaired ability to generate either Th1 or T regulatory responses, a lack of exposure to Th1- and T_{reg}-promoting agents, or a combination of each of these. This balance is influenced by a number of genetic, environmental, and epigenetic factors that control both the innate and adapative immune responses to allergens at mucosal surfaces. There is supportive data for each of these determinants in atopic diseases.

Genetic Influences on Allergen Sensitization

There is substantial evidence suggesting that the development of atopic diseases is genetically controlled.[125,126,127,128,129] Familial aggregation and twin studies have confirmed a fundamental contribution of genetic factors to the development of atopy and specific clinical atopic phenotypes.[125] Specifically, individuals with a first-degree relative with atopy are at a significantly greater risk of developing atopy. Moreover, individuals with two “atopic” parents are at a greater risk of developing an allergic disease than those with only

one atopic parent. Further support for a genetic basis of atopy is the fact that there is a greater concordance for atopic disease between monozygotic twins compared to dizygotic twins.[126] The concordance is not 100%, suggesting that atopy is a polygenic disorder with strong environmental influences. Despite the

complex genetic nature of atopic disorders, multiple studies have reported evidence of linkage of atopic related traits with five primary chromosomal regions including 1) the Th2 cytokine gene cluster on 5q31-q33 including the IL-4, IL-13, CD14, SPINK5, LTC4S, and CYFIP2 genes; 2) the HLA region on 6p21 including both classical (HLA-DRB1, HLADQB1, HLA-G) and nonclassical HLA genes (TNF, LTA); 3) the region that contains the high-affinity IgE receptor gene (FcεRIb) on 11q13; 4) a large region on chromosome 12q14 that spans several candidate genes (Stat6, IFNγ, stem cell factor, nitric oxide synthase 1); and 5) a region of 16q containing the IL4RA.[127] Disease-specific genes have also been identified through candidate gene approaches and genome-wide association studies: asthma (IL33, IL18R1, IL2RB, SMAD3, ORMDL3, HLA-DAQ),[128] AD (the epithelial barrier gene, filaggrin),[129] and eosinophilic eosphagitis (thymic stromal lymphopoietin [TSLP]).[130]

Environmental Influences on Development of Atopic Disease

Despite the clear heritable component of allergies, the incomplete concordance of disease in twin studies and the rapid shift in the rate at which the incidence of atopic disorders is rising suggests a recent change in environmental influences on this process. Changes in exposures to allergens, infectious agents or their byproducts, and/or pollutants have all been suspected. It is likely that multiple environmental factors influence the development of allergic diseases, and that there may be complex interactions between these individual factors (Fig. 45.1).

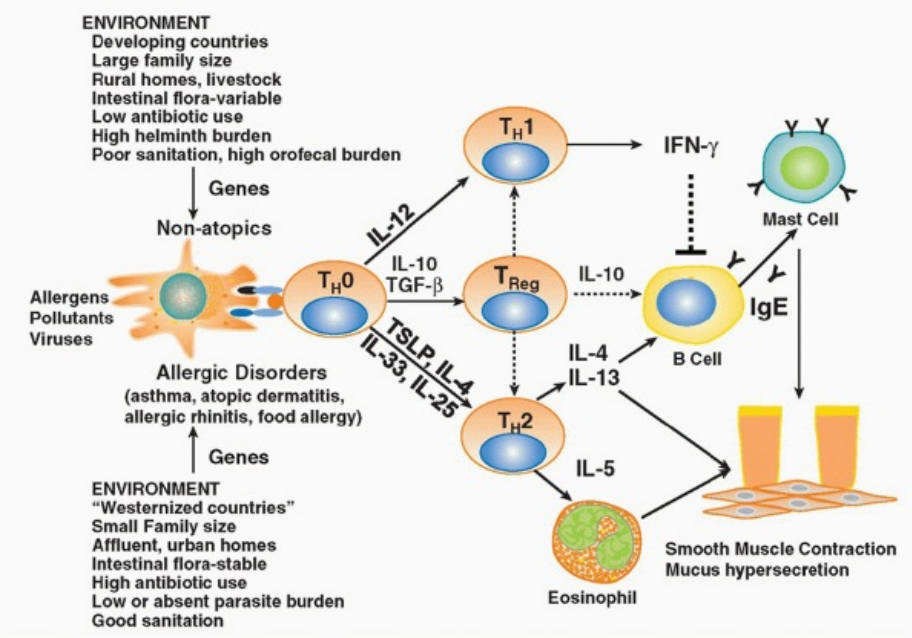

FIG. 45.1. Allergic Diseases are Associated with Aberrant Adaptive Immune Responses to Innocuous Environmental Antigens. The development of allergic responses to harmless antigens is influenced both by environmental factors and the

genetic background of the individual. Under conditions in which microbial exposure is minimal such as in developed countries, T cells differentiate along a Th2 pattern with elaboration of interleukin (IL)-4, IL-13, IL-5, and IL-9. In contrast, microbial exposure in early life protects against the development of harmful Th2 immune responses via the induction of regulatory T cells.

Timing of Allergen Exposure

The spectrum of antigens an atopic individual is sensitized to is dependent on their environment in early life. This tenet is based on the positive correlations observed between allergen exposures present during the month of birth and the development of sensitization to the same allergens later in childhood (eg, birch, grass, and dust mite allergens).[131,132,133] For example, Scandinavian babies born in late winter or early spring are more likely to develop IgE antibody to birch pollen, which is prevalent during the spring, than those born at other times of the year.[131] In addition, avoidance or withholding certain allergenic foods during the first few months of life tends to prevent sensitization and subsequent allergic responses to these particular foods.

It has recently been hypothesized that exposure to environmental antigens occurs both prenatally and postnatally. In this regard, several independent studies have provided support for the postulate that prenatal events may influence susceptibility to allergic diseases.[134,135] For example, it has been shown that cord blood mononuclear cells respond to inhalant and food allergens, suggesting that initial priming

of allergen-specific T-cell responses may occur before birth.[134,135] It has been demonstrated that the responding cord blood T cells were indeed of fetal origin, as they did not respond to common vaccine antigens such as tetanus toxoid, which the majority of adults in the study population expressed active immunity against.[134] These findings suggest that transfer of substances from mother to child (eg, allergens, antibodies, toxins, hormones, or other immune mediators via the placenta) may occur during gestation, which might prime or sensitize the developing infant to environmental antigens. In addition, factors present in the in utero environment may serve to influence the nature of the immune response of the fetus to allergens that cross the placenta. Indeed, mediators such as PGE2 and high levels of progesterone, which has been shown to alter the Th1/Th2 balance by either suppressing Th1 cytokine production or inducing a Th2 pattern, are present during pregnancy. Th2 skewing is thought to take place to suppress IFNγ production that is toxic to the fetus. Accordingly, exogenous antigens that leak across the placenta are likely to be presented to the fetal immune system within a milieu conducive to selection for Th2 immunity. This contention is supported by studies showing that cord blood cells from both allergic and noallergic infants both produce high levels of Th2 cytokines and low IFNγ levels.[135,136] Although immune responses in neonates are skewed toward a Th2 phenotype, studies of human infants indicate that this Th2 skew gradually diminishes during the first 2 years of life in nonallergic individuals.[137] In allergic infants, the reverse occurs, with the strength of neonatal Th2 responses increasing over a similar period. This has been supported by Holt and colleagues,[138] who showed that although the levels of IgE vary considerably during

early childhood, atopic subjects eventually lock into a stable pattern of increasing antibody production and Th2-polarized cellular immunity that is associated with stable expression of the IL-4 receptor in allergen-specific Th2 memory cells, which is absent during infancy. The persistence of this neonatal bias and the failure to produce Th1 or T_{reg}-type responses may be an important feature of the atopic disease state.

The redirection of Th2 responses is thought to occur simultaneously with childhood bacterial or viral infections in early life. This relationship has been capsulated in the “hygiene hypothesis,” which argues that early childhood infections inhibit the tendency to develop allergic disease.[139,140] Several epidemiologic studies have provided support for this hypothesis by demonstrating an inverse relationship between farm living,[141] pet ownership,[142] or drinking unprocessed cow's milk[143] in early life and atopy. Although the general implication of these studies is that protection from allergy seems to be associated with an increase in microbial exposure, the link has remained fairly indirect.

The complex interface with the microbial world provided by the gastrointestinal tract might well be important to the interrelationship between infection and allergy. The endogenous flora of the gut provides a wealth of stimuli for the developing immune system at birth. There seem to be both quantitative and qualitative differences in early childhood patterns of bacterial colonization between the developed and developing world. For example, a study of Swedish and Pakistani infants indicates that intestinal colonization with aerobic gram-negative bacteria tends to occur later in developed than developing countries.[144] Once they are colonized, infants in developed countries tend to carry the same enterobacterial strains, whereas infants in developing countries are often colonized serially with different strains. Differences in intestinal flora have also been found between allergic and nonallergic children in Europe.[145,146] Allergic children seem to be colonized less often with lactobacilli in Sweden and Estonia than nonallergic controls. This idea is consistent with the observation that oral tolerance cannot be induced in germ-free mice.[147] Furthermore, elimination of commensal intestinal microflora with broadspectrum antibiotics also prevented oral tolerance from developing and resulted in susceptibility to intestinal inflammation. These observations suggest that TLR signaling by commensal bacteria under normal steady-state conditions is required for maintenance of intestinal epithelial homeostatsis, and possibly for the induction of some forms of T_{reg}s. The intestine has been shown to affect immune responses at other mucosal surfaces including the respiratory tract and lacrimal, salivary, and mammary glands through secretory IgA antibodies.[148,149] A recent study suggests that not only are there differences in gut flora between individuals living in developed versus developing countries, but that allergic asthmatic individuals display a different spectrum of bacterial species in their lungs than do healthy control individuals.[150] In both compartments, a shift from protective bacteriodes to clostridial species has been observed. Recent studies demonstrating the role of a specific clostridial species, segmented filamentous bacteria, in the generation of Th17 responses further support a role for an altered microbiome in the pathogenesis of allergic disorders.[151] Further studies on the influence of the microbiome are likely to provide tremendous insight into the mechanisms underlying the hygiene hypothesis.

Further support for the hygiene hypothesis is the striking association between polymorphisms in genes in the TLR pathways and atopic phenotypes. Specifically, an association has been

consistently reported between a polymorphism in the CD14 gene, increased levels of sCD14, and decreased levels of IgE, reflecting the importance of bacterial LPS in downregulating Th2 responses.[152] Moreover, a polymorphism in the coding region of the TLR4 gene (A/G 896) resulting in reduced cell surface expression of TLR4 and subsequent disruption of LPS-mediated signaling, has been associated with atopy in children.[153] However, the data in asthma is conflicting with some studies showing an association between asthma and TLR4 polymorphisms[153] while others do not.[154] Interestingly, inheritance of both the TLR4 SNP (A/G+896) and the IL-4 SNP (-590) confers greater risk of asthma pathogenesis in females.[155] Similarly, a polymorphism in the TLR2 gene (TLR2-16934) was shown to be a major susceptibility gene for children living on farms.[156] Clearly these innate immune pathways play a critical role in determining the inflammatory reactions of the airways and the outcome of T-cell responses to inhaled allergens.

Although the hygiene hypothesis is likely oversimplified, it is theoretically possible that APCs at mucosal surfaces in atopic individuals receive less innate immune stimulation or stimulation of a different type in the form of microbial stimuli (LPS, peptidoglycans, mycobacterial antigens) and therefore they fail to redirect weak Th2 responses into protective Th1 responses or T_{reg} responses. This hypothesis may provide a plausible explanation for the rising prevalence of these disorders in developed countries.

Exposure to other environmental agents such as diesel particles, ozone, secondhand tobacco smoke, and viruses (respiratory syncytial virus [RSV], rhinoviruses) can also enhance sensitization to allergens in young children. Numerous epidemiologic studies illustrate clear associations between exposures to these agents and enhanced antigenic sensitization and worsening of disease.[157,158] Nasal challenge with diesel alone increased IgE production in both atopic and nonatopic individuals, suggesting that indeed diesel may be a sensitizer.[157] When evaluated together with allergen, diesel exposure of ragweed-sensitive subjects resulted in a significant increase in allergen specific IgE with an increase in Th2 cytokine production. Ozone can alter both immediate and late-phase responses of asthmatics and allergic rhinitics to inhaled allergen.[158] Epidemiologic studies have shown that exposure to environmental tobacco smoke in childhood is associated with increased skin test reactivity, serum IgE, and prevalence of eosinophilia.[159,160] Recently, it has been shown that controlled chamber exposures of ragweed-sensitive subjects to environmental tobacco smoke resulted in enhanced production of allergen-specific IgE, Th2 cytokines, and decreased IFNγ levels in nasal lavage fluids.[161] Although there is controversy regarding whether RSV is an inducer of allergic asthma or rather a predictor of aberrant immune responses, severe RSV infections are strongly associated with asthma.[162] Similarly, rhinoviral infections are strongly associated with exacerbations in atopic airway disease.[163] In summary, the complex interplay between genetic and environmental factors likely governs susceptibility to the development of atopic disorders.

Epigenetic Influences on Development of Atopy

The inheritance of atopic disorders appears to be preferentially associated with the atopic status of the mother. As asthma risk alleles are inherited from both parents, the preferential

link of atopy with the atopic status of the mother suggests that factors present in the in utero environment contribute to subsequent risk of atopy in the offspring[164] (Fig. 45.2). These modifications in gene expression in response to environmental cues can result from modifications of deoxyribonucleic acid (DNA; eg, by methylation) or of proteins that intimately associate with DNA (eg, acetylation, methylation, or phosphorylation of histones). Such differences could result in differential "prenatal programming" of immune cells in the fetus depending on the asthma status of the mother or from exposure to asthma medications taken by asthmatic mothers during pregnancy.

The first evidence that fetal genotype interacts with "maternal asthma" to determine risk for asthma in the child was provided by a positional cloning study that identified HLA-G as an asthma susceptibility gene.[165] In that study, the -964G allele was associated with asthma only in families with an affected mother, and the -964A allele was associated with asthma in families with an unaffected mother. Subsequent studies implicated a SNP (+3142C/G; rs1063320) that resides in the 3′ untranslated region within a target site for three micro ribonucleic acids (miRNAs).[166] In the presence of any of these miRNAs, expression of the G allele is suppressed whereas expression levels are unchanged for the C allele. The GG genotype, which is suppressed in the presence of the miRNAs, was associated with significant protection from asthma

among children of mothers with asthma but with modest risk for asthma among children of mothers without asthma. The mechanism through which the "maternal asthma-fetal HLA-G genotype" interaction influences subsequent risk for asthma in the child is still unknown, but modulation of expression via miRNA targeting could be involved. Because asthma in the mother is such a strong predictor of asthma in her children, it is likely that other, as yet undiscovered, genes also play a role in modulating this effect.

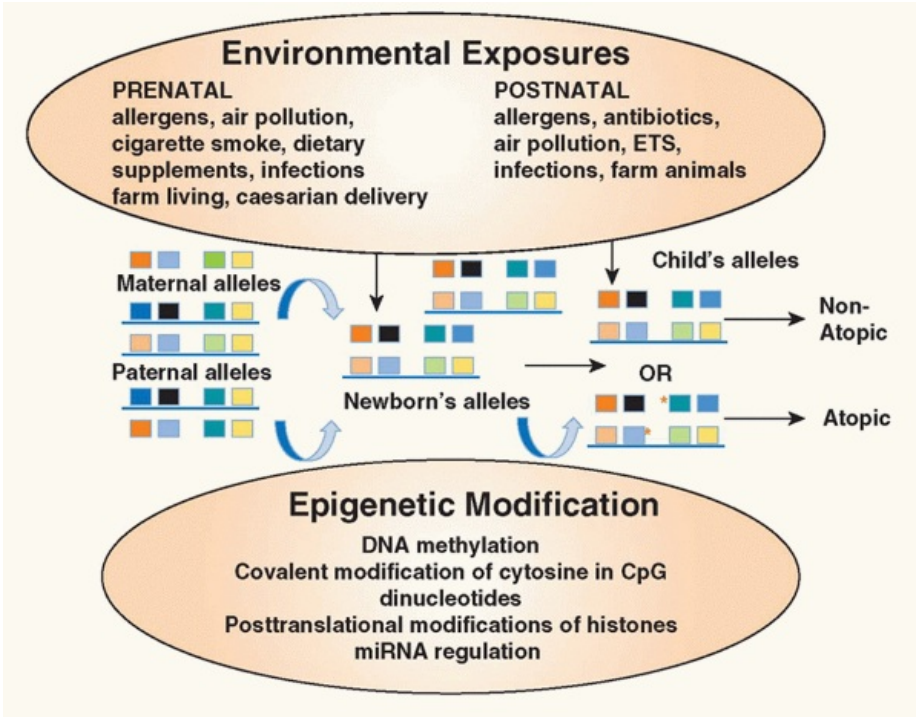

FIG. 45.2. Environmental Epigenetics and Atopy. Exposure of the mother to environmental factors (environmental tobacco smoke, air pollution, allergens, antibiotics, dietary supplements) during pregnancy may induce epigenetic changes (deoxyribonucleic acid methylation, covalent modification of cytosine in cytosin-phosphatidyl-guanosin dinucleotides, posttranslational modifications of histones, micro ribonucleic acid regulation) in gene expression in the offspring providing an explanation for the heretofore unexplained maternal influence on the inheritance of atopic diseases. In addition, exposure of the infant in early childhood to environmental factors may also alter expression of genes important in allergic inflammation. Collectively, these influences contribute to the risk of the child developing atopic diseases. *Red asterisks* refer to sites of epigenetic changes. Adapted from Miller and Ho.[164]

Recent evidence suggests that prenatal and postnatal exposures to the key environmental triggers of allergic disease described previously (ie, allergens, microbial infections, tobacco smoke, other pollutants, dietary supplements) can induce epigenetic changes in gene expression and alter disease risk through activating or silencing immune-related genes with subsequent effects on immune programming. For example, Fedulov and Kobzik et al.[167] demonstrated that DNA from splenic DCs harvested from pups born to mothers previously sensitized and challenged to OVA was hypermethylated. Moreover, adoptive transfer of these DCs from pups of allergic mothers into offspring from nonatopic mothers transferred increased susceptibility to allergic disease to recipients despite there being no differences in DNA sequences. The specific genes conferring this susceptibility remain to be determined.

There is also strong evidence that the association of maternal smoking in pregnancy with asthma risk may be due to epigenetic changes.[164] Indeed, altered DNA methylation patterns have been observed in several genes in buccal cells from children exposed in utero to tobacco smoke.[168] Likewise, exposure to diesel exhaust partially augmented the production of IgE following allergen sensitization through hypermethylation of IFNγ cytosin-phosphatidyl-guanosins (CpGs) and hypomethylation of CpGs in the IL-4 locus.[169] Further evidence for epigenetic contributions to disease risk is provided by the observation in mouse models of asthma that a maternal diet rich in methyl donors (folate) can increase susceptibility to allergic disease in offspring that is mediated through increased DNA methylation.[170] Studies in humans examining the role of folate have been conflicting, with one study showing no association,[171] whereas another showed an association between folate supplementation in late pregnancy and a physician's diagnosis of asthma in the offspring.[172]

Several lines of evidence suggest that the protective effects of maternal exposure to farm environments, which increase microbial burden prenatally, may occur through epigenetic changes. Specifically, studies have shown that nonpathogenic microbial strains isolated from farm environments can induce epigenetic effects when administered to pregnant animals and protect the offspring from experimental asthma.[173] The protective effects were IFNγ-dependent and associated with protection against the loss of histone 4 acetylation of the IFNγ gene in the CD4+ T cells of the offspring. In contrast, a decrease in H4 acetylase was observed in the IL-4 promoter. Moreover, pharmacologic inhibition of H4 acetylation in offspring abolished the protection. Further examination of epigenetic changes in allergy will

undoubtedly enhance our understanding of the ontogeny of allergic diseases.

FACTORS REGULATING TYPE 2 IMMUNE RESPONSES IN ALLERGIC INDIVIDUALS

Differentiation of naïve CD4+ T cells into the various subsets requires several signals derived from either APCs or accessory cells. These include presentation of antigen in the context of MHC II, signals conveyed through costimulatory ligand-receptor interactions, and signals conveyed through the actions of specific cytokines. Although the factors driving Th1, Th17, and T_{reg} subsets are well defined, the factors critical for the initiation of the type-2 response have long eluded investigators. In contrast to the steps involved in the differentiation of other T subsets, traditional antigen loaded APCs themselves are not sufficient to drive the early IL-4 required for Th2 differentiation or for full development of Th2 effector functions. Recently, however, several critical observations have led to a more detailed understanding of the type 2 response. First, three type 2-inducing cytokines, TSLP, IL-25, and IL-33, were identified as being necessary for the upregulation of type 2 effector cytokines, mirroring the role of IL-12 in the type 1 response. Secondly, recent evidence suggests that these type 2-promoting cytokines are produced by resident cells in mucosal tissues in response to innate immune receptor stimulation, not by the APCs themselves. Thirdly, exciting evidence suggests that type 2 effector cytokines can be produced by the newly described lineage negative innate lymphoid cell (ILC) populations in response to the type 2-promoting cytokines (IL-25, IL-33). Thus the overall emerging scenario is one in which allergens uniquely interact with mucosal epithelial cells and resident cells to produce these Th2-promoting cytokines through stimulation of various PRRs or danger associated molecular patterns expressed on resident mucosal cells. These cytokines (IL-33, IL-25) can themselves drive type 2 effector cytokines in innate cells (mast cells, basophils, ILCs) independently of APCs. In parallel, they also license traditional APCs to present allergenic peptides to conventional naïve T cells in draining lymph nodes, driving Th2 differentiation and T-cell memory development. The relevance of each of these steps to the development of allergic diseases will be discussed in the following sections (Fig. 45.3).

Innate Immune Responses to Environmental Antigens

Allergens interact with innate recognition systems present on a diversity of cells at the mucosal surface of the respiratory tract, skin, and gastrointestinal tract, including epithelial cells and phagocytic cells (DCs, macrophages). As the primary interface with the environment, the epithelial cell layer represents the front-line defense against injury by pathogens or environmental irritants. Emerging evidence suggests that epithelial cells play a critical role in both antigen recognition and danger recognition. Allergenic particles and their associated soluble components interact directly with epithelial cells through a variety of diverse mechanisms including 1) binding of PRRs including various members of the TLR family, the C-type lectin receptor (CLR) family, and nucleotide oligomerization domain (NOD) receptor family; 2) the activation of protease-activated receptors (PARs); and

3) activation of various danger sensing pathways (extracellular nucleotides, uric acid).

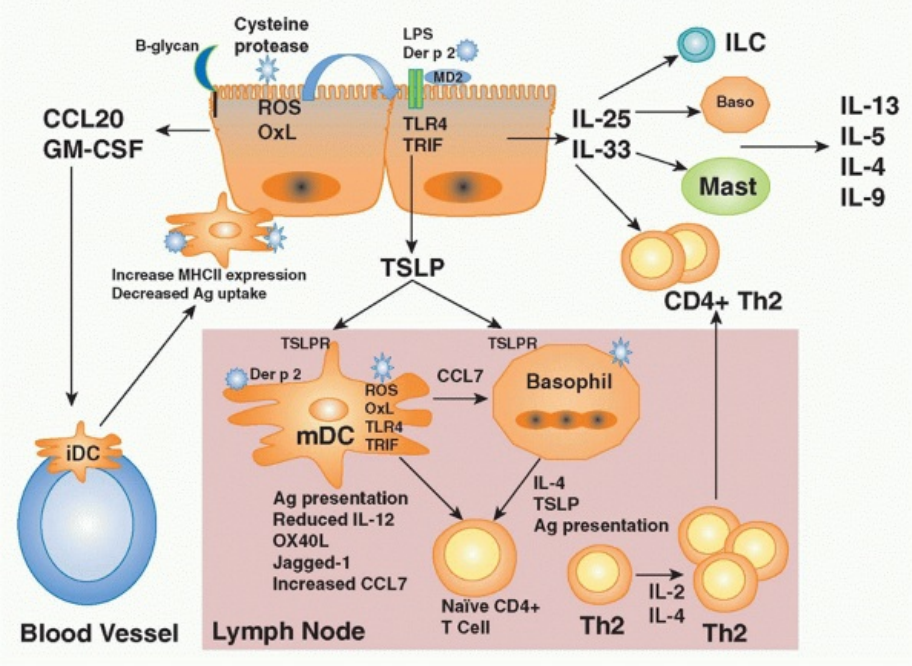

FIG. 45.3. Schematic of Events Leading to the Initiation of Th2-Mediated Immune Responses. Upon encounter with allergen, epithelial cells of the respiratory tract, the intestinal tract, and the skin release mediators that recruit (CCL20), activate (granulocyte macrophage-colony stimulating factor [GM-CSF]), and/or drive Th2 cell differentiation (thymic stromal lymphopoietin [TSLP], interleukin [IL]-25, IL-33). IL-25 and IL-33 recruit and activate a variety of innate immune cells such as basophils, mast cells, and innate lymphoid cells, which can produce the protypical type 2 cytokines IL-4, IL-5, and IL-13 driving the allergic phenotype. The elevations in IL-25 and IL-33 can perpetuate the allergic response by further type 2 cytokine production from basophils, eosinphils, or by initiating conventional Th2-cell expansion through activating dendritic cells (DCs) during encounters with allergens. In parallel, immature myeloid DCs are recruited to mucosal surfaces following the release of chemokines (ie, CCL20) and cytokines (GM-CSF) by epithelial cells in response to inflammatory stimuli such as allergens, pollutants, irritants, and/or viral infections. Once in the tissues, DCs mature and express costimulatory molecules (ie, CD86, OX40L, Jagged-1) under the influence of cytokines (TSLP, IL-33, IL-25) derived from surrounding tissues through stimulation of pattern recognition receptors (likely TLR4, -2; C-type lectins) expressed on their surface. In atopic individuals, it has been postulated that myeloid DCs appear to be the predominant population of DCs taking up antigen and driving the differentiation of naïve T cells toward a Th2 profile. They then migrate to the draining lymph node to stimulate naïve T-cell differentiation and proliferation. Proteasecontaining allergens induce the production of TSLP by epithelial cells through a series of steps including generation of reactive oxygen species, production of oxidized lipids, which in turn stimulate TLR4-TRIF signaling pathways leading to TSLP expression. These same pathways induce the production of the chemokine CCL7 by DCs, which recruits basophils to the lymph node. In the lymph node, they can also directly stimulate basophils to produce TSLP and IL-4. Basophils and DCs drive Th2 cell differentiation under the influence of various cytokines such as TSLP, IL-4, and IL-25. These Th2 cells proliferate in response to IL-2 and IL-4 in an autocrine fashion. Activated Th2 cells in turn migrate back to the site of antigen

stimulation under the influence of Th2 selective chemokines (CCL17, CCL12). Once in the tissues, Th2 cells secrete a profile of Th2 cytokines (IL-4, IL-5, IL-13, IL-9) that initiate a cascade of downstream pathways that collectively lead to the development of the allergic phenotype. Not shown on the figure is the fact that through their effects on the airway epithelium, Th2 cytokines may further amplify Th2 immune responses through the induction of Th2-selective chemokines (CCL17, CCL12) and/or IL-25 and IL-33 initiating a positive feedback loop. baso, basophil; iDC, immature dendritic cell; ILC, innate lymphoid cell; mDC, myeloid dendritic cell; ROS, reactive oxygen species.

Activation of epithelial cells through these diverse pathways can induce the release of cytokines (TSLP, IL-25, IL-33), chemokines, and growth factors that both facilitate entry of antigens into the mucosa; recruit APCs; and provide instructive signals to antigen APCs. As the absence of PRR activation and instruction of APCs results in the development of tolerance to exogenous antigens, alterations in these innate immune responses occurring at the epithelial-environmental interface may be important determinants of susceptibility or resistance to the development of allergic diseases (Fig. 45.4).

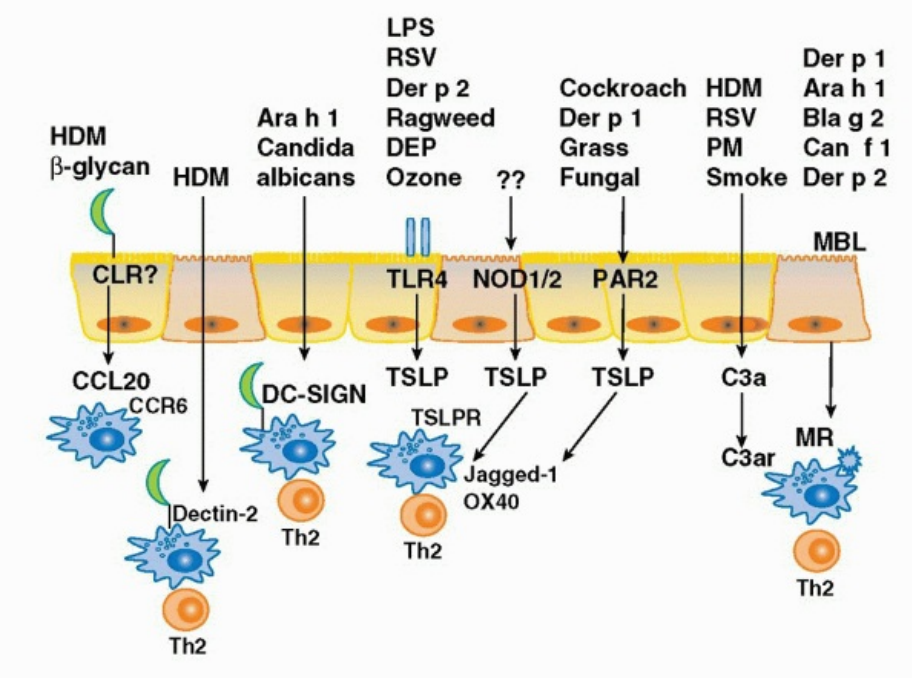

FIG. 45.4. Innate Immune Pathways Activated by Allergens. Allergenic peptides are recognized by several traditional pattern receptors including toll-like receptors, C-type lectin receptors, and nucleotide oligomerization domain receptors. In addition, other classes of allergens initiate Th2-mediated immune responses through the activation of protease-activated receptors and the cleavage of complement pathways. Activation of these innate immune pathways on mucosal epithelial cells leads to the production of chemokines which recruit immature demdritic cells (DCs), the production of Th2-promoting cytokines such as thymic stromal lymphopoietin, the enhancement of DC internalization of allergens, and the upregulation of expression of costimulatory molecules associated with Th2 differentiation such as OX40L and jagged-1. DEP, diesel

exhaust particles; HDM, house dust mite; MBL, mannan-binding lectin; MR, mannose receptor; PM, particulate matter. Der p 1 and Der p 2 are house dust mite-derived allergens; Ara h 1 is the major peanut allergen; Blag 2 is the major cockroach allergen; Can f 1 is the major canine allergen.

Role of Toll-Like Receptor Stimulation in Allergic Inflammation

The most well-studied family of PRRs in allergic inflammation is the TLR family. Epidemiologic studies have consistently reported an inverse correlation between high levels of bacterial products such as LPS in the ambient environment during very early life and the subsequent development of atopy and allergic disease.[174,175] It has been postulated that such exposures drive counterregulatory immune responses in the developing immune system.[176] On the other hand, controlled human challenge studies have shown that LPS exposure of sensitized individuals can exacerbate existing disease.[177] Although the mechanisms underlying this apparent paradox are not entirely clear, the complexity of the responses to TLR agonists may be due to several factors including the array of TLR receptors activated by complex allergens (TLR9 versus TLR4), their relative abundance, and the timing of exposure during the life of the individual. For example, TLR9 stimulation clearly prevents and inhibits the development of experimental allergic inflammation at all doses,[178] whereas TLR2 and TLR4 pathway stimulation has been shown to both drive[179,180] and inhibit[180,181] the development of Th2-mediated allergic inflammation in experimental mouse models. Bottomly and colleagues[180] have shed some light on this complexity, demonstrating that the impact of TLR4 stimulation on allergic inflammation is highly dependent upon the dose of TLR4 agonist. Specifically, they showed that although airway sensitization with the normally tolerizing antigen, OVA along with 1 ng of LPS (LPS-depleted) was reported to induce tolerance, sensitization in the presence of “low-dose” (0.1 μg) LPS promoted TLR4-dependent, Th2 inflammation, and sensitization in the presence of “high-dose” (100 μg) LPS led to a Th1 response. Although these studies provided a plausible explanation for the LPS dose effects observed in epidemiologic studies, they did not explain how stimulation through the same receptor could result in two distinct biologic outcomes. To address this issue, Tan and colleagues[182] examined allergic responses in a series of bone marrow chimeric mice expressing TLR4 in specific compartments. They show that strong (high-dose LPS) TLR4 signaling always results in a Th1 response despite the fact that high LPS stimulation of mice expressing TLR4 only in the stromal compartment drives Th2 responses, as a result of the dominant influence of the hematopoietic cell compartment under these conditions. Surprisingly, they found that at very low LPS levels, mice expressing TLR4 only in the stromal compartment did not mount Th2 or Th1 immune responses. However, when mice that had competent TLR4 signaling in both the stromal and hematopoietic compartments were exposed to low levels of LPS+OVA, they mounted Th2 immune responses, suggesting that once a threshold level of TLR4 stimulation is reached in the stromal compartment, Th2 responses ensue. The authors propose that the ability of stromal cells (presumably epithelial cells) to drive Th2 responses is likely through their ability to secrete TSLP and to promote the maturation of Th2-inducing DCs that express the Notchligand Jagged-1, but not the Th1-inducing ligand, Delta-4. As Jagged-1 has been shown to induce the expression of the critical

Th2 transcription factor, GATA3 in CD4+ T cells through binding Notch ICD, these findings may explain the association between low-level activation of TLR4 pathways and Th2-cell differentiation.[183] In contrast to Tan's findings, another group[184] showed that stromal cell TLR4 signaling was sufficient to drive Th2 immune responses when mice were exposed to dust mite extracts containing low levels of LPS, suggesting that the dust mite extracts might contain endogenous TLR4 agonists that shift the dose response of the stromal compartment to TLR4 stimulation into the Th2-inducing range.

A recent study has provided a compelling mechanism by which endogenous components of dust mites may drive TLR4 signaling. Based on the recent discovery of a structural homology between Der p 2, one of the major house dust mite allergens, and MD-2, a member of the lipid-recognition (ML) domain family of proteins, which is the LPS-binding member

of the TLR4 signaling complex, Trompette and colleagues[25] asked the question whether Der p 2 and MD-2 exhibited functional homology as well. Indeed, they reported that Der p 2 facilitates TLR4 signaling through direct interactions with the TLR4 complex, reconstituting LPS-promoted TLR4 signaling in the absence of MD-2. They also demonstrated that Der p 2 could facilitate LPS signaling in primary APCs, with or without MD-2 being present. Finally, they reported that in vivo delivery of Der p 2 drives the development of experimental allergic asthma in a TLR4-dependent manner, retaining this property in mice with a genetic deletion of MD-2. These data suggest the possibility that Der p 2-mediated activation of TLR4 signaling in the airway epithelium under conditions of low bacterial product exposure—those associated with increasing rates of aeroallergy in the urban, developed world— may shift the LPS/TLR4 response curve from the tolerizing into the Th2-inducing range. Der p 2 exposure may serve to facilitate TLR4 signaling by airway epithelial cells as they have been reported to express TLR4, but little or no MD-2, in the basal state.[185]

The fact that the major dust mite allergen, Der p 2, is a molecular mimic of an endogenously expressed mammalian lipid binding family member has several important implications for our understanding of allergenicity. As numerous other members of the MD-2-like lipid binding family are major allergens, the activation of innate immune pathways via lipid binding is likely to be a common feature of allergens. Indeed, the recently solved structures of several allergens including Der p 5 and Der p 7 suggest that they possess the propensity to bind hydrophobic compounds.[186,187] Of note, Der p 7 has been shown to resemble the LPS binding protein and to bind to the lipopeptide polymyxin B from gram-positive bacteria. More broadly, a wide range of allergens are lipid binding proteins (ie, lipid transfer proteins [peach allergen Pru p 3], steroid-like molecules [cat allergen Fel d 1], lipocalins [horse allergen Equ c 1, mouse allergen Mus m 1]). Further studies are clearly needed to define the lipids naturally bound by these allergens, the receptors activated by such lipids, and the precise pathways of innate and adaptive immune responses driven by such activation.

Despite our rudimentary understanding of the role of PAMPs in allergic responses, one may speculate that either differences in exposures to microbial products or polymorphisms in genes of the TLR pathway may both be important determinants of the risk of developing allergic disease through altering the phenotype and function of DCs. Along these lines, as discussed previously, genetic studies show that polymorphisms of different components of the TLR pathways (CD14, TLR4, TLR2) may partly explain susceptibility to

atopy.[152,153,154,155,156]

Role of Carbohydrate Recognition in Th2 Immunity

Just as the mammalian immune system has evolved mechanisms to recognize bacterial proteins in association with PAMPs that induce appropriate Th1 responses, recent studies suggest an important role for complex carbohydrates in driving Th2 immune responses to allergens. In particular, fucosylated glucans are a diverse class of naturally occurring glucose polymers that are widely expressed in the cell walls of fungi, helminths, pollens, and certain bacteria, but they are not found in mammalian cells. Evidence is emerging that these carbohydrates drive strong Th2-biased immune responses through their interaction(s) with a large array of CLRs.

The C-type lectin family of soluble and transmembrane receptors demonstrate unique specificity for carbohydrate residues via distinct clustering of carbohydrate recognition domains.[188] Transmembrane members of the CLR family include collectins, the mannose receptor family, selectins, dectin 1 and 2, and DC-specific intercellular adhesion molecule-3-grabbing nonintegrin. Ligand engagement of these receptors is involved in processes ranging from cellular trafficking to cell signaling and pathogen recognition mediated through FcRγ and Syk activation.[188]

Several studies suggest the involvement of various C-type lectins in regulating allergic inflammation. For example, it has been reported that β-glucan structures present in the peanut glycoallergen Ara h 1 have Th2-inducing characteristics; native, but not deglycosylated, Ara h 1 has been shown to activate human monocyte-derived DCs and induce IL-4- and IL-13-secreting Th2 cells.[26] The Th2-promoting actions of Ara h 1 were mediated through binding of DC-specific intercellular adhesion molecule-3-grabbing nonintegrin and activation of ERK/MAPK signaling in DCs. Consistent with a role for lectins in promoting Th2 immune responses, a recent study showed that the CLR dectin-2 was required for the development of house dust mite-induced allergic inflammation.[189] Consistent with a major role for CLRs in initiation of Th2 immune responses, β-glucans have been shown to mediate several aspects of DC function including antigen uptake, recruitment and activation of DCs, and instruction for Th2 differentiation. For example, blockade of the mannose receptor, an endocytic CLR, significantly reduced Der p 1 uptake by DCs.[190] Moreover, recent studies have shown that β-glucans contained in house dust mite extracts and in molds may initiate immune responses through the induction of the chemokine, CCL20, which recruits immature DCs. The induction of CCL20 was shown to occur through β-glucan and Syk-dependent signaling pathways.[191] Although the study of the role of carbohydrates as Th2-inducing PAMPs is only in its infancy, the evidence thus far suggest that carbohydrate moieties contained in common allergens function as strong Th2 inducers through activation of variety of CLRs on DCs.

Allergens containing lectins may also activate the lectin pathway of complement pathway activation, a highly conserved component of innate immunity. The complement system is a sophisticated network of soluble and membranebound proteins, which serve as both immune sensors and immune activators. Like other PRR pathways, the complement system can be activated by “hardwired” PRRs that have elvolved to recognize both endogenous and exogenous “danger” motifs. Lectin recognition receptors in the complement system include:

mannan-binding lectin, and ficolins. Recognition of pathogen-associated carbohydrate residues by the soluble mannan-binding lectin triggers the serine protease-mediated cleavage of complement components C4 and C2 resulting in the generation of C3 convertase that carries out the rest of the complement cascade. Recognition by mannan-binding lectin is an integral part of the first line

of defense against a large number of microbial pathogens including bacteria, fungi, protozoa, and viruses. Indeed, it has recently been shown that the major cat allergen, Fel d 1, is a novel ligand of the cysteine-rich domain of the mannose receptor and the development of allergic inflammation induced by Fel d 1 was attenuated in mannose receptor-deficient mice.[192] Likewise the mannose receptor has been shown to mediate the internalization of a diverse range of allergens (Der p 1, Der p 2, Can f 1, Bla g 2, Ara h 1) into monocyte-derived DCs through their carbohydrate moieties.[193] Alterations in these pathways may lead to enhanced recognition of allergens as sequence variations in the MRC1 gene have recently been associated with the development of asthma in two independent and ethnically diverse populations (Japanese and African American).[194]

Nucleotide Oligomerization Domain Receptors in Allergic Inflammation

Although NOD receptors have not been as well studied as other PRRs, it has recently been shown that NOD1 (which binds cell wall peptidoglycans of gram-negative bacteria) and NOD2 signaling in stromal cells drives Th2 immune responses through the TSLP-dependent induction of OX40L.[195] Studies demonstrating that polymorphisms in the intracellular NOD1 protein were associated with atopic eczema and asthma[196] suggest that alterations in these pathways may play an important role in susceptibility to some atopic disorders.

Proteases in Allergic Inflammation

Several of the common allergens (house mite-derived, Der p 1, and Der p 3; Fed d 1 from domestic cats; cockroach allergens; fungal allergens) possess intrinsic protease activity. While the link between protease activity and type 2 inflammation is well documented, the mechanistic basis for these observations has been unclear. Allergens containing protease activity, such as Der p 1, a cysteine protease, have been demonstrated to produce changes in the barrier function of the epithelium, probably by disrupting the epithelial tight junctions by degrading the tight junction proteins ZO-1 and desmoplakin.[197] Disruption of the tight junctions may both facilitate access of allergens to the underlying cells including DCs and may also directly initiate inflammatory cascades (modulate the function or immune and structural cells) in DCs and/or airway epithelium. For example, Der p1 cleaves several important immunomodulatory molecules including CD25, CD23, and various complement components.[198,199] As a result of cleavage of CD25, peripheral blood T cells show markedly diminished proliferation and IFNγ secretion in response to potent stimulation by anti-CD3 mAb. These findings suggest that Der p1 decreases the growth and expansion of antigen-specific Th1 cells augmenting expansion of the antigen-specific Th2 cells that favor a proallergic response. Der p 1 cleavage of CD23 on murine B cells that would normally serve to inhibit IgE synthesis would further potentiate allergic responses by disrupting an important negative regulator of IgE production.[199]

Although the cellular mechanisms by which protease activity induces cytokine release remain unclear, members of a recently identified G protein-coupled family of cell surface receptors, designated PARs, have been implicated. Indeed, allergens such as the house dust mite serine proteases, Der p 3, Der p 9, cockroach extracts, and pollens activate PARs. Asokananthan et al.[200] have shown that endogenous peptidases caused the release of cytokines through the activation of PARs on the respiratory epithelium, and that all four members of the PAR family were expressed on respiratory epithelial cells. In vivo experiments in experimental allergen models support the contention that activation of PAR pathways is associated with enhanced allergic responses. Specifically, PAR-2 overexpression enhanced OVA-induced eosinophilia and bronchial hyperresponsiveness, whereas PAR-2 deficiency was associated with reduced allergendriven eosinophilia and IgE production.[201] Although the exact mechanisms by which PAR-2 mediates Th2 induction is unknown, PAR-2 was shown to mediate, in part, the induction of TSLP from airway epithelial cells in vitro in response to the protease activity of the common environmental fungus *Alternaria alternata*, as well as in response to the cysteine protease papain.[202]

Role of Danger-Associated Molecular Patterns in Regulation of Th2 Immunity

Several sensors of cellular damage have recently been implicated in the development of allergic inflammation. First, Eisenbarth and colleagues[203] showed that the adjuvant alum promotes humoral responses by activating the nucleotide binding domain-leucine rich repeat (LRR)-containing receptor (NLR) inflammasome. Moreover, it has been shown that allergen stimulation of airway epithelial cells results in an upregulation of extracellular adenotriphosphate levels that trigger the migration of myeloid DCs (mDCs) into the airways and mediate the development of allergic inflammation in vivo.[204] Idzko and colleagues[205] have recently shown that these adenotriphosphate-triggered effects on airway inflammation are regulated via the P2Y(2)R. Another sign of cellular damage is the release of the potent antioxidant uric acid. Recent studies show that administration of uric acid crystals together with protein antigen was sufficient to promote Th2 cell immunity and the features of asthma.[206] Surprisingly, the adjuvant effects of uric acid did not require the inflammasome (Nlrp3, Pycard) or the IL-1 (Myd88, IL-1r) axis, but promoted Th2 cell immunity by activating DCs through spleen tyrosine kinase (syk) and PI3-kinase δ signaling. Recently, a member of the trefoil factor family (TFF2), which has previously been shown to be a sensor of damage to the gut epithelium, has been shown to regulate Th2 immune responses to both allergens and helminth infections via induction of IL-33 by the epithelium and alveolar macrophages.[207]

These studies demonstrated that in contrast to Th1-inducing factors, which directly license DCs through PRRs, allergens license antigen-loaded DCs and accessory cells through a variety of innate signals derived from the mucosal epithelium to induce Th2 immunity. Thus, licensing of APCs in trans by signals emanating from the stromal compartment appears to be a unique feature of Th2 immune responses. As will be discussed subsequently, this concept is entirely consistent with studies showing that the primary cytokines driving Th2 differentiation are stromal cell (epithelial cell)-derived.

Cytokine Regulation of Th2 Differentiation in Allergic Disease

One of the most important variables in instruction of T-cell differentiation comes from the local cytokine milieu at the time of antigen presentation. Recently, Th2 cell-polarizing factors have been finally identified, these include TSLP, IL-25, and IL-33 (Fig. 45.5). Alterations in either the production of or responsiveness to these signals could lead to the development of aberrant Th2 immune responses in atopic individuals. Indeed, there is evidence to support each of these possibilities.

Thymic Stromal Lymphopoietin Initation of Th2 Immune Responses

TSLP is an IL-7-like cytokine originally characterized by its ability to promote the activation of B cells and DCs.[208] The TSLP receptor is comprised of the IL-7Rα chain and the unique TSLPR chain. TSLP is expressed by epithelial cells with the highest levels being found in lung- and skin-derived epithelial cells. TSLP has been shown to activate DCs such that they acquire the ability to prime naïve T cells for the production of Th2 cytokines, while downregulating IFNγ and IL-10. In support of a role for TSLP in Th2 responses, TSLP levels have been shown to be elevated in the airways of asthmatic individuals[209] and in animal models[210,211] of atopic disease. Overexpression of TSLP in the lungs of mice has been shown to lead to the development of Th2 immune responses, whereas TSLPR knockout mice develop strong Th1 responses to allergen and are protected against the development of allergen-driven asthmatic responses.[210,211] Finally, overexpression of TSLP in the skin of mice results in an atopic eczema-like phenotype.[212] In humans, the gene encoding TSLP is located on chromosome 5q22 in a strong linkage region for asthma. Polymorphisms in TSLP have been associated both with asthma[213] and eosinophilic eosophagitis.[130] Although the IL-7Rα gene is located on chromosome 5p13, it remains to be determined whether polymorphisms in the IL-7Rα receptor influence TSLP signaling. Although the precise mechanisms underlying the ability of TSLP to prime DCs is not known, one mechanism that has been postulated is that TSLP induces DCs to express OX40 ligand (OX40L) and decrease IL-12 production.[214] In support of this contention, TSLP-induced OX40L on DCs was required for triggering naive CD4+ T cells to produce IL-4, -5, and -13.[215]

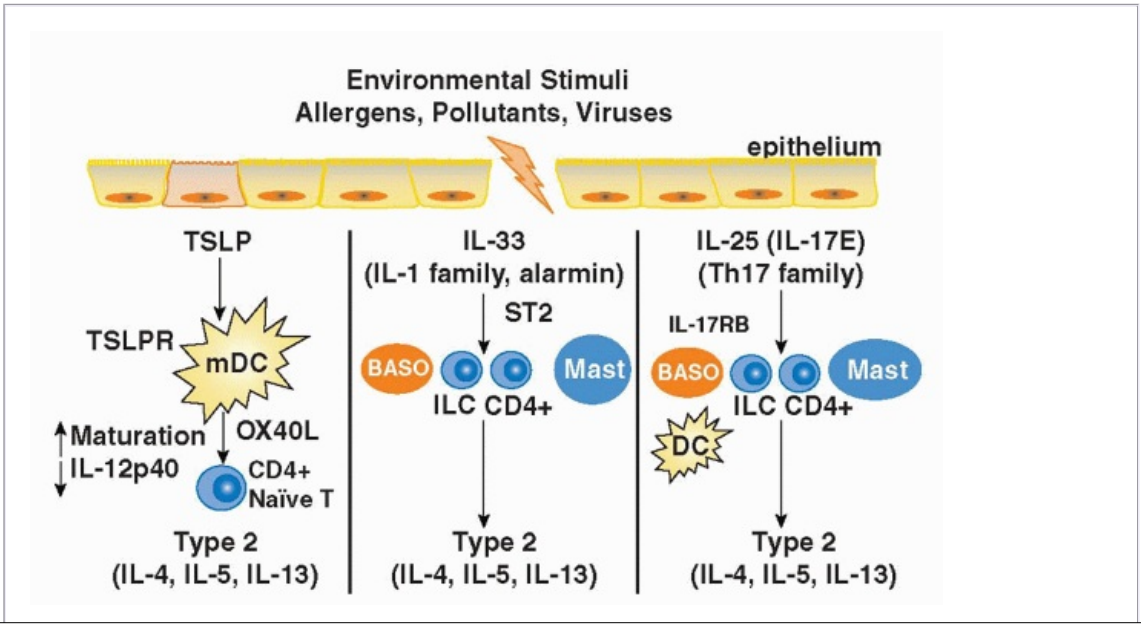

FIG. 45.5. Members of Three Distinct Cytokine Families Promote Th2 Differentiation. Thymic stromal lymphopoietin (TSLP), an interleukin (IL)-7-like cytokine released from mucosal epithelial cells, binds its receptor TSLPR on dendritic cells and induces the expression of OX40L and the suppression of IL-12 production, thus driving the differentiation of naïve T cells toward a Th2 phenotype. IL-33 is an IL-1 family member that binds its unique receptor ST2 on a variety of innate immune cells including basophils, innate lymphoid cells, conventional CD4+ T cells, and mast cells driving the production of type 2 cytokines. IL-25, a member of the IL-17 cytokine family, binds its receptor IL-17RB on a variety of innate immune cells including basophils, innate lymphoid cells, mast cells, and conventional CD4+ T cells driving their production of type 2 cytokines. IL-25 and IL-33 can also stimulate type 2 cytokine production indirectly by activating dendritic cells to promote Th2 differentiation.

Interleukin-25 in Allergic Inflammation

IL-25 is a novel member of the IL-17 cytokine family (IL-17E) that promotes CD4+ T-helper 2 lymphocyte-like (Th type-2) inflammatory responses. IL-25 is produced by epithelial cells, activated human basophils, eosinophils, and mast cells. Recombinant IL-25 administration to mice has been shown to induce IL-4, IL-5, and IL-13 production, and systemic Th2-cell responses, characterized by elevated IgE production, eosinophilia, and remodeling in several organs including the lungs, gastrointestinal tract, and skin of naïve mice.[216] Interestingly, IL-25 can induce these Th2-mediated immune responses in mice lacking T and B cells, suggesting that IL-25 acts upon another cell type besides T cells to drive IL-13 production.[217] A search for the cellular targets of IL-25 has led to the discovery of a family of ILCs that produce type 2 cytokines (ILC2 cells).[217] These ILC2 cells belong to a heterogeneous family of innate cells that do not express surface markers of adaptive immunity (non-T, non-B cells) and are not antigen restricted like their adaptive counterparts. However, as they express CD45 and are dependent on traditional T-cell growth factor signaling pathways such as those mediated through the common γ-chain and IL-7 receptor α-chain (CD127), they have been called ILCs. The population of ILC2s that produce type 2 cytokines in response to IL-25 and IL-33 are lineage-negative (CD4-CD127+IL-1RL1+IL-17RB+, RORγt-). Several ILC2 cells have been discovered in the mouse by independent groups and have been designated natural helper cells,[218] multipotent progenitor type 2 cells,[219] nuocytes,[217] and innate helper type 2 cells.[220] Recently, it has been shown that adoptive transfer of wild-type nuocytes producing IL-13, but not IL-13-/-nuocytes, into IL-13-deficient mice was sufficient to induce allergic inflammation.[221] Although there is much to learn about these populations and the mechanisms regulating their function, increased IL-25 and IL-25R expression has been detected in patients with asthma, suggesting that overproduction of IL-25 may be associated with aberrant type 2 immune responses.[222]

Interleukin-33 and Nuocytes in Atopy

IL-33 is a member of the IL-1 family that stimulates type 2 cytokine production through binding its receptor composed of the IL-33 specific receptor chain, IL-1RL1 (ST2) and the

IL-1 receptor accessory protein (IL-1RAcP),[223] both of which are widely expressed, particularly by innate immune cells (mast cells, basophils, DCs), Th2 cells, and innate lymphoid populations described previously.[217,223] IL-33 is thought to function as an "alarmin" released from stromal cells (epithelial cells, endothelial cells, and airway smooth muscle) following cellular injury to alert the immune system to tissue damage or stress. A role for IL-33 in type 2-cytokine dependent immune responses in vivo is supported by the finding that administration of IL-33 to naive mice induces eosinophilia, increased serum IgE levels, IL-5 and IL-13 production, and mucus cell changes in the respiratory and gastrointestinal tracts.[224] Moreover, blocking IL-33 with an ST2 fusion protein decreases eosinophilic airway inflammation, concomitant with a decrease in IL-4 and IL-5 expression.[225] Notably, the levels of soluble ST2 protein and IL-33 mRNA protein are increased in sera and tissues from patients with asthma.[226,227] Genome-wide association studies have identified polymorphisms in the genes encoding Il1rl1 and Il33 in patients with asthma, hypereosinophilic diseases, and allergic rhinitis, suggesting an association with atopic disorders in general.[228,229,230]

Although the exact mechanisms by which IL-33 induces type 2 cytokine production are unknown, it has been shown to induce Th2 cytokines from a number of innate immune cells including basophils, mast cells, and the newly described ILC populations. In support of a role for the activation of ILCs by IL-33, it has recently been shown that administration of rIL-33 induces AHR and eosinophilic inflammation in mice independently of adaptive immune cells.[224] Interestingly, it was initially reported that OVA-induced AHR was not dependent on ILCs,[231] whereas another study suggest that fungal antigen-induced allergic inflammation was dependent upon IL-33 and innate lymphoid populations.[232] Collectively, these results suggested that antigens, which contain PAMPs that activate or injure the epithelium, recruit and/or activate ILCs. Consistent with this hypothesis, it has recently been shown that IL-13-producing ILCs are important in protection of the mucosal epithelium following viral infections, despite the fact that the type 2 cytokines do not play a role in clearance of the virus.[233] In support of a role for ILCs in allergic disorders, Mjosberg et al.[234] recently reported that a lineage-negative CD127(+)CD161(+) ILC population that responded to both IL-25 and IL-33 by producing IL-13 was enrichment in nasal polyps of patients with chronic rhinosinusitis. Although much remains to be learned about the role of ILC2 cells in type 2-mediated immunity, these new studies raise the possibility that expansion of these unique ILCs in response to exposure to allergens, infectious agents, or environmental toxins may unwittingly lead to the establishment of type 2-mediated diseases.

Antigen-Presenting Cells in Atopic Individuals

Although as discussed previously, type 2 immune responses can arise independently of conventional CD4+ T cells, it is clear that sensitization to allergens involves the development of memory T cells directed against these proteins, which requires the presentation of antigen to CD4+ T cells. A number of professional APCs such as DCs, Langerhans cells, B cells, and macrophages are present at mucosal surfaces and have the cellular specialization to capture and process antigen for presentation to T cells, it has become increasingly clear over the last

decade that DCs and Langerhans cells are the most important professional APCs at mucosal surfaces. However, recent evidence suggests that in specific instances, basophils may also serve as an important APC.

Dendritic Cells in Allergic Inflammation

DCs migrate as precursor cells to sites of the body where antigen entry occurs (ie, lung, skin, gastorintestinal tract). At these sites, they form an extensive network of cells, extending cell projections between resident cell types that ensure accessibility to allergens. DCs that reside in the periphery have an immature phenotype, specialized for uptake and recognition of antigens, but not yet capable of stimulating naive T cells, because they lack costimulatory molecules on their surface (CD80, CD86). Normally, DCs present antigens quite inefficiently; however, when antigen is encountered in an inflammatory context (eg, in the presence of antigen-derived danger signals) or through indirect sensing of “danger” from surrounding cells via the release of inflammatory cytokines, DCs undergo a developmental program referred to as maturation. During maturation, they lose their ability to take up antigen and acquire a phenotype of professional APCs expressing all the costimulatory molecules and chemokines required to attract and stimulate naïve T cells. Once DCs have acquired antigens at the mucosal surface, they migrate to T-cell areas of draining lymph nodes and present their antigen cargo to naive T cells. During this interaction with naive T cells in the lymph nodes, DCs have an opportunity to influence T-cell differentiation along a Th1, Th2, Th17, or T_{reg} cell pattern by secretion of a specific cytokine pattern, depending upon their lineage, their maturation status, and the consequent costimulatory molecule pattern. Thus, alterations in the signals provided by DCs to T cells may underlie the development of polarized Th2-cell responses in the context of allergic disease. Considerable evidence is accumulating to support this tenet.

Indeed, several lines of evidence in murine models of allergic disease as well as in human atopic support a pivotal role for DCs in the development of allergic responses. For example, Lambrecht et al.[235] have demonstrated that infusion of antigen-pulsed bone marrow-derived DCs into the respiratory tract of mice primed them for development of Th2-mediated immune responses upon subsequent antigen challenge. Conversely, using a suicide gene approach to specifically deplete DCs, it was demonstrated that antigen exposure did not induce allergic responses in the absence of DCs. In humans, a critical role for DCs in generation of allergic responses is the demonstration that the numbers of HLA-DR-expressing DCs are increased in the mucosal tissues of patients with asthma, allergic rhinitic, or AD when compared to the low level of DCs found in specimens from normal controls.[236,237,238,239] Moreover, the improvement in lung function associated with regular use of steroids is associated with a reduction in the number of CD1a+HLA-DR+DCs in the airways of patients with asthma.[240]

DCs play a major role in the surveillance of peripheral tissue sites for incoming antigens, a function that is dependent on their capacity for tightly controlled migration between different compartments. Under steady state conditions, there is a continuous turnover of DCs at mucosal surfaces, with the recruitment of immature DCs from circulating precursors, balanced by the exit of mature, antigen-loaded cells to regional lymph nodes. In both humans and mice, DCs are not constitutively present in the tracheal-bronchial mucosa in the first year of life[241]; their occurrence appears to be dependent on exposure to inflammatory stimuli from

the local environment.[242,243] Although the exact signals that regulate the rapid recruitment of immature DCs from the blood into the mucosal tissues are not fully understood, exposure to a number of environmental triggers (allergens, particulate matter, smoke, RSV, ozone) have been shown to dramatically increase the recruitment of DCs in both animal models of atopic disease and atopic humans.[243,244] These triggers likely attract DCs to mucosal surfaces through their ability to induce a set of chemokines that bind to receptors exclusively expressed on immature DCs. Indeed, it has been shown that epithelial cells synthesize and secrete the CCR6 ligand, MIP-3α/CCL20, in response to allergens and particulate matter.[245] Interestingly though, Der p1 stimulation of bronchial epithelial cells from patients with asthma results in CCL20 production and migration of Langerhans cell precursors; however, this is not observed in cells from healthy individuals.[246] The ability of these triggers to induce DC chemokines may explain the adjuvant effect of each of these irritants in induction of allergic responses. These studies suggest that responsiveness of mucosal epithelial cells to certain pathogens and/or environmental stimuli early in childhood may enhance or inhibit sensitization to allergens by affecting DC recruitment.

The maturational state of DCs is thought to be an important determinant of the development of tolerance or immunity. It has been suggested that DC immaturity may contribute to the development of tolerance. Indeed, studies from both animal models and atopic humans suggest that the magnitude and pattern of costimulatory molecule expression on DCs is strongly associated with susceptibility to atopic disease. In this regard, DCs influence the nature of the immune response to antigen stimulation through the balance of positive signals provided by CD28 engagement of B7-1, B7-2, B7-H3, and B7-H4 on resting T cells and negative signals provided through ligation of CTLA4 and PD-1 on resting T cells. Indeed, differences in the relative expression of these positive and negative signals have been shown to be important in various murine models of allergic disease. Specifically, it has been reported in numerous studies that Th2-mediated immune responses are predominantly dependent upon DC expression of CD86, not CD80.[247] In contrast, stimulation of CTLA4 and BTLA have been shown to decrease allergic responses.[248] CTLA4 in particular is predominantly expressed on T_{reg}s and is thought to mediate its inhibitory effects through T_{reg} suppressive functions. While studies have shown that B7RPICOS interactions mediate tolerance through the induction of IL-10-secreting Tr1 cells,[249,250] another study has reported that ICOS-ICOSL interactions positively regulates allergic responses.[251]

Several studies have suggested that DCs from atopic individuals have a different phenotype from those of nonatopic individuals.[252,253,254,255] First, the functional capacity of DCs from atopic individuals has been elegantly studied in a humanized severe combined immune deficiency mouse model.[254] In this model, it has been demonstrated that adoptive transfer of DCs from atopic individuals reconstitutes Th2-polarized immunity associated with allergic inflammation in the lungs of mice. In contrast, transfer of DCs from nonatopics resulted in combined Th1/Th2 responses. Purified T cells from house dust mite-sensitive patients stimulated by autologous Der p1-pulsed DC preferentially produced IL-4.[255] Interestingly, DCs from nonatopic individuals stimulated with Der p 1 expressed CD80, produced IL-12, and stimulated IFNγ production in T cells. Another intriguing finding of this study was that the effects of Der p1 on costimulatory molecule expression in DCs from allergic patients was

dependent on the enzymatic activity of Der p1, as a cysteine protease inhibitor prevented these effects. It has also been shown that differences in inhibitory molecule expression may play a role in susceptibility to allergic disease. Specifically, Akdis et al.[255] showed that allergenspecific (Der p1) T cells from nonatopic individuals produced high levels of IL-10 that were associated with elevated T-cell surface expression of IL-10R, CTLA4, TGF-βR1 and Il, CD25, and PD-1 as compared to those of atopic individuals. Neutralization of these suppressor pathways led to increased production of Th2 cytokines, suggesting that ligation of these inhibitory receptors on T cells by their DC ligands is critical in maintaining the balance between Th2 and tolerogenic T-cell responses. These studies suggest that DCs from atopic individuals display altered costimulatory molecule patterns as compared to normal individuals in response to direct stimulation with allergens and the PAMPs they may contain. Although the pattern and level of expression of costimulatory molecules on DCs and their ligands on T cells may be controlled by exogenous signals, polymorphisms in several costimulatory molecules have been shown to be associated with increased risk of development of Th2-mediated immune responses and atopic diseases such as asthma and atopic dermatitis. Specifically, polymorphisms in ICOS (1413G/A) are associated with allergic sensitization and Th2 cytokine production,[256] and polymorphisms in the CTLA4 gene are associated with infant atopic dermatitis[257] and asthma.[258,259]

Several lines of evidence suggest that alterations in the relative proportion of specific DC subsets taking up antigen at mucosal surfaces may play an important role in the development of immunity or tolerance. For example, adoptive transfer of mDC to the murine airway prior to antigen exposure has been shown to induce Th2-mediated immune responses to a tolerogenic antigen,[235] whereas depletion of plasmacytoid DC (pDC) in mice during inhalation of the normally inert antigen OVA via the airways without systemic priming led to a Th2 response and all the features of asthma.[260] These results strongly suggested that pDCs might provide intrinsic protection against inflammatory responses

to harmless antigens. Although the precise mechanisms by which pDCs promote tolerance are unknown, several possibilities exist. First, pDCs can produce the tryptophanmetabolizing enzyme indoleamine 2,3-dioxygenase, which has a strong inhibitory activity on T-cell proliferation.[261] Moreover, human pDCs activated by CpG oligonucleotides induce the generation of T_{reg}s.[262] Although the exact factors regulating the recruitment and/or activation of different DC subsets is unknown, Kohl et al.[263] have shown that complement activation at the airway surface is an important regulator of DC subset recruitment and activation. Specifically, they demonstrate that C5a preferentially results in the recruitment of pDCs to the lung, which is associated with protection against the development of Th2-mediated allergic airway responses. Taken together, these studies suggest that the balance between mDCs and pDCs may play a pivotal role in T-cell responses to antigen encounter at mucosal surfaces with myeloid cells driving immunity, while pDCs mediate tolerance to mucosal antigens.

Due to the difficulty in sampling DC populations in tissues from atopic individuals, the role of mDCs and pDCs in atopic individuals remains controversial. For example, Hagendorens and colleagues[264] compared DC populations in cord blood from children at low versus high risk of atopy and did not detect any differences. In contrast, a moderate reduction in pDC

numbers in the blood was reported in atopic asthmatic children compared with healthy controls, which the authors suggested might be due to increased migration of pDCs to the target organ. In contrast, Matsuda et al.[265] showed that adult patients with asthma have increased numbers of pDCs in the blood as compared to healthy controls. In patients with atopic dermatitis, Hashizume et al.[266] reported an overall increase in the numbers of DCs in the blood with a relative increase in pDCs over mDCs. However, when DCs were evaluated in the nasal epithelium of atopic rhinitis patients, the number of pDCs was reduced. Although there is controversy as to the relative proportion of individual DC subsests present in the blood and tissues of atopic individuals, there is evidence that DC subsets may be functionally different between atopic and healthy individuals. Specifically, Der p1-pulsed mDCs from healthy donors produced IL-10, whereas mDCs from allergic patients did not.[267] Although the study of DC subsets in human disease is in its infancy, these studies suggest that differences in the balance of DC subsets and their activation state may play an important role in determining the development of tolerance or immunity to environmental antigens. However, additional studies of DC subsets in relevant tissues are needed. Collectively, these studies suggest that altered DC function may underlie the propensity of atopic individuals to mount Th2-biased immune responses to environmental allergens.

Basophils as Drivers of Th2 Immunity

Although there is a wealth of evidence suggesting a pivotal role for DC in driving Th2 immunity, recent evidence suggests that they may not be sufficient to induce Th2 immune response to certain allergens. Medzhitov and colleagues recently provided surprising evidence that MHCII-positive IL-4-producing basophils were both necessary and sufficient for the generation of type 2 immunity to protease antigens.[268,269] Specifically, they demonstrated that immunization with the cysteine protease allergen papain resulted in the transient recruitment of basophils to lymph nodes that peaked 1 day prior to the peak of IL-4-producing CD4+ T cells. These papain-elicited basophils within the lymph node were shown to express IL-4 and TSLP. In vivo depletion of TSLP or basophils correlated with impaired Th2 cell differentiation following papain immunization, suggesting a role for basophil-derived TSLP in papain-mediated Th2 cytokine responses. Of note, treatment of basophils with papain in vitro also resulted in the production of IL-4 independently of IgE. These findings were unexpected as basophils had been thought to be MHC class II negative. However, the authors showed in a subsequent study that papain stimulation upregulated the basophil expression of MHCII and costimulatory molecules.[268] Moreover, papain stimulation of basophils induced the production of IL-2, IL-4, IL-6, and IL-13. They formally demonstrated the antigen-presenting capability of basophils in an adoptive transfer experiment in which antigen-loaded MHCII basophils transferred into Ciita-deficient mice induced Th2-mediated responses following papain exposure. Quite surprising, the authors found no role for traditional DCs in papain-induced Th2 immune responses in vivo. These results suggested that through their ability to rapidly secrete IL-4 and TSLP in response to both proteolytic allergens and IgE stimulation, basophils are uniquely poised at the interface between the innate sensing of antigens and the initiation of adaptive Th2 cytokine responses.

Lambrecht and colleagues[270] subsequently examined the role of basophils to dust mite allergens and found that IL-4 competent basophils and inflammatory DCs were recruited to the draining mediastinal lymph nodes in a TLR4-/MyD88-dependent manner. They also

demonstrated that depletion of basophils only partially reduced Th2 immunity and that they did not take up inhaled dust mite antigens, present them to T cells, or express antigen-presentation machinery, whereas a population of FcεRI+DCs readily did. Inflammatory DCs were necessary and sufficient for induction of Th2 immunity and features of asthma, whereas basophils were not required. The discrepancies in these two studies may reflect differing requirements for Th2-inducing pathways depending on the nature of the allergen and its adjunct properties or the fact that a population of FcεR1-positive cells contributed to the results of the Medzhitov study.

In an elegant series of studies, Tang et al.[271] resolved the conflict between the DC and basophil camps by showing that neither DCs nor basophils were sufficient to drive Th2 immune responses to papain immunization, but that they worked in concert to drive robust Th2 immune responses. Mechanistically, they found that DCs were essential for providing sufficient antigen presentation and costimulation to drive T-cell proliferation, but were unable to induce sufficient IL-4 production to drive Th2 differentiation. In contrast, basophils provided the critical IL-4 production, but were unable to drive T-cell proliferation. Thus, together they synergized to drive robust Th2 immune responses to papain. Their studies also provided a putative scheme by

which papain may activate DCs and basophils. Papain plus antigen exposure initially induced ROS generation in lymph node DCs, dermal DCs, and epithelial cells of the skin. Subsequently, ROS orchestrated Th2 responses by inducing oxidized lipids that triggered the induction of TLR4-TRIF signaling and the upregulation of TSLP production by keratinocytes. TSLP subsequently drove Th2-cell differentiation by suppressing production of the Th1-inducing molecules IL-12 and CD70 in lymph node DCs and by inducing the chemokine CCL7, which mediated recruitment of IL-4+ basophils to the lymph node. Whether basophils contribute to all allergen-driven Th2 immune responses remains unknown. These results suggest that the diversity of Th2 inducing pathways presumably reflects the functional diversity of allergens that can trigger them (Fig. 45.5).

Alterations in Molecular Mechanisms of Th2 Cell Differentiation

Although the exact molecular events that drive Th2 differentiation have not been fully elucidated, a picture is beginning to emerge.[272] A model has been put forth in which following presentation of antigen in the context of MHC II and TCR stimulation of naïve CD4+ T cells, a modest increase in the mRNA levels of GATA3, the master regulator of Th2 differentiation,[273] occurs that steadily accumulates over the first 24 hours. Once produced, GATA-3 remodels chromatin (demethylation) around the Th2 cytokine locus resulting in opening of the Th2 locus and marked upregulation of IL-4.[272] GATA-3 also enhances Th2 differentiation by inhibiting expression of the IL-12 receptor B2 chain and the Stat4 genes, which are required for Th1 differentiation programming. In parallel, TCR stimulation induces IL-2 production, which in turn activates STAT5.[274,275] TSLP and IL-7 may also contribute to STAT5 activation. The combination of STAT5 activation and GATA3 induction stabilizes Il4 expression in developing Th2 cells.[276] Another potential signal involved in early IL-4 production is the binding of Jagged-1 on APCs with Notch ICD expressed on naive CD4 T cells.[183] The induction of IL-4 by Notch is thought to be partially due to its ability to increase

expression of GATA3.[277]

Once the early IL-4 accumulates, it binds its receptor composed of the IL-4Rα and the common gamma chain (γc) and activates STAT6, which further enhances GATA-3 and induces the expression of other Th2-specific factors such as c-maf,[278] which together in combination with continued STAT5 activation results in further upregulation of IL-4, initiating a positive feedback loop that drives commitment to a Th2 phenotype. The expression of specific Th2 cytokine genes (IL-4, IL-5, IL-13, IL-9) is controlled by the synergistic actions of the GATA-3 and c-Maf, and by the more widely expressed and transiently induced transcription factors such as NF-ATc, NF-κB, AP-1, and c-EBPb, respectively.[277] NFATc, unlike GATA3, has been shown to directly activate the IL-4 promoter.[279] In contrast, NF-κB appears to be more important for antigen-induced IL-5 gene expression than for IL-4 gene expression.[280] During subsequent antigenic stimulation of the effector/memory cells, which maintain an open chromatin structure with high levels of GATA-3 and c-Maf expression, they are able to rapidly induce Th2 cytokine gene expression.

Altered regulation of one or more of the primary transcription factors involved in Th2 differentiation may drive susceptibility to the development of allergic diseases. This is supported by several lines of evidence including the fact that GATA-3 expression has been shown to be elevated in bronchoalveolar lavage fluids and bronchial biopsies of asthmatics when compared to normals.[281] There are several lines of evidence that support a role for altered IL-4R signaling in Th2 polarization in atopic disorders including the following 1) a specific polymorphism in the IL-4 gene itself has been shown to correlate with high serum IgE levels and enhanced IL-4 gene expression[282]; 2) a similar association has been reported between the T allele of the -590C/T polymorphism of the IL-4 gene promoter region and atopic dermatitis[283]; and lastly 3) a GT repeat polymorphism in the first exon of the STAT6 gene has recently been associated with increased prevalence of several atopic disorders (bronchial asthma, atopic dermatitis, food allergies).[284] Although it is not currently known whether inheritance of a single gene variant or a combination of genetic variants is required to drive Th2-cell commitment in atopic individuals, considerable evidence is mounting to suggest that genetic differences in factors important in Th2-cell commitment may underlie susceptibility to development of atopic disorders.

Altered Tregulatory Cell-Promoting Cytokines in Atopic Disorders

Several lines of evidence suggest that the production of cytokines by DCs leading to T_{reg} generation is altered in atopic individuals. The DC cytokines that are known to regulate T_{reg} differentiation are IL-10 and TGF-β. Although altered levels of IL-10 have been observed in atopic disorders, the relationship is not straightforward. For example, there are conflicting reports about the levels of IL-10 in atopic patients, with some studies demonstrating elevations in IL-10 levels in bronchial biopsies,[285] peripheral blood mononuclear cells,[286] BAL fluids,[287] and in the gut mucosa of patients with asthma,[288] while others report diminished IL-10 production in sputum from patients with asthma[289] and isolated T cells from children with asthma or atopic dermatitis.[290] Results from animal studies show similar disparities. IL-10 knockout mice have been shown to have both reduced allergic

responses[291] as well as enhanced responses to allergen challenge.[292] Investigators have suggested that the discrepancies in the results of studies with IL-10-deficient mice may be dependent on the genetic background of the strain.[292] In contrast, studies in which animals have been treated with recombinant IL-10[293] or overexpress the IL-10 gene[294] uniformly demonstrate that IL-10 suppresses inflammation and decreases development of Th2-mediated immune responses. Moreover, adoptive transfer of IL-10-expressing DCs induced tolerance to allergen exposure.[295] The variability in the results may reflect the pleiotrophic actions of IL-10 during the course of allergic reactions. IL-10 can clearly influence T-cell differentiation through its inhibitory actions on IL-12 as well as its ability to reduce antigen presentation to

T cells by limiting class II, CD80, and CD86 expression on APCs. IL-10 not only generates tolerance in T cells, but it is a potent anti-inflammatory cytokine that can serve to dampen inflammation once initiated.[296] In this regard, it has been shown to reduce total and specific IgE production while increasing protective IgG4 levels.[297] The fact that steroids,[298] lactobacillus,[299] and standard immunotherapy regimes,[300] all of which successfully resolve symptoms in atopic diseases, induce IL-10 production suggests that perhaps IL-10 is protective and that IL-10 production may be impaired in atopic individuals. Diminished IL-10 production may lead both to loss of tolerance to environmental antigens as well as an inability to control inflammation once initiated. The elevations in IL-10 tissue levels observed during challenge with allergens may reflect compensatory mechanisms designed to suppress harmful inflammatory responses. In this regard, genetic polymorphisms in the promoter of the IL-10 gene (C to A change at position 571) have been associated with asthma and elevated serum IgE levels.[301]

Another DC-derived factor that regulates T_{reg} differentiation is TGF-β. Although TGF-β is a pleiotrophic cytokine, it has been shown to play an important role in T_{reg} differentiation and function. Specifically, it plays a role in the conversion of naïve CD4 T cells into the regulatory phenotype and has been reported to mediate the cell-contact dependent suppressive activity of T_{reg}s. Elemental to this conversion process is induction of expression of the forkhead transcription factor, Foxp3 in CD4+CD25- T cells by TGF-β. Importantly, in a murine asthma model, administration of these TGF-β-induced suppressor T cells prevented house dust mite-induced allergic responses.[302] More recent studies show that the induction of T_{reg} suppressor function and FoxP3 expression by TGF-β is dependent upon TGF-β's ability to enhance CD80:CTLA-4 interactions on T cells.[303] Consistent with an important role for TGF-β in regulation of T-cell differentiation, several studies,[304] but not all,[305] suggest that SNPs in the TGF-β1 gene may be associated with atopic and asthma phenotypes.[255] Collectively, these studies suggest that dysregulation of factors controlling T_{reg} cell differentiation and/or function may predispose to the development of deleterious Th2-mediated allergic responses to environmental antigens.

TH2 CYTOKINE REGULATION OF ALLERGIC INFLAMMATION

The dependence of the immunopathogenic consequences of allergic immune responses on

Th2 cells likely stems from their pivotal role in regulating the primary effectors of both the acute- and late-phase reactions, namely, IgE and eosinophils. In addition, as will be discussed in a later section, Th2 cell-derived cytokines themselves also serve as effector cells of the allergic response.

One of the major roles of IL-4 in allergic inflammation is as the primary inducer of Ig-class switching in B cells that leads to the synthesis and secretion of IgE.[306] The importance of IL-4 to IgE synthesis has been demonstrated by the fact that STAT6-deficient mice do not produce IgE.[307] The exact mechanisms by which IL-4 regulates IgE class switching will be discussed in the following. IL-13 is also able to regulate IgE synthesis in humans, but its role in IgE synthesis in mice is controversial.[308] The combination of the effects of IL-4 on IgE synthesis and mast cell growth suggests a primary role for IL-4 in the development of the early-phase response. As will be discussed in greater detail in a later section, IgE activation of mast cells leads to the synthesis and release of a number of inflammatory mediators that may contribute to the vascular, smooth muscle, and mucus changes observed in the early-phase response to allergen challenge.

Through their unique and overlapping actions, IL-4, IL-13, and IL-5 coordinately regulate the development, recruitment, and activation of eosinophils. IL-4 and IL-13 have both been shown to contribute to the recruitment of eosinophils into sites of inflammation as evidenced by the fact that inhibition of either IL-4 or IL-13 by antibody blockade or gene deletion eliminates allergen-driven increases in tissue eosinophils.[50,52] Because IL-5 has been shown to be the primary determinant of eosinophil differentiation, activation, and survival, it plays a critical role in eosinophil regulation in allergic responses. The importance of IL-5 in antigen-induced eosinophilia has been examined in numerous animal studies.[51,53] For example, blockade of endogenous IL-5 levels in antigen-sensitized mice has resulted in significant suppression of both BAL and tissue eosinophilia.[51] More definitively, mice in which the IL-5 gene has been disrupted do not develop eosinophilic inflammation.[53] Reconstitution of these mice with IL-5 completely restored aero-allergen-induced eosinophilia. Thus through the coordinate regulation of IgE and eosinophilia, Th2 cytokines orchestrate the elicitation phase of allergic immune responses. In the next section, we discuss in more detail the steps involved in IgE regulation.

REGULATION OF IMMUNOGLOBULIN E SYNTHESIS

Ishizaka and colleagues purified IgE in 1966.[4,309] IgE has the shortest half-life (2.5 days) of all classes of Igs. In addition, it is present in serum at levels considerably lower than other Ig classes such as IgG. There is considerable heterogeneity in the levels of IgE among individuals. For example, levels of <100 ng/mL are observed in most normal individuals, whereas in parasitized or atopic individuals IgE levels can reach as high as 1000 ng/mL. The high variability in serum levels contrasts strikingly to other Ig isotypes and suggests that tight control of IgE may therefore be important to prevent the potentially lethal consequences of IgE-mediated inflammation. Indeed, synthesis of IgE and its receptor expression appear to be regulated by a series of steps involving both cell-cell contact with CD4+ Th2 cells and activation by cytokines secreted by these cells. In this section, we will discuss our current knowledge of the complex steps involved in regulation of IgE synthesis and expression of its receptors.

Isotype Class Switching to Immunoglobulin E Production

The production of IgE antibodies by B cells is triggered by a complex series of secreted signals and cell surface

interactions, followed by molecular genetic rearrangements at the Ig heavy chain locus, IgH (Figs. 45.6 and 45.7). The first step in IgE production is the binding of allergen to allergen-specific B cells via their membrane-bound Ig receptor. The B cells then internalize and process the allergen, and present the processed allergen to T cells as peptide fragments in association with MHC II molecules. The peptide-MHC II complex is then recognized by the TCR on Th2 cells. Initially, all B cells produce IgM antibodies. At this point, a $V_H(D)J_H$ cassette of sequences encoding the variable domain is immediately adjacent to the Cμ exons, which encode the IgM constant regions at the 5′ end of the IgH locus. Further downstream in IgH are several widely spaced clusters of exons. C regions encode the constant region domains of the IgG, IgE, and IgA heavy chain isotypes. Upon stimulation by cytokines, along with critical cell-cell interactions with CD4+ T cell surface accessory molecules, B cells can change the isotype of the antibodies they produce while retaining their original antigenic specificity. This process requires that genomic DNA be spliced and rejoined to move the VDJ elements from their location proximal to Cμ to a position many kilobases downstream next to the C-region exons encoding the heavy chains of other isotypes. A large amount of intervening DNA is excised and discarded in this irreversible process, and therefore the mechanism is referred to as deletional switch recombination.

Isotype switching to IgE production requires two signals.[310] The first signal is provided by the Th2 cytokines, IL-4, and IL-13, and is IgE isotype specific. IL-4 and IL-13 stimulate transcription at the Cε gene locus, which contains the exons encoding the constant-region domains of the IgE ε heavy chain. This transcription is initiated at a site upstream the ε switch region designated Iε. The second signal is a B cell-activating signal provided through CD40/CD40L interactions. Together, these interactions result in induction of the necessary deletional switch recombination that brings into proximity all of the elements of a functional ε heavy chain.

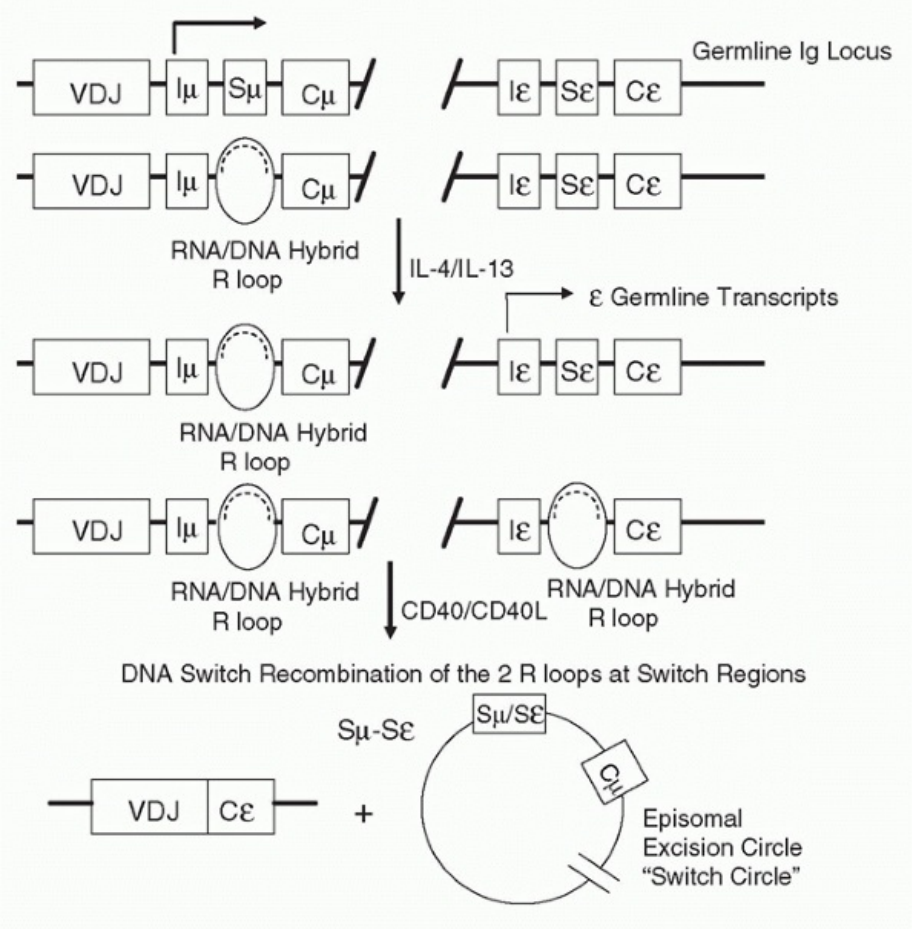

FIG. 45.6. Schematic Representation of the Molecular Steps Involved in Immunoglobulin E Class Switching. In naïve resting B cells, the VDJ sequences encoding the variable region are located at the 5′ end of the Ig locus. After stimulation by interleukin (IL)-4 or IL-13, transcription is initiated at the Iε promotor to produce ε germline transcripts. Sε ribonucleic acid (RNA) remains hybridized to the Sε deoxyribonucleic acid (DNA) forming an RNA-DNA hybrid structure, called an R loop. The R loop serves as a substrate for nucleases that result in doublestranded DNA breaks. Switch recombination and joining is dependent on a second signal provided by the CD40/CD40L interaction. This process results in the formation of an episomal excision circle that is eventually lost during cell division.

The first signal for IgE class switching is provided by the T cell-derived cytokines, IL-4/IL-13. IL-4 induces ribonucleic acid (RNA) transcription at the Cε locus via stimulation of STAT6 through binding the type I IL-4 receptor composed of the IL-4Rα chain and the γ c chain or, if expressed, the type II receptor composed of the IL-4Rα and IL-13Rα1 chains. IL-13 has also been shown to regulate IgE class switching in humans through binding the type II receptor. However, there is considerable controversy about the role of IL-13 in IgE class switching in mice. Following either IL-4 or IL-13 binding to its respective receptor complex, JAK kinases phosphorylate tryrosine residues in the intracellular domains of the receptor chains, providing docking sites for STAT6. These STAT6 molecules become phosphorylated and then form homodimers that translocate to the nucleus. In the nucleus, they bind to specific sequences (TTCN(N)GAA) in the promoter of IL-4/IL-13 responsive genes, including Iε. The importance

of STAT6 in IL-4-induced isotype switching is supported by the fact that germline transcription and IgE class switching are markedly impaired in STAT6-deficient mice.[311] Other transcription

factors are also important in induction of germline transcription of Cε locus. The importance of NF-κB for the induction of germline transcripts has been recently confirmed by the finding that expression of germ line transcripts for Cε are severely diminished in NF-κB p50 knockout mice.[312]

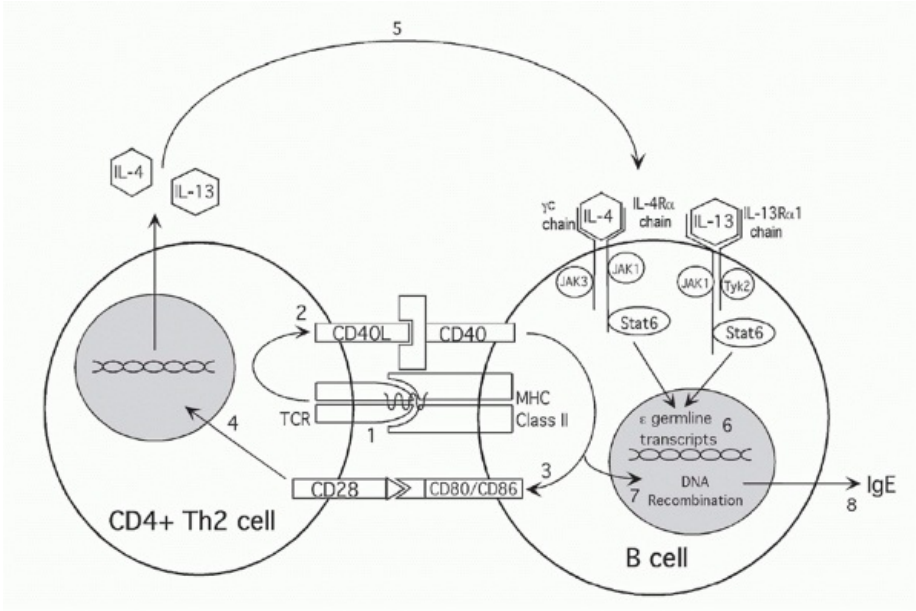

FIG. 45.7. The regulation of immunoglobulin E synthesis involves many sequential steps: 1) recognition of antigen/major histocompatibility complex class II by the T-cell receptor (TCR); 2) TCR activation leads to the induction of cluster of differentiation (CD)40 ligand on the T cell, which is then recognized by CD40 on the B cell; 3) CD40/CD40L cognate interaction leads to induction of CD80/CD86 on the B cell, which can then interact with CD28; 4) the Th2 cell secretes IL-4 and IL-13; 5) IL-4 and IL-13 bind their cognate receptors on B cells and result in activation of Stat6; 6) IL-4 and IL-13 signaling events result in initiation of transcription at the Iε promotor and the production of immature germline ε transcripts; 7) the CD40/CD40L interaction provides the necessary second signal required for recombination of the germline locus; and 8) transcription of mature ε transcripts from the rearranged locus followed by translation and secretion of IgE.

IL-4- and/or IL-13-induced transcription factor binding to the Cε locus results in germline transcription of the Cε locus. Germline transcripts originate from a 5′ promoter of the Iε exon, which is located just upstream of the 4 Cε exons. IL-4 induces the appearance of 1.7 to 1.9 kb germ-line Cε transcripts that contain an Iε exon, located 2 kb upstream of Sε, spliced to the Cε1-Cε4 exons. After processing, the mature germline mRNAs include the 140-bp Iεexon and exons Cε1-Cε4. These transcripts have been referred to as sterile because of the presence of stop codons in each of the three reading frames of Iε. However, it is the process of transcription itself that appears to facilitate the deletional switch recombination event. For

example, Harriman et al.[313] analyzed IgA switching using mice retaining a normal Iα promoter in which the Iα exon was replaced by an HPRT minigene and found that switching can occur to the locus despite the absence of complete Iα-containing transcripts. This has been demonstrated at the Cε locus in that switch recombination occurred at the Cε locus when the Iε exon and promoter were intact, but Cε exons were absent.[314]

The second signal for IgE class switching is dependent on cell-to-cell contact between T and B cells. Specifically, the interaction between CD40 on the surface of B cells with CD40L on the T-cell surface is critical to drive the IgE switch to completion and lead to IgE production. CD40 is a 50kd surface glycoprotein that is constitutively expressed on all human B-lymphocytes. CD40L is transiently induced on T cells after stimulation of the TCR by antigen/MHC complexes. Binding of newly expressed CD40L with CD40 on B cells provides the second signal for induction of deletional switch recombination to IgE.

Several lines of evidence support a critical role for CD40/CD40L interactions in isotype switching. First, it had been shown by numerous groups that isotype switching required the presence and contact with T cells. After an extensive search for the T-cell contact signal, it was discovered that CD40/CD40L interactions were responsible for the T-cell dependency of this process. Proof of this was provided by the observation that activation of CD40L could completely

substitute for T-cell help.[315] Furthermore, a soluble form of CD40 inhibits its interactions with CD40L, blocking IL-4 driven IgE synthesis in human B cells.[316] Lastly, genetic deficiencies in CD40L or CD40 in humans and mice, respectively, disrupt IgE synthesis. In humans, CD40L is encoded on the X chromosome and individuals with the X-linked hyper-IgM syndrome are deficient in CD40L. Their B cells are unable to produce IgG, IgA, or IgE.[317] Similarly, mice deficient in either the CD40L or CD40 genes have the same defect in antibody production.[318,319]

CD40/CD40L interactions are thought to provide a second signal via stimulation of a number of signaling pathways that likely synergize with those initiated by IL-4 and IL-13 to achieve ε-germline transcription. Specifically, after interaction with CD40L on the B-cell surface, CD40 aggregation triggers signal transduction through four intracellular proteins, which belong to the family of TNF receptor-associated factors (TRAFs). TRAFs-2, -5, and -6 are known to associate with the intracytoplasmic domain of CD40 after its multimerization by interaction with CD40L. TRAF-2, TRAF-5, and TRAF-6 promote the dissociation of NF-κB from its inhibitor, IκB. In turn, NF-κB can synergize with STAT6 induced by IL-4/IL-13 signaling to activate the Iε promoter, as described previously. In addition to triggering TRAF associations, engagement of CD40 activates protein tyrosine kinases, such as JAK kinases.

Another mechanism by which cytokine and CD40L activation may induce class switching is via induction of expression of proteins required in deletional recombination. Specifically, both cytokine and CD40L induction of class switching has been shown to require the synthesis of new proteins. One of these proteins is activation-induced cytidine deaminase (AID).[320] AID is expressed in activated B cells and in germinal centers of lymph nodes. Mice deficient in AID have a dramatic impairment in isotype switching, with elevated IgM levels and low or absent IgE, IgG, and IgA isotypes.[321] Interestingly, a rare autosomal form of hyper-IgM syndrome

has now been attributed to mutations in this gene.[322] These studies indicate that this protein is critical to isotype switching.

Although not completely elucidated, the mechanisms through which AID is recruited to the appropriate S region and facilitates class switch recombination are becoming clearer. It appears that regulation of AID activity occurs in two distinct phases: recruitment of AID to the S regions at both the donor and acceptor sites, and then local control of AID activity. In the first phase, once chromatin is opened at a given germline Ig locus (in the case of Cε, triggered by stimulation through CD40 in the presence of IL-4), gene transcription begins through the Iε and Sε regions. Due to the highly repetitive nature of the S regions, RNA Pol II stalls during transcription. Stalled RNA Pol II is known to be bound by Spt5. RNA Pol II-bound Spt5 then recruits AID to the complex, effectively targeting the S regions (both Sε and Sμ) for AID recruitment. Although Spt5 is a critical factor, there is additional evidence that both the scaffold protein 14-3-3 (perhaps through direct interactions with ACGT sequence in the S region) and PTBP2 are also involved in recruiting AID to the switch regions.

Once recruited, AID is activated by phosphorylation of S38 by the protein kinase PKA, which associates independently with the S region. Also involved in activating AID is PP2A, which removes an inhibitory phosphate at S3. Phosphorylation S3 appears to limit the ability of AID to associate with the Sμ region. Once activated, AID is then able to deaminate cytidines in both strands of DNA (partly through interactions with RPA and the RNA exosome), converting them to uracils. These uracil bases are subsequently removed by uracil DNA glycosylase, creating multiple abasic sites, in both DNA strands. Two enzymes, AP endonuclease 1 and AP endonuclease 2 then create breaks at the abasic sites, resulting in double-stranded breaks in both donor (in this case, Sμ) and acceptor (Sε) sites. The intervening DNA is spliced out, and the two switch regions are joined together, placing the Cε locus immediately adjacent to the VDJ regions.[323]

Negative Regulation of Immunoglobulin E Synthesis

Several cytokines including TGF-β, IFNα, and IFNγ can inhibit IL-4-dependent IgE synthesis in both mice[324] and humans.[325] IFNγ suppresses the expression of ε germline transcripts in murine B cells stimulated with IL-4 and LPS. IFNγ may affect recombination events without affecting the expression of ε germ-line transcripts. Other agents, including IL-12[326] and IL-10,[297] have been reported to inhibit IgE while enhancing IgG4.[326] Interestingly, IL-21 has recently been shown to inhibit IgE isotype class switching and IgE+ cell clonal expansion.[327] Although the exact mechanism by which IL-21 regulates IgE production is not entirely understood, it is thought that IL-21 directly antagonizes IL-4- and LPS-induced Iε switch recombination.[328] Because IL-21 does not alter proliferation or STAT6 phosphorylation of murine B cells in response to IL-4, the mechanism is unknown. Recent studies suggest that IL-21 regulates IgE synthesis through STAT3-mediated processes,[329] and indeed patients with mutations in STAT3 do not respond to IL-21.[330] Mutations in STAT3 are associated with hyper-IgE syndrome, a condition in which patients have extremely elevated serum IgE levels and recurrent eczema.[330] Another mechanism of regulation of IgE is through the competition with IL-4-driven IgG4 blocking antibodies. IgE mediated-hypersensitivity reactions are rare in patients with chronic helminth infections even though FcεRI-bearing cells are sensitized with

antiparasite IgE. The inhibition of allergic reactivity is mainly due to IgG4-blocking antibodies as evidenced by the fact that the depletion of IgG4 specifically removes the blocking activity from the sera of microfilaremic patients. IgG4-blocking activity has also been detected in patients receiving immunotherapy for insect venom[331] and house dust mite hypersensitivity.[332] Blocking IgG4 competes with cell-bound IgE for allergen binding. Because the IgG4 molecule is functionally monovalent, does not fix complement, and binds weakly to Fcγ receptors, antigen binding to IgG4 has no harmful consequences. However, competition between IgG4 and IgE can occur only if the two antibody isotypes have at least in part the same antigen specificity. A molecular mechanism for this overlap in specificity was provided by the demonstration that isotype switching can occur sequentially from IgM to IgE through IgG4. This has been formally demonstrated in that IgG antibody in mice can completely suppress IgE-mediated anaphylaxis.[333]

Immunoglobulin E Receptors

The two major Fc receptors for IgE are called FcεRI and FcεRII (CD23).[334] They are distinguished by their structure and their relative affinities for IgE. The high affinity IgE receptor FcεRI binds monomeric IgE with an affinity constant of $10^{10}M^{-1}$ while CD23 binds with a much lower affinity ($10^{8}M^{-1}$). The high-affinity receptors are constitutively expressed at high levels on mast cells and basophils. They are also found, albeit at lower levels, on peripheral blood DCs, monocytes, and human Langerhans cells. The low-affinity receptor is also expressed on a wide variety of cells including B cells, T cells, Langerhans cells, monocytes, macrophages, platelets, and eosinophils.

FcεRI-Mediated Signal Transduction

FcεRI is a member of the multisubunit immune response receptor family of cell surface receptors that lack intrinsic enzymatic activity but transduce intracellular signals through association with cytoplasmic tyrosine kinases.[335] In rodents, FcεRI is expressed on mast cells and basophils as a heterotetramer consisting of a single IgE binding α subunit, a β subunit, and two disulfide-linked γ subunits. The α chain consists of two extracellular Ig-like loops, a single transmembrane region containing an aspartic acid residue, and a short cytoplasmic domain that lacks signal transduction motifs. The charged amino acid within the transmembrane domain mediates the association of the α subunit with the signaling component of the γ subunit. The β subunit consists of four membrane-spanning domains and a cytoplasmic tail capable of transducing intracellular signals that amplify γ-mediated signaling events. In rodents, all three subunits are required for the cell surface expression of FcεRI.[334,335] In contrast, in humans the receptor can be expressed as two different isoforms, a tetramer (αβγ2) or a trimer (αγ2). The tetrameric complex (αβγ2) is expressed on mast cells and basophils, whereas the trimer is expressed on Langerhans cells, DCs, monocytes and macrophages, and eosinophils.

FcεRI signaling occurs upon IgE binding to the receptor. This requires two sequential events: 1) binding of IgE antibody to the FcεRI, and 2) cross-linking of IgE antibody by bivalent or multivalent antigen. Cross-linking of the receptor initiates a coordinated sequence of biochemical and morphologic events that result in 1) exocytosis of secretory granules

containing histamine and other performed mediators, 2) synthesis and secretion of newly formed lipid mediators such as prostaglandins and leukotrienes, and 3) synthesis and secretion of cytokines. Although the exact signaling pathways governing each of these functions are not known, the following model has been proposed. The β and γ subunits each contain a conserved immunoreceptor tyrosine-based activation motif (ITAM) within their cytoplasmic tails that is rapidly phosphorylated on tyrosine after FcεRI aggregation.[335,336] Tyrosine phosphorylation of the β and γ ITAMs is mediated by Lyn, which is constitutively associated with the β subunit and activated after antigen mediated FcεRI aggregation. FcεRI cross-linking leads to recruitment and activation of the tyrosine kinase Syk, which binds to the tyrosine phosphorylated γ ITAMs through its tandem SH2 domains.[334] Recruitment of Syk occurs upstream of several signal transduction pathways. The importance of Syk is demonstrated by using Syk-deficient mast cells, which fail to degranulate, synthesize leukotrienes, and secrete cytokines after FcεRI stimulation.[337] Ultimately this pathway leads to the activation of mitogen-activated protein kinases and activation of protein kinase C pathways. Protein kinase C pathways are thought to be important in exocytosis and granule content release and gene expression. Activation of mitogen-activated protein kinases also regulates the enzymatic activity of PLA_2, leading to generation of a variety of lipid mediators (platelet-activating factor [PAF], PGD_2, and LTC_4). Antigen-mediated aggregation of FcεRI also stimulates the recruitment and activation of p21ras, which has been implicated in FcεRI induced cytokine transcription and secretion.[336]

Regulation of FcεRI Surface Expression

Although the expression of FcεRI on the surface of mast cells appears to occur early in their differentiation and/or maturation in vivo, the levels are known to be regulated by several factors post maturation. Studies in both mice and humans have revealed that the levels of FcεRI on mast cells can be regulated by IgE itself as well as by Th2 cytokines. Indeed, atopic individuals with high serum IgE levels show markedly upregulated mast cell and basophil FcεRI levels.[338,339] Moreover, anti-IgE treatment of atopic individuals results in downregulation of FcεRI expression on human basophils.[340] Further evidence is provided by murine studies in which IgE-deficient mice exhibit dramatically reduced levels of receptors on mast cells and basophils. As IgE-deficient mice still express receptors, albeit at lower levels, other mechanisms of regulation are thought to exist. In fact, cytokines such as IL-4 and IL-13 have been shown to upregulate FcεRIα expression on mast cells, basophils, and monocytes. Glucocorticoids have been shown to inhibit IL-4- and IL-13-induced upregulation of the FcεRIα chain on monocytes.[341] These results suggest that through a multistep positive feedback process, Th2 cytokines enhance both the production of IgE and the expression of its receptor, which leads to further mast cell activation and release of Th2 cytokines in the local microenvironment, serving to perpetuate the allergic response.

Mast cell activation is subject to negative regulation by a growing family of structurally and functionally related inhibitory receptors. These include FcγRIIB, CTLA4, killer cell inhibitory receptors, and gp^{49b1} on mast cells. Indeed, gp^{45b1}-deficient mice exhibit more severe anaphylactic reactions than their normal counterparts.[342] Each of these receptors possesses an immunoreceptor tyrosine-based inhibitory motif. Coaggregation of FcεRI and these inhibitory receptors on the surface of mast cells results in inhibition of FcεRI-induced

mast cell activation.[343,344] In general, inhibitory receptors are thought to inhibit the actions of activation receptors containing ITAMs by recruiting phosphatases through an immunoreceptor tyrosine-based inhibition motif.[345]

FcεRII (CD23)

In humans, CD23 (FcεRII, B cell differentiation antigen) is a calcium-dependent C-type lectin of 45 kDa. It has wide distribution among hematopoietic and structural cells and exists in two forms, CD23a and CD23b, resulting from alternative splicing at the N terminus and differing by five amino acids in the cytoplasmic domain. The isoforms of CD23 are found on B cells; one is constitutively expressed (CD23a), whereas the other form, CD23b, is induced by factors such as IL-4[346] and CD40L in conjunction with IL-4. CD23b is also found on non-B cells such as T cells, Langerhans cells, monocytes, macrophages, platelets, and eosinophils,[347,348] and mediates different biologic functions. The b form has been shown to be associated with phagocytosis of soluble IgE complexes, while the a form is associated with endocytosis of IgE-coated particules.[349]

Structurally, CD23 presents a single membrane-spanning domain followed by an extracellular domain that consists of three regions: the alpha-helical coiled coil stalk region, which mediates the formation of trimers, followed by the lectin head, which binds IgE, and at the C-terminus a short tail containing an inverse arginine-glycine-aspartate (RGD) sequence, a common recognition site of integrins.[350,351] CD23 is cleaved at the membrane to yield a series of soluble fragments. sCD23s of varying molecular weights arise by an autocatalytic process involving matrix metalloproteinase cleavage of membrane bound CD23. The endogenous proteases that participate in CD23 shedding have not been identified. Recently ADAM10 and metalloproteinase 9 have been shown to be CD23 sheddases.[352] CD23 expression is upregulated by several factors including by its ligand, IgE,[353] and by IL-4.[354] On the other hand, IFNγ counteracts the inducing effect of IL-4 on CD23 expression.

CD23 is thought to mediate a number of effects including regulation of IgE synthesis, antigen presentation, proliferation and differentiation of B cells, and activation of monocytes, effects that can be ascribed to the membrane and soluble forms of CD23.[354] Binding of IgE to the membrane bound form of the receptor transduces an inhibitory signal that prevents further IgE synthesis.[355] In contrast, the soluble forms described previously upregulate IgE production; their release has been found to be inhibited by IgE binding.[356] Soluble CD23 also ligates CD11b/CD11c to promote release of proinflammatory mediators such as IL-1β, IL-6, and TNF-α.[357]

CD23 expression on B cells and monocytes and sCD23 production is markedly increased in allergic disorders.[358,359] Moreover, reduction of allergen-induced CD23 expression on B cells has been observed after successful desensitization therapy.[359] A recent clinical trial using anti-CD23 (lumiliximab) directed against the lectin part of the molecule showed that while lumiliximab treatment of allergic patients reduced serum IgE levels by two-thirds, this reduction was insufficient to reduce disease symptoms.[360] This antibody is thought to work by mimicking IgE binding and stabilizing CD23 resulting in less cleavage by ADAM10.

Dysregulation of the CD23 pathway in atopic patients might be part of their propensity to develop IgE antibodies and may cause an enhancement of the inflammatory reaction through the action of sCD23 as well as through IgE-dependent triggering of CD23 on non B cells.

EFFECTOR CELLS OF THE ALLERGIC RESPONSE

Overview

Once a genetically susceptible individual is sensitized to a given allergen and IgE antibody has been formed, subsequent exposure to allergens readily induces the manifestations of atopic disease. Although these responses are generally a continium, they have been categorized into three types based on their temporal sequence: 1) acute or immediate responses, 2) late-phase reactions, and 3) chronic allergic inflammation.

Exposure of a sensitized individual to allergens results in immediate reactions, the characteristics of which are dependent upon the site of entry of the allergen. In the nasal mucosa, allergen provocation of sensitized individuals results in sneezing, itching, and nasal discharge. Acute allergic reactions, elicited in the skin at the sites of allergen injection, are characterized by intense itching, redness, and edema. In patients with asthma subjected to allergen inhalation, these mediators rapidly elicit bronchial mucosa edema, mucus production, and smooth muscle constriction. Acute or immediate responses are thought to be due to the release of preformed mediators released by antigen interaction with Fc receptors and IgE on IgE-bearing cells (mast cells and basophils). The release of mast cell products produce multiple local effects, including enhanced local vascular permeability (leading to leakage of plasma proteins, including fibrogen, resulting in local deposition of cross-linked fibrin and tissue swelling), increased cutaneous blood flow with intravascular fluid from postcapillary venules producing erythema, and other effects, such as itching, due to the stimulation of cutaneous sensory nerves by histamine. Typically, these reactions are detectable within a few minutes of allergen challenge, reach a maximum in 30 to 60 minutes, then rapidly wane.

In many individuals, the acute phase is followed by what has been termed a late-phase reaction that occurs within 6 to 48 hours after allergen exposure and can persist for several days without therapy. The characteristic signs and symptoms of late-phase reactions are reddening and swelling of the skin, sneezing and nasal discharge, and wheezing and cough upon lower airways challenge. Late-phase reactions are thought to occur as a result of recruitment of circulating leukocytes to the site of allergen exposure following antigen presentation to T cells. Both eosinophils and T cells are assumed to mediate the late-phase response. However, mast cells may also contribute to the late-phase response. The importance of leukocyte recruitment is supported by the fact that a variety of treatments that are associated with a reduction in the leukocyte recruitment elicited at sites of late-phase reactions can also reduce the signs and symptoms of these responses.

In naturally occurring allergic diseases, patients typically experience repeated exposure to the offending allergens over a period of weeks to years. Although the specific features of pathology of each of these diseases vary according to the anatomic site affected, it has been generally recognized that the structural changes that occur in each tissue are due

to the persistence of inflammation. These tissue changes range from thickened skin and fibrotic papules to extensive remodeling of the airway wall with smooth muscle hypertrophy, subepithelial fibrosis, and mucus cell hypertrophy. In each case, these structural changes are

associated with significant alterations in their function.

Development of Mast Cells and Basophils

History and Overview

Mast cells and basophils were discovered by Paul Ehrlich in the late 1800s based on staining of their cytoplasmic granules with aniline and basophilic dyes, respectively.[361] It was once thought that basophils might be circulating precursors of mast cells or that mast cells were "tissue basophils," but current evidence suggest that they are indeed distinct cell types. Although these cell types have unique functions and release a unique profile of mediators, they also produce an overlapping array of mediators that are known to contribute to the allergic diathesis. It is hypothesized that IgE produced by allergen-reactive B cells binds to FcεR receptors present on the surface of mast cells and basophils, and that when challenged with allergen, these cells release vasoactive mediators as well as chemotactic factors and cytokines that promote leukocyte infiltration and exacerbate the inflammatory response. Through the production and release of these proinflammatory molecules, mast cells and basophils set into motion a series of events that result in immediate responses to allergens in the skin, lungs, and nose of atopic individuals and may also contribute to the late-phase response (Fig. 45.8).

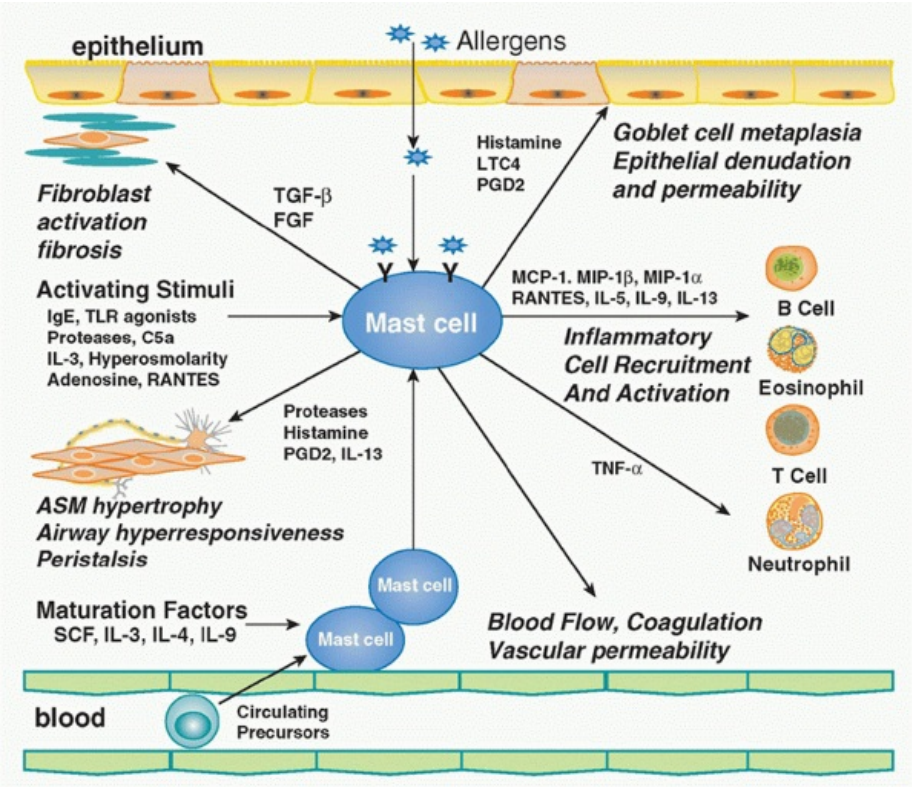

FIG. 45.8. Mast Cells are Produced in Bone Marrow and Released into Circulation as Immature Precursors. They mature in tissues under the influence of stem cell factor, interleukin (IL)-3, IL-4, and IL-9. Once activated by either antigen cross-linking of surface immunoglobulin E or via a variety of other factors (toll-like receptor ligands, proteases, C5a, IL-3, hyperosmolarity, adenosine, RANTES), mast cells degranulate and release a variety of mediators including vasoactive and bronchoactive mediators

(histamine, LTC4, PGD_2, proteases), chemokines (MCP-1, MIP-1α, MIP-1β, RANTES), cytokines (IL-9, IL-13, IL-5, tumor necrosis factor-α), and growth factors (transforming growth factor-β and FGF). Through the release of this vast array of mediators, mast cells induce many features of the early-phase allergic response including enhanced vascular and epithelial permeability, mucus secretion, and airway hyperresponsiveness. They also contribute to the last-phase allergic response via the recruitment and activation of a number of inflammatory cells including neutrophils, eosinophils, T cells, and B cells. Through the activation of inflammatory cells as well as direct effects on mucosal cells, mast cells also contribute to the remodeling (goblet cell metaplasia, tissue fibrosis, and smooth muscle hypertrophy) of mucosal tissues observed in chronic stages of the allergic response.

Basophils

Basophils are a small population of peripheral blood leukocytes containing cytoplasmic granules that stain with basophilic dyes. They typically exhibit a segmented nucleus with marked condensation of nuclear chromatin and contain round or oval cytoplasmic granules. Basophils are thought to arise from pluripotent CD34+ progenitors found in cord blood, peripheral blood, and bone marrow. They have been suggested to evolve from CD34+/IL-3Rα+/IL-5Rα+ eosinophil/basophil progenitors, as supported by the occurrence of granulocytes with a hybrid eosinophil/basophil phenotype in patients with chronic or acute myelogenous leukemia or in cell culture.[362,363,364] Unlike mast cells, basophils differentiate and mature in the bone marrow and then circulate in the blood where they constitute < 1% of circulating leukocytes. IL-3 appears to be an important developmental factor for basophils,[365] although many other growth factors such as IL-5, GM-CSF, TGF-α, and nerve growth factor likely influence their development.[366,367,368] Like mast cells, basophils possess high affinity IgE receptors (FcεR1) that are cross-linked upon engagement of receptor-bound IgE by their cognate antigens, resulting in release of a number of mediators that are in part common for both cell types.

Until recently, the lack of specific markers for detection of basophils in tissues and the inability to isolate significant numbers of these cells from peripheral blood had hampered the study of basophil biology. Participation of basophils in allergic reactions has traditionally been documented by indirect means such as by determining the pattern of mast cell- or basophil-specific mediators like histamine (derived from both), PGD_2 (mast cells only), and LTC_4 (primarily from basophils). Despite the difficulties in studying basophils, recent studies suggest that they rapidly produce large amounts of the immunoregulatory cytokines IL-4 and IL-13 and constitutively express CD40L and chemokine receptor 3 (CCR3) on their surface. These findings taken together with the demonstration that they are rapidly recruited to the skin,[369] lung,[370] and nose[371] after allergen challenge suggests that they likely play an important role in allergic diseases. However, as much more is known about the role of mast cells in the immune response, we will confine our discussion to mast cells except where specific information about basophils is available.

Mast Cells

Mast cells typically appear as round or elongated cells with a nonsegmented or occasionally bi- or multinucleated nucleus. Their intracellular granules stain purple with aniline blue dyes. This change in color represents the interaction of the dyes with the highly acidic heparin contained in the mast cell granules. Mast cells like other granulocytes are derived from CD34+ hematopoietic progenitor cells; however, they are distinct from other granulocytes in that they mature in the periphery. Several lines of evidence suggest that interactions between the tyrosine kinase receptor c-kit, which is expressed on the surface of mast cells, and the c-kit ligand stem cell factor (SCF) are essential for normal mast cell development and survival. For example, mice with mutations that either result in markedly impaired c-kit function or a reduction in c-kit virtually lack mast cells. rSCF can induce mast-cell hyperplasia in vivo in mice, rats, primates, and humans.[372]

Mast cells are distributed throughout normal connective tissues where they often lie adjacent to blood and lymphatic vessels, near or within nerves, or beneath epithelial surfaces that are exposed to the external environment, such as those of the respiratory tract, gastrointestinal tract, and skin (see Fig. 45.6). At these locations, they are ideally situated to encounter foreign antigens and to release their products in close proximity to their respective target cells (ie, epithelial cells, vascular endothelium, smooth muscle, and fibroblasts). In humans and mice, the number of mast cells in a tissue varies markedly depending on the anatomic site and the immunologic status of the host.

The mast cell population is composed of a heterogeneous group of cells with respect to their structure and function.[373] On the basis of their content of neutral serine proteases, they had previously been divided into two phenotypes. One subset, designated MC_{TC}, contains tryptase, chymase, cathespsin G, and carboxypeptidase, whereas the other phenotype, designated MC_T, contains only tryptase. MC_{TC} are found predominantly in skin and at subepithelial locations in the bronchial, nasal, and gastrointestinal mucosa, whereas MC_T are located predominantly in alveolar walls, intestinal epithelium, and in airway epithelium in patients with allergic disease. However, more recent studies in both humans and animal models suggest that mast cells in different anatomic sites and even within a single site can vary in several aspects of their phenotype including morphology, responsiveness to various stimuli and activation, and mediator content.

The tissue levels of mast cells and their specific phenotypes are likely controlled by a complex interplay between SCF, other growth factors, and cytokines. SCF is necessary to elicit the c-kit-mediated signaling that ensures the expansion of cells of the mast cell lineage, whereas the development of different phenotypes appears to be determined by their responsiveness to signals from T cells. Specifically, MC_T-cell expansion appears to be T cell dependent, while expansion of the MC_{TC} population is T cell independent. This contention is supported by the fact that humans with T-cell deficiencies have a lack of intraepithelial intestinal mast cells while maintaining submucosal mast cell populations.[374] Similarly, athymic mice lack intraepithelial cells and are unable to expand this population in the gastrointestinal tract in response to helminthic infections.[375] IL-3, IL-4, and IL-9, in particular, are among the T cell-derived cytokines known to influence mast cell development and phenotypic characteristics. A role for IL-3 in mast cell hyperplasia has been demonstrated in intestinal helminthic infections in which IL-3 depletion inhibits the intraepithelial mast cell

hyperplasia normally observed in the jejunum of infected mice.[376] A similar case can be made for IL-9 as IL-9 transgenic mice spontaneously develop intraepithelial mast cell hyperplasia in the jejunum.[377] The action of IL-9 can be blocked by depletion of SCF. Moreover, IL-9 and IL-10 reversibly induce MMCP-1 and MMCP-2 expression in mast cells through transcript stabilization, suggesting that T cell-derived cytokines can influence the spectrum of mediators produced by a given

mast cell. These studies suggest that the regulation of mast cell phenotype in the microenvironment is dynamic and that T cell-derived cytokines are major determinants of both the numbers, distribution, and phenotype of mast cells in tissues.

Mast Cell-Derived Mediators

Mast cells and basophils release a wide array of potent biologically active mediators that have both unique and overlapping activities on various target cells. Some of these products are stored preformed in the cytoplasmic granules, whereas others are synthesized upon activation of the cell by IgE-dependent processes or non-IgE-dependent stimuli. These mediators can be categorized into three main groups: 1) performed secretory granule-associated mediators, 2) lipid-derived mediators, and 3) cytokines.

Preformed Mediators

The secretory granules of human mast cells contain a crystalline complex of preformed inflammatory mediators ionically bound to a matrix of proteoglycan. When mast cell activation occurs, the granules swell and lose their crystalline nature, and the individual mediators are released by exocytosis. The mediators stored in mast cells include histamine, proteoglycans, serine proteases, carboxypeptidase A, and small amounts of sulphatases. In mouse and rat mast cells, the granules also contain serotonin.[378,379,380]

The mediator most associated with the mast cell is histamine. Histamine is a biogenic amine formed in mast cells and basophils by the decarboxylation of histidine. It is present in the granules at approximately 100 mmol/L or 1 pg/cell. Histamine has many potent activities that are pertinent to the early phase of the allergic response including vasodilatation, increased vasopermeability, smooth muscle contraction, and increased mucus production. Histamine exerts its biologic and pathologic effects via specific receptors on various cells such as smooth muscle, endothelial cells, and nerves. At least three types of histamine receptors have been identified: H1, H2 and H3. Histamine is very rapidly metabolized with a half-life of about 1 minute by histamine-N methyltransferase and histaminase. Increased levels of histamine have been found in BAL fluids of patients with asthma, atopic dermatitis, and allergic rhinitis.[381] Interestingly, although antihistamines inhibit the immediate allergic responses, they do not seem to inhibit late-phase responses.

Heparin is the predominant proteoglycan in human mast cells. It constitutes about 75% of the total. The remainder is comprised of chondroitin sulphates. The proteoglycan is the storage matrix inside the granule, and the acid sulfate groups of the glycosaminoglycans provide binding sites for the other preformed mediators. Proteoglycans also have anticoagulant, anticomplement, and antikallikrein effects. In addition to regulating the kinetics of release of mediators from the granule matrices, proteoglycans can also regulate the activity of some of the associated mediators.

The major mast cell protease, which is present in all types of mast cells, is tryptase. Tryptase is a serine protease, and it is stored fully active in the granule. There are two distinct forms of tryptase with 90% amino acid sequence homology: α-tryptase and β-tryptase.[382,383] The β-tryptase form is a useful clinical biomarker for anaphylaxis. Tryptase levels measured within 4 hours of a presumed anaphylactic reaction are more sensitive than serum or urine histamine in implicating mast cell activation and degranulation.[384,385] By weight, tryptase is the major enzyme stored in the cytoplasmic granules of human mast cells and occurs in all human mast cell populations. It has many activities, including cleavage of peptides such as vasoactive intestinal peptide, bronchodilator peptides, and calcitonin gene-related peptid, but not substance P. It mediates sensitization of smooth muscle; cleavage of type IV collagen, fibronectin, and type VI collagen; upregulation of intercellular adhesion molecule-1 on epithelial cells; and mitogenic activity for fibroblasts and epithelial cells.[380] Some of these activities have led to speculation that mast cells may be involved in chronic inflammation and tissue remodeling.[386]

The other major neutral protease in mast cells is chymase. It is also a serine protease that is stored in the active form in the granules of some human mast cells. Unlike tryptase, chymase is only present in a subset of mast cells. Chymase can cleave angiotensin I and neurotensin, but has no activities on vasoactive intestinal peptide (VIP) or substance P. Importantly, it can degrade IL-4. Some subsets of mast cells also contain other proteinases such as carboxypeptidase and cathepsin G.

Newly Synthesized Mediators

Lipid Mediators

Activation of mast cells not only results in release of preformed granule-associated mediators but can also initiate the de novo synthesis of certain lipid-derived substances. Of particular importance are the cycloxygenase and lipoxygenase metabolites of arachidonic acid. These products possess potent inflammatory activity. Lipoxygenases generate leukotrienes, hydroperoxyeicosatetraenoic acids, and the reduced products of hydroperoxyeicosatetraenoic acids, hydroxyeicosatetrenoic acids, whereas cycloxygenase products include prostaglandins and thromboxanes.

Leukotrienes are produced by the activity of 5-lipoxygenase on arachidonic acid. Arachidonic acid is converted to 5-hydroperoxyeicosatetraenoic acid, which can then be converted to LTB_4 through the action of the LTA_4 hydrolase or to LTC_4 via LTC_4 synthase. LTC_4 can then be converted to LTD_4 and LTE_4. Human mast cells generally produce more LTC_4 than LTB_4. The leukotrienes were originally discovered in 1938 and referred to as the slow-reacting substance of anaphylaxis until their structural elucidation in 1979.[387]

Leukotrienes induce a prolonged cutaneous wheal-and-flare response, stimulate prolonged bronchoconstriction (10 to 1000 times more potently than histamine), enhance vascular permeability, promote bronchial mucus secretion, and induce constriction of arterial and pulmonary smooth muscle.[388] Cysteinyl leukotrienes have been detected in the BAL fluid of patients with asthma and in the urine of patients following inhaled allergen challenge or aspirin challenge in sensitive individuals.[389] Cysteinyl leukotriene receptor antagonists and

leukotriene synthesis blockers have been introduced into clinical practice as novel therapies for asthma.[390,391,392,393]

In patients with asthma, clinical trials have demonstrated that approximately 80% of the early bronchoconstrictor response can be eliminated with cysteinyl leukotriene antagonists.[393] These blockers also inhibit 50% of the late-phase response to inhaled allergens, supporting the importance of cysteinyl leukotrienes in the late phase of the allergic response. However, the fact that PGD_2 and tryptase are not found in the BAL fluid during the late-phase reaction suggests that the cysteinyl leukotrienes noted in the late phase are the product of basophils or eosinophils and not mast cells.

In contrast to the cysteinyl leukotrienes, mast cells produce very little LTB_4. LTB_4 is a potent chemotactic factor for neutrophils and to a lesser extent for eosinophils.[394] Certain mast cell types, including bone marrow-derived murine mast cells and human lung mast cells, may also secrete PAF.[395,396] PAF has several actions that suggest that it is an important mediator of anaphylaxis including 1) its ability to induce aggregation and degranulation of platelets, 2) its induction of wheal and flare reactions in human skin, 3) its ability to increase lung resistance, and 4) induction of systemic hypotension.

The major cyclooxygenase-derived product in mast cells is PGD_2, which is a potent bronchoconstrictor. PGD_2 is rapidly degraded to 9α,11β-PGF_2, producing another potent bronchoconstrictor. Maximal activation of mast cells yields 50 to 100 ng PGD_2 per 10^6 mast cells.[397] Although PGD_2 is 100-fold less potent than cysteinyl leukotrienes, it is released in larger molar amounts and, thus, is important in the early bronchoconstrictor response to airway allergen challenge.[398] PGD_2 exerts its effects by interacting with the thromboxane receptor on airway smooth muscle.[399] PGD_2 is also chemotactic for neutrophils and is an inhibitor of platelet aggregation. There is considerable evidence that prostanoids are generated during allergic reactions in vivo. PGD_2 is elevated in the BAL of asthmatic subjects following inhaled allergen challenge.[400] Furthermore, the metabolite of PGD_2, 9α,11β-PGF_2, rises markedly in the urine after allergen or aspirin challenge of sensitive asthmatics.[401] Significantly raised PGF2α and PGE_2 levels are reported in the serum of asthmatics.[402] These findings are confused by the fact that there is no therapeutic benefit from cyclooxygenase inhibitors and, in fact, cyclooxygenase inhibitors often exacerbate underlying asthma.[403,404]

Mast Cell-Derived Cytokines

Mast cells may be important initiators of both the early- and late-phase allergic reaction by their ability to synthesize and secrete cytokines. Mast cells express messages for a number of cytokines including 1) proinflammatory cytokines, 2) immunoregulatory cytokines, and 3) chemokines.

Mast cells contain preformed stores of several proin-flammatory cytokines including TNF-α, IL-8, IL-6, and IL-1α. Release of these cytokines early in the immune response likely contributes to the recruitment of leukocytes during the late-phase response via their ability to

increase expression of adhesion molecules such as P- and E-selectin, vascular cell adhesion molecule (VCAM-1) and intercellular adhesion molecule-1 on vascular endothelial cells. Mast cells appear to be an important initial source of TNF-α during allergic responses. Mast cells produce a number of immunoregulatory cytokines such as IL-3, IL-4, IL-5, GM-CSF, IL-13, and IL-16. In the human bronchial mucosa, IL-4 immunoreactivity is seen in approximately 80% of mast cells.[405,406] Indeed, it has been suggested that mast cells are the primary source of IL-4 protein in inflamed airways. Although cytokine production by basophils has not been as extensively studied as that in mast cells, they have been shown to produce large quantities of IL-4 and IL-13. The rapid and perhaps sustained production of cytokines by these cells at sites of allergic inflammation may intensify or perpetuate IgE production and Th2 cell differentiation. Mast cells have also been shown to produce a number of chemokines such as MCP-1, MIP-1β, MIP-1α, and RANTES. Elaboration of these chemokines may contribute to the cellular component of the late-phase response.

Mast Cell Activation

Mast cell activation may be initiated upon interaction of a multivalent antigen with its specific IgE antibody attached to the cell membrane via its high affinity receptor, FcεR1. Cross-linking of IgE by the interaction of allergen with specific determinants on the Fab portion of the molecule brings the receptors into juxtaposition and initiates mast cell activation and mediator generation and release. Mast cells may also be activated by non-IgE-mediated stimuli such as neuropeptides, complement components, and drugs such as opiates. In addition to IgE-dependent stimuli, several non-IgE-dependent stimuli activate mast cells and basophils. C5a, IL-3, fMLP, certain cytokines (IL-33), and chemokines (RANTES) are known to induce histamine and mediator release in mast cells and basophils. Hyperosmolarity itself also stimulates mediator secretion from these cells. Degranulation produced by both IgE-dependent and non-IgE-dependent stimuli appear similar. However, the biochemical processes that lead to mediator release may differ.

Role of Mast Cells in Acute-Phase Responses

Several lines of evidence suggest that mast cells and basophils play a pivotal role in the generation of acute-phase responses. First, allergen provocation of atopic individuals is associated with extensive activation of mast cells as judged by the detection of the release of mast cell-associated mediators (histamine, tryptase) at the site of allergen challenge. Secondly, therapeutics that inhibit the release of these mediators (mast cell stabilizers) or their actions (antihistamines) effectively attenuate acute allergic responses. Despite this evidence in humans, the data in animal models is conflicting. While the preponderance of studies in mice suggests that acute responses are mast cell- and IgE-dependent, others suggest that these responses are IgE-independent. For example, it has been shown that responses induced in mice by passive transfer of allergen-specific IgE antibodies and subsequent intravenous allergen challenge are inhibited in genetically mast cell-deficient $Kit^{W}/Kit^{W\text{-}v}$ mice. When these mice were reconstituted with mast cells by adoptive transfer, their acute-phase responses were restored.[407] In contrast, some investigators have reported that anaphylactic responses

develop normally in IgE-deficient mice.[408] Although these conflicting results may reflect inherent differences in mast cell biology between humans and mice, they imply that both mast

cell- and IgE-dependent and -independent processes are likely involved in the expression of the physiologic features of the acute-phase reaction.

Role of Mast Cells in Late-Phase Responses

Although it has long been thought that mast cells only contribute to the early acute response, recent evidence demonstrates their potential contribution to the late-phase response. First, through the elaboration of proinflammatory cytokines, chemokines, and immunoregulatory cytokines as discussed previously, mast cells may contribute to the cellular component of the late-phase response as well as favor the acquisition of the Th2 phenotype by providing a continuously high concentration of IL-4. Secondly, mast cell-derived mediators may also contribute to the chronic remodeling of mucosal tissues as many of the mediators they release influence connective tissue turnover. Specifically, histamine and tryptase have been shown to stimulate fibroblast growth and collagen synthesis in vitro and in vivo. Lastly, studies in humans have shown that stabilization of mast cells with sodium nedocromil effectively inhibits both the early- and late-phase response to allergen exposure.[409] Furthermore, recent clinical trials utilizing a monoclonal antibody against IgE resulted in reductions in symptoms and improvement in lung function in asthmatics.[410] Although these reports support a role for mast cells in the late-phase response, studies of animal models of AD and asthma suggest that late-phase reactions are similar in wild-type and IgE-deficient mice,[411] suggesting that although mast cells are capable of inducing late phase responses, additional mast cell-independent processes also contribute to the development of late-phase responses.

EOSINOPHIL BIOLOGY

Eosinophil blood and tissue levels are generally quite low in the absence of parasitic infection or atopy. One of the hallmarks of allergic disorders is heightened production of eosinophils in bone marrow and the accumulation of eosinophils in tissues and blood. Eosinophil differentiation, recruitment, and activation are under the regulation of a series of molecular events orchestrated by Th2 cytokines. Although the exact role of eosinophils in the pathology of allergic responses is not known, eosinophils are known to release a myriad of mediators and cytokines that have the potential to induce the symptoms of allergy as well as amplify the allergic response through the release of immunoregulatory and proinflammatory cytokines.

Eosinophils are bone marrow-derived granulocytes that are characterized by their bilobed nuclei and their distinctive cytoplasmic granules (Fig. 45.9).[412,413] They contain three distinct types of cytoplasmic granules: 1) eosinophil specific granules, which contain electron-dense crystalloid cores; 2) primary granules, which lack a crystalloid core and develop early in eosinophil maturation; and 3) smaller granules, which contain arylsulfatase and other enzymes. Eosinophils also contain varying numbers of lipid bodies. Lipid bodies are nonmembrane-bound, lipid-rich inclusions that are also found in macrophages and mast cells and are thought to contribute to the formation of eicosanoid mediators. Eosinophils are generally identified in blood and tissues by the affinity of their cytoplasmic granules for acid aniline dyes such as eosin and in tissues by immunostaining for eosinophil-specific proteins such as major basic protein (MBP).

Eosinophil-Derived Mediators

Eosinophil-Specific Cationic Proteins

Eosinophils store four highly basic, low-molecular-weight proteins in their cytoplasmic granules: MBP, eosinophil-derived neurotoxin (EDN), eosinophil peroxidase (EPO), and eosinophil cationic protein (ECP). MBP, EPO, and ECP are potent toxins for helminths and bacteria; they are strongly implicated as mediators of allergic diseases such as asthma, atopic dermatitis, and allergic rhinitis. MBP is potently toxic for mammalian cells in vitro, and high levels of MBP are found in the body fluids of patients with asthma and other allergic disorders.[414] Both MBP and ECP exert their toxicity by damaging target cell membranes through charge-mediated interactions. In addition to its toxic properties, MBP activates platelets, mast cells, and basophils, which in turn release histamine. Furthermore, MBP administration to primates induces AHR. MBP may induce AHR through its demonstrated ability to competitively inhibit binding to cholinergic muscarinic M2 receptors on parasympathetic nerves.[415] These receptors normally function as autoreceptors that inhibit the release of acetylcholine from the nerve ending. Thus, inhibition of these receptors by MBP would enhance the release of acetylcholine in the airway wall, resulting in heightened contractile responses. Both ECP and EDN have partial sequence identity with pancreatic ribonucleases; however, EDN is more potent as a ribonuclease than is ECP.

EPO, which is distinct from the myeloperoxidase of neutrophils and monocytes, consists of two polypeptides of about 15 and 55 kDa. It catalyzes the formation of hypobromous acid from hydrogen peroxidase and halide ions (preferentially bromide). HOBr reacts with primary amines to form bromamines, and it converts tyrosine to 3-bromotyrosine. Increases in the levels of 3-bromotyrosine in BAL proteins have been observed in asthmatics following allergen provocation.[416] Thus, the oxidative pathways induced in activated eosinophils may damage biomolecules in vivo.

Another prominent component of eosinophil primary granules are Charcot-Leyden crystals (CLCs). This protein comprises up to 10% of the total cellular protein in human eosinophils. Although the CLC protein possesses lysophospholipase activity, structural analysis suggests that the CLC protein is similar to that of galectins 1 and 2, members of the “S-type” lectin superfamily.[417] Recent studies in the mouse lung suggest that CLCs may contain a protein called YM-1 (T-lymphocyte-derived eosinophil chemotactic factor), which has sequence homology to chitinase.[418] Chitinase activity of these proteins may explain the strong association between eosinophilia and parasite infestations. These crystals are often found in sputum, feces, and tissues in patients

with allergic asthma and other eosinophil-related diseases characterized by significant eosinophilia.

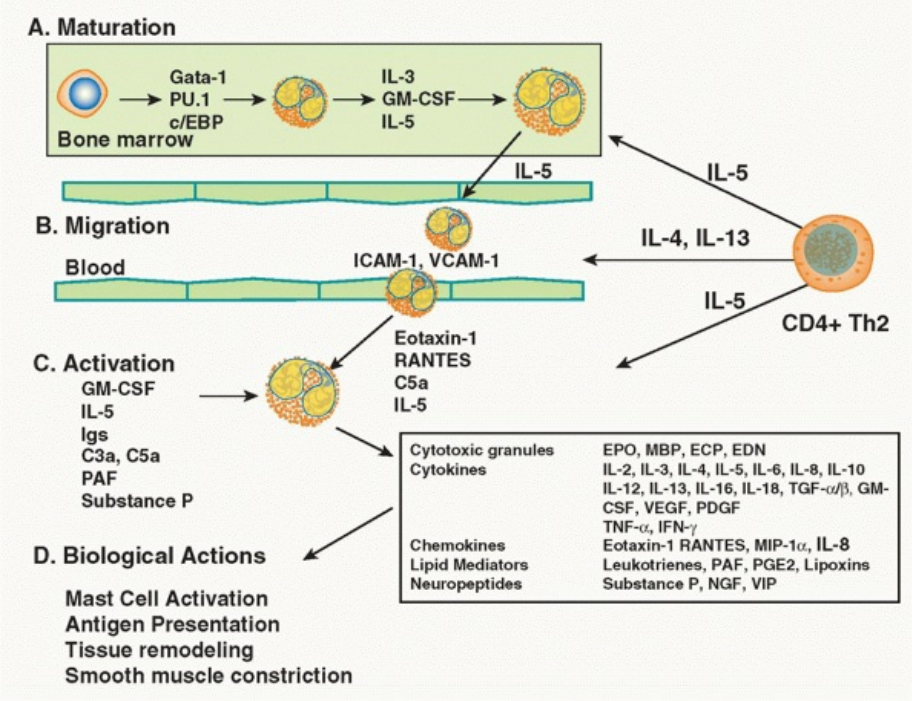

FIG. 45.9. Schematic Representation of Eosinophil Actions During Allergic Immune Responses. A: Maturation. **B:** Migration. **C:** Activation. **D:** Pleiotrophic Actions. Eosinophils develop in bone marrow where they differentiate from hematopoietic progenitor cells into mature eosinophils under the control of several transcription factors including GATA-1, PU.1, and c/EBP. Th2 cytokines coordinately regulate eosinophil recruitment, activation, and accumulation at the site of antigen exposure. Following allergen-specific induction of Th2 cytokine production (interleukin [IL]-5, IL-4, IL-13, IL-3, granulocyte macrophage-colony stimulating factor [GM-CSF]), IL-5 rapidly induces differentiation of eosinophils from myeloid precursors in bone marrow to stimulate their release into the bloodstream. IL-4 and/or IL-13 promote eosinophil egress from the vascular compartment by upregulating vascular cell adhesion molecule-1 expression on vascular endothelial cells. Subsequently, IL-4 and IL-13 guide eosinophils to the site of allergen exposure by regulating the production of various chemokines (eg, RANTES, eotaxin) by local cells such as macrophages and epithelial cells. Once these cells accumulate in tissues, locally produced IL-5 along with other cytokines, such as GM-CSF and IL-3, promote their actions by prolonging their survival in tissues. Eosinophils store and release a number of proteins in their specific granules. Specifically, major basic protein is stored in the core of the granule, while eosinophil cationic protein, eosinophil-derived neurotoxin, and eosinophil peroxidase are found in the matrix of the granules. Eosinophils also contain lipid bodies in which products of lipoxygenase and cycloxygenase are formed. Eosinophils also release a number of cytokines, chemokines, and neuropeptides that are important in the allergic diathesis.

Lipid Mediators

Upon stimulation, eosinophils elaborate several bioactive lipids, including products of the 5- and 15-lipooxygenase pathway, products of the cyclooxygenase pathway, and PAF. Lipid bodies, or intracellular lipid-rich domains, are induced to develop in many activated

eosinophils in vivo and are sites for enhanced synthesis of both lipoxygenase- and cyclooxygenase-derived eicosanoids. The activities of eosinophil-derived lipids, which are generally proinflammatory, are multiple and include potent smooth muscle contraction, vasoactivity, and mucus secretion activities.

Cytokines

In recent years, it has been recognized that eosinophils are a major source of cytokines and appear to store some if not all of these cytokines in cytoplasmic-specific granules. Triggering of eosinophils by engagement of receptors for cytokines, Ig, and C3 can lead to secretion of an array of proinflammatory and immunoregulatory cytokines, chemokines, and growth factors including IL-2, IL-3, IL-4, IL-5, IL-6, IL-8, IL-10, IL-12, IFNγ, TNF-α, GM-CSF, TGF-β, TGF-α, RANTES, MIP-1α, eotaxin, VEGF, platelet-derived growth factor-β, and heparin-binding epidermal growth factor.[61] Through the quick release of this diverse array of cytokines at the inflammatory loci, the eosinophil is poised to perpetuate and/or intensify the eosinophil-mediated

inflammatory response, both by enhancing its own activation and through the release of Th2 cytokines.

Recruitment of Eosinophils to Sites of Inflammation

Preferential accumulation of eosinophils at sites of allergic inflammation involves multiple molecular events that are integrated and controlled by Th2 cytokines.[419] These include a) differentiation and release of mature eosinophils from bone marrow into the bloodstream,; b) upregulation of specific adhesion molecules on eosinophils and endothelium, c) stimulation of C-C chemokine production and egress of eosinophils from the blood into the tissues, and d) production of eosinophil-active cytokines that increase eosinophil survival in tissues.

Eosinophils are terminally differentiated granulocytes that develop from CD34+ hematopoietic progenitor cells in the bone marrow. Under the influence of GM-CSF, IL-3, and IL-5, they differentiate into mature eosinophils. These cytokines likely promote eosinophilopoiesis via induction of GATA-1, PU.1, or C/EPS through their shared common β-chain.[420,421] Of these, IL-5 has the most specific effects on eosinophil differentiation and production. In addition to its effects on eosinophil differentiation, IL-5 can rapidly induce the release of developed eosinophils from bone marrow into peripheral circulation. The importance of IL-5 to blood and tissue eosinophilia has been repeatedly shown in in vitro and in vivo studies of gene targeted and overexpressing mouse lines.[422]

Circulating eosinophils are recruited to sites of inflammation by the combined actions of inflammatory mediators, adhesion molecules, and chemoattractants. Several cell adhesion molecules have been implicated in eosinophil adherence to cytokine-stimulated vascular endothelium, including intercellular adhesion molecule-1, E-selectin, L-selectin, and the very late antigen-4/VCAM-1. The importance of VCAM-1 to eosinophil recruitment has been shown in primate and mouse studies in which blockade of VCAM-1/very late activation antigen-4 interactions inhibits eosinophil infiltration of tissues.[423] IL-4 and IL-13 induce VCAM-1 expression on the surface of vascular endothelial cells, leading to preferential recruitment of eosinophils into sites of allergic inflammation.

Eosinophil migration to the sites of inflammatory loci is mediated by a number of chemoattractants. Until the last decade, mediators such as PAF, C5a, and LTB_4 were considered to be the most important eosinophil chemoattractants. Although potent chemoattractants, they do not show any specificity for eosinophils. However, there are a number of C-C chemokines that are eosinophil chemoattractants (RANTES [CCL5], eotaxin [CCL11], monocyte chemoattractant protein, MCP-4 [CCL13], MCP-3 [CC17], and MIP-α [CCL3]). The levels of most of these chemokines have been shown to be upregulated in the mucosal tissues of patients with asthma, atopic rhinitics, and atopic dermatitis. Although each of these chemokines is implicated in eosinophil chemotaxis, it was originally hypothesized that eotaxin would play a pivotal role in eosinophilic inflammation in that it binds specifically to the CCR3, while the other C-C chemokines bind multiple receptors. The fact that CCR3 is highly expressed on eosinophils, basophils, and Th2 cells but not on neutrophils suggests that it plays an important role in Th2-mediated inflammatory responses.[424,425] Surprisingly though, eotaxin-deficient mice have shown only minor defects in eosinophil accumulation,[426,427] indicating that eotaxin is not uniquely required for eosinophil accumulation. Along these lines, complete abrogation of eosinophil migration has not been observed by inhibition of any one chemokine,[426,427,428] suggesting that multiple chemokines working in concert are required to direct leukocytes to specific sites of inflammation. Thus, it has been postulated that a panoply of chemokines may be required to establish the multiple chemical gradients required for eosinophils to migrate through several local compartments from the vascular spaces to the mucosal surfaces in the nose, airway, and skin.

Based on the independent and overlapping roles of IL-4, IL-13, and IL-5, discussed previously, we would envision the following paradigm for regulation of allergen-induced tissues eosinophilia. Following allergen-specific induction of Th2 cytokine production, IL-5 would rapidly induce differentiation of eosinophils from myeloid precursors in bone marrow and stimulate their release into the bloodstream. IL-4 and/or IL-13 would promote eosinophil egress from the vascular compartment by upregulating VCAM-1 expression on vascular endothelial cells. Once the cells accumulate in tissues, locally produced IL-5 along with other mediators such as eotaxin would promote their actions by prolonging their survival in tissues. Within this paradigm, allergendriven eosinophil recruitment into tissues is coordinately regulated by the Th2 cytokines IL-4, IL-13, and IL-5.

Mechanisms of Eosinophil Activation

The effector functions of eosinophils are mediated by stimuli that induce degranulation. Eosinophil degranulation can be regulated by multiple components including those that primarily stimulate the cells (eg, Igs and lipid mediators), priming agents (eg, cytokines), and chemokines. However, the precise mechanisms by which eosinophil degranulation occurs in vivo are still poorly understood.

Eosinophils express receptors for several Igs including IgG, IgA, and IgE. Surfaces coated with IgG, IgA, and secretory IgA stimulate eosinophil degranulation in vitro. Of these Igs, sIgA is the best for inducing eosinophil degranulation and does not stimulate neutrophil degranulation. As IgA is the most abundant Ig isotype in mucosal secretions of the respiratory and gastrointestinal tracts, it may be an important regulator of eosinophil activation at these sites. IgE may also be important for eosinophil activation as eosinophils can bind IgE via

three distinct structures: the S-type lectin galectin-3, FcεRII/CD23, and FcεRI. It was initially shown that eosinophils, isolated from patients with parasite-induced eosinophilia, degranulate in response to IgE antibody or IgE-coated parasites.[429,430] Subsequent studies showed that local allergen provocation induces expression of FcεRI by eosinophils infiltrating into the airways[431] and skin of patients with allergic diseases.[432,433] In studies using sera from ragweed-allergic patients with hay

fever, ragweed-specific IgG, but not IgE, induced allergendependent eosinophil degranulation in vitro.[434,435] Thus, it remains to be determined whether IgE is an important regulator of eosinophil degranulation in atopy.

Eosinophil degranulation may also be induced by soluble stimuli alone. Cytokines, especially those with eosinophilopoietic activity, such as GM-CSF and IL-5, are potent inducers of eosinophil granule protein release. Interestingly, eosinophil granule proteins themselves, including MBP and EPO, stimulate eosinophils and cause degranulation, suggesting an autocrine mechanism of eosinophil degranulation.[436] Other physiologic stimuli for eosinophil degranulation include PAF, the complement fragments, C5a and C3a, and the neuropeptide substance P.[437] As previously discussed briefly, chemokines may also activate eosinophils by binding CCR3. In this regard, eotaxin induces eosinophil degranulation and leukotriene C_4 (LTC_4) release.

Eosinophils as Effector Cells in Allergic Responses

Eosinophils through the elaboration of a plethora of preformed and lipid mediators described previously are postulated to play a role in several aspects of the allergic response including antigen presentation, T-cell proliferation and differentiation, as well as mast cell activation and airway remodeling. Although it remains controversial, it has recently been shown that eosinophils may function in antigen presentation.[438] Specifically, eosinophils have been shown to effectively present soluble parasitic antigens to CD4+ T cells, thereby promoting T-cell proliferation and polarization. They may also regulate T-cell proliferation, activation, and polarization via the array of cytokines they produce as well as through their ability to synthesize indoleamine 2,3 dioxygenase.[439]

Circumstantial evidence for a causative role of eosinophils in allergic inflammation as well as the clinical symptoms of atopic disorders comes from a variety of studies.[440] First, elevated levels of activated eosinophils and their protein products (MBP, ECP, EPO, EDN) have been consistently demonstrated in BAL fluids and airway biopsy tissues from patients with asthma,[440] in nasal biopsy specimens from patients with allergic rhinitis (nasal fluids and nasal biopsies),[441] and in skin lesions from patients with atopic dermatitis.[442] Secondly, in each of these diseases, increased levels of eosinophils and their proteins correlate with disease severity. Lastly, successful steroid treatment is associated with a marked reduction in both blood and tissue eosinophil levels in asthma, atopic rhinitis, and atopic dermatitis.[443,444]

Despite the substantial body of circumstantial evidence that supports a causative role for eosinophils in the pathophysiology of atopic disorders, the results of studies designed to

define a pathogenic role for eosinophils in atopic disorders are conflicting. Studies in IL-5 gene knockout[53] and IL-5 transgenic mice[422] show that both eosinophilia and AHR are IL-5-dependent. In contrast, other investigators have demonstrated that blockade of eosinophils by IL-5 ablation did not affect AHR in animal models.[445] A caveat of these experiments is that IL-5 depletion did not completely deplete eosinophils. To address this issue, several groups have undertaken the task of developing eosinophil-deficient mice.[446,447] One group generated an eosinophil-deficient mouse via insertion of a cytocidal protein (diphtheria toxin A) in the promoter of the EPO gene. These mice were reported to be completely devoid of eosinophils in all tissues. Moreover, all features of the allergic phenotype were absent (AHR, mucus, eosinophilia, Th2 cytokine production) in these mice following allergen challenge. The other eosinophil-deficient mouse line (BALB/c background) harbors a deletion of a high-affinity GATA-binding site in the GATA-1 promoter leading to the specific ablation of the eosinophil lineage.[446,447] In these mice, complete eosinophil depletion had no effect on AHR, mucus production, or Th2 cytokine production, but did reduce airway remodeling assessed by collagen deposition. In contrast, when the GATA1 mutation was bred onto the C57BL/6 background, mature eosinophils were found to contribute to the generation of a Th2 response by producing or promoting the production of chemokines that recruit T cells that subsequently produce a Th2 response.[448] The safest conclusions to draw from these observations are that eosinophils and IL-5 are sufficient to induce AHR and goblet cell hyperplasia in the C57BL/6 mice, but that redundant mechanisms may exist in BALB/c mice that

bypass the requirement for eosinophilic inflammation.

The results in human anti-IL-5 asthma trials mirror that observed in experimental asthma models. Specifically, an initial multiple center study showed that treatment of mild asthmatics with mepolizumab, a humanized mouse IgG1 monoclonal anti-IL-5 antibody, did not benefit patients with asthma despite significantly lowering blood eosinophilia.[449] The interpretation of this early study was that anti-IL-5 treatment was insufficient to completely suppress tissue eosinophilia. Other studies conducted on patients with mild asthma also failed, although analyses of bronchial biopsies showed that mepolizumab only reduced the numbers of eosinophils by about 50% and did not appreciably reduce the degree of eosinophil granule protein deposition.[450,451] However, more recent studies that have evaluated anti-IL-5 monoclonal antibody effects in patient populations with more severe disease have shown some benefit. In one study, intravenous injection of anti-IL-5 monoclonal antibody improved the ability to rapidly exhale air (volume of air expelled during the initial second of forced expiration) and decreased asthma exacerbations, steroid requirement, and blood and sputum eosinophilia in patients with steroid-resistant asthma with sputum eosinophilia.[451] In another study, it decreased severe exacerbations and blood and sputum eosinophilia, and increased quality of life without increasing volume of air expelled during the initial second of forced expiration, decreasing symptoms, or decreasing AHR.[452] Thus the exact contribution of IL-5 and eosinophils to asthma pathogenesis is complex and remains to be fully elucidated. Despite the complex picture in asthma, anti-IL-5 therapies have shown some efficacy in the treatment of patients with the hypereosinophilic syndrome.[453]

Th2 Cytokine-Producing Cells as Effector Cells

Our recent understanding of the role of Th2 cells in the allergic diathesis suggest that they are important effector cells in

the allergic response in addition to their well-accepted role as orchestrators of the inflammatory process. Specifically, the Th2 cytokine IL-13 has been implicated as an effector molecule in allergic disease. Evidence for this contention comes from studies in which blockade of endogenous levels of IL-13 in antigen-sensitized mice by administration of a soluble form of the IL-13Rα2 chain, which binds only IL-13, completely reversed AHR and pulmonary mucus cell hyperplasia.[63,64] Furthermore, it was shown that recombinant IL-13 was able to recreate the symptoms of asthma (AHR, mucus hypersecretion, eosinophilia) in the absence of functional T cells or B cells.[39] These effects were shown to be independent of eosinophils as well.[454] These results suggested that the effects of IL-13 were not due to its known role in regulating IgE or eosinophil recruitment. Interestingly, despite the similarities in function between IL-13 and IL-4, IL-4 blockade at the time of antigen challenge does not ablate AHR.[60] This was further supported by the finding that transfer of Th2 cells derived from IL-4-deficient mice was still able to confer AHR.[44] Moreover, chronic expression of IL-13 in the mouse lung results in development of these features as well as subepithelial fibrosis and the formation of CLCs.[455] In contrast, overexpression of the IL-4 gene in the murine lung does not result in AHR or subepithelial fibrosis.[456] These studies suggest that IL-4 is essential for the initiation of Th2 polarized immune responses to allergenic peptides, whereas IL-13 alone may mediate the main physiologic consequences of allergic airway disease, namely AHR, mucus hypersecretion, and subepithelial fibrosis.

As IL-4 and IL-13 share a functional receptor, one of the questions puzzling immunologists is how IL-13 may play a preferential role in the effector arm of the allergic response. Several explanations have been postulated including the possibility that IL-4 production at the site of inflammation is short lived and that IL-13 may persist, giving the illusion that IL-13 is the more important mediator of the effector phase of the response. This hypothesis is not without merit as IL-4 is difficult to measure at the site of inflammation and kinetic studies have shown sustained IL-13 production in the lungs of patients with asthma.[457] However, several in vitro studies have also claimed to observe unique functions of these cytokines in systems in which the level of cytokines is controlled. It can always be debated that any differences observed in these systems may be due to differences in degradation of these two proteins in culture or that the recombinant forms of these proteins do not have equivalent potency. Another potential hypothesis is that IL-13 may act through an as yet unidentified receptor complex. In support of this hypothesis, a recent study demonstrates that although AHR and eosinophilia induced by adoptive transfer of IL-13-sufficient T cells are STAT6 dependent, these effects appear to occur independently of the IL-4Rα chain.[458] These studies suggest that an as yet unidentified IL-13 binding chain may exist or that different configurations of the existing chains may mediate distinct effects of IL-13 stimulation. As will be discussed subsequently, the IL-13Rα2 chain may play a role in mediating processes unique to IL-13 under some circumstances. Alternatively, it has recently been shown that IL-4 may induce inhibitory pathways through the type I receptor, which limit its proallergic effects mediated through the type II receptor.[459] On the other hand, it has been shown that IL-13 induces a small set of

epithelial-specific genes that are not upegulated by IL-4 in vivo but are however STAT6 dependent. This apparent IL-13 selectivity either occurs via IL-13 stimulation of a unique receptor complex or as a result of IL-4 inhibition of these putative pathways. Although the mystery underlying the unique functions of IL-4 and IL-13 is far from solved, multiple explanations for their apparently unique functions are emerging.

IL-13 has several actions that implicate it as an effector in the allergic diathesis such as its role in mucus production, fibrotic processes, and perhaps bronchoconstriction (Fig. 45.10). First, it has been shown to play an important role in mucus hypersecretion. Mucus hypersecretion is a consistent feature of the allergic phenotype in both the upper and lower respiratory tract. In fact, extensive plugging of the airway lumen has been associated with fatal episodes of asthma. This response is a Th2 cell-dependent process as adoptive transfer of Th2 cells into the murine lung reconstitutes the effect of antigen challenge.[44] Several lines of evidence suggest that mucus cell metaplasia is an IL-13-, not IL-4-, dependent process. For example, transfer of Th2 cells devoid of IL-4 or IL-5 genes still induce extensive goblet cell metaplasia in the murine lung. However, blockade of the IL-4Rα chain or deficiency in STAT6 prevents the development of mucus cell metaplasia following allergen challenge suggesting that IL-13 may be the ligand for the IL-4/STAT6 pathway in mucus cell changes.[50,307] Indeed, administration of soluble IL-13Rα2 reversed the metaplastic response of goblet cells induced by allergen sensitization and challenge. Administration of rIL-13 in vivo or overexpression of the IL-13 gene recapitulates antigen effects on mucus production. Conversely, allergeninduced goblet cell metaplasia is significantly reduced in IL-13-deficient mice.[460] This was not further reduced when IL-4 was blocked with neutralizing antibodies, suggesting that indeed IL-13 is the primary regulator in vivo of mucus cell hyperplasia. The mechanisms by which IL-13 regulates mucus production are not entirely clear. However, IL-13 has been shown to coordinately regulate a number of processes in the airway epithelium that may contribute to mucus hypersecretion such as the induction of mucin gene expression and ion channel gene expression and activity.[461]

Another feature of the chronic inflammatory response in both the skin and the airways is the presence of a fibrotic process. Recent data suggests that IL-13 is an important regulator of fibrotic processes. For example, overexpression of IL-13 in the murine lung induces a dramatic fibrotic response in the airway wall.[455] Furthermore, IL-13 transgenic mice express matrix proteases such as metalloproteinase and cathepsins that are thought to be important in the fibrotic response.[462] A clear demarcation of function for IL-4 and IL-13 in fibrosis has been demonstrated in Th2-mediated pathology of *Schistosome mansoni* infection in mice. *Schistosome*-induced collagen deposition is reduced in the lungs of STAT6-deficient animals but not in IL-4-deficient mice.[463] Furthermore, sIL-13Rα2-Ig delivery completely prevented the fibrotic response in parasite-infected mice. Thus in several models of Th2-mediated fibrosis, blockade

of IL-13 selectively inhibited fibrotic remodeling processes, suggesting that this cytokine may be an important mediator of inflammation-induced tissue fibrosis.

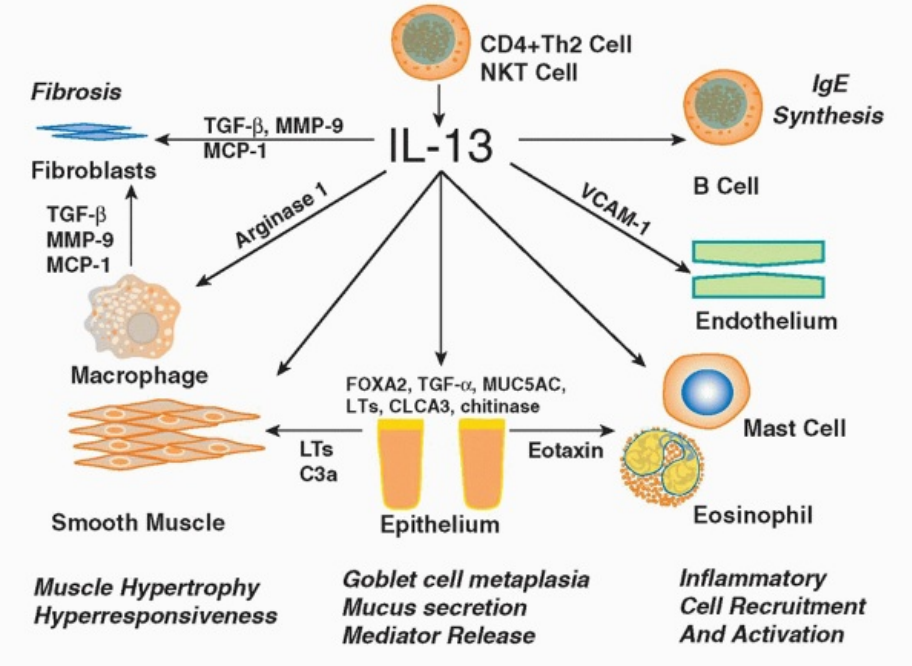

FIG. 45.10. Schematic Representation of the Role of Interleukin (IL)-13 in the Effector Phase of the Allergic Response. IL-13 is produced in the airway by a variety of cells including T cells (cluster of differentiation4+, natural killer T cells), eosinophils, and mast cells. IL-13 binds its receptor on multiple cell types and induces the expression of a variety of genes in target cells. The consequencecs of IL-13 receptor activation include immunoglobulin E synthesis, adhesion molecule expression on endothelial cells and egress of inflammatory cells into mucosal tissues, inflammatory cell activation (eosinophils and mast cells), epithelial cell activation leading to mucus hypersecretion (FOXA2, CLCA1/3, transforming growth factor [TGF]-α, MUC5AC) and mediator release (LTs, C3, eotaxin), smooth muscle activation and hypertrophy, airway hyperresponsiveness, activation of macrophages and fibroblasts leading to the production of various enzymes involved in collagen synthesis (arginase I, MMP-9, TGF-β, PDGF-AA), and deposition leading to tissue fibrosis. C3a, complement factor 3; CLCA1/2, $Ca+^{2}$ activating chloride channel gene 1/3; FOXA2, forkhead box a2 transcription factor; MMP9, metalloproteinase 9; MUC5AC, mucin gene 5AC; TGF-a, transforming growth factor alpha; VCAM-1, vascular cell adhesion molecule 1.

Although the mechanisms by which IL-13 induces tissue fibrosis are far from understood, several recent studies have begun to shed light on the sequence of events leading to IL-13-induced fibrosis. IL-13 likely regulates tissue fibrosis through a series of coordinated actions on a number of cells types within the lung. First, IL-13 has been shown by several investigators to upregulate the synthesis of arginase I.[464,465] Arginase I is an enzyme that hydrolyzes L-arginine to urea and L-ornithine, which is a necessary metabolite for the production of polyamines and prolines required for collagen synthesis by fibroblasts. Evidence of an in vivo role for this pathway in tissues fibrosis was provided by Hesse and colleagues.[464] Specifically, they showed that blockade of ornithine-aminodecarboxylase, which ultimately results in the generation of proline, markedly enhanced parasite-driven

tissue fibrosis. Consistent with a role for arginase I in asthma, Rothenberg and colleagues[465] demonstrated that the enzyme is upregulated in an ovalbumin model of asthma and in animals exposed to recombinant IL-13 as well as in lung tissues of asthmatic as compared to normal individuals. Secondly, the ability of IL-13 to induce the profibrotic mediator TGF-β also contributes to IL-13-dependent lung fibrosis.[466] In this regard, IL-13 induces the production of TGF-β both directly in epithelial cells and indirectly in monocytes/macrophages via its ability to recruit and activate these cells.[467] This is thought to occur via the interaction of MCP-1 with its receptor CCR2 on monocyte/macrophages, as both lung fibrosis and TGF-β production in IL-13 transgenic mice are diminished in mice devoid of CCR2.[468] Further support for this argument is the fact that MCP-1 has been shown to stimulate TGF-β1 production in lung fibroblasts.[469] In addition to stimulation of TGF-β synthesis, IL-13 also activates latent TGF-β through the induction of MPP9.[466]

Lastly, IL-13 may also have a direct effect on fibrotic processes by stimulating the proliferation of myofibroblasts via a STAT6-dependent process involving platelet-derived growth factor AA.[470] Lung fibrosis may also arise as a result of the ability of IL-13 to stimulate the accumulation of the nucleoside adenosine.[471] Specifically, it has been shown that IL-13-overexpressing mice have increased adenosine levels

and reduced adenosine deaminase gene expression and enzyme activity, while exhibiting marked increases in lung collagen. Furthermore, blockade of adenosine levels in the lung by adenosine deaminase enzyme therapy diminished IL-13-induced fibrosis concomitant with a reduction in elaboration of a selective set of chemokines (MCP-1, 2, 3, 5, and eotaxin). Collectively, these studies suggest that a number of IL-13-driven processes culminate in the generation of fibrogenic processes in the lung.

AHR or an exaggerated response to specific and nonspecific stimuli is a hallmark of asthma. The exact mechanisms by which IL-13 induces AHR are currently unknown. Several lines of evidence suggest that IL-13 can induce AHR in the absence of inflammatory cells. The initial IL-13Rα2Ig studies showed that IL-13 blockade inhibited AHR without affecting inflammatory cell recruitment or IgE synthesis.[61] Moreover, Grunig et al.[64] demonstrated that T and B cells were not essential for the effects of IL-13 on AHR. Support for this contention is provided by Vargaftig and colleagues,[472] who demonstrated that pretreatment of mice with vinblastine, a granulocyte inhibitor, failed to inhibit IL-13-induced AHR. In support of this theory, IL-13 has been shown to induce hyperresponsiveness as early as 6 hours after administration, long before significant inflammation has occurred.[473] More definitely, studies in eotaxin/IL-5 double knockout mice[454] confirm the contention that the traditional effector cells, B cells, mast cells, and eosinophils are not required for IL-13 to induce AHR. These results suggest that although IL-13 is able to direct the recruitment of inflammatory cells into the airways, they are likely not necessary for induction of AHR. Alternatively, IL-13 may induce AHR via direct effects on resident airway cells. Both airway epithelial cells and airway smooth muscle have been implicated by studies in driving AHR. However, whether AHR is mediated by direct effects on airway smooth muscle or indirectly via effects on resident airway cells such as the epithelium is currently a matter of debate. The importance of the IL-13-epithelial cell axis was illustrated by the demonstration that AHR develops in mice that

overproduce IL-13 in their lungs and express Stat6 only in airway epithelium.[474] However, a subsequent study showed that IL-13 also induced AHR in mice that selectively lack IL-4Rα in airway epithelial cells.[475] The suggestion that other cell types may contribute to IL-13-induced AHR led Finkelman and colleagues[476] to explore the role of the IL-4Rα in mice that express IL-4Rα only on smooth muscle cells or on all cell types other than smooth muscle. Studies with these mice demonstrate that direct effects of IL-13 on smooth muscle, as on airway epithelium, are sufficient but not necessary to induce AHR. Additional studies are required to determine whether IL-13-induced AHR can be totally accounted for by its effects on epithelial and smooth muscle cells or by as yet unidentified pathways.

The importance of IL-13 in allergic disorders in humans is supported by numerous reports of exaggerated IL-13 production in allergic diseases.[477,478,479] In asthma, in particular, message levels of IL-13 are elevated in bronchial biopsy specimens from allergic individuals when compared with those of control subjects.[477] Conversely, IL-13 levels are reduced in patients with asthma undergoing steroid treatment.[478] Moreover, a recent cohort study of neonates demonstrates that high IL-13 productive capacity of cord blood CD4+ T cells is a significant predictor of risk for subsequent development of atopic diseases.[479] In support of the notion that IL-13 is a central effector of allergic immune responses, several groups have reported strong associations of polymorphisms in the IL-13 promoter and coding region with various features of the asthmatic phenotype.[480,481] Of particular interest is the Arg130/Gln substitution in the coding region of IL-13 noted by multiple groups and detected across multiple ethnic groups. Moreover, Arima and colleagues have recently provided evidence that the Arg110Gln may be a functional variant.[482] Utilizing a mutant recombinant IL-13, they show that recombinant IL-13 containing the Gln110 variant bound the IL-13Rα2 chain with lower affinity than the wild-type IL-13, resulting in a lower clearance rate of the cytokine. Interestingly, they demonstrated that although the IL-13 variant did not alter any biologic properties of IL-13, patients with asthma homozygous for the Gln110 variant have higher serum levels of IL-13 than those without the variant. They postulated that impaired binding of IL-13 by the soluble IL-13Rα2 chain leads to higher serum levels and prolonged activity of IL-13 in vivo. Vercelli and colleagues[483] have shown that the -1112T variant of the IL-13 promoter is functional as expression of it in human and murine CD4+ Th2 lymphocytes enhanced IL-13 promoter activity. Interestingly, increased expression of IL-13-1112T in Th2 cells was associated with the creation of a Yin-Yang 1 binding site that overlapped a STAT motif involved in negative regulation of IL-13 expression and attenuated STAT6-mediated transcriptional repression. The enhanced IL-13 secretion in IL13-1112TT homozygotes suggests that expression of this allele may underlie its association with susceptibility to allergic inflammation.

Unifying Hypothesis

The elicitation of allergic airway responses in a sensitized individual upon reexposure to offending allergens is likely the culmination of a complex network of cellular and molecular events (Fig. 45.11). Following antigen challenge, cross-linking of antigen and IgE on IgE-bearing cells leads to the immediate release of substances such as histamine, leukotrienes, PGD_2, and tryptase. The actions of these mediators account for the immediate symptoms, such as smooth muscle constriction, vasodilation, and increased vascular permeability. It is

possible that the release of IL-13 by either mast cells or basophils can also induce many of these same symptoms. Secretion of chemokines (eotaxin) and cytokines (IL-4, IL-5) by basophils and mast cells also serve to attract more T cells, APCs, and effector cells such as eosinophils to the site of insult. Simultaneously, DCs within the mucosa are presenting allergen to T cells and within 6 to 48 hours, additional T cells are recruited to the area. The expression of FcεRI on the surface of DCs greatly facilitates their uptake, processing, and presentation of allergens to T cells during the elicitation phase of the response. Furthermore, the cytokine milieu created as a result of mast cell and basophil activation, namely a Th2

cytokine environment, most likely drives a polarized Th2 response. Further production of Th2 cytokines at the local site augments the recruitment and activation of additional eosinophils and T cells. During the late phase, release of mediators from both mast cells, basophils, eosinophils, and T cells act in concert to induce the vascular changes, bronchoconstrictor, and mucus changes observed during the late-phase response. Many repetitions of this sequence leads to persistent inflammation resulting in alterations in the structure and function of resident mucosal cells such as smooth muscle, fibroblasts, and epithelial cells. As many of the actions of these effector cells are redundant, it is not surprising that neither depletion of mast cells nor eosinophils has been sufficient to significantly ablate the physiologic consequences of allergen exposure. One point of convergence is the production of IL-13 by all of the likely suspects (eg, basophils, mast cells, eosinophils, and T cells). Given its ability to induce effector functions, elevations in IL-13 levels may not only provide a unifying explanation for the importance of multiple effector cells in allergic responses, but may also provide an ideal target for therapy.

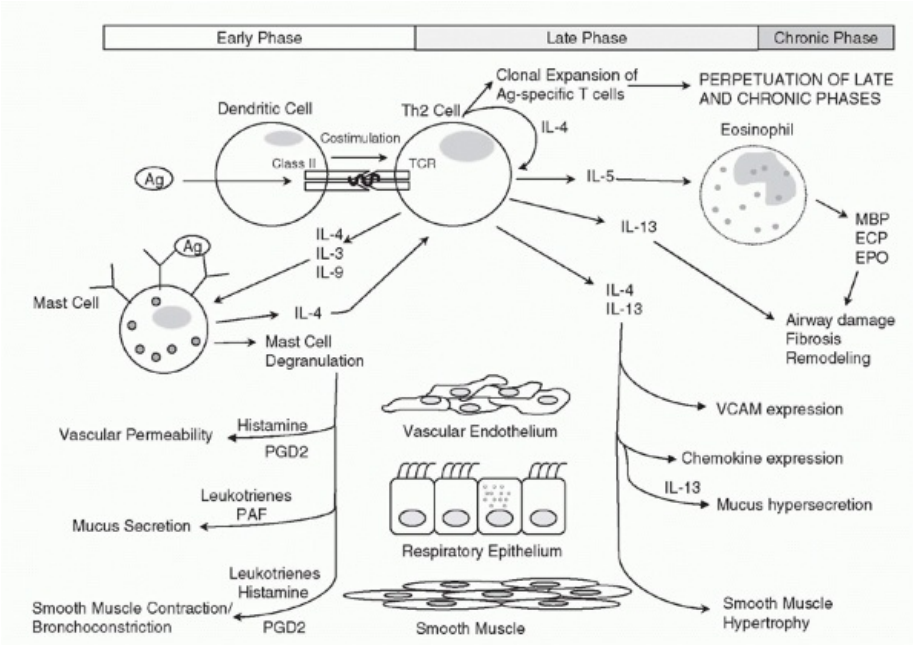

FIG. 45.11. Overview of the Acute, Late, and Chronic Phases of the Allergic Response. Cross-linking of surface immunoglobulin E on sensitized mast cells by antigen results in mast cell degranulation and release of numerous mediators including histamine, tryptase, PDG_2, and cytokines. These mediators are largely responsible for the early phase of the allergic response. Antigen presentation by dendritic cells to Th2

cells results in activation and clonal expansion of antigen-specific T cells and the subsequent release of Th2 cytokines, interleukin (IL)-4, IL-5, and IL-13. These cytokines result in recruitment of eosinophils, chemokine expression, smooth muscle hypertrophy, and mucus hypersecretion. Ultimately, long-term exposure to IL-13 and eosinophilic effector molecules leads to the structural changes observed in tissues of individuals with chronic disease.

CHARACTERISTICS OF SPECIFIC ATOPIC DISORDERS

In this section, we briefly discuss the clinical manifestations, pathogenesis, and therapeutic strategies for the treatment of the classical atopic syndromes including anaphylaxis, allergic rhinitis, atopic dermatitis, and asthma. Readers should consult clinical allergy textbooks for further details on these disorders.

Anaphylaxis

Anaphylaxis refers to a systemic, immediate hypersensitivity reaction that results from IgE-mediated release of vasoactive and inflammatory mediators from mast cells and basophils. Death from anaphylaxis is most often due to respiratory obstruction and/or cardiovascular collapse. The initial experimental description of the phenomenon dates to a paper published in 1902, in which Portier and Richet[484] described the sensitization of dogs to sea anemone venom, a process with fatal sequelae upon subsequent exposure to nonlethal doses of the venom. In opposition to prophylaxis, this was

termed anaphylaxis, meaning against or without protection. Common causes of anaphylaxis in humans include exposure to antibiotics and other drugs, radiocontrast media, latex, venom, and foods. The cause of anaphylaxis remains unidentified in up to two-thirds of patients. Whereas anaphylactic reactions involve IgE-mediated mast cell and basophil degranulation, anaphylactoid reactions result from mast cell and basophil degranulation by IgE-independent means. Underlying etiologies, where known, include drugs, biologic agents, and physical factors (eg, pressure, cold, sunlight); a substantial proportion of cases are idiopathic.

Recently anaphylaxis to ingestion of peanuts has become a common problem particularly in children.[485] The exact reasons for the rise in incidence of peanut-induced anaphylaxis are unknown. However, in a series of elegant experiments, Finkelman and colleagues[486] demonstrated that the high incidence, persistence, and severity of peanut allergy might result from a combination of properties that make it a perfect allergen: high content of several poorly digestible proteins that have strong B- and T-cell epitopes, the ability of at least one of these proteins to directly activate APCs, and the ability of soluble peanut molecules to rapidly activate complement with production of large amounts of the anaphylatoxin C3a. The rapid production of C3a through an antibody-independent pathway stimulates macrophages, basophils, and, to a lesser extent, mast cells to secrete PAF and histamine, which contribute to the induction of shock by increasing vascular permeability. Because activated complement is a potent adjuvant, peanut activation of complement might contribute to induction of the IgE response to peanut allergens in addition to the effector phase of peanutinduced shock. The fact that complement is activation by both hymenoptera venom[487] and metabolites of

penicillin[488] suggest that it may be a common mechanism of anaphylaxis.

Allergic Rhinitis

In 1819, John Bostock first described catarrus aestivus or hay fever.[489] In 1873, Charles Blackley recognized that pollen grains were the causative agents of hay fever. In the 1800s, hay fever was considered a rare disorder that was restricted to the privileged class. This is certainly no longer the case. According to recent estimates, up to 40% of children in the United States are affected by allergic rhinitis,[490] making it the most common atopic disorder in the industrial north. Allergic rhinitis is an IgE-mediated disease characterized by sneezing, rhinorrhea, nasal congestion, and nasal pruritis.[491,492] The seasonal form is caused by allergens released during tree, grass, or weed pollination; the perennial form is associated with allergies to animal dander, dust mites, and/or mold spores. Skin testing-the experimental interrogation of the ability of a panel of antigen extracts to induce cutaneous immediate type hypersensitivity responses—is often employed for diagnostic confirmation of atopy and to determine the allergens to which an individual is sensitized.

Treatment strategies include allergen avoidance, antihistamines, α-adrenergic agonists, intranasal steroids, topical ipratropium bromide, and immunotherapy regimes. Immunotherapy, introduced by Noon and Freeman in 1911 as a method for protecting patients against the effects of "pollen toxin,"[493] has been used since as a treatment for patients with allergic rhinitis and allergic asthma. Conventional allergen immunotherapy involves the subcutaneous injection of graded quantities of allergen. While such immunotherapy has been associated with therapeutic benefit, the relevant immunologic mechanisms remain obscure. In patients with venom anaphylaxis, allergen immunotherapy is the prophylactic treatment of choice.

Food Allergy

Food allergy needs careful distinction from the more common adverse reactions to ingested substances (eg, food intolerance, dose-related toxic reactions) that are not immune-mediated. True food allergy afflicts approximately 8% of children under the age of 3 years and 2% of the adult population. Such food hypersensitivity comprises several disorders that vary in time of onset, severity, and persistence. The most common type of food allergy is immediate gastrointestinal hypersensitivity. Symptoms, consisting of nausea, abdominal pain, colic, vomiting, and/or diarrhea, develop within minutes to 2 hours of antigen exposure. Infants with this syndrome may present with intermittent vomiting and poor weight gain. The predominant response to orally ingested antigens is the induction of tolerance. Food allergy represents an aberration of this process. Only a small number of foodstuffs account for the vast majority of offending allergens. In childhood, the most common allergens derive from milk, egg, peanut, soy, and wheat. In adults, the most common foods implicated are peanuts, tree nuts, fish, and shellfish. Most food allergens are relatively small, watersoluble, heat- and acid-stable glycoproteins that are resistant to proteolytic degradation. The higher incidence of disease in childhood is presumably related to factors regulating the ontogeny of the gut and immune system development.[494,495] Therapy revolves around avoidance of the offending allergen. Interestingly, patients with AD commonly have subclinical food hypersensitivity, with ingestion of the relevant allergen leading to worsening of their dermatitis.

Oral allergy syndrome represents a second type of food hypersensitivity. This is an

immediate type contact allergy that leads to pruritus, tingling, and swelling of the lips, palate, and throat following ingestion of the offending allergen, usually in fruits or vegetables. Oral allergy syndrome affects up to 40% of adults with defined pollen allergy due to crossreacting allergens. Therapy involves allergen avoidance.

The eosinophilic gastroenteritides (eosinophilic esophagitis, gastritis, gastroenteritis), though not thought in general to be due to food allergy, deserve brief mention here. These syndromes are characterized pathologically by eosinophil infiltration and clinically by a variety of nonspecific symptoms, including abdominal pain, nausea, vomiting, and diarrhea, although the etiology and pathogenesis remain unclear in most cases. Some cases are due to hypersensitivity reactions to antigens derived from *Anycylostoma caninum*, a common dog hookworm that is poorly adapted to and causes nonpatent infection of humans.[496] Some cases may indeed be due to food allergy. Eosinophilic esophagitis is an inflammatory

disease of the esophagus characterized by the presence of a dense infiltrate of eosinophils restricted to the mucosa of this organ. It is manifest by chronic and/or recurrent dysphagia and episodes of esophageal alimentary impaction, with great variation in terms of intensity, frequency, and duration of the attacks. Eosinophilic esophagitis appears to be an antigendriven hypersensitivity reaction characterized by a mixed IgE-dependent/delayed-type reaction and a type 2 cytokine profile. Treatment options include nonpharmacologic approaches including elimination or elemental diets and/ or treatment with corticosteroids. The topical administration of fluticasone propionate has been demonstrated to improve symptoms and mobilize the pathologic infiltrate of eosinophils. The anti-IL-5 monoclonal anitbody (mepolizumab) has been shown to be effective in inhibiting both blood and tissue eosinophils in patients with eosinophilic esphagitis[453]; however, further studies are necessary to determine whether this treatment will eliminate the symptoms of disease. Acid suppression by a proton pump inhibitor may also be considered in view of the overlap between eosinophilic esophagitis and gastroesophageal reflux disease.

Atopic Dermatitis

AD is a common, chronic, relapsing, inflammatory skin disease characterized by dry skin, severe pruritis, secondary excoriation that can lead to lichenification, and a heightened susceptibility to cutaneous infections. AD can lead to significant suffering, both physical and psychologic. The prevalence of AD has increased in the last few decades; currently, 10% are affected at some point during childhood in the United States. Both environmental and genetic factors seem to play a role in susceptibility. Given the fact that the hereditability of atopy appears to be largely disease type-independent, it is notable that parental AD confers a higher risk for the development of AD than for either allergic asthma or allergic rhinitis in offspring, suggesting the likelihood of atopic dermatitis-specific genes.[497] Disease generally presents early in childhood and is associated with sensitivity to food and/or inhalant allergens. In adults, disease is primarily associated with sensitivity to inhalant allergens. Apart from exposure to specific food and inhalant allergens, environmental triggers such as irritating substances, emotional stress, climactic factors, hormones, and local infections are all known to be important in the expression of atopic dermatitis. Skin lesions generally display evidence of mast cell, eosinophil, and T-cell infiltration and activation. In contrast to other atopic disorders, a biphasic pattern of T-cell polarization or reactivity is present in atopic dermatitis: Th2 cytokines predominate in acute lesions, whereas chronic lesions express a mix of Th1

and Th2 cytokines.

Current treatment of AD is directed at symptomatic relief, skin hydration, reduction of cutaneous inflammation, and avoidance of inciting antigens. Therapies include antihistamines, topical immunosuppressive agents (glucocorticoids, FK506), moisturizers, environmental control measures for inhalant allergens, and food elimination diets for food allergens. However, in a subgroup of patients with moderate to severe AD, the disease is recalcitrant to topical therapy and systemic treatments become necessary. Shortterm treatment with a number of immunosuppressive and immunomodulating substances such as cyclosporine, azathioprine, mycophenolate mofetil, and methotrexate has proven effective in patients with moderate to severe AD.[498] Intravenous Igs and IFNγ exert immunomodulatory effects and thus may improve severe AD. In patients for whom cyclosporin is not suitable, or when there is a lack of response, alternative drugs should be considered, such as azathioprine or IFNγ. Intravenous Igs and the monoclonal antibody infliximab only have a place in the systemic therapy of AD when other drugs have failed. Mycophenolate mofetil has recently been introduced in the treatment of recalcitrant AD. Omalizumab is a monoclonal antibody with a possible future role in the treatment of AD, but further studies are needed.[499]

ASTHMA

The term asthma was coined by Hippocrates to refer to attacks of breathlessness and wheezing. Asthma is a complex inflammatory disease of the lung in which the prevalence, morbidity, and mortality have been increasing markedly over the last few decades. Asthma is a heterogeneous disorder with variations in the age of onset, severity of disease, and underlying pathogenesis. Although asthma is multifactorial in origin with both environmental and genetic influences, atopy is the strongest identifiable predisposing factor for the development of asthma. Most childhood asthma is allergic in nature and referred to as extrinsic or atopic asthma; however, asthma that develops in adulthood and some forms of childhood asthma are not associated with elevated IgE; this form is referred to as intrinsic or nonatopic asthma. In the most common form of the disease, extrinsic asthma, the inflammatory process is thought to arise as a result of inappropriate immune responses to commonly inhaled antigens. The inflammatory response in the asthmatic lung is characterized by infiltration of the airway wall with lymphocytes, predominantly CD4+ T cells, eosinophils, and degranulated mast cells. Structurally, the airways of asthmatics are characterized by mucus cell hyperplasia, subepithelial membrane thickening, and loss of epithelial cell integrity. These cellular findings have consistently been associated with the main physiologic abnormalities of the disease, including variable airflow obstruction and AHR. As discussed extensively in this chapter, the pathologic consequences of this disease are thought to arise as a result of skewed T-cell responses to inhaled antigens, which, in turn, lead to activation and recruitment of the primary effector cells, mast cells, eosinophils, and T cells. Activation of these cells results in the release of a plethora of mediators that individually or in concert induce changes in airway geometry and produce the symptoms of the disease.

David H. Sachs

INTRODUCTION

The transplantation of organs and cells between individuals saves or prolongs thousands of lives each year. The growing list of organs transplanted includes corneas, kidneys, livers, hearts, lungs, small intestines, pancreata, and even hands and faces. Currently, clinical cellular transplantation includes islets of Langerhans and hematopoietic cells, but the list is likely to expand in the future to include other cell types, such as hepatocytes and myoblasts, which are currently under investigation in experimental models. Success of all types of transplants depends on the ability to avoid rejection due to a host-versus-graft immune response. Hematopoietic cell transplantation (HCT) is, in addition, associated with some special considerations, as the administration of a donor graft that contains mature T cells to a conditioned, and consequently immunoincompetent recipient, is associated with the risk of rejection in the graft-versus-host direction (ie, graft-versus-host disease [GVHD]). These transplants, performed between different members of the same species, are referred to as allotransplants. However, the success of organ transplantation has presented a new limitation, namely the insufficient supply of human organs. This organ shortage has led to consideration of alternative sources of organs, such as artificial organs, tissue grafts engineered from stem cells, and other species. The latter, referred to as xenografts, are a promising alternative, but present even greater immunologic challenges than allografts. This chapter presents an overview of the immunology of organ and cellular allotransplantation and xenotransplantation.

Allogeneic and xenogeneic responses differ from other immunologic responses in at least two fundamental ways. First, they exhibit extraordinary strength that includes multiple, redundant pathways. Second, they involve two different sets of antigen-presenting cells (APCs): those of the donor and those of the recipient. In this chapter, we will emphasize the uniqueness of and challenges presented by the immune response to transplantation.

ORIGINS OF TRANSPLANTATION IMMUNOLOGY

Early History

Although there were sporadic reports of tissue transplants in ancient times, skin grafting did not become an accepted practice until the late 1800s. Even then, however, many workers did not distinguish between autografts (where the donor and recipient are the same individual) and allografts (where the donor and recipient are of the same species), or even xenografts (where donor and recipient are of different species). The last of these formed the basis for an

extensive practice known as zoografting in which patients were subjected to grafts from animals ranging from pigs to frogs. According to Billingham, no one apparently cared whether the grafted skin “took” or merely promoted healing of the wound.[1] The results of these efforts led to a period of confusion in transplantation. Without any clear understanding of the processes involved, surgeons embarked on all sorts of transplants, and a series of operations were reported that we know, from our present understanding of the laws of transplantation, could not possibly have been successful. The transplantation of internal organs awaited the development of techniques for vascular anastomosis. In 1908, Carrel, one of the pioneers of vascular surgery, reported the results of en bloc allotransplantation of both kidneys in a series of nine cats.[2] He was able to obtain up to 25 days of urine output in some cats, but ultimately all of them died. The first successful clinical renal transplant was not performed until 1952 in Boston, using the kidney of an identical twin.[3]

During this same period, the closely related field of tumor transplantation gained momentum. Although many of the experiments with tumor transplants provided information essential to an understanding of transplantation immunology, this was not clear at the time. Many workers were committed to the idea that they were studying an effect peculiar to tumor tissues. In his Harvey lecture, Medawar summed up the confusion neatly by the statement, “Nearly everyone who supposed that he was using transplantation to study tumors was in fact using tumors to study transplantation.” Medawar was largely responsible for establishing the immune basis of transplant reactions. Following a series of grafting experiments in rabbits and mice, he concluded in 1945 that rejection of skin “belongs to the general category of actively acquired immune reactions.”[4]

History, Principles, and Discoveries of Immunogenetics

Inbred Strains

Rodents have provided an invaluable model for the study of the genetic basis for graft rejection, largely due to the availability of a large number of inbred strains. Such strains consist of genetically identical animals that have been produced by sequential pedigreed brother-sister matings for at least 20 generations. They are, therefore, homozygous for all autosomal chromosomes and produce identical homozygous

progeny. The reason that sequential inbreeding leads to homozygosity is illustrated in Figure 46.1. In essence, the probability of fixation of a given autosomal locus at each broter-sister mating is 1 in 8, which is mathematically equivalent to stating that on average, 1 in 8 of all segregating loci are fixed at each generation. If the locus in question is not fixed during this random breeding, then the chances that it will be fixed at the next breeding are just a little less than 1 in 8 (ie, 1 in 8 of the remaining unfixed loci). Thus, as indicated in Figure 46.1, the probability of fixation is given by the following formula:

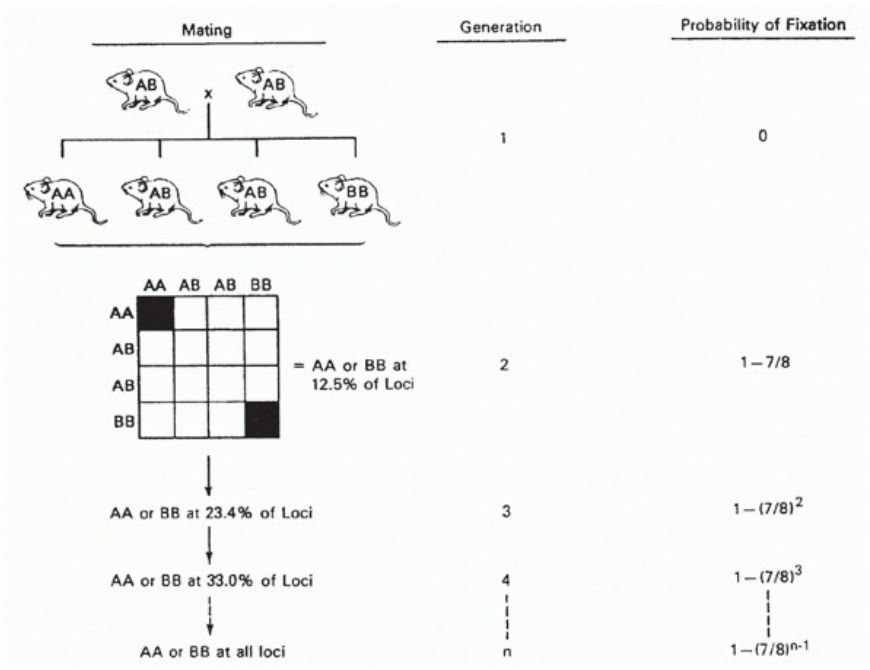

FIG. 46.1. Breeding Scheme for Inbred Strains.

Probability of fixation = 1- $(7/8)^{n-1}$ which describes a curve that asymptotes toward 100% fixation (Fig. 46.2). For practical purposes, one considers a strain inbred after 20 such brother-sister matings, as at this point there is a very small chance that any locus will not have reached homozygosity. Hundreds of such well-characterized inbred strains are now available.

Inbred strains have also been produced in several other species, including rats, guinea pigs, and rabbits, although in much more limited numbers. Both space requirements and other genetic features, such as gestation times, age of sexual maturity, and litter size, make production of inbred strains in larger species much more difficult. Over the past 40 years, studies in one of our laboratories (D.H.S.) have produced highly inbred miniature swine.[5,6] Swine were chosen for this purpose because they are one of the few large animal species in which breeding characteristics make genetic experiments possible. These characteristics include a large litter size, a short gestation time, early sexual maturity, and an estrous cycle every 3 weeks,[5] and have made it possible to develop major histocompatibility complex (MHC) homozygous lines

of miniature swine in a relatively short time, to isolate and characterize new MHC recombinants, and to carry out experiments involving the segregation of genetic characteristics. The Massachusetts General Hospital (MGH) miniature swine thus represent the only large animal model in which MHC genetics can be reproducibly controlled, and they have been particularly useful in studying the role of MHC matching on rejection and/or tolerance induction.[7]

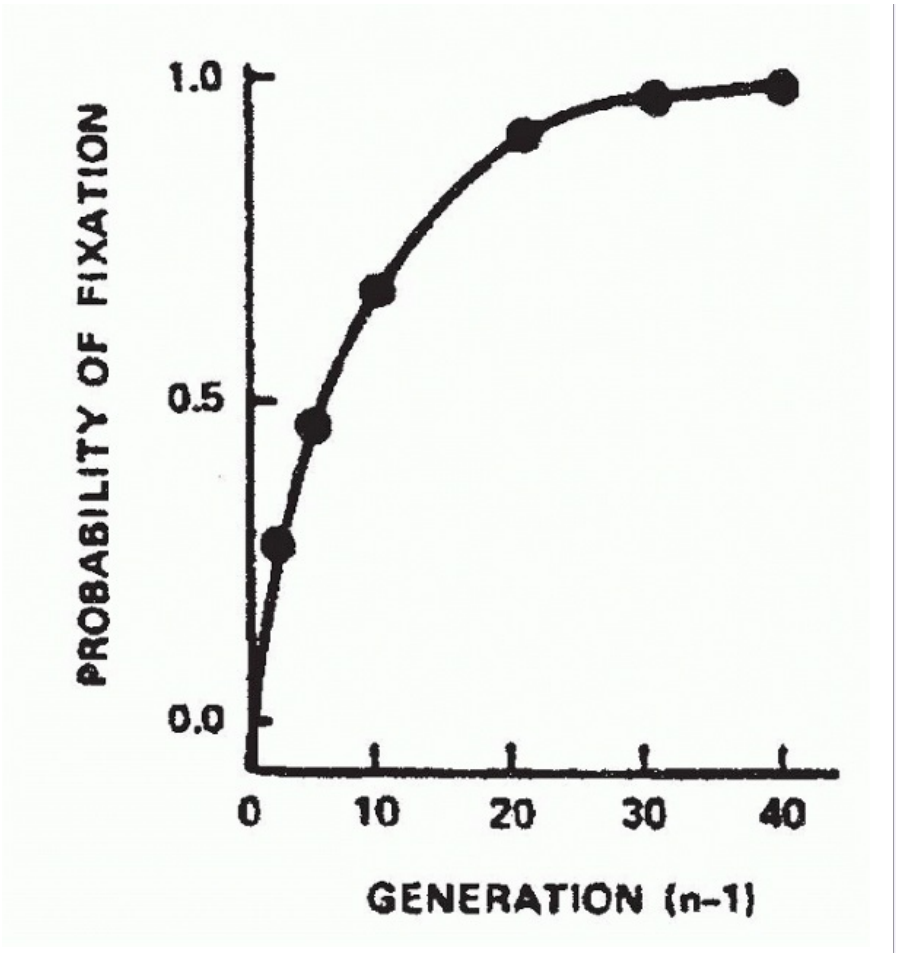

FIG. 46.2. Probablity of Fixation Curve.

At present, swine of three homozygous swine leukocyte antigen (SLA) haplotypes, SLA^a, SLA^c, SLA^d, and five lines bearing intra-SLA recombinant haplotypes are maintained, as illustrated in Figure 46.3. All of these lines differ by minor histocompatibility loci, thus providing a model in which most of the transplantation combinations relevant to human transplantation can be mimicked. In addition, one subline of SLA^{dd} animals was selected for further inbreeding in order to produce a fully inbred line of miniature swine. This subline has now reached a coefficient of inbreeding of > 94% and is now sufficiently inbred that reciprocal skin grafts among the offspring are not rejected.[6] This histocompatibility makes these animals particularly appropriate for adoptive transfer studies for the first time in a large animal model.[8]

Genetic Principles Governing Tissue Transplantation: The "Laws of Transplantation"

In the early 1900s, it was noted by tumor biologists that tumors arising in inbred animals could frequently be transplanted successfully to other animals of the same line, while this was usually impossible in outbred animals. Little studied this phenomenon systematically and in the process produced and characterized a large number of inbred strains of mice.[9] In summarizing the results of these studies of tumor grafting in mice, Little described what have since been called the five laws of transplantation (Table 46.1). Little's remarkable insight was

to reconcile these observations with the classical Mendelian principles by proposing that recipients would reject grafts if the donor expressed a product of any histocompatibility locus that was not expressed by the recipient. His explanation for the unusual inheritance pattern in Table 46.1 was to suggest, first, that there must be codominant expression of the histocompatibility genes, and second, that there must be a relatively large number of histocompatibility loci. Under these conditions, members of the F1 generation would express both parental alleles at all histocompatibility loci (and thus would fail to reject grafts from parental, F2, or subsequent generations) and members of the F2 generation would be unlikely to express all of the products of histocompatibility genes that are expressed by either parental generation (and thus would usually reject parental allografts).

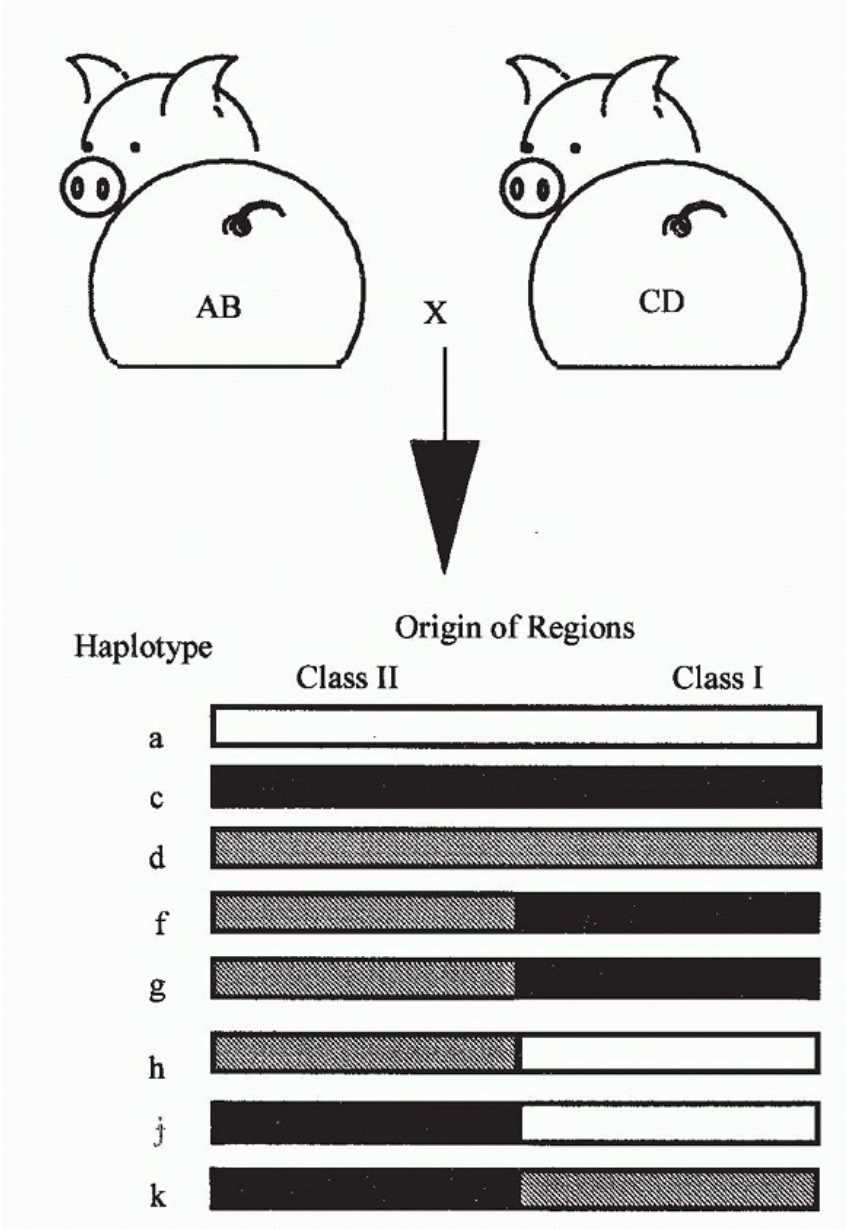

FIG. 46.3. Origin of Miniature Swine Haplotypes.

TABLE 46.1 The Laws of Transplantation

1. Transplants within inbred strains will succeed.

2. Transplants between inbred strains will fail.

3. Transplants from a member of an inbred parental strain to an F1 offspring will succeed but those in the reverse direction will fail.

4. Transplants from F_2 and all subsequent generations to F_1 animals will succeed.

5. Transplants from inbred parental strains to the F_2 generation will usually, but not always, fail.

Adapted from Little.9

Estimating the Number of Histocompatibility Genes

One can experimentally determine the number of histocompatibility loci by which any two inbred strains differ by breeding a large F2 population between these strains and then transplanting tissues from one of the parental strains to all of the F2 offspring, measuring the fraction of grafts that survive. As illustrated in Figure 46.4, if the two strains were to differ at only one histocompatibility locus,

one would predict that three-quarters of the grafts would survive. If, however, the two strains differed by two independently segregating histocompatibility loci, then one would predict that (three-quarters)^2 or nine-sixteenths of the grafts would survive. Similarly, if there were n loci by which these two strains differed, one would expect (threequarters)^n to be the fraction of surviving grafts. When this equation has been solved for “n” experimentally, using skin grafts as the challenging transplant, numbers as high as 30 to 50 have been reported.[10] Because there are only 20 chromosome pairs in the mouse genome, these larger numbers imply that many chromosomes carry more than one histocompatibility locus.

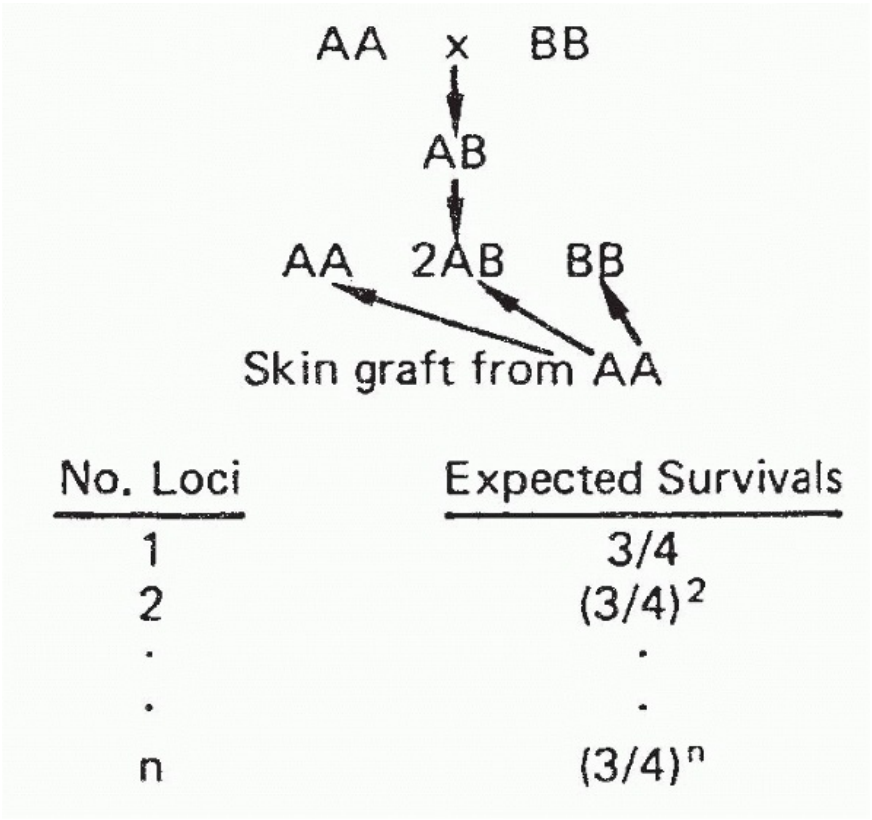

FIG. 46.4. Estimating the Number of Histocompatibility Loci.

Producing Congenic Strains: Identifying the Major Histocompatibility Complex

A process to generate strains differing from one another genetically at only a single one of these numerous histocompatibility loci was pursued by Snell at Jackson Laboratory and involved the production of congenic strains (inbred strains that differ from one another at only one independently segregating genetic locus) using the rejection of parental skin grafts as the trait used to select successive matings.[11] It became apparent during this process that one histocompatibility locus could be distinguished from all the others by the speed with which it caused skin graft rejection. This is now called the MHC. All of the other 30 to 50 histocompatibility loci have since been called minor histocompatibility loci. There are now a very large number of H-2 congenic strains of mice available (Table 46.2), as well as some that isolate minor histocompatibility loci and some rat congenic strains.

MHC, major histocompatibility complex.

One of the most useful breeding schemes to produce congenic resistant (CR) lines is illustrated in Figure 46.5. Starting with two inbred strains, labeled Strain A and Strain B for simplicity, the objective is to obtain a strain that will share its entire genome with Strain A except for the major histocompatibility locus H-2, which will be derived from Strain B. The end product will be designated Strain A.B. Using the cross-intercross scheme illustrated in Figure 46.4, a skin graft or tumor graft from Strain A is placed onto all F2 offspring. Animals that reject the graft must be of genotype bb in at least one histocompatibility locus. Obviously, as there are many histocompatibility loci, most animals at this generation will reject the graft. However, if only animals rejecting vigorously are chosen, and if numerous such animals are selected, then one can be reasonably certain to have selected bb homozygotes at the H-2 locus by this procedure. Because mammalian genes are transferred as linked units in chromosomes, this process will always lead to the retention of a variable amount of bb genetic information at genes closely linked to the locus being selected. However, as described in the following, the occurrence of recombination during intercrossing generations leads also to fixation of the aa genotype at loci on the same chromosome as the MHC (chromosome 17 in mice) but at a variable distance from H-2. For practical purposes, animals that have been through at least nine cycles of such selected breeding are considered to be congenic.

As indicated in Table 46.2, H-2 congenic mouse strains are available on a variety of backgrounds. In general, the names of each of these strains follow the rule A.B, with Strain A being the background strain used in the production of the congenic and Strain B being the other parental strain from which the alternate allele at H-2 was selected. All of the early inbred mouse strains were assigned a small letter designation to represent the particular constellation of alleles that they possessed at genes in the MHC. This small letter designation is often called the haplotype designation, as indicated in Table 46.2. Thus, for example, Strain C57BL/10 (or B10) is assigned the haplotype designation H-2b and Strain DBA/2 the haplotype designation H-2d. Thus, the congenic strain B10.D2 represents a line in which the background is derived from the C57BL/10 and the MHC from the DBA/2. It thus resembles in almost every way the C57BL/10 congenic partner, except that it differs from this partner for all properties controlled by MHC-linked genes.

Intra-Major Histocompatibility Complex Recombinant Strains: Class I and II Antigens

As can be seen in Figure 46.5, every alternate generation in this mating scheme involves the crossing of animals heterozygous at H-2. Whenever heterozygotes are bred, there is always a possibility of recombination between autosomal chromosomes at meiosis. During the production of congenic lines, such recombination will tend to decrease the amount of linked genetic information carried into the congenic from the H-2 source. Therefore, the more backcrosses a particular congenic line has been subjected to, the closer

will be the boundaries on either side of H-2 at which the chromosome reverts to the background strain. Because it soon became apparent that the MHC was in fact made up of multiple loci, there was also the possibility for recombination within H-2 to occur during such crosses. Fortunately, mouse geneticists were aware of this possibility and saved numerous recombinants during the production of H-2 congenic lines. Indeed, it was through the detection and characterization of such recombinants that the linkage map of H-2 was constructed. Thus, for example, there are now a series of recombinants between strain C57BL/10(H-2b) and A/WySn(H-2a) that were isolated by Stimpfling during production of the

B10.A CR line and which have provided a great deal of information on the genetic fine structure of the H-2 complex. Strains B10.A(2R) and B10.A(4R), for example, have been used to map a variety of immune response genes within the MHC. Table 46.3 presents a listing of many of the most useful congenic recombinant strains now available and their known or presumed points of recombination. Among the most important contributions that came from the study of intra-MHC recombinant strains was the progressive understanding that the loci within the MHC encoded two general types of MHC antigens, now referred to as class I and class II MHC antigens.

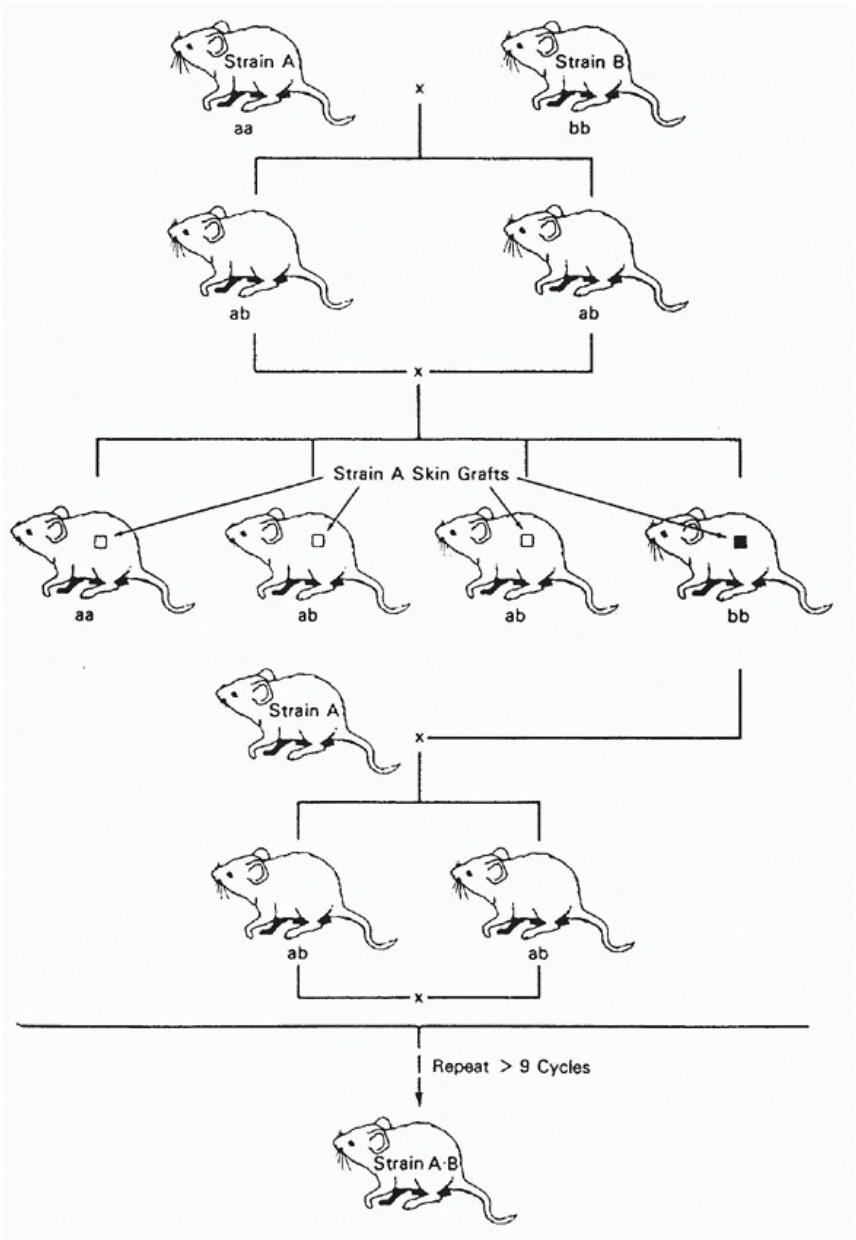

FIG. 46.5. Schematic Representation for Production of a Congenic Line.

Congenic recombinant haplotypes available from The Jackson Laboratory.

Note that many of the recombinants involve at least one haplotype already containing a point of recombination. These are indicated by “Yes” and are listed only under the recombinant interval representing the most recent recombination in the haplotype's history.

DONOR ANTIGENS RESPONSIBLE FOR GRAFT REJECTION

Major Histocompatibility Antigens

As discussed previously, the genetic analysis of graft rejection indicated that the antigens encoded within the MHC are of particular importance in graft rejection. Table 46.4 summarizes important aspects of the MHC antigens that are especially relevant for transplantation, while a much more detailed description of their structure and function can be found in Chapter 21.

Basic Features of Major Histocompatibility Complex Antigens

Polymorphism. The MHC antigens exhibit extraordinary polymorphism, providing the species with a broad capacity to present the peptides of, and thus respond to, a large number of pathogens. In the human leukocyte antigen (HLA) complex, for example, there are currently >600 named alleles at each of the HLA-A and B (class I) and >300 at the DRB1 (class II) locus.[12] The high degree of polymorphism has important consequences for transplantation. Given that there are three class I loci (A, B, and C) and three to four class II loci (DQ, DP, DRB1, ± an expressed DRB 3, 4, or 5 locus present in some haplotypes) on each haplotype, the likelihood of achieving identity for MHC antigens in two unrelated humans is extremely small, though for individuals with two major conserved HLA haplotypes,[13,14] the likelihood is increased.

TABLE 46.4 Summary of Features of Major Histocompatibility Complex

Class I antigens	Single polymorphic chain Three domains: alpha 1, 2, and 3 MW: 45,000 Associated with beta 2 microglobulin A, B, and C loci in humans Expressed on all tissues and cells
Class II antigens	Two polymorphic chains: alpha and beta Each with two domains: alpha 1 and 2, beta 1 and 2 MW: 33,000 and 28,000 DP, DQ, and DR loci in humans Expressed on macrophages, dendritic cells, and B cells; vascular endothelium; activated human T cells

Tissue Distribution. The tissue distribution of the two types of MHC antigens differs. Class I antigens are constitutively expressed on all nucleated cells, but at low levels on some types of cells.[15] Class II MHC antigens are more selective in their distribution.[16] They are especially frequent on macrophages, dendritic cells (DCs), and B-lymphocytes. They are present on other lymphoid cells under some circumstances and on vascular endothelium. Their expression on some tissues of the body is regulated (eg, by interferons [IFNs]).[17] One of the important distinctions between rodents and many larger species is the lack of constitutive expression of class II antigens on the vascular endothelium and other cell populations in rodents. In contrast, pigs, monkeys, and humans express class II antigens on

these tissues.[18,19,20]

Physiologic Function of Major Histocompatibility Complex Antigens . MHC antigens are called “histocompatibility” antigens because of their powerful role in causing graft rejection; however, they did not evolve in nature to prevent tissue grafting. While the name serves to emphasize the historical importance of transplantation in the discovery of the MHC, the essential role of MHC antigens is now understood to involve the presentation of peptides of foreign antigens to responding T cells (see Chapter 22).

The Importance of Major Histocompatibility Complex Antigens in Alloreactivity . MHC antigens are exceptionally important in stimulating T- and B-cell alloresponses. This section will

focus mainly on T-cell responses to MHC, as alloantibody responses are discussed later in the chapter.

VIGOROUS GRAFT REJECTION. Mouse skin grafts differing only in their MHC antigens are typically rejected in 8 to 10 days, whereas MHC-matched grafts may be rejected more slowly, depending on the number of minor histocompatibility antigen (MiHA) differences. In pigs, primarily vascularized organs, such as the kidney, may survive indefinitely in some cases, even without immunosuppression, if all of their MHC antigens are matched, whereas MHC-mismatched kidneys are always rejected within 2 weeks.[18]

STRONG IN VITRO ALLORESPONSES. Allogeneic MHC antigens stimulate an extraordinarily strong T-cell response in vitro, whereas responses to non-MHC antigens generally require in vivo priming. For the most part, cluster of differentiation (CD)4 cells recognize class II alloantigens and CD8 cells recognize class I alloantigens. However, this strong bias is more stringent for CD4 cells than CD8 cells. The standard in vitro assay of T helper function is the mixed lymphocyte response, which measures proliferation of T cells after allogeneic stimulation. Limiting dilution assays can be used to quantify alloreactive proliferating or cytokine-producing cells. Such analyses have led to frequency estimates of approximately 1% to 7% of T cells responding to a particular allogeneic donor,[21,22,23,24] whereas naïve T cells reactive with an exogenous peptide generally represent only approximately one in tens to hundreds of thousands of the same T-cell pool.[25,26,27]

Strong primary direct alloresponses of CD8+ T cells can be measured in vitro, either in standard cell-mediated lympholysis assays or in limiting dilution assays measuring cytotoxic T-lymphocyte (CTL) precursor frequencies. CTLs against MHC alloantigens can easily be generated from naive T cells following stimulation in vitro, whereas generation of CTLs to MiHAs generally requires that the T cells first be primed in vivo. Direct (without in vitro stimulation) cytotoxic activity,[28] increased alloreactive precursor frequencies, and modified CTL assays[29] have been used to demonstrate in vivo activation by alloantigens. ELISpot and flow cytometric carboxyfluorescein diacetate succinimidyl ester dye dilution assays and intracellular cytokine staining have enhanced the ability to detect alloreactive T cells.[24,30]

Direct Recognition of Allogeneic Major Histocompatibility Complex Antigens . The extraordinary strength of alloreactivity largely reflects the ability of T cells to recognize allogeneic MHC antigens presented on donor APC, referred to as “direct” allorecognition. Three different but not mutually exclusive hypotheses have been proposed to explain the high frequency of alloreactive T cells.

GENETIC BIAS. Because the thymus only positively selects T cells with some MHC reactivity,

a T-cell receptor (TCR) gene pool with intrinsic affinity for MHC molecules would allow for more efficient thymic selection. TCRs indeed have intrinsic affinity for MHC molecules.[31,32,33,34,35,36,37,38,39,40] Intrinsic allogeneic MHC reactivity is thereby prominent within a T-cell repertoire that has been negatively selected only by "self" MHC-peptide complexes.

THE "DETERMINANT DENSITY" HYPOTHESIS. As illustrated in Figure 46.6A, the density of specific peptide determinants presented by an APC would be quite low (as most MHC antigens present other peptides), whereas the density of a peptide-independent allogeneic MHC determinant on allogeneic APCs would be very high (as every MHC antigen would include the foreign determinant). These abundant allogeneic MHC determinants would activate many crossreactive T cells with relatively low affinities. This hypothesis requires that allogeneic MHC molecules can be recognized at least partly independently of the peptides they present. While peptide-independent and peptide-"promiscuous" alloreactive T cell clones have been described,[41,42,43,44,45,46,47,48,49,50] potential artefacts of in vitro culture and assay systems might have biased these results. Notably, human alloreactive T cells expanded in vivo in a graft-versus-host response were strongly dominated by peptide-specific clones,[51] and recent studies demonstrated that the requirement for peptide recognition limits TCR alloreactivity from being extended more broadly by their inherent MHC-binding capacity.[52]

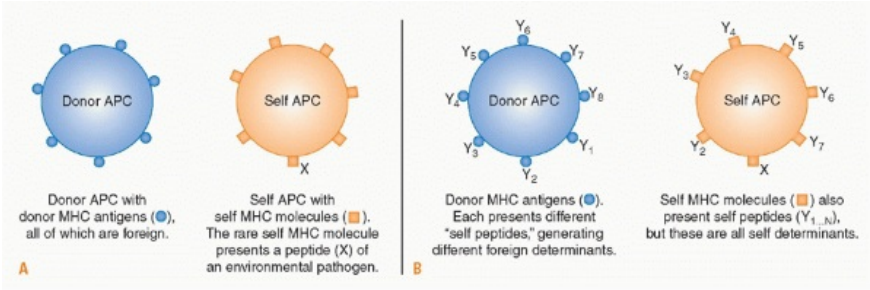

FIG. 46.6. A: Determinant density hypothesis. **B:** Determinant frequency hypothesis. APC, antigen-pressenting cell; MHC, major histocompatibility complex.

THE "DETERMINANT FREQUENCY" HYPOTHESIS. The third explanation for alloreactivity is based on the idea that allospecificities include the specific peptides presented by allogeneic MHC molecules,[53] for which there is strong evidence. Positive selection, which requires lower TCR affinity for self-MHC/peptide complexes than that involved in negative selection,[38] enriches for TCRs capable of seeing modified self-MHC antigens, which may cross-react on allogeneic MHC molecules. The repertoire of T cells positively selected with low affinity for self-MHC molecules plus peptides of self-proteins (say $X_{1,2...n}$), may cross-react with allogeneic MHC antigens presenting peptides of polymorphic or nonpolymorphic allogeneic proteins (eg, "Allo + X_1, Allo + X_2, …Allo + X_n") (see Fig. 46.6B). Nonpolymporphic peptides presented by allogeneic MHC molecules would be seen by different TCRs than those recognizing the same peptide with self-MHC, as both peptide and

MHC alpha helix residues contribute to the surface that is recognized by a TCR.[54,55,56,57] Thus, the set of determinants represented by "Self + $X_{1...n}$" would differ from that represented by "Allo + $X_{1...n}$." T cells strongly responsive to self-peptides on self-APCs (Self + X_1, Self + X_2, etc.) are eliminated by negative selection, which would not affect the response to the many peptides on allogeneic APCs (Allo + X_1, Allo + X_2, etc.). Consistent with this hypothesis, many alloreactive T cells have been shown to be peptide-specific or at least partially peptide-selective.[41,42,48,58,59,60,61,62,63] Cardiac allografting studies using DM-/-mice, which lack the capacity to replace invariant chain-derived CLIP peptide with a more diverse array of peptides, provide strong in vivo evidence for the importance of peptides in direct allorecognition.[64]

Overall, the available information supports the inherent MHC binding capacity of TCRs, combined with the determinant frequency notion, to explain the high frequency of T cells recognizing alloantigens directly.

Minor Histocompatibility Antigens

While initially defined by their ability to cause rapid graft rejection, MHC antigens are defined in part by the location of the genes encoding them and in part by the well-characterized structure of both class I and class II antigens (see Chapter 21). MiHAs, on the other hand, are those capable of eliciting a T-cell immune response, but which lack the structural characteristics of MHC products.[65] Rather than being allelic cell surface proteins, MiHAs are donor-specific peptides presented by MHC molecules that are shared by donor and recipient.[66,67,68,69,70,71,72,73] As individuals are tolerant to the peptides derived from their own proteins, they only respond to the peptides of another individual's proteins that have allelic variation. Unlike MHC antigens, MiHAs do not readily stimulate primary in vitro cell-mediated responses in mixed lymphocyte response and cell-mediated lympholysis assays, reflecting the low frequency of T cells recognizing them in the unprimed T-cell repertoire.

It has been estimated that there may be as many as 720 minor histocompatibility loci in mice,[74] some of which are autosomal and others of which are encoded on the Y chromosome. MiHAs can be expressed ubiquitously or in a tissue-selective manner.[75] Many proteins producing MiHAs have been identified,[71,72,73,76,77,78,79,80,81,82,83,84,85,86,87,88,89] some of which are intracellular proteins such as nuclear transcription factors and myosin, while others, like CD31 and CD19, are polymorphic cell surface glycoproteins.[90,91,92]

Some MiHAs are diallelic peptides, both of which can be represented by a particular MHC molecule,[76,78] resulting in bidirectional recognition (eg, the murine H13 locus[78]). Alternatively, allelic variation in MHC-binding capacity of a peptide can result in one allele being presented and the other not (eg, the human HA-1 minor antigen, in which only one of two allelic peptides binds effectively to HLA-A2[76]). Minor antigenic determinants can also result from the failure of one allele to be processed to a peptide. An example is HA-8, for which only one allele is effectively transported by the TAP complex, resulting in a null allele despite the presence of the MHC-binding peptide sequence in the molecule.[79]

Both helper determinants, recognized by CD4+ cells, and cytotoxic determinants, recognized by CD8+ cells, are required for effective cytotoxic T-cell responses to MiHAs.[93,94] When

multiple MiHA disparities exist, a phenomenon known as “immunodominance” may occur.[95,96,97,98,99,100] Removal of the immunodominant recognition can reveal strong responses to antigens that evoked weak or no responses before. This phenomenon may be due to competition between peptides for presentation by MHC molecules,[74] as well as differing durations of antigen presentation and TCR avidities.[101] An exceptional peptide, H60, is derived from an NKG2D-binding protein and produces responses that are comparable in potency to those elicited by MHC alloantigens, apparently due to the existence of a very high frequency of TCR in the naïve repertoire recognizing this peptide,[102] which may be a useful target for graft-versus-leukemia (GVL) effects in HCT.[103] However, immunodominance of CTL responses measured in vitro does not necessarily reflect the immunodominance of the same antigens in vivo.[74,104] possibly reflecting the importance of tissue distribution of minor antigen expression or of helper T-cell responses.[84]

The H-Y antigens are encoded on the Y chromosome and therefore expressed only by males.[81,82,105,106,107,108] They are of biologic significance, as they cause rejection of male skin grafts in syngeneic female mice and, in humans, female-to-male HCT is associated with increased GVHD rates compared to other combinations in the HLA-identical-related donor setting.

Human MiHAs have been identified as determinants recognized by CTLs, mainly in the setting of HLA-identical sibling donor HCT, in association with GVHD and marrow graft rejection.[77,79,84,85,109,110] Certain MiHA incompatibilities (eg, HA-1) may predispose to GVHD.[77,111] Immunodominance of CTL responses to particular H-Y and HA determinants as well as expansion of minor antigen-specific CTLs detected with tetrameric complexes of HLA molecules and minor antigenic peptides[85,110,112] have been associated with GVHD and marrow graft rejection.[113]

Most MiHAs identified to date are determinants recognized by CTL, reflecting the relative ease with which CTL assays can be used to measure peptide-specific responses. Newer techniques have allowed the recent identification of minor antigenic peptide epitopes recognized by CD4+ T cells.[114,115,116]

It is difficult to detect humoral responses to MiHAs, presumably because individual peptide/MHC complexes are too low in abundance on the cell surface to either stimulate an antibody response or be detected on the cell surface with antibodies. An exception is the recent discovery of antibodies against H-Y (Y chromosome-encoded) antigens in association with chronic GVHD (cGVHD).

Other Antigens of Potential Importance in Transplantation

Superantigens

Superantigens include products of endogenous retroviruses in mice, such as mammary tumor viruses, and bacterial products such as staphylococcal enterotoxin B. Like MHC antigens, superantigens can stimulate primary in vitro T-cell proliferative responses and activate a high proportion of the T-cell repertoire. However, these antigens are not presented as peptides in the binding groove of MHC molecules, but instead bind to distinct regions of class II MHC molecules, and engage nonvariable portions of Vβ components of the TCR, rather than the

hypervariable regions that recognize peptides. Endogenous superantigens are not classical transplantation antigens, perhaps because of their restricted tissue expression patterns.[117,118,119,120,121] However, they may contribute to GVHD in mice.[122]

Tissue-Specific Antigens

Some peptides are derived from proteins with limited tissue distribution,[123,124,125] which may not include hematopoietic cells used in traditional assays of alloreactivity. One implication is that transplantation tolerance induced by one set of donor cells might not always induce complete tolerance to donor cells of a different sort. For example, skin-specific antigens may be targets of skin graft rejection despite the presence of stable hematopoietic chimerism induced by HCT.[126] Tissue-specific proteins lacking allelic variation may still serve as alloantigens because the determinant formed by a given peptide with an allogeneic MHC molecule would be different from that formed by the same peptide with a recipient MHC molecule.

Several human MiHAs may be expressed only on hematopoietic cells,[75,127] and these may provide an opportunity to use graft-versus-host-alloreactive donor T cells (that recognize such antigens) to achieve GVL effects without GVHD (largely a disease affecting epithelial tissues). However, disparities for some of these minor antigens (eg, HA-1) have in fact been associated with an increased incidence of GVHD.[77,111]

Endothelial Glycoproteins

Blood Group Antigens. Blood group antigens are the products of glycosylation enzymes that are not the same in all individuals. They are expressed on erythrocytes and other cells and, importantly, on vascular endothelium where they may serve as the targets for “natural” antibody-mediated attack on blood vessels of organ grafts. Blood group A and B individuals each express their respective antigen, but O individuals have neither. “Natural” antibodies against blood group antigens an individual lacks probably arise due to cross-reactions with common carbohydrate determinants of environmental microorganisms. Type O individuals have antibodies to the antigens of A and B donors, whereas A and B individuals only have antibodies reactive with antigens from each other, and AB individuals have antibodies to neither. Therefore, O recipients can only receive transfusions from O donors, A and B recipients can receive transfusions from O donors or from individuals sharing their blood type, and AB recipients can receive blood from donors of any blood type. The same rules apply to the transplantation of most organs.[128] Recently, advances have been made in the ability to successfully transplant kidneys across ABO barriers by adsorbing antibody from the plasma and depleting B cells.[129,130,131] Other non-ABO blood group antigens on erythrocytes are irrelevant to organ transplantation because they are not expressed on vascular endothelium.

Blood group antigens are of lesser importance, but nevertheless significant, in HCT. ABO incompatibility in the hostversus-graft direction (“major” ABO mismatch) can lead to prolonged red cell aplasia following HCT; incompatibility in the graft-versus-host direction (“minor” mismatch) can result in initial hemolytic anemia, but this complication can be avoided by washing the donor HCT preparation to rid it of plasma.[132,133]

***Species-Specific Carbohydrate Determinants*.** Closely analogous to the blood group antigens are the carbohydrate determinants expressed on vascular endothelium that show species selectivity. For example, pigs, which are of interest as an organ source for xenotransplantation, have a glycosyl-transferase enzyme not expressed by humans that

glycosylates β-galactosyl N-acetyl glucosamine to form a Galα1-3Galβ1-4GlcNAc (αGal) determinant. This enzyme is present in most species but underwent a loss of function mutation in our nonhuman primate ancestors. In humans, a fucosyltransferase generates instead the H-substance from the same substrate, leading to blood group O. Preformed or "natural" antibodies are present in human serum that react to the nonself-pig determinant. Like the blood group antibodies, these natural antibodies probably arise from cross-reactions with environmental microorganisms,[134,135] and they also cause hyperacute rejection (HAR) of most primarily vascularized xenogeneic transplants.

"Missing Self" and Natural Killer Cell Recognition

In apparent violation of the laws of transplantation described previously, (AxB) F1 mice are capable of rejecting bone marrow from parental donors, a phenomenon termed hybrid resistance. This phenomenon, as well as rapid rejection of fully allogeneic marrow, is mediated by natural killer (NK) cells.[136] NK cells are large granular lymphocytes that lack TCRs and that have the ability to mediate cytolysis against certain tumor targets and hematopoietic cells. NK cells also produce a number of proinflammatory, hematopoietic, and even anti-inflammatory cytokines, and may be divided into subsets on the basis of their cytokine production pattern.[137]

The originally puzzling specificity of NK cell-mediated marrow rejection is due to the expression by NK cells of inhibitory receptors that recognize specific groups of class I

MHC alleles on target cells and prevent cytolysis by the NK cell. These class I receptors are type II C lectins (Ly49 family) or dimers of CD94 with NKG2 lectins in the mouse, and are either immunoglobulin family members (KIR) or CD94/NKG2 in humans. Recognition by an inhibitory receptor of a class I ligand results in intracellular transmission of an inhibitory signal via an immune receptor tyrosine-based inhibitory motif that interacts with a tyrosine phosphatase and counteracts activating signals transmitted from other cell surface molecules. Recognition of "self" class I inhibitory ligands prevents NK cells from killing normal autologous cells.[138,139] Other molecules expressed by infected or stressed cells activate NK cells, counterbalancing these inhibitory signals (see Chapter 17).

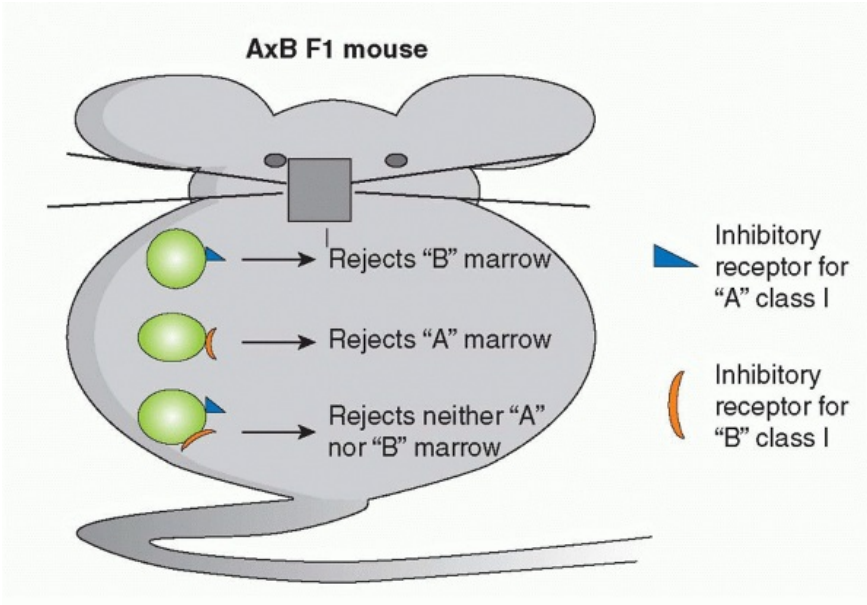

FIG. 46.7. An Explanation for Hybrid Resistance. Each *filled circle* represents a subset of natural killer cells.

Inhibitory receptors are clonally distributed on NK cells, each of which may express one or more different inhibitory receptor. For NK cells to be functional yet tolerant of "self," they must express at least one inhibitory receptor for a "self" class I MHC molecule.[140,141] Thus, as is illustrated in Figure 46.7, an AxB F1 recipient will have subsets of NK cells with inhibitory receptors that recognize MHC of either the A parent, the B parent, or both. The absence of "B" class I molecules on, for example, AA parental hematopoietic cells, permits subsets of (AxB)F1 NK cells that have inhibitory receptors only for class I molecules from the B parent to destroy AA cells. Thus, hybrid resistance and NK cell-mediated resistance to fully allogeneic marrow grafts can be explained on the basis of "missing self."[142] The roles of NK cells in transplantation are discussed in later sections.

MECHANISMS OF REJECTION

At least four distinct mechanisms that can cause graft rejection have been defined. According to the timeframe in which they tend to occur in clinical practice, they are, namely, HAR, accelerated rejection, acute rejection, and chronic rejection.

Rejection Caused by Preformed Antibodies (Hyperacute Rejection)

HAR occurs within minutes to hours after blood flow is established to a transplanted vascularized organ.[143,144,145] The phenomenon is visible and dramatic: the organ turns blue and its function ceases. Microscopically, there is extensive evidence of vascular thrombosis and hemorrhage. The important components involved in the mechanism of HAR include 1) donor endothelial antigens, 2) preformed antibodies that can bind these antigens, 3) complement, and 4) coagulation cascades, which are activated by the binding of preformed antibodies to the vascular endothelium. The interaction of these components leading to hyperacute rejection is diagrammed in Figure 46.8.

The role of complement in HAR is inferred both from the accumulation of various complement components in the grafts and from the fact that complement depletion leads to prolonged survival of xenografts.[146] Complement activation leads to production of active protein fragments and complexes of complement components, which cause tissue injury either directly or by recruiting effector cells that mediate destruction of the graft. In allogeneic combinations, this is initiated by antibody-mediated activation of complement through the classical pathway, whereas in xenogeneic combinations, the alternative pathway may also be involved.[147] In both cases, the membrane attack complex, produced by the ordered interaction of several complement components, initiates the destructive pathway.

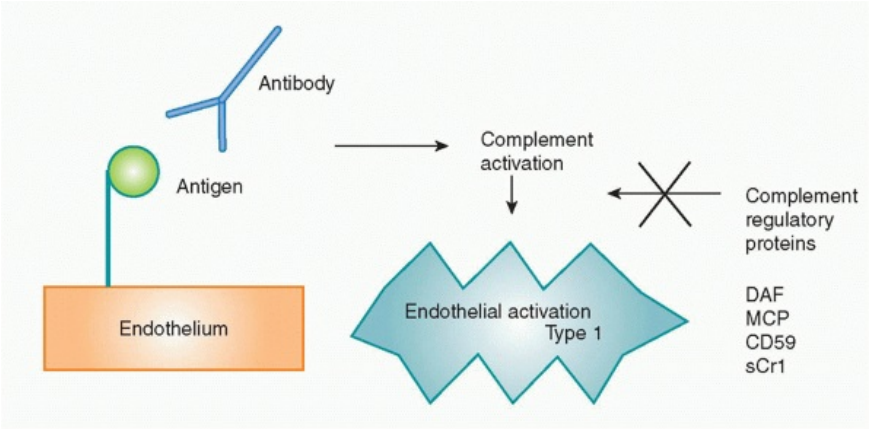

FIG. 46.8. Schematic Representation of Hyperacute Rejection.

Complement activation is controlled by several regulatory molecules, including complement receptor 1, decay accelerating factor (DAF; CD55), membrane cofactor protein (CD46), and CD59, which act at different stages along the cascade (see Chapter 36). Many of these molecules are produced by the vascular endothelial cells. Because these regulatory proteins prevent unwanted complement activation in the face of low levels of perturbation to the system, the titer and avidity of the preformed antibodies must be high enough to activate despite these downregulating molecules. Thus, preformed antibodies directed at MHC antigens almost always accomplish this activation, whereas the lower-affinity blood group antibodies lead to hyperacute rejection in only about 25% of kidneys. One of the reasons that hyperacute rejection is such an important feature in xenogeneic transplantation is that the complement regulatory proteins produced by the donor vascular endothelium of one species often do not function effectively with complement molecules derived from a different species. Because of this incompatibility, lower levels of an initial triggering signal lead to explosive complement activation.

Although the membrane attack complex is often thought of as a lytic molecule, its effect on the donor vascular endothelium, even before cell lysis, is to cause endothelial activation. This occurs rapidly, before there is time for new gene transcription or protein synthesis, and has been referred to as type I endothelial activation. The two principal manifestations of this activation are cell retraction, leading to gaps between endothelial cells, and initiation of coagulation pathways due to the loss of antithrombotic molecules from the endothelium.[148] Thus, type I endothelial activation is responsible for the two principal pathologic findings in hyperacute rejection: extravascular hemorrhage and edema, and intravascular thrombosis.

There are no known treatments that can stop the process of hyperacute rejection once it has started and, thus, it is essential to avoid the circumstances that initiate it. Experimentally, this can be accomplished for relatively short periods of time by administration of complement inhibitors, such as cobra venom factor, which depletes complement. In clinical practice, this is accomplished by avoiding transplantation in the face of preformed antibodies, both by avoiding blood-group antigen disparities and by testing recipients before transplantation (ie, a “cross-match”) to determine whether they have performed antidonor antibodies.

Not all organs and tissues are equally susceptible to hyperacute rejection. Most primarily vascularized organs, such as kidneys and hearts, are very susceptible, but the liver can often

survive without hyperacute rejection despite preexisting antidonor antibodies.[149] It is not clear whether this unusual feature of the liver reflects the large surface area of its vascular endothelium or an intrinsic property of liver endothelial cells. Nonetheless, hyperacute rejection of the liver has occurred in some cases, especially involving xenogeneic transplantation, indicating that its resistance to hyperacute rejection is not absolute. Skin grafts are relatively resistant to hyperacute rejection but high levels of antibody can cause a "white graft" (ie, a failure of blood vessels to communicate with those of the recipient)[150] Pancreatic islets are likewise resistant to this form of rejection.[151] Free cellular transplants, such as bone marrow cells or hepatocytes, that express some of the antigens recognized by preformed antibodies, are cleared quickly from the circulation by the reticular endothelial system, leading to resistance to engraftment.[152] In the case of HCT, this resistance can be overcome by transplanting larger numbers of cells.[152,153,154] Additionally, antibody-independent complement activation has been shown to be a significant factor diminishing the engraftment of porcine bone marrow in mice.[155]

Acute Humoral Rejection (Accelerated Rejection)

A second mechanism of rejection, also caused by antibodies, occurs as a result of antibodies that are induced very rapidly after a transplant is performed. This type of rejection has been called "acute humoral" or "accelerated" rejection because it typically occurs within the first 5 days after transplant. The process is characterized by fibrinoid necrosis of donor arterioles with intravascular thrombosis.[156]

Accelerated rejection is rare in allogeneic combinations because it requires that an antibody response occur before the T-cell response that is typically responsible for acute rejection episodes (see following discussion). Indeed, most allogeneic B-cell responses are T-cell-dependent. The best examples of accelerated rejection are probably those observed in vascularized organ transplants between closely related, concordant xenogeneic species and between discordant species following adsorption of anti-Gal antibodies. In these cases, the levels of preformed antibodies are not sufficient to cause hyperacute rejection, but antidonor antibodies appear rapidly (within 3 to 4 days) in association with the onset of rejection. The pathology of acute humoral rejection reveals a paucity of lymphocytes infiltrating the donor graft, antibody binding to donor vascular endothelium, and fibrinoid necrosis of the donor vessels. Vigorous anti-T-cell immunosuppression has little effect on acute humoral rejection, whereas immunosuppression with reagents that affect B-cell responses, such as cyclophosphamide, delays its onset until more typical T-cell-mediated rejection occurs.[157]

As in hyperacute rejection, the process of acute humoral rejection is usually initiated by antibody binding to antigens on the donor vascular endothelium. In this case, however, the subsequent endothelial changes occur more slowly, allowing time for gene transcription and new protein synthesis. This later form of activation has been called type II endothelial activation.[147,158] Many of its features appear to be mediated by the transcription factor NF-κB, which generates many of the responses associated with inflammation, including the secretion of inflammatory cytokines such as interleukin (IL)-1 and IL-8, and the expression of adhesion molecules such as E-selectin and intercellular adhesion molecule (ICAM)-1.[159] In addition, type II endothelial activation causes the loss of thrombomodulin and other prothrombotic changes.[160] Thus, the events following type II endothelial activation are associated with the pathologic changes that occur with "accelerated" rejection, including the tendency toward intravascular thrombosis and the inflammatory destruction of donor vessels

that occurs in the absence of infiltrating lymphocytes.

Just as there are regulatory processes for complement activation, there are regulatory molecules that counter the tendency toward intravascular coagulation and the process of type II endothelial activation (eg, tissue factor protein inhibitor [expressed by vascular endothelium, which inhibits factor Xa of the clotting cascade] and a number of other protective molecules, including Bcl-x_L, Bcl-2, and A20).[147,161] Although these are often thought of as antiapoptotic molecules, they also tend to inhibit activation mediated by NF-κB. Like the regulatory molecules of complement, some of these regulators may not function across species differences, leading to disorder regulation of the coagulation system.[162]

Although vigorous early antibody responses generate type II endothelial activation and accelerated rejection, later antibody responses often fail to do so. The process that enables transplanted organs to survive in the face of circulating antibodies that can bind endothelial antigens has been called “accommodation.”[147,163] This phenomenon has been observed in some allogeneic and xenogeneic combinations with preformed antibodies, but has so far been disappointingly ineffective in discordant xenotransplants. Resistance to type II endothelial activation has been achieved in vitro by pretreatment with low levels of antiendothelial antibodies that are insufficient to trigger activation.[164] The achievement of accommodation is associated with increased expression of the antiapoptotic genes described previously and with changes in the isotype of the recipient's antibody responses.[158,165]

An important difference between HAR and acute humoral rejection is that there is no known therapy to stop graft destruction by HAR, whereas acute humoral rejection can sometimes be reversed by desensitization.

Rejection Caused by T Cells (Acute Rejection and Graft-versus-Host Disease)

“Acute cellular rejection,” which is characterized by a mononuclear cell infiltrate in the graft, is the most common type of organ allograft rejection. Acute rejection is most common during the first 3 months after transplant, but may occur at any time, especially if immunosuppressive medication is withdrawn. Acute rejection is T cell-dependent, and its treatment, which is usually successful, includes increased doses of standard immunosuppressive drugs or antilymphocyte antibodies.

The use of newer immunosuppressive drugs and anti-T-cell antibodies has markedly reduced acute rejection rates. For example, the vast majority of kidney transplant recipients never experience an episode of acute rejection. It is now quite rare to lose a transplanted organ to cellmediated rejection during the first year after transplantation. However, the use of these highly effective immunosuppressive treatments is associated with significant morbidity.

Experimental models for acute rejection include nonprimarily vascularized skin grafts, heart graft fragments, artificial “sponge” allografts, or islet transplants in rodents, which may not accurately reflect the processes of rejection for primarily vascularized organs. While there are models of heart, kidney, liver, and other types of primarily vascularized organ transplants in rodents, these types of transplants are more tolerogenic and hence more easily accepted than similar transplants in large animals and humans. Studies of primarily vascularized organ transplants in large animals, such as monkeys or pigs, have obvious clinical relevance, but are expensive and require many special resources.

Acute GVHD is the counterpart of cellular rejection that involves graft-versus-host

alloreactivity, usually in the context of HCT, but also sometimes with organ transplants that carry significant amounts of donor lymphoid tissue (eg, liver). Like acute rejection, acute GVHD is T cell-dependent. T-cell depletion of the donor hematopoietic cell graft prevents GVHD but is associated with increased rates of graft rejection and relapse of malignant diseases.

The concepts of “direct” and “indirect” allorecognition introduced previously must be considered at both the sensitization and effector phases of an immune response. The definition of “indirect” recognition used in this chapter is based on which set of APCs (donor versus recipient) is presenting donor antigen. “Cross-priming” is a term specifically denoting sensitization of CD8 T cells through the indirect pathway. As shown in Figure 46.9, there are three major T-cell pathways to consider in relation to graft rejection. These include 1) direct recognition of donor alloantigens by CD4+ T cells, which generate effector CD4 cells and provide help for the generation of effector CD8 cells; 2) direct activation of CD8 T cells by donor APCs; and 3) CD4+ T-cell activation by recipient APCs presenting re-processed donor antigens (the indirect pathway of sensitization). This pathway is important in providing help for immunoglobulin production by B cells. A role in rejection for cross-primed CD8+ T cells is not included in Figure 46.9, because this pathway has not been shown to play a role in allograft rejection except under certain circumstances, as described in the following. The multiplicity of T-cell sensitization and effector pathways involved in graft rejection and GVHD is demonstrated by the frequent observation of rejection or GVHD when only CD4+ or CD8+ T cells are depleted.[166,167,168] As a result of the high precursor frequency of T cells that respond to allogeneic MHC antigens directly, populations of T cells that ordinarily have minimal significance become functionally important.

Sensitization and Cell Trafficking during Rejection and Graft versus Host Disease

Transplanted tissue contains passenger leukocytes of donor origin that have the characteristics of immature DCs.[169] In response to the inflammatory signals that are triggered by retrieval and transplantation, both within the tissue itself as well as in the recipient,[170] the donor-derived passenger leukocytes rapidly leave the graft and migrate to the secondary lymphoid tissues of the recipient.[171] Secondary lymphoid tissues comprise the spleen, lymph nodes, and gut- or mucosal-associated lymphoid tissue, and depending on the location of the graft, the passenger leukocytes will migrate to the tissue that drains the graft site where they encounter naïve T cells. After transplantation, both in situ within the tissue and during migration, the passenger leukocytes

acquire the phenotypic and functional characteristics of mature DCs, expressing high levels of MHC class I and II molecules as well as other cell surface costimulatory molecules necessary to fully activate naïve CD4+ and CD8+ T cells.[172] Once in the secondary lymphoid tissues they act as professional APCs, presenting antigens expressed in the transplanted tissue to recipient T cells via the direct pathway of allorecognition.[173]

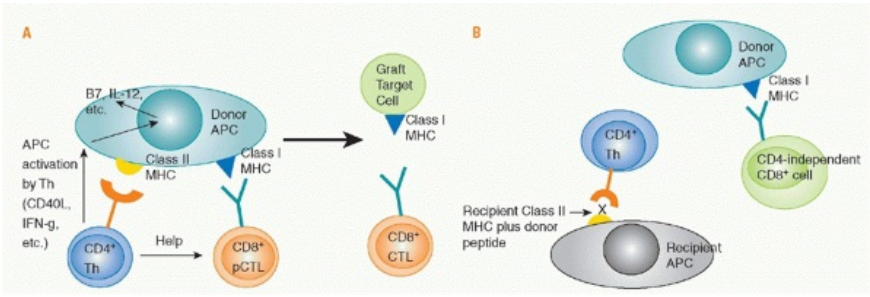

FIG. 46.9. Model of T-Cell-Mediated Rejection. A: Interactions between cluster of differentiation (CD)4+ Th, donor antigen-presenting complex, and CD8+ cytotoxic T lymphocyte. **B:** Additional pathways of T-cell sensitization that can lead to rejection. MHC, major histocompatibility complex.

Naïve T cells recirculate around the body and are constantly moving through the secondary lymphoid tissues sampling the APC, both host- and (after transplantation) donor-derived, for antigen.[174] If a naïve T cell with a TCR that can recognize a donor MHC molecule encounters the donor-derived passenger leukocyte in the draining lymphoid tissue as it recirculates, it will stop, interact, and differentiate into an antigen-experienced effector T cell. In support of the secondary lymphoid tissue being the primary site for sensitization of naive T cells and initiation of rejection after solid organ transplantation, Lakkis and colleagues[175] showed that cardiac allografts were not rejected in splenectomised aly/aly mice that lack secondary lymphoid tissue as a result of a mutation in the gene encoding NF-kB-inducing kinase[176] and suggested that in this situation permanent graft acceptance was due to immunologic ignorance. Other studies supporting the concept that secondary lymphoid tissues draining the graft are the key site for initiation of the immune response have followed the fate of T cells of a known specificity for donor antigen as they respond.[177]

Similarly, after bone marrow transplantation (BMT) the initiation of GVHD also takes place in the secondary lymphoid tissue, with evidence for the initial proliferation of donor CD4+ T cells followed by CD8+ T cells in secondary lymphoid organs with subsequent homing to the intestines, liver, and skin.[178,179,180] Visualization of T cells responding during the initiation of GVHD showed that while Peyer patches are involved, other secondary lymphoid tissues contribute to the activation of T cells that can home to the gut; mesenteric lymph nodes and spleen are also sites where gut homing T cells were activated.[179]

In solid organ transplantation, exclusive initiation of rejection in the secondary lymphoid tissues conflicts with the earlier hypothesis that rejection was initiated within the graft itself by donor endothelial cells lining the vessels that could activate T cells directly as they passed through the graft.[181,182] Since these early papers, there have been a number of studies that support this hypothesis. For example, human endothelial cells have been shown to activate naïve T cells in vitro.[183] In the mouse, APCs that are not of hematopoietic origin have been shown to activate CD8+ T cells in vitro and in vivo,[184] thus supporting the concept that T cells may be activated in the graft rather than in the secondary lymphoid tissue. Moreover, splenectomized lymphotoxin α and lymphotoxin β knockout mice that also lack secondary lymphoid tissues were found to reject cardiac allografts, albeit at a slower

than normal tempo.[185] Each of these models is subtly different immunologically, and therefore different components of the immune response to an allograft may be differentially affected by the presence or absence of secondary lymphoid tissues. Clearly, in the absence of secondary lymphoid tissue, the initiation of the rejection response by naïve T cells is less aggressive.

While antigen presentation via the direct pathway plays a dominant role in initiating the response to a transplant, a finite number of donor-derived passenger leukocytes is transferred within a transplanted organ. Thus the role of the direct pathway initiated by passenger leukocytes may diminish with time as eventually only "nonprofessional" APCs, including endothelial cells, remain to stimulate direct pathway T cells. Thus the role of endothelial cells within the graft may assume a greater significance with time after transplantation both for the initiation of the response and as a target for direct pathway effector cells. While activation of naïve T cells may occur predominantly in the secondary lymphoid tissues after transplantation, activation of memory T cells in presensitized recipients is quite different. Unlike naïve T cells, memory T cells can migrate to nonlymphoid tissues in the periphery[186] and can trigger rejection through pathways that are independent of secondary lymphoid tissues.[187]

Thus, in humans, where there are likely to be both naïve and memory T cells that can recognize or cross-react with donor MHC molecules, rejection may be initiated both within the secondary lymphoid tissue as well as within the allograft by naïve and memory T cells, respectively.

At the same time that donor-derived passenger leukocytes are leaving the graft, recipient leukocytes including APCs are attracted to the graft by the inflammatory mediators and chemokines released in the vicinity of the transplanted tissue. As these cells traffic through the graft, they phagocytose debris arising from tissue damage at the time of transplantation before migrating to the draining lymphoid tissue. The ingested antigens are processed and presented on recipient MHC molecules to T cells in the recipient lymphoid tissue.[188] In addition, soluble antigens released from the graft will also be transported in the blood to the draining lymphoid tissue, where they will be taken up and presented by resident APCs. Common antigenic peptides presented by the indirect pathway are the hypervariable peptide binding regions of MHC molecules.[189] Indirect pathway responses undoubtedly contribute to acute rejection, although the tempo of rejection may be slower due to the lower frequency of T cells that can respond. However, unlike direct pathway allorecognition, the indirect pathway is available for antigen presentation for as long as the graft remains in situ, and therefore becomes the dominant mode of allorecognition long term.

A third pathway of allorecognition has been described more recently, the so-called semidirect pathway that involves the capture of donor MHC-peptide complexes by host APCs. The exchange of fragments of cell membrane between cells that interact with one another is a well described phenomenon in cell biology. In the context of the immune response to an allograft, the transfer of membrane fragments from allogeneic cells expressing donor MHC molecules can result in the presentation of intact donor MHC molecules by recipient APCs to T cells. The significance of the semidirect pathway is still under investigation.[190]

Traffic of naïve lymphocytes is usually restricted to recirculation between the blood and lymphatic systems. However, once they have been primed in the secondary lymphoid tissues, activated lymphocytes as well as other activated leukocytes must be able to migrate into the

graft in order to destroy the transplanted tissue, a process known as leukocyte recruitment.

The inflammatory processes at the site of transplantation generate chemotactic cytokines called chemokines, and upregulation of chemokine receptor expression by activated leukocytes enables them to migrate along the chemoattractant gradient to reach the graft.[191]

Inflammatory signals also affect blood vessels in the vicinity of the transplant, causing vasodilation and endothelial activation. Activated endothelial cells rapidly externalize preformed granules called Weibel-Palade bodies that contain the adhesion molecule P-selectin[192] and rapidly upregulate expression of vascular cell adhesion molecule and CD62E (E-selectin). At the same time, chemokines released from the graft become tethered to the endothelium, and these alterations in endothelial surface markers advertise to passing leukocytes that an inflammatory process is occurring in the neighboring tissue.

Leukocytes are usually conveyed within the fast laminar flow at the center of blood vessels, but once activated leukocytes reach postcapillary venules in proximity to the graft, they are able to leave this rapid flow and move toward the edge of the vessel. This occurs in response to the local chemokine gradient and is assisted by the slower blood flow in the vasodilated blood vessels near the graft. Leukocyte extravasation is a multistep process. Initially, low-affinity interactions develop between endothelial P-selectin and sialyl-Lewis^X moieties that are present on the surface of activated leukocytes. These interactions continually form and break down, and the leukocyte "rolls" along the endothelial surface. If chemokines are present on the endothelial surface, conformational changes in leukocyte integrin molecules occur that allow them to bind other endothelial adhesion molecules such as ICAM-1. These higher-affinity interactions cause arrest of the leukocyte on the endothelial surface, allowing it to commence extravasation. Having entered the tissues, the activated leukocytes continue to migrate along chemokine gradients in order to invade the graft.

Antigen Recognition and T-Cell Help in Graft Rejection and Graft-versus-Host Disease

Role of Direct Cluster of Differentiation 4 Allorecognition . Priming of naïve, directly alloreactive T cells requires professional APCs that leave the graft and enter the recipient's lymphoid tissues. Direct CD4 T-cell sensitization by donor class II MHC antigens may both generate CD4+ effector cells and provide help for the activation, differentiation, and proliferation of cytotoxic CD8+ cells that directly recognize donor class I MHC antigens and destroy the graft (see Fig. 46.9). Depletion of donor APCs can markedly prolong graft survival,[193,194,195,196,197,198] illustrating the importance of direct allorecognition in inducing rejection. The CD4 help for CD8 cells consists of both cytokine (eg, IL-2) production and "conditioning" of the APC, for example by interactions of CD40 on the APC with CD40L on the activated CD4 cell. These interactions upregulate APC expression of CD80 and CD86 costimulatory molecules and cytokines such as IL-12 and MHC, making the cell a more effective APC. Studies of antiviral immunity indicate that CD4 help is needed for development of full effector function,[199] and for CD8 memory cell survival[200] and function.[201]

Studies involving very limited (not clinically relevant) antigenic disparities between donors and recipients suggested that a "three-cell cluster" model involving interactions between helper T cells, effector T cells, and APCs was essential for rejection.[202,203,204,205] However, studies involving more extensive, clinically relevant histoincompatibilities[206,207] suggest that CD4 helper cells sensitized by antigen presented on recipient APCs can provide help for directly alloreactive CD8+ effector cells. It remains possible that a "three-cell cluster"

is still essential for CD4 cells to provide help to CD8 cells mediating rejection, and that donor class I MHC/peptide complexes are transferred and picked up by recipient APCs. Recipient APCs with directly alloreactive CD8 T cells would thereby encounter their ligands on the same recipient APC that an indirectly alloreactive CD4 cell recognizes. Such transfer of class I/peptide antigens, resulting in this type of

"semidirect" antigen presentation, requires consideration in transplant models.[208,209,210,211]

CD4+ T cells alone can cause graft rejection (without CD8 cells) in the setting of class II or multiple minor histoincompatibilities,[198,212,213,214,215] indicating that CD4 T cells can mediate rejection effector functions. In BMT recipients, they can induce GVHD in the absence of CD8 cells in the setting of class II, full MHC, or multiple minor histoincompatibilities,[216,217,218,219] and can reject class II and minor antigen-mismatched bone marrow.[220,221]

Role of Indirect Cluster of Differentiation 4 Cell-Mediated Allorecognition. Indirectly alloreactive CD4 T cells have roles in skin and solid organ graft rejection,[210,222,223,224,225,226,227,228,229,230,231,232] including the provision of help for class-switched alloantibody responses.[233] This help requires cognate interactions between recipient class II-restricted indirectly alloreactive CD4 cells and host B cells that recognize donor MHC molecules through their immunoglobulin receptors, process them, and present donor MHC peptides with their class II molecules. CD4 cells also contribute to rejection of bone marrow grafts differing only at class I MHC loci, possibly implicating indirect allorecognition.[220,221]

Rejection by CD4 cells of skin grafts lacking class II MHC shows the strength of the indirect pathway of rejection.[206,222] Rejection of islet xenografts in mice may depend on indirectly xenoreactive CD4+ T cells.[234] Sensitization of indirect CD4 responses to donor MHC-derived peptides has been demonstrated in patients undergoing graft rejection, and these may be correlated with poor outcomes.[235,236,237,238,239,240,241,242] A major role for indirect allorecognition has been suggested in the setting of chronic rejection,[230,243,244,245,246] in part because of its role in inducing antibody responses, which are implicated in chronic rejection.[247,248,249,250,251] Moreover, the eventual replacement of donor APCs by recipient APCs implicates the latter in long-term graft recipients.[196,241,252,253] Consistently, direct alloresponses tend to subside over time in transplant patients.[254,255,256]

Nevertheless, donor APC depletion or the lack of donor class II MHC can prevent rejection in some situations.[193,194,195,196,197,198] An essential role for indirect allorecognition has not been demonstrated for acute rejection.[21,253,257,258] Indirectly alloreactive CD4+ cells alone fail to reject skin grafts with minimal class I or minor histoincompatibilities,[202,259,260] or to induce GVHD against class I MHC or minor histocompatibility barriers alone.[216,217] With rodent primarily vascularized allografts, donor APC depletion may, by preventing the strong direct alloresponse, allow the inherent tolerogenicity of the organ to prevail.

Role of Helper-Independent Cluster of Differentiation 8+ T Cells . CD8 T cells can readily reject skin and bone marrow allografts in the absence of CD4

cells,[166,202,220,221,261,262] and alloreactive CD8 T-cell memory can be generated and maintained without CD4 cells.[263] CD8 cells can also induce GVHD without CD4 T cells in the setting of full MHC, class I only, and minor antigen histoincompatibilities.[264,265] Direct recognition of recipient MiHAs on recipient APCs is essential for the induction of CD8-dependent, CD4-independent GVHD in MHC-identical, lethally irradiated mice,[266] but indirect[267] or "semidirect"[211] CD8 recognition of recipient antigens presented by donor APCs amplifies the process.

Together, these studies show that CD4 help is not critical for CD8 cell-mediated rejection or GVHD. However, the requirement for CD4 help may increase in the absence of inflammatory stimuli, as indicated by marked differences in the need for CD4 help for CD8-cell activation and GVL effects in the presence and absence of inflammation.[268,269] Grafts expressing only class I antigen disparities are usually rejected quite slowly, and CD4-independent rejection is relatively easily suppressed by cyclosporine.[270,271,272] Many primarily vascularized grafts that express only a class I antigen disparity require CD4+ cells to initiate rejection, and, when it occurs, CD4-independent rejection by CD8+ cells is dependent on the number of donor APCs in a graft.[166,222] CD4-indepenent CD8+ cells do not reject grafts expressing only a small number of minor antigen disparities and generate only weak helper responses even in the presence of multiple MiHA disparities. CD8+ helper cells also differ from CD4+ helper cells in being unable to provide help for other cell populations.[273] CD8+ cells alone cannot reject skin grafts with only limited class II antigen disparities.[202,218,259,274]

Cross-Primed Cluster of Differentiation 8 Cells . Peptides of exogenous antigens were originally thought to be presented by MHC class II antigens, whereas those of endogenous cellular antigens are presented by MHC class I molecules.[275,276] However, it is now clear that class I presentation of exogenous peptides (cross-presentation) is essential for many immune responses, including those against microbial and tumor antigens.[277,278,279,280,281] Several pathways have now been delineated for cross-presentation by class I molecules.[282,283,284] CD8 cell crosspriming was originally demonstrated in a transplantation model by Bevan[70] when minor antigen-disparate grafts with MHC antigens of type A were placed on MHC (A × B) F1 recipients and CD8+ cells became sensitized to the minor antigens presented by both A and B types of class I MHC molecules. Activation of cross-primed CD8 cells is strongly dependent on CD4 help and IL-2.[285] Cross-primed CD8 cells recognizing donor MiHAs and MHC-derived peptides are most likely to participate in rejection when there is sharing of class I alleles between the donor and recipient. Without such sharing, the self-class I/allogeneic peptide epitope cannot be presented by the parenchymal or endothelial cells of the graft.[286] However, even without class I sharing, indirect CD8+-cell sensitization can lead to skin allograft rejection, perhaps due to recognition of donor peptides presented by recipient endothelial cells on host-derived vessels that revascularize the graft.[287,288] Cross-primed CD8 cells might also contribute to graft rejection via indirect effector mechanisms upon antigen recognition on host APCs in the graft or by producing inflammatory cytokines.[289] Some of the rejection processes previously attributed to cross-primed CD8 cells may in fact be mediated by CD8 cells seeing intact donor MHC-peptide complexes on recipient APCs ("semidirect" presentation).

Effector Mechanisms of Rejection and Graft-versus-Host Disease

While cytotoxic T cells are important effectors of graft rejection and GVHD, additional mechanisms involve effector cells of the innate immune system and cytokines as final mediators of tissue destruction. The net result of this multiplicity of pathways is considerable redundancy of mechanisms of graft rejection and GVHD.

Cytotoxic Mechanisms of Graft Rejection and Graftversus-Host Disease . Rejecting organs contain proteins and messenger ribonucleic acid (RNA) encoding perforin, granzymes, and proteases associated with cell-mediated cytotoxicity.[290,291,292,293,294,295,296,297] The presence in urine of RNA encoding perforin and granzyme B has been associated with renal allograft rejection in humans.[298] Although the perforin/granzyme pathway is the major cytolytic pathway for CD8 T cells and CD4 cells tend to utilize the Fas/FasL pathway,[299] both subsets are capable of both types of cytolytic activity,[300,301] and the perforin pathway is available to both T-cell subsets mediating GVHD.[302] All of these cytotoxic proteins play contributory roles, and no single protein has been found to be critical for solid organ graft rejection,[303,304,305,306] GVHD,[307,308,309,310] or bone marrow graft rejection[311] in the presence of clinically relevant mismatches. Critical cytotoxic interactions have been identified in less relevant animal models involving Fas-dependent GVHD directed at isolated class II MHC disparities[310] and perforin-dependent rejection of K^b mutant class I-only mismatched heart allografts.[303] Fas ligand promotes lymphoid hypoplasia[312] and skin and liver GVHD,[312] and both Fas ligand and TRAIL are required for GVHD-related thymic destruction.[313] While the perforin-granzyme pathway contributes to GVHD,[310,312] the Fas pathway appears to be of greater overall importance. In contrast, the perforin/granzyme and TRAIL pathways predominate in antileukemic effects, especially of CD8 cells, and selective blockade of the Fas/FasL pathway may ameliorate CD8-mediated GVHD without eliminating GVL effects.[309,314,315,316,317,318]

Non-Cytotoxic T-Lymphocyte Effector Mechanisms in Graft Rejection and Graft-versus-Host Disease. T cells can effect rejection of grafts whose parenchymal cells do not express the TCR ligand, indicating the existence of “indirect” effector mechanisms. Entire skin grafts can be rejected when only the APCs are foreign,[319] indicating that nonselective destruction of grafted tissue can occur. Several studies have implicated indirect CD4 cell-mediated rejection of skin[320,321] and cardiac[322] allografts. Replacement of graft endothelium by the host was shown to be needed for rejection through this indirect effector mechanism.[322] GVHD of the liver and intestine can be induced by donor T cells in MHC-deficient hosts receiving wild-type host DCs, suggesting that indirect effector mechanisms may also mediate tissue injury of GVHD.[323,324] However, CD4-mediated GVHD against MiHAs is markedly attenuated when the target antigens are expressed only on hematopoietic cells.[325] Thus, “indirect” effector mechanisms can destroy transplanted tissue or recipient tissue in the case of GVHD, but less efficiently than direct cytotoxic mechanisms.

Another non-CTL graft rejection mechanism involves antibodies, which cause hyperacute rejection, acute humoral rejection, or chronic rejection through Fc receptor, complement-mediated, and other inflammatory pathways. B cells[326,327] and antibodies[327] contribute to

cGVHD in animal models and are implicated in human cGVHD.[328,329,330] B-cell depletion with rituximab has been reported to have efficacy against cGVHD.[330,331,332]

Cytokines as Mediators of Graft Rejection and Graftversus-Host Disease **.** Interactions between alloreactive CD4 helper cells producing cytokines of the "Th1" type and alloreactive cytotoxic CD8+ effector cells can mediate rejection and GVHD via direct cytotoxicity.[333] The "indirect" mechanisms of graft rejection and GVHD are likely to include cytokines.[298] "Th17" cells producing IL-17 and other proinflammatory cytokines promote rejection and GVHD.[334,335,336,337,338,339,340,341,342,343,344,345,346,347,348] The generation of Th-17 cells is antagonized by Th-1 cells and promoted by IL-23, transforming growth factor (TGF)-β, and IL-6. A great redundancy of rejection pathways is suggested by studies detecting both Th1 (IL-2, IFNγ) and Th2 (IL-4, IL-5, IL-10) cytokines in rejecting allografts.[296,349,350,351,352,353,354,355,356] Th2 can also mediate GVHD and rejection. There appears to be strain-dependent tissue specificity to the type of GVHD induced by the various Th subsets.[337,357,358] Thus, while the concept that Th2 cytokines are anti-inflammatory attracted interest in the transplantation field,[359,360,361,362,363,364,365,366,367] Th2 responses can clearly contribute to both graft rejection[359,368,369,370] and GVHD.[357,371,372,373] With a few special exceptions,[374,375,376,377] studies using various cytokine knockout mice as recipients have failed to reveal any single molecule that is essential for rejection[378,379,380,381,382,383,384] or GVHD.[371,385,386]

In GVHD, cytokines such as tumor necrosis factor (TNF)-α and IFNγ play a role. Macrophages are activated by lipopolysaccharides from the damaged gut epithelium and by IFNγ to release TNF-α, nitric oxide, and other mediators of tissue injury.[387,388,389,390,391] In certain models, TNF-α had been shown to be critical for wasting disease and intestinal GVHD.[392,393] While the relative contribution of cytokine-dependent mechanisms versus direct cell-mediated cytotoxicity to GVHD is still a matter of debate, GVHD is induced by T cells incapable of both perforin-mediated and Fas-mediated cytotoxicity, even in recipients lacking TNF receptor 1-mediated signaling,[310,394,395] demonstrating the redundancy of GVHD effector mechanisms.

Graft-Infiltrating Cells**.** Many types of cells infiltrate rejecting grafts, including CD4+ and CD8+ T cells, NK cells, and macrophages.[396,397,398,399,400,401,402,403,404] While B cells may be less prominent,[405] their presence has been associated with both acute and chronic rejection, and they are attracting increasing interest for their role not only as producers of antibody effectors of rejection, but also as APCs.[406] B cells may be located in tertiary lymphoid organs found in chronically rejecting allografts.[407]

The number of invading T cells in a graft is not necessarily correlated with the speed of rejection.[405] This finding has

suggested that certain critical elements of the graft, such as its blood vessels, are the actual site of graft destruction and, indeed, endothelialitis is an important hallmark of clinically significant rejection activity.[408]

Repertoire analysis of graft-infiltrating T cells in acutely rejecting grafts reveals marked

polyconality,[22,409,410,411,412] but only the donor-reactive CTLs show evidence of having been activated in vivo.[413] Oligoclonal dominance has been suggested in studies of tolerated rodent allografts[412] and in long-term rejected human kidneys.[414] T cells infiltrating xenografts included a broad TCR repertoire.[415,416,417] T cells mediating GVHD in the setting of multiple minor histoincompatibilities demonstrated a markedly skewed repertoire involving several different Vβ families.[418,419] Clinical studies suggest that the anti-MiHA TCR repertoire is most often polyclonal.[420]

Role of Natural Killer Cells . Although the role of NK cells in marrow rejection is well established in mice, the amount of resistance mediated by NK cells to allogeneic hematopoietic stem cells is limited and can be readily overcome by increasing the dose of donor stem cells administered.[421,422] Furthermore, a role for NK cells in resisting human allogeneic marrow engraftment has not been clearly demonstrated, although they might be expected to be important in recipients of reduced toxicity conditioning regimens. Indeed, patients with severe combined (T- and B-cell) immunodeficiency who have functional NK cells require cytotoxic conditioning to permit engraftment of haploidentical marrow, whereas those lacking NK cells do not.[423]

The ability of NK cells to be triggered by “missing self” may have utility in HCT.[424] Donor-derived NK cells with graft-versus-host reactivity due to the lack of donor class I MHC inhibitory ligands in the recipient can kill residual host leukemia cells and alloreactive cells that resist the marrow graft without causing GVHD. The alloreactive donor NK cells may also reduce susceptibility to GVHD by killing recipient APCs needed to activate donor T cells.[424,425] While striking antileukemic effects of KIR mismatching were detected in heavily conditioned patients receiving high doses of haploidentical CD34+ stem cells,[424] the effect of KIR incompatibility has been more variable in other clinical studies,[426,427,428,429,430,431] and the antitumor benefit is most evident for acute myelogenous leukemia.[432]

The possible role of NK cells in rejecting solid organ grafts is somewhat controversial. NK cells are prominent among cells infiltrating rejecting organ allografts and may be the earliest producers of inflammatory cytokines and chemokines and inducers of DC maturation.[433,434,435,436] If NK cells make an important contribution to solid organ allograft rejection under normal circumstances, they must be dependent on T cells, as mice lacking T cells are unable to reject nonhematopoietic allografts. Furthermore, whereas bone marrow allografts from class I deficient donors (β2m-/-) are subject to potent NK-mediated rejection (because these cells cannot trigger inhibitory receptors on host NK cells[437]), β2m-/- skin grafts are not rejected by β2m+ recipients.[438] NK cells have recently been reported to play a critical role in cardiac allograft rejection in CD28 knockout mice,[439,440] and NK cells can mediate a particular form of chronic allograft vasculopathy in a murine cardiac allograft model.[435] This lesion may be triggered by viral infection.[441]

Inhibitory receptors on NK cells are quite broad in their class I specificity,[442] and fully allogeneic class I MHC marrow is less susceptible to NK-mediated marrow destruction compared to class I-deficient marrow.[437,443] Because of the increased disparity of xenogeneic compared to allogeneic MHC molecules, NK cells may receive fewer inhibitory signals from xenogeneic than allogeneic cells. Indeed, transduction of HLA molecules into

porcine endothelial cells reduces NK cell-mediated xenogeneic cell adhesion and cytotoxicity.[444,445,446] However, some inhibitory receptors, such as killer cell lectin-like receptor G1, do recognize xenogeneic ligands such as e-cadherin.[447] NK cells may also be activated by interactions of activating receptors with ligands on xenogeneic cells,[448,449] of which several examples have been identified.[450,451] On balance, activating xenogeneic NK cell-target interactions are more effective than inhibitory interactions. Indeed, NK cells resist xenogeneic marrow engraftment to a greater extent than allogeneic marrow.[421,452,453,454] NK cells have also been implicated in the acute vascular rejection[455] that can destroy solid organ xenografts that have escaped hyperacute rejection (see following discussion) and in xenogeneic skin graft rejection.[456] As one mechanism by which NK cells mediate cytolysis is antibody-dependent cell-mediated cytotoxicity, it is possible that immunoglobulin G natural antibodies play a significant role in initiating NK cell-mediated rejection. NK cells also release cytokines, such as IFNγ, and TNF-α, which activate macrophages and endothelial cells, and induce inflammation.[455]

Role of Natural Killer T Cells . While NKT cells have apparent inhibitory effects on graft rejection[457,458,459,460] and GVHD,[461,462] they have also been reported to participate in rejection of tissues and bone marrow in mice.[463,464,465] The latter is due to the ability of NKT cells to activate NK cells.[465] NKT cells promote skin graft rejection by cross-primed CD8 cells via their ability to produce IFNγ.[466]

Role of Monocytes/Macrophages and Eosinophils as Effectors of Rejection . Classical delayed-type hypersensitivity (DTH) responses are thought to depend on the activation of macrophages by helper T cells through production of IFNγ. It is likely that proinflammatory cytokines and chemokines produced by activated monocytes and macrophages play a role in endothelial cell activation and lymphocyte recruitment. Additionally, activated macrophages may damage tissue through the production of toxic molecules such as nitric oxide.[467]

Macrophages play an especially important role in the rejection of cellular xenografts such as islets[468,469] in a T cell-dependent manner.[470] Macrophages cause almost immediate rejection of xenogeneic bone marrow, even in the absence of adaptive immunity.[471,472,473] Human macrophages can phagocytose porcine cells in an antibody- and complementindependent manner.[474] Additional studies have implicated macrophages in solid organ and skin xenograft rejection.[475,476,477,478,479,480] This prominent role for xenogeneic macrophages may reflect the combined ability of certain xenogeneic

receptors to activate macrophages,[481] whereas important inhibitory interactions, such as that between CD47 and its macrophage ligand SIRPα, are not effective.[482] Surprisingly, a system for monocyte-mediated recognition of allogeneic non-MHC nonself has been described.[483]

Eosinophils recruited to allografts by Th2 T-cell responses have been reported to be effectors of graft rejection in some experimental models, and eosinophils are often found clinically in rejecting allografts.[333] Th2-derived IL-4 and IL-5 recruit and activate eosinophils, which release highly cytotoxic substances from granules into the tissue.

Chronic Rejection and Chronic Graft-versus-Host Disease

Most experimental studies of rejection are performed without immunosuppression and, therefore, graft destruction usually occurs within the first several days or weeks by one of the mechanisms described previously. In clinical practice, however, the use of immunosuppression usually allows graft survival for much longer periods of time. Nonetheless, clinical survival statistics reveal that even when 1-year graft survival has been achieved, the loss of transplanted organs continues to occur at a rate of about 3% to 5% per year, and a significant proportion of this delayed or late graft failure appears to be due to immunologic mechanisms.

The term "chronic rejection" is commonly used to describe this later process of delayed graft destruction, although in kidney transplantation the Banff classification schema has proposed to replace this term with interstitial fibrosis and tubular atrophy.[484] As immunosuppressive reagents have become more effective at controlling acute rejection, chronic rejection has emerged as one of the most important problems in clinical practice. Indeed, while there has been ongoing improvement over the past 30 years in the 1-year graft survival rates for kidney transplants, the halflife for organs that have survived for 1 year has not changed significantly over that entire period of time; as a result of this ongoing loss, only about 50% of transplants are still functioning 10 years later.

Although almost every type of organ transplant suffers from deterioration in function over time, the pathologic manifestations are different in each case. Kidney biopsies tend to show interstitial fibrosis along with arterial narrowing from hyalinization of the vessels—hence the terminology interstitial fibrosis and tubular atrophy. In the heart, the process is manifested principally as a diffuse myointimal hyperplasia, proceeding to fibrosis of the coronary arteries that has often been referred to as "accelerated atherosclerosis" or "transplant arteriosclerosis." Chronic rejection in lung transplants primarily affects the bronchioles with progressive narrowing of these structures and is referred to as "bronchiolitis obliterans." The liver may be the one type of organ transplant that is relatively resistant to chronic rejection, but the progressive destruction of bile ducts referred to as the "vanishing bile duct syndrome" may be another manifestation of this process.

Some of the causes of chronic graft destruction may not be immunologic in origin.[485,486] Analysis of sequential kidney transplant biopsies suggests that chronic rejection represents cumulative and incremental damage to the graft from time-dependent nonimmunologic and immunologic causes.[487,488] Potential nonimmunologic factors that have been considered to contribute to the development of chronic rejection include the initial ischemic insult, the reduced mass of transplanted tissue (especially in the case of kidney transplants leading to hyperfiltration injury), the denervation of the transplanted organ, the hyperlipidemia and hypertension associated with immunosuppressive drugs, the immunosuppressive drugs themselves, and chronic viral injury, amongst others. Nonetheless, while these factors undoubtedly contribute to the process, there is a marked difference in survival between syngeneic and allogeneic transplants in experimental models. Thus, there is almost certainly an important immunologic component in most cases of chronic rejection.

Several important observations regarding the pathogenesis of chronic rejection have emerged from clinical practice, particularly the analysis of biopsy samples. In kidney transplants, two distinctive phases of injury of chronic allograft nephropathy have been described.[487] Previous studies have suggested that there is a high correlation between the onset of chronic rejection and a history of early acute and subclincial rejection

episodes.[489,490] Analysis of protocol biopsies has revealed that the onset of mild chronic rejection by 1 year after kidney transplantation is associated with an initial phase of early tubulointerstitial damage from ischemic injury that occurs before severe rejection is detected. Beyond 1 year, a later phase of chronic allograft nephropathy was characterized by microvascular and glomerular injury.[487] Importantly for long-term outcomes, the clinical data show that the process of chronic rejection is usually refractory to increases in immunosuppressive therapy, in contrast to acute rejection episodes that almost always respond to treatment. The development of chronic rejection has also frequently been associated with the presence of antidonor antibodies,[491,492] and the deposition of complement component C4d in the allograft.

Taken together, these clinical observations have suggested to some that chronic rejection is the result of donorspecific alloantibody production.[493] Moreover, there are also now data emerging to suggest that components of the innate immune system such as NK cells can also contribute,[494] in some cases in conjunction with alloantibody.[495] All of these suggestions may be correct, but neither the logic nor the evidence fully supports the exclusive involvement of one mechanism. The relationship between alloantibody, C4d deposition, and neointimal fibrosis is complex.[496] In the first place, alloantibody production often reflects activation of indirect pathway T cells (see previous discussion), and hence it might equally well be a marker for other rejection mechanisms as opposed to a cause of chronic rejection. Moreover, the presence of alloantibody and C4d may be transient, and there are clear examples of chronic changes in the graft in their absence.[496] In addition, early rejection episodes probably reflect primarily the degree of antidonor immunoreactivity, and there is no proven direct link with later deterioration of graft function. Therefore, even if sufficient

immunosuppression were given to prevent acute rejection, chronic rejection might still occur when the levels of immunosuppression are reduced over the long term, even if acute rejection had never occurred. Finally, experimental studies have suggested that the mechanisms of chronic rejection are not absolutely dependent on either antibody formation or on the occurrence of acute rejection episodes.

The uncertainties that arise from the interpretation of the clinical data make it important to develop experimental models for studying the mechanisms of chronic rejection. It is difficult in the laboratory, however, to mimic a process that may take 5 or 10 years to develop in patients treated with immunosuppressive drugs. Thus, the effort to study chronic rejection experimentally has depended on surrogate short-term pathologic markers that are thought to predict the long-term changes of chronic rejection. In particular, these studies have concentrated on the development of the myointimal proliferation that is thought to be the precursor of the chronic vascular changes typically observed in patients. In rodents, pigs, and primates, this has often been done with grafts after an initial period of immunosuppression that prevents acute rejection.[497,498,499] All of these experimental studies are subject to the caveat that the surrogate pathologic lesion occurs much earlier than the typical changes of chronic rejection in patients. Thus, the process being studied experimentally may not be the same as the clinical process.

Pathologic Manifestations of Experimental Chronic Rejection

The typical pathologic features of the experimental lesion associated with chronic rejection are shown in Figure 46.10.[500] The marked narrowing of the vascular lumen is caused by the

substantial proliferation of endothelial and then smooth muscle cells that can be host-derived.[501] Associated with this proliferation is progressive destruction of the media. In time, the cellular proliferation becomes less pronounced and is replaced by concentric fibrosis that narrows the vascular lumen. Immunohistologic staining indicates that there is increased expression of several adhesion molecules,[500] intracellular proteins such as vimentin,[502,503] and easily detectable levels of several molecules, including nitric oxide synthase,[504] acidic fibroblast growth factor, insulin-like growth factor, IFNγ,[505] and endothelin,[506] each of which may play a role. The abnormal expression of self-molecules in allografts undergoing chronic damage can lead to autoantibody formation.[507] Ultimately, the ischemia resulting from vascular occlusion results in fibrosis in the parenchyma of the organ and consequent organ dysfunction.[508] In the case of the lung or the liver, chronic injury may cause changes most prominently in the bronchioles or the bile ducts, but this is also associated with arterial lumen loss, which may be the primary lesion causing bronchiolitis obliterans or bile duct fibrosis, respectively.[508]

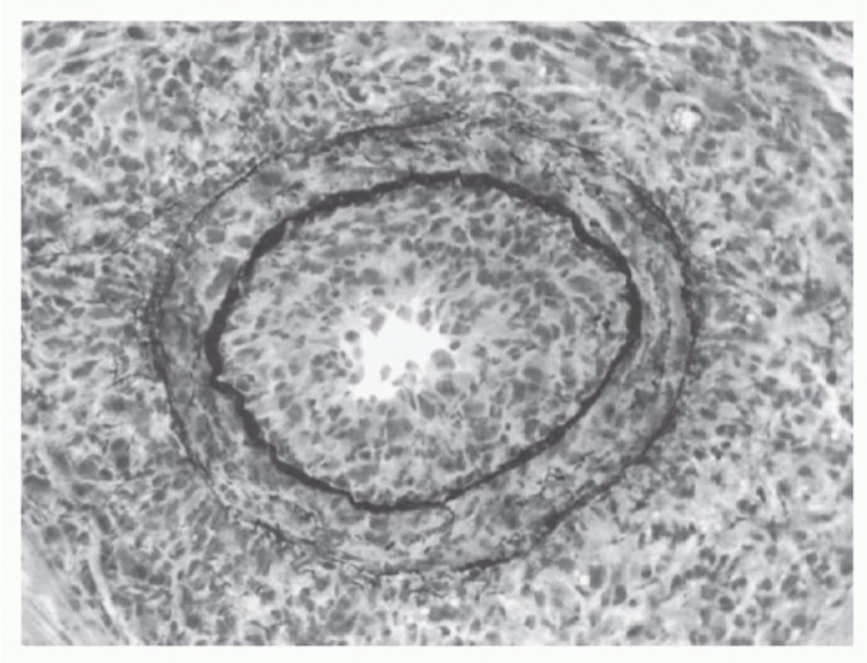

FIG. 46.10. Histology of Chronic Rejection.

Immunologic Mechanisms of Chronic Rejection

Rejection requires a dialogue between the innate and adaptive immune systems.[509] Innate immunity is most likely involved at the outset of the process that leads to the development of chronic rejection, and there is evidence to suggest that NK cells[494,510] and complement activation can be involved.[511] At the level of the adaptive response, because it is assumed that stimulation of direct pathway T cells is likely to diminish over time as donor APCs are replaced by recipient APCs (see previous discussion), it is commonly assumed that the predominant immune response that causes chronic rejection occurs through the indirect pathway.[512]

Studies in pigs have suggested that the vascular changes of chronic rejection are more apt to develop when there are class I antigenic disparities than when there are only class II disparities and that the development of the lesion depends especially on CD8+ T cells.[513] In mouse models, in contrast, there is evidence that either CD4+ or CD8+ T cells can produce the lesion and that either class I or class II antigenic disparities are sufficient to stimulate chronic rejection.[514] The finding that class II antigenic disparities are themselves sufficient to induce this pathology is consistent with the observation of class II MHC expression on the vascular endothelium and medial smooth muscle cells of mouse cardiac allografts with these vascular lesions.[515] Because class II MHC is not constitutively expressed by mouse vascular endothelial cells, indirect recognition of donor class II transferred from passenger leukocytes may be responsible for inducing an inflammatory response that leads to subsequent upregulation of class II on the donor vascular endothelium. In keeping with the prediction of many clinical studies, adoptive transfer experiments into mice with severe combined immunodeficiency have shown that alloantibodies in the absence of T cells can induce the typical pathologic vascular changes, and lesions can develop in T-cell-deficient mice.[516] However, T cells without B cells have also been shown to cause the lesion, although there may be somewhat less tendency to progress to end-stage fibrosis.[517]

Several studies have indicated that the induction of donor-specific tolerance can prevent the development of the vascular changes of chronic rejection, although not all of the short-term manipulations that have been effective in preventing acute rejection have necessarily prevented the later onset of chronic rejection. Remarkably, mice rendered

tolerant by neonatal injection of donor splenocytes, or by the induction of high levels of lasting, multilineage mixed chimerism with demonstrated central deletion of donorreactive T cells and permanent acceptance of donor-specific skin grafts, demonstrate graft vasculopathy in donor cardiac allografts.[510] Thus in the complete absence of antidonor T-cell reactivity, other cell types such as NK cells may induce these types of lesions in cardiac allografts. In addition, T-cell recognition of cardiac-specific antigens presented by donor MHC and not shared by donor hematopoietic cells could play a possible role in the development of these lesions in immunocompetent, tolerant mice.[494]

From these data, it seems likely that multiple immunologic mechanisms may be capable of creating the graft arteriosclerotic lesions that are characteristic of chronic rejection, and that T-cell alloreactivity is not essential for their induction. Whether there is a critical final common mediator involved in all of these pathways is not currently known. However, IFNγ has been shown to play an important role in the development of lesions in several models,[518,519] and signal transducer and activator of transcription (STAT)4-deficient mice, which do not respond to IL-12 and therefore cannot generate Th1 responses, show markedly reduced severity of graft vasculopathy compared to wild-type mice.[520] TGF-β has been shown to attenuate the lesions, but has also been detected within the lesions and implicated in the development of fibrosis.[521]

Chronic Graft-versus-Host Disease

cGVHD is the most common and severe complication among patients surviving for more than 100 days after allogeneic BMT. Clinically, acute and cGVHD can be distinguished on the basis of the time of onset, clinical manifestations, and distinct pathobiologic mechanisms. Acute GVHD usually occurs within 2 to 6 weeks following allogeneic BMT and primarily

affects the skin, liver, and the gastrointestinal tract with T-cell infiltration of the epithelia of the skin, mucous membranes, bile ducts, and gut. However, acute GVHD has been noted to occur later in recent protocols involving nonmyeloablative conditioning for HCT. In contrast, cGVHD involves a wider range of organs and clinical manifestations include scleroderma, liver failure, immune complex disease, glomerulonephritis, and autoantibody formation.

The pathogenesis of cGVHD, like chronic rejection, is poorly understood. The disease involves T-cell responses to alloantigens or autoantigens.[522] Because most BMT is performed between HLA-identical or closely HLA-matched pairs, alloreactivity may be directed against miHAs presented by shared MHC molecules, or against MHC alloantigens when present. T cells developing de novo in a recipient thymus that is damaged due to GVHD may result in the emergence of autoreactive T cells into the peripheral repertoire. The injury to target organs is poorly understood, but may involve inflammatory cytokines and fibrosis, as well as B-cell activation and production of autoantibodies.

The main risk factors for the onset of cGVHD are HLA disparity, donor and patient age and sex, source of progenitor cells, graft composition and previous acute GVHD. cGVHD can be treated providing it is identified sufficiently early after initiation. Even with treatment, extensive skin involvement, thrombocytopenia, and progression are poor prognostic factors.

PHYSIOLOGIC INTERACTIONS THAT MODULATE GRAFT REJECTION AND GRAFT-VERSUS-HOST DISEASE

Although graft rejection and GVHD often involve exceptionally strong immune responses, these responses are still accompanied by downregulatory components that can be manipulated to promote graft survival. While many of these manipulations are described in the section on tolerance, some of the regulatory components of the rejection response are briefly described here.

Downregulating Signals Following T-Cell Activation

Interactions between Fas and Fas ligand (FasL), which is upregulated during rejection responses, can mitigate GVHD and graft rejection by killing activated T cells and APCs.[306] FasL-deficient recipients are more susceptible than normal mice to the development of GVHD,[523] and FasL can promote resistance to rejection of tissues transplanted to some “privileged sites,” such as the testis or the anterior chamber of the eye.[524] However, forced overexpression of FasL causes a nonspecific inflammatory syndrome associated with prominent neutrophil infiltration[525] and can promote graft destruction.[526,527] Overexpression of FasL has, however, been reported to promote survival of heart allografts in recipients of FasL-expressing donor-specific transfusions (DSTs),[528] and of bone marrow[529] and islet[530] allografts.

CTL antigen (CTLA)4 helps maintain self-tolerance, as evidenced by the T-cell lymphoproliferative autoimmune syndrome that develops in CTLA4 knockout mice.[531,532] CTLA4 has been shown to play a role in T-cell tolerance in many systems.[384,533,534,535,536,537,538,539,540,541,542,543,544,545,546] Blockade of CTLA4 accelerates cardiac allograft rejection[547] and increases GVHD.[548] PD1, an additional downregulatory molecule expressed by activated T cells that recognizes the B7 family members PDL-1 and PDL-2, also mitigates graft rejection[549,550,551,552,553,554] and GVHD.[555,556,557] Interaction of one of the PD1 ligands, PD-L1, with its alternative

receptor B7.1, also mitigates graft rejection.[558] While PD1 plays an important modulatory role in the presence of extensive antigenic disparities between murine heart graft donors and recipients, the B- and T-lymphocyte attenuator (BTLA)-herpesvirus entry mediator (HVEM) inhibitory pathway predominates in the presence of more restricted antigenic disparities.[559] BTLA-HVEM interactions may also control GVHD,[560] but the opposing effects of BTLA and HVEM expressed by T cells on T-cell activation complicate interpretation of experiments, which have produced conflicting results with respect to GVHD[560,561] and islet allograft survival.[562,563]

Immunomodulatory Effects of Cytokines

There is considerable evidence of roles for IL-10 and TGF-β in downmodulating graft rejection[564,565,566] and GVHD,[372,567,568,569,570] and these cytokines may have therapeutic utility.[571,572,573,574,575] These

activities may reflect the important role of these cytokines in regulatory T (T_{reg})-cell and B-cell generation and function. On the other hand, IL-10 can enhance cytolytic mechanisms of islet graft rejection,[576] and high doses can accelerate GVHD.[372] Moreover, TGF-β is an important mediator of fibrotic pathologies in both chronic rejection and GVHD.[577,578] TGF-β, in concert with proinflammatory cytokines such as IL-1 and IL-6, also promotes the development of proinflammatory Th-17 cells.[579]

The inflammatory condition that develops in IL-2 knockout mice is clear evidence of the important immunomodulatory role of this cytokine, and studies in several graft rejection[580] and GVHD[581] models have confirmed such a role in transplantation. Much of this effect is due to the important role of IL-2 in survival and expansion of T_{reg} cells,[582,583] as is discussed elsewhere in this chapter. IL-2 can also promote activation-induced cell death of alloreactive CD8 cells.[582,584]

While IFNγ can also promote graft rejection, rejection is rapid or even accelerated in IFNγ knockout mice.[383,564,585,586,587] IFNγ has also been shown to play a downregulatory role in GVHD.[371,385,588] IFNγ has antiproliferative effects on T cells,[384,587] increases activation-induced cell death via the Fas/FasL pathway,[589,590,591] upregulates nitric oxide production,[592,593,594,595] and is necessary for T_{reg}-cell function in certain conditions.[596,597,598] Consistently, the major cytokines that induce IFNγ, IL-12 and IL-18, can inhibit graft rejection[382,384,599] and GVHD.[385,600,601] IL-12 and IL-18 act in an IFNγ and Fas-FasL-dependent manner,[385,601,602] which preserves or enhances GVL effects.[588,603,604,605,606] IFNγ promotes the GVL effect of CD8 T cells,[385,607,608] apparently by promoting lymphohematopoietic grat-versus-host responses while inhibiting tissue GVHD,[609] perhaps due in part to increased PDL1 expression by APCs,[610] promotion of donor T_{reg}-cell expansion,[610] and reduced Th17 differentiation.[337]

Despite interest in the notion that Th2 cytokines are antiinflammatory and may suppress rejection and GVHD,[359,360,361,362,363,364,365,366,367] IL-4 deficiency does not

accelerate graft rejection[564,611] and can actually downmodulate GVHD.[371] However, there clearly are situations in which an immunomodulatory effect is achieved by Th2 cytokines. For example, the use of total lymphoid irradiation can alter the balance between NKT cells and conventional T cells in BMT recipients, and IL-4 production by enriched recipient NKT cells downmodulates GVHD.[612] This approach, which also apparently involves T_{reg} cell enrichment when combined with antithymocyte serum,[613] has recently been extended to clinical trials of HLA-identical HCT for treatment of hematologic malignancies and renal allograft tolerance induction.[614,615,616,617]

The Presence of the Transplanted Organ

Vascularized organ allografts may be accepted spontaneously[618,619,620,621] or with a short course of immunosuppression in rodents or pigs.[621,622,623,624,625,626,627,628,629] The long survival of these transplanted organs can prevent rejection of other allografts from the same donor.[618,630,631] In clinical transplantation, long survival of a transplanted organ may diminish the rejection response, as much less immunosuppression is required late after transplantation than in the early period. Studies in transiently chimeric monkeys and patients achieving tolerance with HLA-mismatched combined kidney and BMT strongly implicate a role for the kidney itself in promoting tolerance.[632,633,634,635,636] T_{reg} cells have been implicated in many of these models (see following discussion). The capacity of transplanted organs to regulate their own survival is often confused with the capacity of a treatment to induce tolerance. For example, many transient immunosuppressive regimens achieve vascularized allograft survival in rodents, but the role of the immunosuppression is to allow a strong T_{reg} cell response induced by the graft to predominate under the controlled experimental conditions. These conditions do not usually apply to human transplantation, thus explaining the failure to translate the many tolerance regimens that succeed in rodents into clinical practice.

Role of Graft and Tissue Injury

Graft injury, such as that associated with ischemia-reperfusion and host tissue injury induced by conditioning therapy in the case of HCT, play an important role in promoting graft rejection and GVHD, respectively. Local inflammatory processes activate innate and consequently adaptive immunity and T-cell activation. Inflammation plays an important role in promoting APC migration from tissues to lymph nodes[637,638,639,640,641] and also promotes trafficking of activated T cells into tissues, as is illustrated dramatically in HCT models. Administration of large numbers of nontolerant donor lymphocytes to established mixed bone marrow chimeras (ie, animals not recently treated with conditioning therapy) leads to a graft-versus-host response that attacks only lymphohematopoietic tissues and does not cause GVHD, a disease of epithelial tissues such as skin, intestines, and liver.[642,643] In contrast, similar numbers of T cells cause rapidly lethal, severe GVHD in freshly irradiated hosts.[642,644] Conditioning rapidly induces production of chemokines in the GVHD target tissues, promoting immigration of T cells that then elicit a further cascade of chemokines that amplifies the response.[645] Upregulated adhesion molecules also promote leukocyte infiltration through the microvasculature of these tissues. Lethal total body irradiation (TBI) and cyclophosphamide, for example, upregulate the proinflammatory cytokines IL-1, IL-6 and TNF-α,[646,647,648] which can upregulate endothelial cell E-selectin, P-selectin, ICAM-1, and

vascular cell adhesion molecule-1.[649,650] In the absence of such host target tissue inflammation, mature, activated graft-versus-host-reactive effector T cells are unable to traffic into skin and induce injury.[644] Provision of a local tolllike receptor (TLR) stimulus promotes the entry of such cells into the skin and induces localized GVHD,[644] indicating that tissue inflammation provides a critical checkpoint for T-cell recruitment to GVHD target tissues. A systemic TLR stimulus in this setting promotes severe, multiorgan GVHD.[644] GVHD can also occur when very large numbers of nontolerant parental T cells are administered to genetically tolerant F1 hosts,[651] indicating that, in the presence of sufficiently powerful graft-versus-host responses, the need for tissue inflammation to induce GVHD can be bypassed, possibly due to inflammation induced by high systemic cytokine levels.

All forms of organ and tissue transplantation involve ischemic and traumatic injury to the donor tissue, which may be one of the reasons that rejection episodes occur most frequently early after transplantation. The surgical trauma associated with transplantation is associated with very early production of chemokines in the graft,[433,652] promoting infiltration of NK cells[433] and neutrophils,[653] which in turn perpetuate inflammation that promotes subsequent T-cell infiltration.[654] At least partly due to the influence of these cells of the innate immune system,[433] chemokines are produced before T-cell infiltration is seen. IFNγ, whose early production may require CD8 T-cell activation,[655] also activates macrophages to become effective APCs and release chemokines.[655,656,657] These phenomena, along with microbial exposures that drive innate immunity, contribute to “danger” signals that promote graft rejection.[658] Nevertheless, skin and cardiac allografts that are allowed to heal before being exposed to alloreactive T cells are rapidly rejected if there is sufficient antigenic disparity between donor and host.[659,660] Similarly, patients with long-standing allografts are rarely able to terminate immunosuppressive therapy without rejection. Therefore, “danger” signals are not a critical requirement for graft rejection, and it is better to picture the antigenic disparity and the recipient's immune responsiveness as the dominant features controlling graft rejection, while danger signals may influence the timing, intensity, or character of the rejection response.

Role of the Innate Immune System

The innate immune system comprises a group of cells and molecules (Table 46.5) that provide a first line of defense against pathogens and which also play an important role in allograft rejection. Primary adaptive immune system responses that rely on the activation and expansion of antigenspecific T and B cells take several days to reach maturity. In contrast, the innate immune system can be considered as a “preformed” defense mechanism that is immediately available to defend the host until either the dangerous stimulus is cleared or the adaptive immune system is able to mount an antigen-specific response.[661] Clearly, this is a somewhat simplistic view; while many components of the innate immune system can be recruited very quickly after transplantation, their activity can be amplified after activation.

TABLE 46.5 Components of the Innate Immune System

Cell	Primary function

Macrophage/neutrophil	Phagocytosis, opsonisation, antigen presentation Release of inflammatory mediators
Dendritic cell	Antigen uptake and presentation to lymphocytes
Natural killer cell	Release of cytokines Cytotoxic to virally infected or mutated cells
Eosinophil	Release of inflammatory mediators Killing of antibody-coated entities
Complement	Opsonisation, target cell lysis, and chemoattraction

The physical process of graft retrieval and implantation generates signals within the graft and the recipient that trigger rejection. The concept of “danger” triggering an immune response has evolved as an idea over many years.[170,661] Pattern recognition receptors exist to detect the unwanted presence of bacterial or viral pathogen-associated molecular patterns, but after transplantation the TLRs that form part of the pattern recognition receptor family can also be used to detect the molecules produced as a result of implantation of the graft, so called damage-associated molecular patterns (DAMPS). These signals include heat shock proteins, reactive oxygen species, high mobility group protein B1, complement breakdown products, nucleic acids (deoxyribonucleic acid and RNA), mitochondrial components, and molecules associated with tissue fibrosis that activate cells of the innate immune system via TLR ligation.

The immune system monitors the health of cells and responds to ones that have been injured and killed. Cell death is an inevitable consequence of the ischemia and reperfusion injury that is caused by organ and tissue retrieval. Dying cells expose intracellular DAMPs that can be recognized by components of the innate immune system.[662] The role of DAMPs may vary depending on the type of transplant performed and the degree of injury resulting from cell isolation or organ retrieval. Some DAMPs may be expressed in a tissue-restricted manner (eg, one class of DAMPs called alarmins include molecules such as β-defensins that are expressed primarily by leukocytes and therefore may be more relevant after hematopoietic stem cell transplantation or BMT). In addition, the location or type of injury may contribute to the outcome of dying cells triggering a response. Thus, the contribution of different DAMPs to triggering the innate immune system may vary with different types of transplant.

Macrophages and other phagocytic cells can ingest dying cells and necrotic tissue; when activated, they release cytokines such as TNF-α, IL-1, and IL-6, which all contribute to the local inflammatory environment. Production of active IL-1β requires proteolytic cleavage of the inactive form, pro-IL-1, a process linked to a multiprotein complex called an inflammasome that acts as a platform for caspase 1, the cysteine protease involved in the proteolytic maturation and secretion of IL-1β.[663] A number of different inflammasomes exist, but the nucleotide oligomerization domain-like receptor protein 3 inflammasome is the best studied to date. IL-1β can be highly deleterious to the tissue in which is produced; therefore, inflammasome activity is tightly controlled. As a consequence of these events, the early infiltration of macrophages into a graft at the onset of rejection has been suggested to be a

poor prognostic sign for transplant survival. Macrophage colony-stimulating factor, produced by tubular and mesangial cells, promotes macrophage infiltration and proliferation, and may play a pathogenic role in acute rejection.

Damaged tissue can also trigger complement activation in the absence as well as the presence of antibody; complement has been demonstrated to contribute to ischemia reperfusion

injury.[664] Activated complement components constitute a proteolytic cascade that generates a range of effector molecules.[170] The anaphylatoxins C5a and C3a are chemoattractant molecules that assist leukocytes to home to the graft while other soluble mediators are able to opsonise cells, targeting them for destruction by phagocytes.[665] Recognition of C3b, C4b, or their fragments covalently bound to target cells by complement receptors on the surface of leucocytes facilitates antigen presentation and T-and B-cell activation.[666,667] Generation of the terminal components of the complement cascade (C5b-9) results in formation of the membrane attack complex within the target cell membrane and initiation of target cell lysis. This has been demonstrated to play an important role in ischemia reperfusion injury.[664] In addition to the potential of the damaged tissue itself to activate complement, there is also evidence that natural immunoglobulin M antibody can trigger complement activation via both the classical and mannose-binding lectin pathway.[668] Studies in muscle reperfusion models initially identified natural immunoglobulin M as a major initiator of pathology through the activation of the complement system and recruitment of inflammatory cells. When the repertoire of natural immunoglobulin M antibodies was altered, significant protection of the myocardial tissue was observed with only limited apoptosis of cardiomyocytes and decreased neutrophil infiltration compared to when natural antibody was present.[669] As mentioned previously, there is also increasing evidence that complement can influence graft outcomes, contributing to the development of acute and/or chronic rejection, either directly or through antibodydependent mechanisms.[511,670]

NK cells are innate immune mediators that express cell surface receptors, including activating receptors that bind to widely expressed carbohydrate residues on self-cells and inhibitory receptors that bind self-MHC class I molecules. Activating NK cell receptors including NKG2D recognize natural stress signal ligands, whereas the inhibitory receptors include the CD94-NKG2A complex, KIR family in humans, and Ly49 family in mice. The possible role of NK cells in graft rejection is discussed previously. Absence of an appropriate MHC class I ligand on an allogeneic cell informs the NK cell that the allogeneic cell should be killed. Some malignant or virally infected cells downregulate MHC class I expression or express altered class I molecules as a strategy to evade CD8+ T-cell cytotoxicity. As a result, they are unable to stimulate inhibitory receptors and are vulnerable to NK cell killing. Thus, NK cells could contribute to tissue damage following cell and solid organ transplantation. While the role of NK cells in rejecting bone marrow (at least in mice) is clearer than for solid organ transplantation,[671] NK cells can have a marked and lasting impact in this setting,[672] particularly with a form of chronic cardiac graft vasculopathy in mice.[494] NK cells likely contribute to acute rejection in certain donor-recipient combinations where, even if they are not the major drivers of the responses, they have a significant impact by secreting IFNγ. Nevertheless the precise role of NK cells requires further elucidation as NK cells have also been shown to promote tolerance induction (see the following discussion) by killing donor APCs.[673]

Increasing evidence demonstrates the important role that components of the innate immune system play in activating the adaptive immune system. In particular, ligation of TLRs on DCs induces maturation, as defined by upregulation of costimulatory molecules and MHC class II, enhancing their ability to act as a bridge between the innate and adaptive immune systems.[674] TLRs are critical sentinels of the innate immune system and contribute to the early response after transplantation. Using HY grafts, Goldstein and colleagues showed that rejection was not triggered in the absence of MyD88 TLR signaling pathway due to the migration of a reduced number of mature DCs to the draining lymph nodes that resulted in the impaired generation of anti-graft-reactive T cells and Th1 immunity.[675] Further studies using fully allogeneic grafts have shown that multiple TLR signaling pathways contribute to the initiation of rejection.[676,677] There are also data indicating that TLR2, TLR4, and/or TLR9 can play a role in the ischemia-reperfusion injury in heart, brain, liver, intestine, and kidney.[678,679] Haptoglobin, a serum acute-phase reactant protein released by necrotic donor skin grafts, has recently been shown to promote graft rejection via a MyD88-dependent pathway.[680] As well as stimulating rejection, TLR signaling and activation of the innate immune system may also prevent or increase the difficulty of induction of tolerance to alloantigens[681] (see following discussion).

MANIPULATIONS TO PREVENT GRAFT REJECTION

Methods of preventing graft rejection can be divided into nonspecific immunosuppression, which reduces the overall immunocompetence of the recipient, and specific suppression of the response to the graft, leaving the immune system otherwise intact. The latter, known as tolerance, is a major goal of transplantation research.

Nonspecific Techniques

Immunosuppressive Medications

Reviewing the pharmacology of the nonspecific immunosuppressive drugs commonly used in clinical transplantation is beyond the scope of this chapter. It is important to note, however, that most of the major advances in clinical transplantation that have occurred over the past four decades have been made possible largely because of these agents. Most recipients of allogeneic organs today receive exogenous immunosuppression in the form of combination therapy with several drugs (Table 46.6), including steroids, a calcineurin inhibitor (cyclosporine or tacrolimus), and an antimetabolite (eg, azathioprine or mycophenolate mofetil). Newer drugs, including sirolimus and several other agents tested as subsitutes for the calcineurin inhibitors in some regimens and both steroid-free and single-drug regimens, are being tested,[682,683,684,685] as are strategies incorporating immunosuppressive antibodies.[686] In general terms, both standard and experimental immunosuppressive drugs suppress immune responses either by depleting immune cells, by blocking costimulation, or by inhibiting lymphocyte gene transcription (eg, cyclosporine, tacrolimus), cytokine

signal transduction (eg, rapamycin), or nucleotide synthesis (eg, azathioprine, mycophenolate mofetil).

TABLE 46.6 Immunosuppressive Medications

Type of Drug	Examples	Mode of Action
Antirejection medication		
First generation	Prednisone	Anti-inflammatory; inhibition of cytokines
	Azathioprine	Antimetabolite (purine analog)
Second generation	Cyclosporin	Calcineurin inhibition (downregulates IL-2)
	FK-506	Calcineurin inhibition (downregulates IL-2)
	MMF	Inhibitor of nucleotide synthesis
	Rapamycin	Inhibitor of signal transduction
Polyclonal antibodies	ATG	T-cell depletion
	Thymoglobulin	T-cell depletion
Monoclonal antibodies	Anti-CD3	T-cell sequestration
	Anti-CD25	Activated T cells
	Anti-CD2	T-cell depletion and costimulation blockade
	Anti-CD154	Costimulation blockade
		Costimulation

	CTLA4-Ig	blockade
	Anti-CD40	Costimulation blockade

ATG, anti-thymocyte globulin; CD, cluster of differentiation; CTLA, cytotoxic T-lymphocyte antigen; MMF, mycophenolate mofetil; IL, interleukin.

Anti-T-Cell Antibodies

The first therapeutic anti-T-cell antibodies used clinically were heterologous antisera prepared against human lymphocytes or thymocytes. These powerful immunosuppressants are still used today, both as induction agents and for the treatment of rejection episodes. Their major side effects include serum sickness and infectious complications. A variety of monoclonal antibodies (mAbs) are also being used actively in clinical transplantation or are being tested in clinical trials[687] (see Table 46.6). These include OKT3, Campath-1, and numerous other, newer mAbs. In general, these antibodies are now either "humanized" from the mouse versions by genetic engineering or prepared in mice carrying human immunoglobulin genes[688] to avoid immunization of the recipients.

mAbs to the α chain of the IL-2 receptor (CD25) have been used in an effort to achieve greater antigen specificity with anti-T-cell antibodies, based on the hypothesis that these mAbs might selectively eliminate only those T cells activated by the transplant. Clinical results using humanized anti-CD25 mAbs have so far demonstrated immunosuppression, but not tolerance induction. Some mAbs have also been used in attempts to block the effector mechanism of graft rejection, including anti-ICAM antibodies and anti-TNF antibodies. Agents that suppress T-cell costimulation, including anti-CD154, anti-CD40, and CTLA4-immunoglobulin, have shown promise,[687] and will be discussed further with regard to their potential value in tolerance induction protocols (see following discussion). CTLA4-immunoglobulin (belatacept) in particular, has recently been reported to have better cardiovascular and metabolic risk profiles than a calcineurin inhibitor in the control arm of a recent clinical trial.[689]

While mAb therapy has been extremely effective, several problems still exist, including toxicities related to the release of cytokines and immunogenicity, leading to antibody production against both constant region and idiotypic determinants of the antibody molecules.

Donor-Specific Tolerance Induction

The Need for Tolerance-Inducing Regimens

Immune tolerance denotes a state in which donor-specific nonresponsiveness is maintained without immunosuppressive agents. For the purpose of this discussion, we will define tolerance as acceptance of a donor organ by an otherwise intact immune system, and will qualify the term as "systemic" when it applies to the entire immune system so that the immune system fails to respond to cells or other grafts from the same donor. Transplantation tolerance is a desirable goal for three major reasons. First, while improvements in immunosuppressive therapy have dramatically increased the success of clinical organ transplantation, these drugs are associated with increased risks of infection and malignancy as well as metabolic

and organ toxicities that can result in additional organ failure. Second, despite improved immunosuppression, chronic rejection still contributes to constantly down-sloping long-term survival curves for organ allografts. Third, a critical shortage of allogeneic organs has increased interest in the use of other species as organ and tissue sources. However, immune barriers to xenografts are greater than those to allografts, and the induction of both B-cell and T-cell tolerance may be essential to the ultimate success of xenotransplantation.

Mechanisms of Transplantation Tolerance

Other chapters in this book describe the mechanisms by which tolerance to self-antigens is achieved (see Chapters 13 and 32). Rather than reiterate these in detail here, we will mention each and provide examples in which they have been implicated in transplantation. Mechanisms for inducing T- and B-cell tolerance include deletion, anergy, and suppression. In addition, a graft may simply be ignored by recipient lymphocytes but in most transplant settings this is unlikely

to be a reliable mechanism for sustaining tolerance. The thymus is the central organ for T-cell development. Induction of tolerance among developing thymocytes is referred to as “central,” as distinguished from the “peripheral” tolerance that may develop among already mature T cells when they encounter antigen in the peripheral tissues. The marrow is the central organ for B-cell development and, as for T cells, B-cell tolerance may also be thought of as central or peripheral.

Clonal Deletion

B Cells. When a developing B cell with autoreactivity encounters self-antigen, it undergoes developmental arrest. Recombination activating gene-dependent light chain receptor editing then takes place. If this results in the formation of a nonautoreactive immunoglobulin receptor, the B-cell survives; if not, the B cell undergoes apoptosis.[690] B cells are susceptible to tolerance at particular stages of development upon recognition of membrane-bound antigen.[691] Several checkpoints for elimination of autoreactive B cells during development in the marrow and after migration to the periphery have been identified.[692] Deletion, rather than receptor editing, eliminates autoreactive peripheral B cells,[693] which may also become anergized, depending on the nature of the antigen.[694,695]

In the context of transplantation, B-cell responses to allogeneic MHC molecules are largely T cell-dependent, so an absence of alloantibodies may not necessarily reflect intrinsic B-cell tolerance; an absence of T-cell help would produce a similar outcome. However, MHC-alloreactive B cells may be intrinsically tolerized by encounter with antigens in the absence of T-cell help, apparently by a deletional mechanism.[696,697]

Elimination of natural antibody (eg, xenoantibody) responses must target B cells in addition to T cells, as these antibodies are produced even in the absence of T cells.[698] Nevertheless, T-cell responses can clearly augment these antibody responses.[699,700,701] Cells of the B-1 subset, which produce natural antibodies responsible for xenograft hyperacute rejection,[702] can be deleted when their receptors are crosslinked by cell-bound antigen.[703] Initial anergy followed by deletion of preexisiting B cells and deletion/receptor editing is responsible for the long-term tolerance of natural antibody-producing B-1 cells in mice given hematopoietic cells expressing an antigen for which natural antibody-producing cells preexist in the

recipient.[153,704,705]

T Cells. Central T-cell tolerance involves deletion of developing thymocytes that recognize self-antigens presented by hematopoietic cells and thymic epithelial cells. In addition, antigens presented only by nonhematopoietic thymic stromal cells can induce T-cell anergy[706] or drive T_{reg}-cell differentiation.[707,708,709] Several hematopoietic cell types, including DCs,[710] B cells,[711] and thymocytes,[712,713] as well as thymic stromal cells,[714,715] can induce intrathymic deletion. Medullary epithelial cells producing tissue-specific antigens can mediate thymocyte deletion by presenting antigens directly or transferring them to DCs.[716] Transplantation tolerance induced by intrathymic deletion should be very reliable, as donor-reactive T cells would be largely absent. Durable mixed hematopoietic chimerism achieved with regimens that completely deplete preexisting T cells in the thymus and periphery results in donor- and recipient-specific tolerance through this central deletion mechanism.[717,718]

Mature peripheral T cells can also be deleted.[719,720,721,722,723,724] Peripheral CD8 cells may undergo "exhaustion" in the presence of persistent antigen.[725,726] Persistent antigen encountered on recipient nonhematopoietic cells leads to deletion and exhaustion of graft-versus-host-reactive CTLs following HCT.[556,727,728] Peripheral deletion of donor-reactive T cells has been demonstrated in mice receiving DSTs and/or BMT with costimulatory blockade,[533,729,730,731,732,733,734] and has been implicated in a model involving tolerance induction with anti-CD154 mAb and rapamycin.[735] While peripheral deletion in the BMT/anti-CD154 model is not simply explained by exhaustion or "activation-induced cell death,"[551,733,736] activation-induced cell death was implicated in tolerance induction with anti-CD154 mAb plus rapamycin.[737] In addition, veto cells (see the following) can delete alloreactive CTLs. A non-veto mechanism mediated by CD4-CD8- cytotoxic regulatory cells has been reported to delete alloreactive CD8+ T cells with the same specificity as the regulatory cells.[738]

Anergy. Anergy is a state that may result when lymphocytes recognize antigen without adequate accessory or costimulatory signals[706,739,740,741,742] or when they encounter ligands for which they have low affinity.[743,744]

Anergy is an important tolerance mechanism for the many self-reactive B cells that escape deletion in the bone marrow,[745,746] particularly if they recognize abundant but low-avidity antigens.[691,747] Anergy requires persistent antigen and is characterized by immunoglobulin receptor downregulation,[691] altered signaling patterns, and increased apoptosis upon antigen encounter.[747] T-cell tolerance and the resulting absence of help is important for the maintenance of B-cell anergy, as anergic B cells can be activated in the presence of high avidity antigen and T-cell help.[747] Anergy is responsible for the early tolerance of natural antibody-producing B-1 cells in mice rendered mixed chimeric with bone marrow cells expressing an antigen recognized by natural antibodyproducing cells in the recipient.[153,704,705]

A T cell is considered to be "anergic" if it cannot proliferate or produce IL-2 in response to the antigen for which it is specific. T-cell anergy has been associated with altered signaling and

tyrosine phosphorylation patterns.[748,749,750,751] T-cell anergy can often,[752] but not always,[753,754] be overcome by providing exogenous IL-2. Thymocytes are also susceptible to anergy induction by antigens presented on hematopoietic[711] or nonhematopoietic stromal[755,756,757] cells. Anergy is generally reversible in vivo and can be overcome by infection[758] or by removal of antigen,[759,760,761,762] and therefore may not be reliable in transplant recipients, in whom infections may perturb a nondeletional state of tolerance by activating innate immunity.[763,764] While deletion may follow the induction of anergy of T cells in the continued presence of antigen,[765,766] anergic T cells may also persist.[767,768] In a transplantation model involving BMT under cover of costimulatory blockade, peripheral donor-reactive CD4 and CD8 T cells are rendered

antigen-unresponsive prior to their deletion.[550,734,769] Anergic T cells may also have a suppressive effect on other T cells,[770,771] which may involve conditioning of suppressive APCs.[772]

Immunoregulation

Regulatory T Cells. The concept of antigen-specific suppression and the existence of a specialized population of T cells, known initially as suppressor cells and more recently as T_{reg} cells, that could control immune responsiveness, originated in the 1970s from the studies of Gershon and Kondo,[773] among others, who demonstrated the existence of complex regulatory networks involving several levels of T-cell-mediated suppression. In the specific setting of transplantation, a role for suppressor cells in tolerance induction was also identified.[774] However, despite the efforts of many groups through the 1980s, the cellular and molecular characteristics of these suppressor cells were never defined with any precision, even though the phenomenon of suppression was highly reproducible in vivo, particularly in transplant models.

In 1990, Hall and colleagues reexamined the function of T-cell subpopulations present in rats with long-term surviving cardiac allografts after cyclosporine treatment. Interestingly, they reported that tolerance could be adoptively transferred by CD25+CD4+ cells.[775] However, interest in characterizing suppressor/T_{reg} cells was not fully revived until Sakaguchi and colleagues followed up on data showing that susceptible strains of neonatally thymectomized mice developed multiorgan autoimmune disease. These workers found that neonatal thymectomy resulted in a loss of T cells with suppressor or regulatory properties that could be enriched amongst T cells expressing CD25, the alpha chain of the IL-2 receptor.[776]

Naturally occurring or thymus-derived CD25+CD4+ T cells with regulatory properties are generated in the thymus through interaction between the developing thymocytes with an intermediate affinity ligand, too low for negative selection, expressed on nonhematopoietic cells of the thymus for their positive selection.[777,778] Cortical thymic epithelium has been found to be the site of MHC class II expression required for the development of functional T_{reg} cells.[779] In addition to the naturally occurring populations of CD25+CD4+ T cells with regulatory activity, populations of T cells with regulatory properties that also express CD25 can be induced in the periphery following exposure to antigen under certain conditions.[780] These populations are known as antigen-induced or adaptive T_{reg} cells. It is likely that

following transplantation or exposure to alloantigen, T_{reg} cells that can control the immune response and prevent rejection will be derived from both the naturally occurring and induced populations (see the following). In addition to the wealth of data in mice, CD4+ T cells expressing high levels of CD25 in the peripheral blood and thymus have also been shown to have suppressive activity in humans[781,782,783,784,785,786] and are present in transplant recipients with long-term surviving liver allografts.[787,788]

CD25 is by no means an exclusive marker for T cells with regulatory activity. Although the kinetics of expression are different, CD25 is also expressed by activated T cells. Indeed in transplantation, mAbs targeting CD25 are licensed for use as antirejection therapies. Thus, there is a need to define other markers for T_{reg} cells. The list of potential cell surface markers has been growing steadily, and includes CD152 (CTLA4), CD103, CD127, LAP, and glucocorticoid-induced TNF receptor (GITR) related proteinl amongst many others. However, as yet, a T_{reg} cell-specific “perfect cell surface marker” has not been identified.

Intracellular proteins and transcription factors can also potentially provide a tool for identifying committed cell lineages. In both humans and mice, forkhead box protein 3 (foxp3), a forkhead/winged-helix transcription factor, has been shown to be a master regulator for the development and function of T_{reg} cells. In humans, mutations in the Foxp3 gene in patients with the immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome results in uncontrolled activation/expansion of CD4+ T cells, resulting in severe immune deficiency.[789,790] Scurfy mice also have mutations in foxp3 and a related immune profile.[791] A direct link between foxp3 expression and regulatory activity came from retroviral gene transfer studies where transduction of naïve mouse T cells with foxp3 resulted in acquisition of regulatory function.[792] This correlation between foxp3 and regulation has been strengthened by the generation of foxp3 transgenic mice where cells expressing FOXP3 protein express either green[793] or red fluorescent protein,[794] allowing such cells to be identified and their function explored. While in mice the relationship between foxp3 expression and regulation may be tightly linked, the situation may not be so straightforward in humans, as FOXP3 protein has also been found to be expressed transiently in activated T cells.[795] The methylation status of the Foxp3 gene turns out to be a marker of the stability of FOXP3 expression.[796,797]

Recipient-derived CD25+CD4+ T cells were shown to have potent regulatory properties in both the induction and maintenance phases of tolerance to alloantigens in vivo in mice.[798,799,800,801] In BMT, donor CD25+CD4+ T cells present in the bone marrow inoculum were found to protect from GVHD.[802,803,804] In humans, $CD25^{hi}$CD4+ T cells have been found in the peripheral blood of immunosuppression-free allograft recipients,[787] and their presence may contribute to long-term graft survival.[805] As mentioned previously, T_{reg} cells with capacity to control immune responses to a transplant most likely comprise naturally-occurring and alloantigeninduced T_{reg} cell populations.[806] Naturally occurring T_{reg} cells present in naïve, unmanipulated adult mice can prevent rejection of allografts mismatched for a single minor histocompatibility antigen (eg, H-Y). However, they appear to be much less potent than T_{reg} cells induced following exposure to alloantigen, as studies comparing the activity of naturally occurring and induced T_{reg} cells directly suggest that 10 times fewer induced T_{reg} cells are needed to prevent allograft rejection. These findings may

explain why in situations where grafts are mismatched for multiple major and MiHAs it has sometimes been difficult to demonstrate that naturally occurring T_{reg} cells can control the rejection response.

Another situation where T_{reg} cells are less effective at controlling allograft rejection arises when donor alloantigen-reactive memory T cells preexist in the recipient. In this case, the kinetics of activation of the memory cells is very rapid and, unless very high numbers of T_{reg}s are present, the

balance between rejection and regulation is overwhelmingly in favor of rejection.[807] Importantly, this critical balance can be shifted in a number of ways, notably by employing strategies that increase the relative frequency and/or the activation status and consequently the functional activity of induced T_{reg}s that can then respond to donor alloantigens before or in the early period after transplantation[801,808] or by inhibiting the activity of the effector cells.

After transplantation, the ability to generate T_{reg}s in vivo may be influenced by the microenvironment. The balance between the presence of IL-6 and TGF-β in vivo can have a dramatic impact on which T-cell population develops. Importantly, T_{reg} generation can be prevented by inflammation,[809,810] which is commonly present in vivo after cell or organ transplantation, leading instead to the generation of cells capable of mediating tissue damage, including T_H17 cells, which produce IL-17.[809,810,811] T_{reg} stability in the face of an inflammatory response remains a controversial issue.[812,813]

The mechanisms of regulation effected by T_{reg}s to prevent allograft rejection involve a variety of different pathways. When T_{reg}s are reactivated by their cognate antigen through the TCR, they can rapidly and transiently produce IFNγ, which is needed to mediate their regulatory activity and prevent graft rejection.[814] IFNγ triggers the STAT-1 signaling pathway that also influences the functional activity of T_{reg}s.[815] Interestingly, IFNγ has been shown previously to be an essential mediator for the induction of tolerance in mouse models where costimulation blockade was used to prevent graft rejection.[816] The transient production of IFNγ by T_{reg}s can have multiple effects on cells with which they interact,[817] including other T cells, mediated either directly or indirectly through effects on APCs.[818] T_{reg} activity can result in inhibition of cytokine production and secretion, downregulation of costimulatory and/or adhesion molecule expression, inhibition of proliferation, induction of anergy, elimination of the effector population by promoting cell death, or even conversion of naïve and/or effector T cells to a regulatory phenotype, a process known as “infectious tolerance. „[783,819,820,821] IL-2, IL-10, and TGF-β may have a role in this phenomenon.[822] If this process is effective, any new T cells entering the repertoire after transplantation where immunoregulation is the dominant mechanism of tolerance will be converted to T_{reg}s, thereby propagating and reinforcing the tolerant state throughout the posttransplant course.

Indoleamine 2,3 dioxygenease (IDO), an enzyme that catalyses the initial and rate limiting step of the kyneurinine pathway of tryptophan catabolism, is known to be subject to transcriptional regulation by IFNγ[823,824] in a manner that is dependent on STAT-1 signaling.[825] IFNγ released by T_{reg}s can lead to the development of IDO-competent DCs

that may acquire the capacity to control T cells locally through tryptophan depletion, inhibiting alloimmune responses.[826,827,828] The molecular mechanism responsible for the inducing DCs to become IDO producers requires further investigation, but roles for TGF-β and IL-10 have been suggested.[820,829]

In addition, the activity of T_{reg}s in transplant models has been shown to be dependent on IL-10,[541,798,799,830,831,832,833,834] TGF-β, and CTLA-4.[799] CTLA-4 (CD152) is constitutively expressed by T_{reg}s, and engagement of CD80/86 on DCs can also induce IDO.[835] In addition, CTLA-4 has been found to modulate T-cell motility by activating leukocyte function-associated antigen (LFA)-1 clustering and adhesion,[836] thereby altering the threshold for T-cell activation.[836] While the mechanistic links between each of these mediators still requires clarification, it is important to note that many of the same molecules have also been found to be required for T_{reg} activity in other settings, including autoimmune diseases, suggesting that T_{reg}s capable of controlling disease states have many properties in common.

One property of T_{reg}s that can potentially be exploited in the context of transplantation is their ability to mediate bystander regulation in a defined microenvironment in vivo. To elaborate their functional activity, T_{reg}s need to be activated through their TCRs. Data obtained by Thornton and Shevach in vitro showed that reactivation of T_{reg}s with a defined antigen specificity through their TCR enabled the cells to suppress the response of other cells present in the same cultures.[837] Bushell and colleagues have shown that it is possible to exploit this observation in vivo to enable T_{reg}s that are generated and respond to an unrelated protein antigen, such as human gamma globulin, to control rejection when the cells are restimulated through TCR immediately before they are asked to function in vivo.[838]

There is evidence that the location in which T_{reg}s function in vivo may change with time after transplantation. Jones and colleagues have shown that while T_{reg}s are active in the draining lymph nodes in the first few days following skin transplantation, later in the posttransplant course T_{reg}s are found within the allograft itself.[839] Indeed, there is increasing evidence that an important site of immune regulation is within the allograft itself, where T_{reg}s function to create an environment that is permissive of control.[801,840] Moreover, reexposing T_{reg}s to antigen in a tissue may enable them to become more potent suppressors.[841]

Despite the current interest in the role of CD25+CD4+ T_{reg}s, it is important to remember that regulatory activity is not exclusive to CD4+ T cells, and CD8+,[842,843,844] CD8+CD28-,[845] TCR+CD4-CD8- ("double negative"),[846] and NKT cells[847,848] have also been shown to have regulatory activities in different situations after transplantation. In fact, regulatory mechanisms in both the innate and adaptive immune systems will most likely contribute to the overall outcome after transplantation. This is highlighted by the finding that both NKT cells and CD25+CD4+ T_{reg}s play a role in preventing acute GVHD after allogeneic BMT,[802,803,804,847] and by a recent study showing that inhibitory NK cell receptors can play a regulatory role in T-cell homeostasis.[849]

It may be possible to exploit T_{reg}s to control the immune response after transplantation either by developing strategies using immunosuppressive agents that promote T_{reg} generation

and/or do not inhibit their function or by generating T_{reg}s ex vivo and using them as a cellular therapy at different stages in the posttransplant course to prevent rejection and reestablish control. Understanding the impact of immunosuppressive drugs on T_{reg} generation and function is an important part of using the potential of T_{reg}s in vivo. Data from mouse models suggest that calcineurin inhibitors have the capacity to inhibit T-cell apoptosis after activation, thereby

preventing a reduction in the frequency of T cells that mediate rejection that would allow T_{reg}s to assume a more dominant functional role[850,851] (Bushell and Wood, personal communication). Similarly, administration of anti-CD25 monocloncal antibodies after the induction of T_{reg}s can prevent long-term graft survival (Fig. 46.11). On the other hand, other classes of immunosuppressive drugs, such as the mammalian target of rampamycin inhibitors sirolimus and everolimus, may enhance the generation of T_{reg}s.

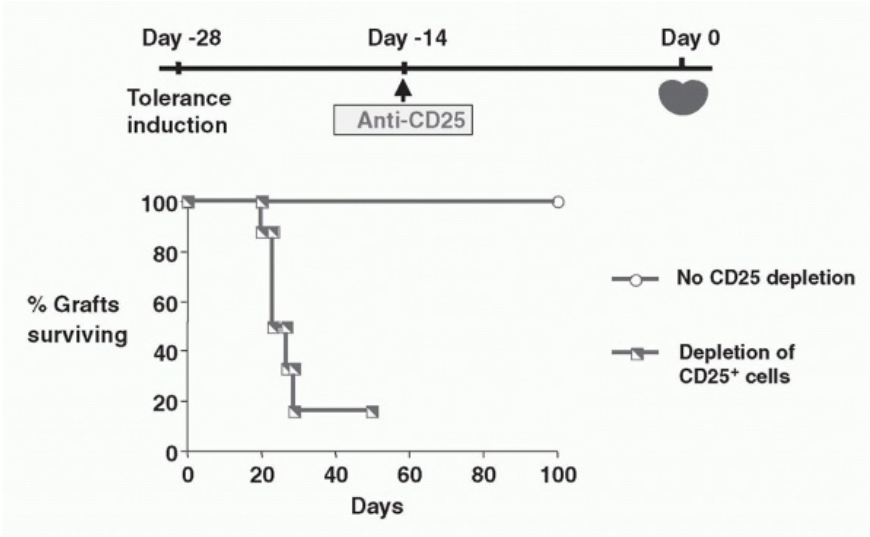

FIG. 46.11. Administration of Anti-Cluster of Differentiation 25 Monocloncal Antibodies after the Induction of Regulatory T Cells can Prevent Long-Term Graft Survival.

Strategies to generate and/or expand T_{reg}s ex vivo for therapeutic purposes are being developed with potential application in cell and organ transplantation. A variety of different approaches have been shown to be successful for generating and/or expanding T cells with regulatory capacity in both mice and humans, including exposure to TGF-β, IFNγ, and stimulation with anti-CD3/CD28 in the presence of IL-2 to name just some.[852,853,854] The development, maintenance, and expansion of T_{reg}s is critically dependent on IL-2.[673,855] Small molecule inhibitors such as phosphodiesterase inhibitors can be used to generate populations of T cells with regulatory activity. In each case, at the end of the culture period, the T cells that emerge have been shown either in vitro and in some studies in vivo to have regulatory activity that can prevent allograft rejection[854] or GVHD.[856,857]

Strategies for expanding human T cells with regulatory activity ex vivo usually rely on selection of a population of CD4+ T cells that contains regulatory cells, either by enriching for cells that express high levels of CD25 alone or low levels of CD127 in addition.[854,858,859]

In proof-of-concept studies using a humanized mouse transplant model, such ex vivo expanded T_{reg}s have been shown to be capable of controlling rejection.[854,860,861]

Antibody-Mediated Suppression. Idiotypes are unique antigenic determinants that characterize the binding sites of antibody or TCRs. These determinants can be antigenic and induce the production of anti-idiotypic antibodies.[862] Antibody-mediated suppression could theoretically occur through the recognition of idiotypes of antidonor immunoglobulin receptors. Anti-idiotypic antibodies can suppress antibody reactivity by directly binding to the antigen-binding site of the antibody, and the development of such antibodies has been suggested as one of the possible benefits of pre-kidney transplant blood transfusions. Such antibodies have also been suggested to contribute to the apparent hyporesponsiveness to noninherited maternal antigens in renal allograft recipients. In the past, it was also considered possible that anti-idiotypic antibodies might inhibit T-cell recognition of antigen, but this now seems unlikely, given that T cells recognize peptide/MHC complexes, whereas antibodies recognize epitopes of intact molecules. It continues to be an intriguing question whether normal regulatory mechanisms for B-cell responses might include anti-idiotypes, as suggested by Jerne.[862a] However, efforts to control transplantation using exogenous anti-idiotypic antibodies to either TCRs or B-cell receptors have been disappointing.[863]

Antibodies can also induce tolerance through a process known as enhancement. Enhancement is defined as prolongation of graft survival achieved by the presence of antigraft antibodies.[864] This phenomenon was first described in experiments involving allogeneic tumor growth. Subsequently, enhancing regimens using anti-MHC antibodies and/or soluble antigen were shown to produce long-term tolerance for rodent allogeneic kidney transplants.[865] The simple interpretation was that anti-MHC antibodies bind to the antigen and thereby block the immune response, but this explanation has not turned out to be sufficient. For example, tolerance following enhancement can be transferred by cells and not serum from enhanced recipients. Apparently, the administered antibody sets up a host reaction that leads to specific immunosuppression. An idiotype/anti-idiotype network would be an attractive explanation for this phenomenon. Unfortunately, the spectacular success obtained using enhancement for kidney graft survival in rats has not been observed for grafts in other species, and this approach has largely been abandoned, at least for the present.

Ignorance and Immune Privilege. Peripheral antigens may be ignored by T cells[866,867,868] or B cells[691] that recognize them. This may be due to the presentation of these antigens by

"non-professional APCs," or it may reflect a failure of recipient T cells to migrate to the antigen-bearing tissue, as in murine solid tumor models.[869] The level of peripheral antigen expression, how recently the responding T cell has emerged from the thymus,[866,870] and the presence of proin-flammatory cytokines[871,872] and costimulatory molecules[873] may all influence the decision of a T cell to ignore or respond to peripheral antigens. However, "ignorance" may be a precarious state, which can be upset by additional immunologic stimuli provoked by inflammation that may be induced, for example, by infections[868] or by presentation of antigen on professional APCs, as observed for endocrine allografts that are depleted of APCs prior to transplantation.[874]

Immunoprotection in specific niches may protect allografts from immune attack, either by

making antigen invisible to the immune system or by providing cell types in the microenvironment that protect the allogeneic cells. An example of the former is corneal transplantation, which is done without systemic immunosuppression due in part to the sequestered status of the anterior chamber of the eye.[875,876,877,878] However, a number of active mechanisms also contribute to this immune privilege.[876,879] An example of a cell that may be protected largely by other cells in its niche is the hematopoietic stem cell, which can survive in an allogeneic stem cell niche without immunosuppression.[880]

Strategies for Inducing Transplantation Tolerance

Strategies to Achieve Central Tolerance

Hematopoietic Chimerism. It has been known for 60 years that hematopoietic chimerism induced in utero is associated with transplantation tolerance.[881,882] The capacity of hematopoietic cells to induce intrathymic clonal deletion achieves tolerance to the most immunogenic allografts, such as fully MHC-mismatched skin and small bowel grafts.[452,883,884] However, HCT has not yet been routinely applied to the induction of tolerance in man. HCT for tolerance induction in rodents originally involved recipient treatment with lethal whole-body irradiation. Removal of mature donor T cells before transplantation prevented GVHD.[885,886,887,888] However, MHC-mismatched allogeneic HCT in humans has proved to be less successful and more dangerous than in rodents because of the toxicity associated with myeloablative conditioning, and the high risk of GVHD, and of engraftment failure when donor T-cell depletion is used to prevent GVHD.[889] Thus, more specific and effective methods of overcoming the barriers to marrow engraftment with minimal GVHD risk are needed for the application of HCT for organ allograft tolerance.

Achievement of a state of mixed rather than full allogeneic hematopoietic chimerism has several advangtages for allograft tolerance induction: 1) Mixed chimerism can be achieved with less toxic (nonmyeloablative) conditioning regimens than those that lead to full donor chimerism. Nonmyeloablative regimens preserve some host hematopoiesis so that life-threatening marrow failure is not a risk if donor marrow is rejected. 2) Mixed chimeras, unlike full chimeras, contain abundant recipient APCs in the periphery, allowing optimal antigen presentation to T cells that have developed in the host thymus, and which therefore preferentially recognize peptide antigens presented by host-type MHC molecules.[126,890] Antiviral CTL responses in mixed chimeras demonstrate exquisite specificity for recipient-derived MHC-restricting elements.[891,892] 3) Mixed chimeras contain hematopoietic cells from both the recipient and the donor in the thymus and hence delete both hostreactive and donor-reactive T cells.[717,893] Thymic stromal cells are less effective at inducing deletion, so intrathymic deletion of host-reactive cells is more complete in mixed compared to full chimeras.[717,894] Tolerance achieved with durable mixed chimerism is “systemic,” as evidenced by specific unresponsiveness to the donor and recipient in mixed lymphocyte response and cell-mediated lympholysis assays, and the acceptance of donor skin grafted at any time post-BMT.[452,895,896,897,898] In contrast, tolerance approaches that do not lead to durable chimerism generally do not induce systemic tolerance, suggesting that tolerance might be less robust.

Several nonmyeloablative approaches have been recently developed to permit the use of BMT to achieve mixed chimerism and specific tolerance, bringing the approach toward clinical application. In mixed chimeras prepared with a nonmyeloablative regimen consisting

of low dose (3 Gy) TBI, T-cell depleting mAbs, and thymic irradiation,[452] intrathymic deletion was shown to be the major mechanism maintaining long-term donor-specific tolerance.[717] Administration of donor MHC-specific antibody to eliminate donor chimerism from established mixed chimeras led to loss of tolerance and to the de novo appearance in the periphery of T cells with receptors that recognize donor antigens. However, if the recipient thymus was removed prior to elimination of chimerism, specific skin graft tolerance was preserved and donor-reactive TCR did not appear.[718] Thus, chimerism is needed only in the thymus and not in the periphery in order to ensure persistent tolerance of a peripheral repertoire that is deleted of donor-reactive cells. In contrast, peripheral anergy and suppression generally require persistent antigen to maintain tolerance. Because thymic APCs are continually turning over, this observation emphasizes the need for hematopoietic stem cell engraftment at sufficient levels to ensure an uninterrupted supply of donor APCs in the recipient thymus for the life of the mixed chimera. The absence of suppressive tolerance mechanisms makes these animals particularly vulnerable to breaking of tolerance when non-tolerant T cells emerge from the thymus after intentional depletion of donor antigen or after exogenous administration of nontolerant host-type T cells.[718,734]

The universal requirements for achievement of lasting chimerism are summarized in Figure 46.12. T-cell alloreactivity in both the thymus and periphery must be overcome in order to permit allogeneic stem cell engraftment and early seeding of the thymus with allogeneic APCs. Intrathymic alloreactivity can be overcome with irradiation,[452] high doses of T cell-depleting antibodies,[899] or costimulatory blockers.[731,896] Peripheral T cell-mediated alloreactivity can be overcome with T cell-depleting mAbs[452,900] or with costimulatory blockers.[731] The need for low-dose TBI or busulfan to facilitate engraftment of donor hematopoietic stem cells[899,901] can be eliminated by administering very high marrow doses[897,900,902] or by adding expanded recipient T_{reg} cells to donor marrow.[903]

The mechanisms of peripheral tolerance achieved with the combination of costimulatory blockade and allogeneic BMT are discussed in the section on peripheral tolerance.

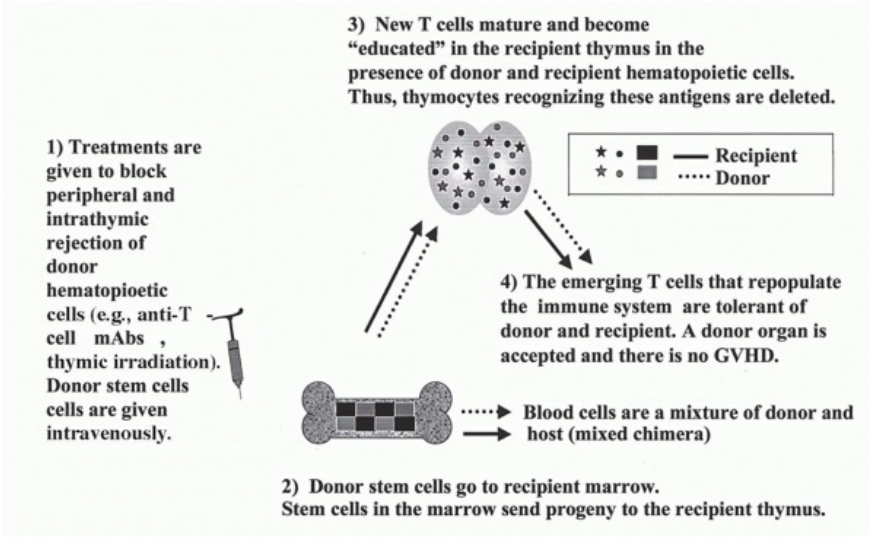

FIG. 46.12. Requirements for Induction of Long-Term Mixed Hematopoietic

Chimerism. GVHD, graft-versus-host disease.

Additional methods for achieving durable mixed chimerism for tolerance induction include the use of total lymphoid irradiation plus BMT[904,905] and various combinations of anti-T cell antibodies, irradiation, and immunosuppressive drugs in both large[906,907,908] and small[909,910,911,912] animals.

It has been difficult to achieve T-cell depletion with antibodies in large animals and humans that is as exhaustive as that achieved in the previously mentioned rodent models, perhaps due to the use of inadequate doses or suboptimal reagents. A second concern is that, if sufficiently exhaustive T-cell depletion could be achieved in humans, T-cell recovery from the thymus might be dangerously slow, especially in older individuals.[913] The ability to replace some[898] or all[731,897,902] T cell-depleting antibodies with costimulatory blockade is therefore of considerable interest.

GVHD does not occur in the rodent models discussed previously, despite the inclusion of T cells in the donor bone marrow graft, probably because of the presence of the T cell-depleting or costimulatory blocking antibodies in the serum of the hosts at the time of BMT.[914]

Extension of the Mixed Chimerism Approach to Xenotransplantation . Host treatment with mAbs to T cells and NK cells along with a low dose (3 Gy) of TBI has also permitted rat marrow engraftment in mice, resulting in mixed xenogeneic chimerism and donor-specific tolerance.[453] Both γδ T cells and NK cells play an important role in resisting xenogeneic marrow engraftment.[454] Anti-CD154 mAbs can overcome the requirement for CD4 cell depletion.[915] Mixed chimerism in the rat-to-mouse species combination was associated with tolerance of both T cells and natural xenoantibody-producing B cells.[453,916,917,918,919] Mixed xenogeneic chimerism thereby prevents HAR, acute vascular rejection, and cell-mediated rejection of vascularized cardiac xenografts.[154]

Pigs are widely believed to be the most suitable xenogeneic donor species for transplantation to humans, but transplantation from this species is impeded by the presence in human sera of Natural Antibodies (Nab) that cause hyperacute rejection of porcine vascularized xenografts. The major specificity recognized by human Nab on porcine tissues is a ubiquitous carbohydrate epitope, Galα1-3Galβ1-4GlcNAc-R (αGal). Humans lack a functional α1-3Gal transferase (GalT) enzyme, as do GalT knockout mice, which also make anti-αGal Nab. Both preexisting and newly developing B cells recognizing anti-αGal are tolerized by the induction of mixed chimerism in GalT knockout mice receiving αGal-expressing allogeneic or xenogeneic marrow.[153,704,920,921] The major immunoglobulin M Nab-producing cells in mice are splenic B-1b cells,[702] and these are tolerized rapidly by an anergy mechanism that is followed later by clonal deletion and/or receptor editing of Gal-specific B cells.[154,704,705,918,922] Splenic B cells, possibly of a similar subset, are also, along with immature plasma cells, the major anti-Gal immunoglobulin M-producing population in nonhuman primates and baboons.[923]

Studies in mixed allogeneic chimeras show that recipient NK cells are tolerized to the donor,[924] and studies in the ratto-mouse combination also indicate a state of NK-cell

tolerance.[925] While this tolerance is specific for the donor in mixed allogeneic chimeras, whose NK cells retain the ability to reject class I-deficient bone marrow,[924] the NK-cell tolerance in mixed xenogeneic chimeras is associated with global NK-cell unresponsiveness.[925] The most plausible explanation for these divergent results is that the presence of a xenogeneic cell population lacking any inhibitory ligand for recipient NK cells results in chronic activation of all NK cells and hence global anergy. Such "disarming" of NK cells could also explain dominant hyporesponsiveness in mixed chimeras involving class I-deficient donors or mosaic class I MHC transgenic mice.[926,927] In general, inhibitory NK receptors are less functional between species than activating receptors.[444,445,446,449,450,928,929,930,931,932,933,934,935,936] In mixed xenogeneic chimeras,

therefore, the xenogeneic cells may lack ligand that inhibit recipient NK cells, which become chronically activated and hence anergic. In contrast, allogeneic cells in mixed allogeneic chimeras express MHC molecules that will inhibit some subsets of recipient NK cells expressing relevant inhibitory receptors. Thus, in mixed allogeneic chimeras, only the subset of recipient NK cells lacking an inhibitory ligand for donor cells will chronically receive unopposed stimulation and hence become anergic; the consequence is a functional NK-cell repertoire that is inhibited by recognition of the donor (in addition to recipient) cells. The dominant tolerance exerted by mixed allogeneic or xenogeneic chimerism favors the "disarming" concept[927] over the "licensing" model, which proposes that inhibitory interactions license NK cells to become functional,[937] as the mechanism for NK-cell tolerance. Consistent with the disarming model, NK cells have been shown to tune their responsiveness in direct proportion to the number of inhibitory interactions they experience in vivo.[938] Moreover, continuous engagement of an NK cell-activating receptor renders NK cells hyporesponsive.[939,940] The complete lack of inhibitory interactions with xenogeneic cells could thereby render all NK cells anergic.

Despite this T-, B-, and NK-cell tolerance in mixed xenogeneic chimeras, the levels of donor chimerism decline gradually over time, due to a competitive advantage of recipient marrow over xenogeneic rat marrow as the host recovers from low-dose TBI.[941] Species specificity or selectivity of cytokines,[942,943] adhesion molecules, and other interactions that regulate hematopoiesis[944] probably account for this advantage. Achievement of xenogeneic hematopoietic repopulation has proved to be an even more formidable challenge in highly disparate (discordant) species combinations. Using immunodeficient mice transgenically expressing porcine hematopoietic cytokines to promote chimerism,[945] proof of principle was obtained that human T cells can be centrally tolerized in a human thymus to porcine xenoantigens via induction of mixed xenogeneic chimerism.[946]

Macrophages pose a major obstacle to engraftment of xenogeneic marrow from highly disparate species,[471,472] probably due to the failure of inhibitory ligands on xenogeneic cells to interact with macrophage inhibitory receptors, as observed for the porcine inhibitory ligand CD47 and the mouse[482] and human macrophage receptor SIRPα.[482,947,948]

Xenogeneic Thymic Transplantation. An alternative approach to achieving xenogeneic T-cell tolerance involves replacement of the recipient thymus with a xenogeneic donor thymus after host T-cell depletion and thymectomy. Immunocompetent mice treated in this way

reconstitute CD4+ T cells in xenogeneic porcine thymic grafts.[949] These cells repopulate the periphery, are competent to resist infection,[950] and are tolerant of porcine donor antigens.[949,951] Tolerance to both donor and host develops, at least in part, by intrathymic deletional mechanisms in these animals, reflecting the presence of class II^{high} APCs from both species within the thymic graft.[951,952] Studies using TCR-transgenic mouse recipients showed that positive selection in such grafts is mediated only by porcine thymic MHC, with no influence of mouse MHC.[953,954] However, excellent immune function is achieved in these mice. Importantly, human T cells can also develop normally and be rendered specifically tolerant of the porcine donor by developing in xenogeneic porcine thymus grafts.[955,956,957,958] This approach has demonstrated promise in pig-to-primate xenograft models.[959,960,961]

Transplantation of allogeneic[962] and concordant xenogeneic[963] thymic epithelial tissue obtained from fetuses before seeding with hematopoietic cells can also induce tolerance by generating donor-specific regulatory cells.[964,965] Transplantation of xenogeneic thymic tissue into congenitally athymic recipients has frequently resulted in the development of a multiorgan autoimmune syndrome, possibly due to the lack of recipient-type thymic epithelium needed for the development of regulatory cells with specificity for certain recipient antigens.[779,966,967,968,969,970] This complication occurs much less frequently in thymectomized, T cell-depleted mice than in congenitally athymic mice receiving porcine thymic transplants,[971] probably due to the persistence of regulatory cells derived from the host thymus prior to thymectomy and T-cell depletion. This autoimmunity can be avoided by adding recipient thymic epithelial cells to the thymic xenograft, resulting in improved deletion of recipient-reactive T cells and generation of T_{reg} cells that suppress autoimmune disease.[972]

Development of Chimerism without Host Conditioning

Developmentally Immunoincompetent Recipients. The first demonstration of allogeneic tolerance was obtained in Freemartin cattle, which are fraternal twins that share a placental circulation and develop mixed chimerism spontaneously in utero.[881,882,973] Injection of allogeneic hematopoietic cells to preimmune human fetuses has been used successfully to correct immunodeficiency diseases diagnosed in utero.[974,975,976] Low levels of chimerism have also been achieved in preimmune normal mouse and sheep fetuses.[977,978,979,980] While the ability of in utero HCT to induce transplantation tolerance has been somewhat unpredictable,[981,982] durable chimerism and renal allograft tolerance were achieved in pigs receiving in utero transplantation of T cell-depleted adult bone marrow.[983]

Acquired immune tolerance was first demonstrated by Medawar and colleagues, who injected allogeneic cells and tissue lysates into neonatal mice.[984] Untreated neonatal rodents can achieve skin graft tolerance if they are given allogeneic hematopoietic cells shortly after birth. Lasting microchimerism and sometimes sufficient levels of chimerism for flow cytometric detection (macrochimerism) have been observed.[985,986,987] Both intrathymic and extrathymic deletional mechanisms of tolerance have been implicated,[985,986] and regulatory cells probably play a role, as tolerance cannot be easily broken by the infusion of nontolerant host-type lymphocytes.[985,988,989] Neonatal mice tend to produce Th2 responses, which

have been implicated in tolerance.[362,363] The ability of allogeneic spleen cell infusions to induce tolerance may also reflect the high ratio of non-costimulatory APCs (T and B cells) in donor inocula to recipient T cells in the neonate.[990]

Adult Recipients. Very low levels of chimerism ("microchimerism") can exist for many years in the tissues of human recipients of solid organ allografts who did not receive HCT.[991] This observation led to the hypothesis that microchimerism, resulting from emigration of passenger leukocytes from the graft to recipient tissues, leads to donor-specific tolerance.[992] Microchimerism, which requires highly sensitive techniques for its detection, should be distinguished from the mixed chimerism discussed previously, in which multilineage chimerism is readily measurable by flow cytometry. Mechanisms by which microchimerism might promote peripheral T-cell tolerance include nonprofessional APC function of donor-derived B or T cells[993,994,995] and "veto" activity of T cells and NK cells.[996] However, microchimerism has not been shown to be required for or even necessarily associated with tolerance in a variety of models.[997,998,999,1000,1001]

Donor bone marrow cell infusions without specific myelosuppressive conditioning have been evaluated in efforts to achieve tolerance in patients receiving organ transplantation with standard chronic immunosuppressive therapy.[1002,1003] Such transplants were initially associated with significant risks[1004,1005] without having a measurable impact on acute rejection episodes or immunosuppressive medication doses in kidney[1006,1007] or liver[1008] transplant recipients, despite the persistence of and gradual increase in low levels of chimerism.[1007] A similar approach failed to achieve islet allograft tolerance in patients.[1009] However, long-term kidney allograft survival was favorable in donor marrow-infused compared to noninfused kidney graft recipients,[1010,1011] and immunologic assays suggested that bone marrow promoted donor-specific unresponsiveness.[1012] Immunosuppression withdrawal was not achieved.

Macroscopically detectable, though transient, chimerism has been observed in a nonhuman primate model that includes sublethal TBI.[1013] Myelosuppressive host conditioning may promote marrow engraftment by creating physical niches due to the destruction of host hematopoietic cells and by upregulating cytokines that promote hematopoiesis. Upregulation of chemokine SDF-1, which binds to stem cell CXCR4, and complement (C3) cleavage fragments are implicated in radiation-induced marrow injury and promotion of stem cell homing to that microenvironment.[1014] In mice, myelosuppression is required to promote engraftment of syngeneic marrow cells given in conventional doses,[899] but this requirement can be avoided using very high doses of marrow.[1015,1016] Engraftment of high doses of allogeneic marrow can be achieved without myelosuppressive treatment in mice and pigs receiving T cell-depleting mAbs,[900,1017] or in mice receiving costimulatory blockade.[897,902] The ability of expanded recipient T_{reg} cells to promote chimerism in nonmyelosuppressed recipients of conventional marrow doses[903] and advances in the ability to expand hematopoietic stem cells ex vivo[1018,1019] hold promise for the achievement of mixed chimerism without host myelosuppression in the future.

Strategies to Achieve Peripheral Tolerance

ANTIGEN INFUSION. DST/gene therapy with autologous cells: In rodents, DSTs have the ability to prolong allograft survival,[1020] and in certain donor/recipient combinations have been shown to induce operational tolerance.[1021] In most other species, DST alone has a less dramatic impact on graft outcome, but there is no doubt that it can influence graft survival in a positive manner and even in humans has been shown to be beneficial to graft outcome.[1022,1023] However, alongside these potential positive effects, infusion of cells expressing alloantigens from the organ donor can also have negative effects, including sensitizing the recipient to donor alloantigens, thereby increasing the risk of HAR. Moreover, with the introduction of erythropoietin into clinical practice, there was no longer a medical need to use transfusions to treat dialysis patients on transplant waiting lists; thus, the practice has largely stopped.

Investigations into the mechanisms by which donor alloantigen, either following infusion or as a result of donor antigens released from the graft at the time of transplantation, modifies the immune response to a subsequent transplant have provided important insights into how the adult immune system can be manipulated in vivo. Studies in rodents have shown that the level of induced unresponsiveness varies considerably depending on the quantity and source of alloantigen infused, as well as the immune status of the recipient.[1024] High doses of donor alloantigens expressed by cells of haematopoeitic origin can result in deletion of donor-reactive leukocytes, even in a host that is otherwise naïve. Lower doses of antigen resulted in the development of T cells with suppressive properties (see the following discussion). Interestingly, it was found not to be necessary to pretreat recipients with every donor major and MiHA they would subsequently encounter on the allograft. Exposure to a single donor alloantigen was sufficient to induce some graft prolongation as long as the allograft also expressed the same alloantigen.[1025,1026] This phenomenon was demonstrated in a number of experimental systems involving both transplantation and autoimmune disease, and is referred to as linked unresponsiveness or suppression.[1027,1028,1029] The mechanisms underpinning this effect have subsequently been elucidated and involve T_{reg} cells[1030] that once activated can mediate so-called bystander suppression, a mechanism identified initially in vitro[837] that also operates in vivo, thereby influencing the functional activity of other leukocytes present in the same microenvironment.[838]

An alternative strategy to using allogeneic cells for inducing specific unresponsiveness is to manipulate recipient cells to express defined MHC molecules that are subsequently expressed by the graft. The first proof-of-concept study using this approach transfected a fibroblast cell line of recipient origin with a mouse MHC class I gene, $H2K^b$.[1026] When the transfectants were used to pretreat recipient mice before transplantation, graft survival was prolonged. Obviously, cell lines are not applicable to the clinical situation, and therefore recipient or autologous bone marrow cells and hematopoietic stem cells were investigated as alternatives. This approach, using either replication defective retroviral or adenovirus constructs, has permitted markedly prolonged survival of class I-disparate skin grafts bearing the class I gene that was introduced into the autologous marrow[1031] and fully allogeneic heart allografts.[1032] In some settings, tolerance to the transduced antigens can be induced either by infusing

the transduced cells alone[1033] or by combining the transduced cells with other immune-modulating agents.[1034,1035] As with other approaches to tolerance induction, the persistence of the antigen, either in the form of the transduced cells, or after transplantation, from the graft, is critical to the maintenance of the unresponsive state in vivo.[1036]

TOLEROGENIC ANTIGEN-PRESENTING CELLS. DCs are central to the activation/priming of an immune response, but paradoxically they can also promote the development of tolerance.[173,1037,1038] One of the keys to both effects is the state of maturation of the DC when it functions in vivo and/or its lineage. Initially, immature myeloid DCs that express low levels of MHC class II and costimulatory molecules at the cell surface were identified as the dominant form of DCs that had the capacity to induce T-cell tolerance. In contrast, mature myeloid DCs expressing much higher levels of both MHC and costimulatory molecules were required for priming T-cell responses. However, mature DCs have subsequently also been shown to have the capacity to induce tolerance; therefore, the relationship between the state of maturity of a DC and its tolerogenic potential is now less clear. In addition, plasmacytoid DCs (pDCs) have also been found to have a role in tolerance induction. pDCs were originally defined by their capacity to secrete large amounts of type I IFNs in response to viruses and to play an essential role in protection against inflammatory responses to harmless antigens, but they have now also been shown to be able to induce human T_{reg} cells in vitro that produce significant amounts of interleukin IL-10, low IFNγ, and no IL-4, IL-5, or TGF-beta.[843] pDCs, unlike myeloid DCs, can rapidly express inducible T-cell costimulator-L upon maturation, which has been found to play a key role in the generation of IL-10-producing T_{reg} cells.[1039] In mice, pre-pDCs appear to be capable of facilitating hematopoietic stem cell engraftment, thereby promoting donor-specific skin graft tolerance in allogeneic recipients.[1040] However, the exact role and practicality of using pre-pDCs in this setting requires clarification as T cells are more abundant and hence more powerful in promoting engraftment. Significantly, donor-derived pre-pDCs infused 7 days before transplant were found to prolong subsequent heart allograft survival (from 9 to 22 days) in the absence of immunosuppressive therapy,[1041] but this effect was markedly enhanced by anti-CD154 mAb administration.[1042]

Immature DCs have been shown to promote tolerance to solid organ allografts and bone marrow grafts. For example, a single injection of immature donor-derived DCs 7 days before transplantation of an MHC-mismatched heart allograft extends[1043] or prolongs survival indefinitely[1044] in a donor-specific manner. The potential tolerogenic effects of immature DCs can be potentiated by the coadministration of immune-modulating agents such as costimulation blockade.[1045] Among several distinct approaches to generate stably immature DCs, pharmacologic manipulation may offer a promising and clinically applicable option. For example, sirolimus has been found to inhibit DC maturation and their effector functions.[1046] “Alternatively activated” or “regulatory” DCs, which have low costimulatory ability, were also found to protect MHC-mismatched skin grafts from rejection and to protect mice from lethal acute GVHD when administered 7 days before transplantation.[1047]

Reports showing that mature DCs can induce tolerance despite expressing high levels of MHC and costimulatory molecules include in vitro data with human cells demonstrating that maturation of human monocyte-derived DC with TNF-α and prostaglandin E2 triggered cross-priming and proliferation of CD8+ T cells with tolerogenic properties[1048] and that mature but not immature DCs can prime CD4+ T cells that inhibit allogeneic mixed leukocyte

reactions.[1049] In vivo, bone marrow-derived DCs matured with TNF-α, but not lipopolysaccharide or antibody to CD40, protected mice from CD4+ T cell-mediated experimental autoimmune encephalomyelitis, despite the expression of high levels of MHC class II and costimulatory molecules.[1041,1042,1050]

The molecular mechanisms used by pDCs to promote tolerance are complex,[1051] including evidence that they can promote the differentiation of Foxp3+ T_{reg}s. In transplantation models, tolerizing pDCs can acquire alloantigen in the allograft and then migrate through the blood to home to peripheral lymph nodes where they induce the generation of CCR4+CD4+CD25+Foxp3+ T_{reg}s.[1052] Infusion of donor-derived pDCs 7 days before transplant were significantly found to be capable of prolonging subsequent heart allograft survival (from 9 to 22 days) in the absence of immunosuppressive therapy,[1041] but this effect was markedly enhanced by anti-CD154 mAb administration.[1042] In mice, pre-pDCs appear to be the principal cell type that facilitates hematopoietic stem cell engraftment and induction of donor-specific skin graft tolerance in allogeneic recipients.[843] Although the concept that pDCs have the potential to promote transplantation tolerance has been suggested, the role of pDCs in experimental transplant tolerance remains poorly characterized and may be context dependent.

Taking the data using different populations of DCs together, it seems that both myeloid and pDCs can promote tolerance, and that maturation by itself is not the distinguishing feature that separates their immunogenic from their tolerogenic function. Indeed, maturation is more of a continuum than an “on-off” switch, and a “semimature” state, in which DCs are phenotypically mature but remain poor producers of proinflammatory cytokines, appears to be linked to tolerogenic function.[1053] The combination of DCs administered with costimulatory blockade may be the most promising approach identified thus far.

T-CELL-DEPLETING ANTIBODIES. Many tolerance induction strategies that have been investigated in small and large animals have used depletion of leukocytes (antithymocyte globulin, anti-CD52) or T cells (anti-CD3 with or without immunotoxin, anti-CD2, CD4, and CD8) to create an environment that allows reprogramming of the immune system.[1054] In small animals, the short-term depletion of T cells appears to be sufficient in some situations for tolerance to develop and be maintained in the long-term. The success rate can be enhanced by removing the thymus before transplantation to prevent repopulation of the periphery with T cells after transplantation.[1055] Initial data from primates

using anti-CD3 immunotoxin conjugated alone before transplantation or in combination with deoxyspergualin, a drug that inhibits NF-κB and therefore monocytes and macrophages, at the time of transplantation suggested that T-cell depletion can be used to induce tolerance to donor alloantigens.[1056,1057,1058] However, follow-up trials in humans undergoing renal transplantation and T-cell depletion with the anti-CD52 mAb alemtuzemab revealed that neither profound T-cell depletion alone or in combination with deoxyspergualin induced tolerance in humans.[1059,1060] Nevertheless, clinical results, across organ systems, reveal that acute rejection is lower[1061] and that steroid-free regimens with reduced maintenance doses of immunosuppression may be used after alemtuzemab therapy.[1062,1063,1064]

Depletion of leukocytes at the time of transplantation creates a transient immunodeficiency in the recipient, compromising the recipient's ability to reject the transplant. The degree and

duration of leukocyte depletion achieved in adults and pediatric transplant recipients determine how effective and for how long the graft is protected from immune attack.[1065,1066,1067] However, memory lymphocytes, including those capable of cross-reaction with allogeneic tissues, are not as readily depleted. Thus, while the intense immunosuppression provided by leukocyte-depleting antibodies prevents rejection in the rejection-prone early transplant period,[1061] active treatment can promote the homeostatic proliferation expansion of memory cells.

The downstream events that occur once leukocytes begin to reappear in the recipient's circulation are not well understood. An increased proportion of T_{reg} cells after alemtuzumab induction has been demonstrated and found to be most pronounced in calcineurin inhibitor-sparing protocols with early introduction of sirolimus.[1068] Interestingly, T_{reg} cells present in the peripheral blood of kidney transplant recipients who had received alemtuzumab induction were able to control the functional activity of Th17 cells that were also present.[1069] Marked enrichment of regulatory cells is observed in blood of patients receiving humanized anti-CD2 T cell-depleting therapy in conditioning regimens for BMT.[1070,1071] Enrichment for T_{reg} cells has also been demonstrated in mice after treatment with antithymocyte globulin.[1072,1073]

Studies using TCR-transgenic recipients have shown that when leukocytes are depleted, the maintenance of tolerance depends on transplantation of the graft within a time window of depletion of donor-reactive cells in the thymus and periphery.[1074] If the organ graft is transplanted at the appropriate time, donor-specific cells fail to repopulate from the thymus, whereas cells with reactivity to other antigens repopulate the periphery of recipients with long-term surviving organ grafts. These data can be used to suggest a mechanism for the long-term survival observed in primates treated with anti-CD3 immunotoxin complex. In this case, one can argue that the CD3+ T cells are depleted by the immunotoxin before transplantation. A window of opportunity is created such that when a renal allograft is transplanted, donor-reactive cells are absent from the periphery. As cells repopulate the periphery with time after the transplantation, donor-reactive cells are deleted or eliminated as a result of the presence of the surviving graft.

Although clinical trials utilizing T-cell depletion strategies alone have yet to demonstrate true immunologic tolerance, they have allowed for further larger-scale trials and have fueled combination of this strategy with administration of donor antigen in an attempt to achieve some level of mixed chimerism.[1075]

Costimulatory Blockade and Other Biologic Proteins

WITH SOLID ORGANS. T-cell activation, and hence rejection, is dependent upon multiple signals. Cell surface costimulatory molecules provide “signal 2” which, when combined with “signal 1” through TCR, triggers the activation of naïve T cells.[1076,1077] When signal 1 is forced to act on its own, T cells have been shown to undergo anergy or apoptosis.[1078] The original concept of a single costimulatory pathway has long been superseded, and it is now clear that there are multiple levels at which costimulation can participate both in initiating and determining the direction that an immune response takes.[1079,1080,1081] Nevertheless, targeting costimulatory pathways with either mAbs or recombinant fusion proteins specific for the costimulatory molecule itself or the ligand with which it interacts can be very effective at suppressing immune responses and in some cases may have the capacity to promote

tolerance to donor antigens in vivo.

Members of the immunoglobulin and TNF/TNF receptor superfamilies make up many of the costimulatory molecules that are integral to positive costimulation in the pathway of T-cell activation.[1082] Two pairs of ligandreceptor interactions that seem to play key roles in positive costimulation are CD40/CD40-ligand (CD154), which are members of the TNF:TNF receptor superfamily and CD80/CD86 and CD28, which belong to the immunoglobulin superfamily.[1083] Although the precise mechanisms that each of these costimulatory pathways plays during rejection and tolerance is still not completely understood, the complete abrogation or attenuation of either of these pathways can modulate the immune response to an allograft in vivo. Data from clinical trials using CD28 blockade as part of an immunosuppressive drug strategy has led to the licensing of CTLA-4-immunoglobulin (abatacept) for clinical use in patients with rheumatoid arthritis and of the mutated version of CTLA-4 immunoglobulin LEA29Y (belatacept) for use in kidney transplantation.[1084] Interestingly, anti-CTLA4 therapy (ipilimumab) has also been developed for clinical use, but in this case the approach is to augment immune responsiveness to tumour antigens.[1085]

The B7:Cluster of Differentiation 28/Cytotoxic T-Lymphocyte Antigen-4 Pathway . CD80 (B7-1) and CD86 (B7-2) are expressed as cell surface molecules by APCs and are responsible for delivering additional signals to T cells when they interact with CD28. CD86 and CD80 can also interact with a second molecule, CD152 (CTLA-4), which is expressed by T cells later in the activation process and is expressed constitutively by T_{reg} cells. CD86 and CD80 can exhibit preferential binding to CD28 and CD152, respectively.[1086] In contrast to CD28, CTLA-4 negatively regulates T-cell activation when it engages its ligand on the APC and, as described previously, is implicated in the control of clone size to maintain normal

homeostasis in the immune system.[1087] CTLA-4 is pivotal in regulating the threshold of signals during T-cell activation, and recent findings suggest that upregulation of CTLA-4 expression increases T-cell motility and overrides the TCR-induced stop signal required for stable conjugate formation between T cells and APCs. This results in reduced contact periods between T cells and APCs, leading to decreased cytokine production and proliferation.[1088]

Utilizing the B7:Cluster of Differentiation 28/Cytotoxic T-Lymphocyte Antigen-4 Pathway for Therapeutics. When CTLA-4-immunoglobulin, an immunoglobulin fusion protein of CTLA-4, was produced, it was shown to inhibit graft rejection in xenogeneic and allogeneic systems[1089,1090] and to promote engraftment of allogeneic stem cells.[731] In rodent models, CTLA-4-immunoglobulin therapy alone promoted tolerance to human islet xenografts in mice and, in combination with anti-CD154 (see the following), to vascularized allografts,[1089,1091] an effect that was enhanced when donor antigen was included in the treatment protocol.[1091,1092,1093]

The mechanism by which CTLA-4-immunoglobulin promotes long-term graft survival has been investigated in a mouse model. Blockade of CD80 and CD86 at the time of alloantigen recognition has been suggested to trigger T-cell apoptosis in the early phase after transplantation.[850,851] However, it should be noted that specific markers for alloantigen-specific T cells were not incorporated into this analysis, and therefore this mechanism has not been definitively demonstrated. When an antiapoptotic gene, bcl-x, was expressed in the responding lymphocytes, deletion did not occur, and graft prolongation was prevented. This

finding suggests that CTLA-4-immunoglobulin facilitates graft survival by reducing the number of donor-reactive cells that have to be controlled after transplant.

Although primate studies failed to achieve tolerance with CTLA-4-immunoglobulin,[1094] the theoretical foundation of blocking this pathway to promote graft survival continues to intrigue researchers.[1095] Additionally, it was known that the binding properties of CTLA-4 could be manipulated to optimize the ligation of both CD80 and CD86, a crucial component to experimental efforts at tolerance induction.[1083]

Belatacept. Experiments using CTLA-4-immunoglobulin laid the groundwork for further development of therapeutic agents targeting the B7:CD28/CTLA-4 pathway. Belatacept, LEA29Y, was originally derived from the fusion protein CTLA-4-immunoglobulin, or abatacept.[1096,1097] It differs from CTLA-4-immunoglobulin by two amino acids, conferring an approximately twofold increased binding capacity to CD80 and CD86. This increase in avidity allows for a 10-fold increase in the in vitro suppression of T-cell activation when compared to CTLA-4-immunoglobulin; in nonhuman primate studies, belatacept was found to prolong renal allograft survival and inhibit donor-specific alloantibody production both alone and in combination with other traditional immunosuppressive regimens.[1096] These and other findings allowed for the translation of LEA29Y to renal transplant patients. Results from clinical trials comparing belatacept to cyclosporine in partially randomized studies across 22 centers in North America and Europe of over 200 patients demonstrated that patients treated with belatacept-based therapy had improved renal function, reduction in chronic allograft nephropathy, and decreased calcineurin-related toxicity.[1098] Additionally, recent experiments in nonhuman primates using neonatal porcine islet grafts have revealed long-term xenograft survival under the cover of CD28-CD154 blockade with maintenance immunosuppression of sirolimus and belatacept.[1099] The use of belatacept in clinical transplantation has revealed some safety concerns, particularly when high doses were used.[1100]

Cluster of Differentiation 40-Cluster of Differentiation 154 Pathway . The CD40-CD154 pathway has been targeted to inhibit graft rejection using mAb therapy either alone[1101,1102,1103] or in combination with alloantigen infusion.[1104] CD154, or CD40-ligand, is a type 2 membrane protein of the TNF family and is expressed predominantly by activated CD4+ T cells and by a small proportion of CD8+ T cells, NK cells and eosinophils,[1105] and, significantly, on platelets as well.[1106] Structural models predict that CD154 forms a homotrimer that binds to CD40 on the surface of APCs. CD40 is expressed by B cells, macrophages, DCs, and thymic epithelium, and is inducible on the surface of endothelial cells and fibroblasts.

The CD40-CD154 pathway interaction is pivotal for the induction of humoral and cellular responses to nominal antigens as well as alloantigens. A CD40-immunoglobulin fusion protein and a blocking mAb to CD154 were shown to inhibit B-cell cycling, proliferation, and differentiation into plasma cells in response to T cell-dependent antigens.[1107] In vivo studies using CD154 mAb or CD40 or CD154 knockout mice[1108,1109] demonstrated a crucial role for this interaction in the generation of primary and secondary humoral responses to T cell-dependent antigens, class switching, and development of germinal centers. The lack of a humoral response in the absence of CD40-CD40L interaction is due not only to a lack of signaling through CD40 on the B-cell surface, but also to inhibition of priming of CD4+ T cells through CD40L.[1110]

The CD40-CD154 pathway is bidirectional. Not only does CD154 engagement on T cells augment T-cell activation, but also CD40 triggering on the APC primes the APC for stimulation. Signals through CD40 have been shown to upregulate expression of CD80 and CD86, as well as induce IL-12.[1111] Activation of DCs through CD40 promotes their ability to present antigen to T cells; this may explain why targeting CD154 and blocking its ability to interact with CD40 has a profound effect on T cell-dependent immune responses in vivo. Blocking CD154-CD40 interactions may promote tolerance induction by altering both this interaction and signals between APCs and immunoregulatory and suppressor T cells.[1112]

Utilizing the CD40-CD154 Pathway for Therapeutic Intervention in Cell and Organ Transplantation. Long-term acceptance of cardiac, renal, and islet allografts in several mouse and nonhuman primate models has been achieved with CD40 blockade using anti-CD154 mAb as monotherapy or in conjunction with anti-CD28.[1101,1104,1113,1114] However, with

the exception of BMT, in which durable chimerism and tolerance can be achieved with anti-CD154 mAb,[731,1115,1116] tolerance is not generated by anti-CD154 therapy alone in stringent models, in which therapy withdrawal leads to rejection.[1117,1118]

Further studies in the mouse revealed that only when rejection was dependent upon CD4+ T cells was CD154 blockade on its own effective at prolonging graft survival. In fact, several studies in donor-recipient combinations in which CD8+ T cells also play a role in rejection have shown that the CD8+ T-cell subset is unaffected by CD154 mAb therapy,[1119,1120] such that CD8+ T cells become activated, proliferate, and home to the graft in the presence of high-dose continued anti-CD154 mAb therapy. The addition of low dose TBI with donor hematopoietic cells can overcome this CD8+ T cell-mediated resistance.[1121]

Interest in this approach was also reflected in reports that a humanized mAb specific for CD154 (hu5c8) was capable of prolonging the survival of renal and islet allografts in rhesus monkeys.[1094,1102,1122] The initial data from these primate studies appeared encouraging, with rejection-free survival of the kidney grafts, provided that antibody therapy at a relatively high dose (25 mg/kg) was continued in the first 6 months after transplant. When anti-CD154 therapy was discontinued after the first month after transplant, rejection episodes did occur. Analysis of the status of recipients with long-term surviving grafts showed that peripheral lymphocytes from the monkeys failed to respond in vitro to donor antigens, but the recipients developed antidonor antibodies and biopsy samples from some of the long-term surviving grafts revealed T-cell infiltrates.

Together, these observations were sufficiently encouraging to initiate a pilot clinical study using Hu5c8 in renal transplantation. In this study, Hu5c8 was administered to seven patients with low-dose steroid alone, and five patients went on to experience episodes of rejection.[1123] Moreover, the unexpected complication of thrombogenesis in some patients treated with anti-CD154 highlighted that CD154 plays a key role in coagulation and clotting, with some reports suggesting that CD154 acts to stabilize thrombi while others implicate CD154 in platelet activation.[1106]

Other variants of costimulatory blockade that target different epitopes of CD154 have been developed with hopes of improved efficacy in transplantation without promotion of thrombogenesis. Experimental results in cardiac allografts of cynomolgus monkeys treated with an inhibitor of CD154, IDEC-131, either alone or in combination with leukocyte depletion in the form of antithymocyte globulin prolonged allograft survival; however, tolerance was not

induced, as alloantibody production and transplant vasculopathy, while delayed, still occurred.[1124] Still other anti-CD154 antibodies, such as ABI793, have been developed, but have been plagued with continued thromboembolic complications.[1125] Whatever the role that CD154 may play in prolonging allograft survival, it is clear that this molecule acts via independent pathways in a variety of cascades unrelated to tolerance induction.[1083]

Further studies have been undertaken to evaluate antibodies targeting CD40 in order to bypass the potential ramifications of CD154 blockade. Initial animal knockout models revealed a propensity of CD154 knockout mice to develop unstable thrombi, a phenomenon not seen in CD40 knockout mice.[1126] Studies in primate renal allograft models reveal promising results with a short course of low-dose calcineurin inhibitor administered concomitantly with anti-CD40/anti-CD86 costimulation blockade[1127] or with anti-CD40 therapy alone.[1128] Trials using a fully humanized anti-CD40 antiagonist are currently in phase II clinical development.

Targeting Cluster of Differentiation 3 and Accessory Molecules . Initially, administration of depleting anti-CD4 and anti-CD8 mAbs was shown to result in prolonged graft survival.[1129,1130,1131] That this treatment strategy resulted in antigen-specific tolerance was first shown most clearly when a protein antigen was administered in conjunction with a depleting anti-CD4 mAb.[1132,1133,1134] Refinements of these types of protocols have resulted in the ability to achieve long-term T-cell unresponsiveness to protein and alloantigens in the absence of T-cell depletion in experimental models.[1135,1136,1137] In fact, many other accessory molecules, other than anti-CD4 and anti-CD8, have been targeted in an attempt to induce tolerance in models of bone marrow,[1138,1139] islet,[1140] renal,[1141,1142] and cardiac allografts,[1139,1143] to name a few.[1144]

OKT3, a murine antihuman CD3 mAb, received approval for human use in 1986 in kidney transplant patients undergoing rejection and eventually for liver and cardiac transplant recipients as well.[1145] Although widely used, OKT3 brings with it the undesired complications of the human antimouse antibody response as well as a first dose reaction characterized by fevers, chills, and gastrointestinal, respiratory, and cardiac complications.[1146,1147] These ramifications are thought to be the result of CD3 cross-linking activating the signaling pathways downstream of the TCR, leading to transient T-cell activation and subsequent cytokine release.[1145] Therefore, investigators have attempted to construct pharmacotherapeutics that mimic the efficacy of OKT3 with less immunogenicity.[1148] These designer anti-CD3 monoclonals retain T-cell stimulatory capacity, albeit greatly impaired, as a consequence of their failure to readily cross-link targeted CD3 molecules on the cell surface. Interestingly, these antibodies stimulate T cells to express TGF-β, a potent, immunosuppressive cytokine, an effect crucial to immune tolerizing effects achieved in autoimmune models.[1148] Early clinical studies using the humanized “nonstimulatory” anti-CD3 antibodies, teplizumab and otelixizumab, showed some benefit in patients with new onset type 1 diabetes,[1145,1149,1150,1151] though lasting insulin independence was not achieved. While anti-CD3 mAbs have the potential to tilt the balance of immunity toward tolerance, adjunctive agents may be required to enable use safe nontoxic doses in attempts to reinstate tolerance. As yet, neither has been introduced into clinical transplantation.

Along with anti-CD3, antibodies to CD11a (LFA-1) and its ligands, ICAM-1, -2, and -3, have been investigated and have led to prolonged graft survival in many of the aforementioned models. LFA-1 has been implicated as an essential molecule for cellular trafficking and motility as well

as T-cell activation.[1152,1153] Additionally, the interaction of LFA-1 and the ICAM molecules may serve as a costimulatory pairing for T-cell activation.[1154] Preclinical studies in transplant models have shown that combining anti-LFA-1 with costimulatory blockade may be efficacious[1155]; these findings are supported by results of a pilot clinical study using efalizumab in islet transplantation.[1156]

Operational tolerance induced in animals by these strategies has been shown to develop over several weeks after the initial antigen encounter.[1157,1158] When a combination of donor antigen and mAb therapy targeting accessory molecules is used, the precise mechanism of tolerance induction in part depends on the amount of antigen infused.[1137] Deletion also may be one of the initial mechanisms of tolerance,[1024,1159] but in the absence of complete deletion of donor-reactive cells, immunoregulation develops. When antibodies targeting accessory molecules are used as therapeutic agents at the time of transplantation, immunoregulation is the dominant mechanism that comes into play to maintain tolerance in the longer term.

In these systems, tolerance to donor antigens is induced and/or maintained as a result of the development of a population of T_{reg} and suppressor T cells that can mediate unresponsiveness to the initiating donor antigen as well as other antigens present on the graft (linked unresponsiveness).[1160] In mice and rats, this type of tolerance has been shown to be infectious[1161]; it can be transferred from one generation of cells to another, provided that there is sufficient period of contact between the two populations.

The maintenance of tolerance in these systems requires the persistent presence of antigen in the form of the organ when the thymus is still functional.[1162] In the absence of donor antigen, tolerance is eventually lost, presumably as a result of the export of naïve T cells from the thymus into the periphery. Quantitatively, if these cells fail to encounter antigen, they eventually outnumber the unresponsive T cells induced by the monoclonal antibody therapy.

Costimulatory Blockade with Infusion of Donor Cells

While long-term tolerance is maintained by intrathymic deletion in mixed chimeras prepared with costimulatory blockade,[731,897,898] initial tolerance of peripheral T cells involves specific deletion of donor-reactive CD4[734] and CD8[533] T cells. The deletion of CD4 cells achieved following BMT with anti-CD154 is not due to binding of anti-CD154 mAb to activated T cells, and only requires absence of the CD154-CD40 interaction.[1163] Peripheral deletion of donorspecific CD8 cells occurs within 1 to 2 weeks. CD25-negative CD4 cells are required for CD8 tolerance only during this initial 2-week period.[533] Deletion of peripheral donor-specific CD4 and CD8 cells is preceded by specific unresponsiveness toward the donor.[550,734,1163] Regulatory cells do not appear to play a major role in maintaining the long-term tolerance in this model, as tolerance and chimerism are obliterated by the infusion of relatively small numbers of nontolerant recipient-type lymphocytes and linked suppression is not observed.[734] Because hematopoietic stem cell engraftment ensures complete central

deletional tolerance in these longterm chimeras,[731,732,897,898] and specific peripheral deletion is quite complete, the absence of donor-reactive T cells may preclude the expansion and maintainence of specific regulatory mechanisms.

Administration of DST with anti-CD40L mAb prevents islet allograft rejection,[1164] but in contrast to BMT, does not achieve central deletion[896,897] and is most effective in thymectomized mice.[540,729,1165] The inability to resist breaking of tolerance by new thymic emigrants in this model argues against powerful peripheral regulatory mechanisms, but CD4 cells are needed to promote skin graft acceptance.[540] DST promotes peripheral deletion of donor-reactive CD8 T cells[729] and can be replaced by CD8 depletion with mAbs.[1166] The combination of anti-CD154, BMT, and DST seems to be particularly effective in achieving mixed chimerism, largely because of the capacity of DST to overcome residual CD8 T cell-mediated alloresistance.[730,1167]

Costimulatory blockers can also be used to prevent GVHD, using B7/CD28 blockade or anti-CD154 mAb,[1168,1169,1170] or pre-BMT exposure of donor T cells to recipient alloantigens in the presence of anti-CD40L.[1171] Clinically, HLA-mismatched BMT has been attempted with T cells anergized by exposures to recipient alloantigens in the presence of CD28/B7 blockade, with apparently reduced GVHD.[1172,1173]

A Large Animal Model

MHC-defined, inbred miniature swine have provided an instructive model for delineation of the role of various histoincompatibilities in tolerance and rejection in large animals. Studies of pig renal transplantation have demonstrated that spontaneous tolerance can be induced by organ grafts when MHC antigens are matched. The ability to achieve such tolerance is dependent on one or possibly two non-MHC-linked genetic loci in the recipient animals. The presence of the “acceptor” phenotype also permits the spontaneous acceptance of single haplotype class I-mismatched kidney grafts.[7] Graft acceptance is associated with donor-specific CTL unresponsiveness, apparently due to a deficiency in help for these CTL, and not due to a deletional mechanism. Thus, in class II-matched, class I-mismatched porcine donor-recipient pairs, a 12-day course of high-dose (10 mg/kg/day) cyclosporine (CsA) permits long-term renal allograft acceptance in 100% of cases.[7]

The requirement that class II antigens be matched between donor and recipient in order for this tolerance to be achieved may reflect the influence of a major difference in class II antigen expression that exists between large and small animals. Unlike large animals and man, in which class II antigens are expressed constitutively on vascular endothelial cells, the corresponding endothelial cells of rodent species do not express MHC class II molecules.[18,19] Consistent with this interpretation, the use of a short course of CsA can facilitate the ability of renal allografts to induce tolerance in rodents across fully MHC-mismatched barriers, but tolerance induction in swine requires class II matching between donor and recipient for uniform success.

Animals accepting class II-matched allografts are systemically tolerant to the donor's class I and minor antigens, as indicated by the fact that the accepted graft can be removed and replaced by a second donor-matched graft,

which is accepted without immunosuppressive therapy. This ability of CsA to facilitate

tolerance induction, and the ability of exogenous IL-2 to prevent the induction of tolerance in this model,[7] is consistent with the interpretation that induction of tolerance of donor class I-reactive CTLs is due, at least in part, to the absence of adequate T-cell "help" during the time of initial exposure to antigen. A selective decrease of expression of the Th1-associated cytokine IFNγ relative to the Th2-associated cytokine IL-10 has been observed in these accepted grafts.[1174] The thymus appears to play a role in the induction of tolerance among preexisting peripheral T cells in this model, as removal of the host thymus prior to kidney allotransplantation leads to rejection.[1175,1176,1177] The possible mechanisms responsible for this role of the thymus in inducing peripheral tolerance phenomena are discussed elsewhere in this chapter. The kidney allograft itself clearly plays an important role in the tolerance induced in this model. Class II-matched cardiac allografts are not accepted after a similar short course of CsA, but they are accepted if grafted to animals that are tolerized in this manner to kidney allografts bearing the same mismatched class I alleles as the donor heart.[631] The mechanisms of this tolerance has been demonstrated to involve T_{reg} cells that can specifically suppress antidonor CTL responses.[1178,1179,1180]

The Relationship between Peripheral T-Cell Tolerance and Central Tolerance

The thymus can play an active role in tolerizing peripheral T cells. For example, in the pig model involving a short course of CsA with kidney transplantation, the recipient thymus is required to achieve tolerance among preexisting peripheral T cells.[1176] In rats, peripheral tolerance can be achieved by intrathymic injection of donor antigens combined with peripheral organ transplantation.[1181,1182,1183] The capacity of T cells that are activated in the periphery to migrate to the thymus,[1184,1185,1186] migration of donor graft APCs to the thymus where they induce thymic T-cell deletion,[1187,1188] or the development of T_{reg} cells that migrate to the periphery and promote tolerance[1189,1190] may contribute to this role for the thymus in peripheral tolerance induction. T_{reg}s have indeed been implicated in both the pig model and the rat intrathymic injection model.[1179,1191,1192] The intrathymic injection approach has not been successful in "high responder" rat strain combinations[1193,1194] and has not successfully prevented xenograft rejection or chronic rejection of cardiac allografts.[1195] While one attempt to use this approach in nonhuman primates was discouraging,[1196] donor-specific skin graft prolongation was reported in three animals receiving allogeneic or xenogeneic (human) CD34+ cells intrathymically.[1197]

From Animal Models to Clinical Transplantation Tolerance

Almost every transplant clinician has treated patients who have chosen to withdraw immunosuppressive therapy for a variety of reasons. While the majority of such patients reject their allograft, rare cases achieve "spontaneous" tolerance in this manner, demonstrating that tolerance can be achieved in humans. Blood biomarkers have been described that identify tolerant patients who have been successfully weaned from immunosuppression,[1198,1199,1200] but so far none have been used to identify such patients before immunosuppression withdrawal and thereby shown to have predictive value. In general, short-term results of most organ allograft transplants are excellent, making it essential to have reliable methods of inducing tolerance in order to ethically justify their use in place of conventional chronic immunosuppressive therapies. Because the risk of rejection

due to immunosuppression withdrawal is difficult to accept in patients, it is our opinion that extension of results from animal models to humans should only be attempted after 1) rodent studies have demonstrated robust tolerance in multiple strain combinations using extensively histoincompatible, highly immunogenic grafts such as skin; 2) efficacy has been demonstrated in large animal models; and 3) acceptable toxicity has been demonstrated in large animal models. When complete removal of immunosuppression is likely to be achieved, the level of toxicity accepted in the short term may be somewhat higher than that which could be acceptable on a longterm basis. Most efforts to achieve peripheral tolerance in larger animals have not been as effective as in rodent models.

The extensive animal data that have been accumulated on the ability of mixed chimerism induced with reduced intensity conditioning to achieve robust transplantation tolerance, including its demonstration in large animal models,[1013,1201] combined with clinical data obtained in patients with a more conventional indication for HCT, have allowed clinical evaluation of this approach for tolerance induction. Mixed chimerism can be achieved with reduced toxicity using nonmyeloablative conditioning in patients with hematologic malignancies,[1202] and lymphohematopoietic graft-versus-host reactions induced by donor lymphocyte infusion (DLI) can be used to achieve graft-versus-tumor effects.[1203] These observations provided an opportunity to evaluate the potential of this approach to induce transplantation tolerance in patients with a hematologic malignancy, multiple myeloma, and consequent renal failure. Recipients of a simultaneous nonmyeloablative BMT and renal allograft from HLA-identical siblings achieved either transient or durable mixed chimerism or, in a few cases, full allogeneic chimerism (some after DLIs). All three subsets of patients accepted their kidney grafts without any immunosuppression for follow-up periods of up to 14 years, with very good tumor responses.[1204,1205] In vitro studies suggested that, in patients who lost their chimerism, tolerance may be specific for donor antigens expressed by the kidney, while responses to antigens expressed on hematopoietic cells but not the kidney may even be sensitized.[1204] T_{reg} cells may also be involved.[634,1204] These promising efficacy results, combined with safety data in patients receiving HLA-mismatched transplants for hematologic malignancies,[1206] cleared the way for trials of HLA-mismatched haploidentical bone marrow and kidney grafts in patients with no malignant disease (ie, BMT was performed solely for allograft tolerance induction), using a regimen that had led to transient mixed chimerism without GVHD in an initial cohort of patients with hematologic malignancies. Donor kidneys were accepted off immunosuppression in 7 of 10 patients, with

follow-up for as long as 10 years in the first patient at the time of this writing. These studies were the first intentional protocol to achieve transplantation tolerance across HLA barriers in humans. Mechanistic studies implicated regulatory cells and the kidney graft itself as possible contributors to long-term, systemic, donor-specific tolerance that may involve eventual peripheral deletion of donor-reactive T cells.[635,636,1207,1208] Several additional protocols have recently used different nonmyeloablative HCT protocols to achieve allograft tolerance across minor histocompatibility[615,617] or HLA[1209] barriers. The different mechanisms involved with these various approaches have recently been reviewed.[1210,1211] Both T_{reg}s and inducible NKT cells have been implicated in the HLA-identical combined kidney-BMT protocol developed at Stanford.[615,617,1211] A poorly understood “facilitating cell” population was suggested to be involved in the full chimerism achieved across HLA barriers, reportedly without GVHD, in five patients at Northwestern University. However, the safety of this latter

protocol remains to be established, and a life-threatening complication led to infusion of recipient lymphocytes for rescue, resulting in graft rejection in one of the patients.[1209] Animal studies would predict that these full chimeras with extensive (up to five of six) HLA mismatches might not regain full immunocompetence.[891,892]

TRANSPLANTATION OF SPECIFIC ORGANS AND TISSUES

Kidney Transplantation

Kidneys are the most frequently transplanted human organs, with approximately 10,000 kidney transplants being performed annually in the United States. Renal allograft survival has increased steadily since its inception, and at present there is over 95% patient survival and over 91% organ survival at 1 year.[1212] However, even well-matched recipients of renal transplants must continue to take immunosuppressive medications for the rest of their lives, with complications including an increased risk of infection, cancer, hypertension, and metabolic bone disease. In addition, even when immunosuppression is well managed, there is an inexorable loss of kidneys to chronic rejection at a rate of approximately 5% to 7% per year. Both of these problems might be eliminated by the induction of tolerance, for which clinical trials have recently begun in earnest[615,635,1204,1208,1213,1214] (see previous discussion).

As for other organs, a major obstacle in kidney transplantation is the shortage of organs, which has been a paradoxical consequence of the success of this field. Unlike hearts and livers, where the inadequate supply of cadaveric organs spells death for many potential recipients, candidates for renal transplants are instead faced with long periods on dialysis while they wait for a kidney. This waiting time can be 4 or more years even for unsensitized candidates and even greater for those with high levels of sensitization. To avoid this delay, many patients are now being offered kidneys from living donors, and in many transplant centers the number of living donor renal transplants performed per year now exceeds the number of transplants from cadaver donors.

Sensitization of renal transplant candidates usually results from prior antigen exposure, either by blood transfusions or previous transplants. Such highly sensitized patients are said to have high “panel reactive antibody”; they may wait many years to obtain a kidney that is cross-match negative, and some never receive a transplant at all, despite the recent development of antibody desensitization procedures.[1215] Indeed, as discussed in the following, these patients may be among the first to benefit if and when xenotransplantation becomes a clinical reality.[1216]

Finally, late failure of kidney transplants, or “chronic rejection,” is a continuing problem to the field. This form of graft loss may occur many years after transplantation and it probably involves both immunologic reactivity and other factors, including the effects of the early ischemic injury and the ongoing effects of drugs and metabolic abnormalities in the recipient.[1217] This process leads to an inexorable loss of organs. Thus, although the 1-year survival rate for kidney transplants has improved from roughly 40% to over 90% over the past 40 years, at 5 years there is only 71% graft survival. Indeed, the half-life for kidney transplants has barely increased during the same period and remains less than 10 years.

Liver Transplantation

Transplantation of the liver represents a major technical challenge. For this reason, the organ

and patient survival rates have not been as high as those for renal transplantation, but have nevertheless increased yearly, with a current 1-year organ survival rate of about 80% and patient survival rate of about 86%.[1212] There are currently about 6,000 liver transplants carried out in the United States per year. The severe shortage of available organs has recently led to use of living donors, although the number is still small, accounting for only about 5% of liver transplants, or about 300 cases per year. Immunologically, the liver is relatively resistant to early antibody-mediated rejection, allowing successful transplantation even across blood group barriers and in the face of a positive cross-match, although a negative cross-match is generally considered preferable.[1218,1219,1220] In addition, longterm survival of liver transplants does not appear to be improved by HLA matching between donor and recipient,[1221] and many centers do not even type recipients and donors. Both of these immunologic features may be responsible for the fact that the long-term results of liver transplantation are almost as good as those for kidney, with 65% graft survival and 71% patient survival at 5 years. Finally, transplantation of the liver carries with it large numbers of donor lymphoid cells, thus creating the potential for inducing GVHD.[1222] The symptoms can range from antibody-dependent hemolysis of recipient red blood cells across a blood-group incompatibility to severe or even fatal, full-blown GVHD.

Heart and Lung Transplantation

There are approximately 2,000 heart transplants performed annually in the United States. As might be expected for this vital organ, the 1-year statistics for heart transplantation are approximately the same for patient (87%) and graft (86%) survival.[1212] One of the immunologic issues of particular importance in heart transplantation is the high rate of

atherosclerotic disease in the coronary arteries of the transplanted organ. This atherosclerotic disease is generally considered to be a manifestation of chronic rejection, although the causes appear to include more than just the immune response. Nevertheless, patient and graft survivals are about 70% for heart transplants at 5 years.

The number of lung transplants performed annually in the United States is approximately 1,200, while only about 30 combined heart and lung transplants are performed. The statistics for lung transplant survival are about the same as for liver (82% graft survival and 83% patient survival) over the first year, but then decrease much faster, with 5-year survivals of only about 45% for grafts and 46% for patients.[1212] A major cause of graft loss is a process called bronchiolitis obliterans, thought to be the pulmonary manifestation of chronic rejection.[1223] However, these patients are also highly susceptible to pulmonary infections, which undoubtedly contribute to the poor long-term statistics.

Pancreas and Islet Transplantation

Transplantation of the whole pancreas was almost without success until about 1980, largely for technical reasons. More recently, successful pancreas transplantation to treat diabetes mellitus has been achieved using new technical approaches, with success rates of about 92% at 1 year, approaching those for kidney transplantation, as long as the two organs are transplanted together. There are approximately 850 simultaneous kidney/pancreas transplants per year in the United States. The lower survival rates (77% graft survival at 1 year) achieved when pancreas transplantation is performed alone (about 500 cases annually) probably reflect the difficulty in diagnosing rejection episodes involving this organ. By the time blood sugar levels begin to rise, destruction of the pancreas is generally so far advanced that

it cannot be reversed by immunosuppressive therapy. Measurement of the serum creatinine, reflecting early dysfunction of a simultaneous kidney transplant, allows much earlier detection of rejection and, thus, better outcomes.

Simultaneous transplantation of both a kidney and a pancreas from a single donor has demonstrated, surprisingly, that rejection activity in one organ is not always associated with rejection activity in the other. It is not known whether this occasional dichotomy reflects tissue-specific antigens or localized inflammatory (or regulatory) events in one but not the other organ.

Most pancreas transplantation is carried out as a curative treatment for diabetes mellitus. For this purpose, the potential also exists of transplanting only the insulin-producing islet cells rather than the whole pancreas. In rodent models, both allogeneic and xenogeneic islet transplants have successfully achieved normoglycemia in diabetic animals.[1224,1225] Attempts to extend these results to patients, however, have met with limited success,[1226,1227] and until recently, the results of whole organ pancreas transplantation in correcting the hyperglycemia of diabetes have been far superior to those of islet transplantation.[1228,1229,1230] In 2000, the “Edmonton Protocol”[1231] showed much improved survival of islet transplants at 1 year in 4 of 12 patients, using a new combination of immunosuppressive drugs that appeared to cause less damage to transplanted islets. However, this protocol required use of two or sometimes three pancreases for a single recipient, and by 5 years, in a much larger series of patients, only 10% of patients have remained insulin independent.[1232,1233,1234] Thus, these results, while representing an improvement, remain much inferior to the results of whole organ pancreas transplantation.

Hematopoietic Cell Transplantation

BMTs, and more recently, transplants of hematopoietic stem cells and progenitors mobilized from the marrow into peripheral blood by treatment with granulocyte-colony stimulating factor, are used most commonly for the treatment of otherwise incurable leukemias and lymphomas, aplastic anemia, and congenital immunodeficiency states. Additional applications include hemoglobinopathies and inborn errors of metabolism. Autologous HCT is used for hematologic rescue following high-dose chemo-/radiotherapy for the treatment of malignancies and is currently being explored as a treatment for autoimmune diseases. However, autologous HCT will not be considered further here as it does not involve the broaching of any immunologic barriers.

One fundamental difference between HCT and the transplantation of all other organs is that the recipient's treatment for his or her malignancy usually results in ablation of the immune and hematopoietic systems prior to transplantation (ie, the “conditioning” for transplantation is myeloablative). Originally, hematopoietic cell allografts were administered only as a means of replacing ablated host hematopoiesis. However, clinical experience revealed that one of the main therapeutic benefits of allogeneic HCT is due to the GVL effect of donor lymphocytes.[1235] With the recognition of this immunotherapeutic benefit of allogeneic HCT, clinicians began to evaluate less toxic, nonmyeloablative conditioning as a means of allowing allogeneic marrow to engraft so that donor lymphocytes can mediate GVL effects.[1202,1203,1236,1237] In contrast to HCT for malignancies and other indications in immunocompetent recipients, transplantation for immunodeficiency states does not require myeloablation or immunoablation in order to achieve alloengraftment.

Another major distinguishing feature of HCT is that the recovering immune system in durable

chimeras is tolerant of the donor alloantigens, so there is no requirement for immunosuppressive therapy to prevent allograft rejection once the initial immune resistance to the allograft has been overcome. However, initial rejection must be prevented in order to achieve this state. Mechanisms of hematopoietic cell rejection have been discussed previously. In humans, while the importance of class I mismatching, and particularly that of HLA-C,[1238] might suggest a role for NK cell-mediated rejection, clear evidence for NK cell-mediated rejection has not yet been obtained.[1239] In contrast, a role for classical CTLs is well established in the rejection of even HLA-identical donor marrow following myeloablative conditioning,[1240] particularly when the donor product is T cell depleted[1241,1242] or lowintensity conditioning is used.[1243] Expanded CTLs and or Th against donor MiHAs have been detected in association

with expanded recipient T cells in patients losing chimerism after nonmyeloablative HLA-identical HCT.[1204,1244] Rejection occurs more frequently in the setting of HLA-mismatched related or unrelated donor transplants[1238,1245] and increases even further with T-cell depletion.[1246,1247] Antidonor CTLs specific for the mismatched donor class I[1248] or class II[28,634] allele and class II-specific helper cells[634] have been associated with HLA-mismatched marrow rejection. Donor-specific alloantibodies in presensitized patients are predictive of rejection of mismatched transplants.[1249]

A third unique feature of HCT (as well as transplants of other organs that are rich in lymphoid tissue, such as small intestinal grafts and, to a lesser extent, liver grafts) is the ability of T cells in the allograft to mount an immunologic attack on the recipient's tissues, resulting in GVHD. While GVHD rates and severity are reduced using prophylaxis with nonspecific immunosuppressive drugs, GVHD still afflicts 30% to 50% of recipients of HLA-matched sibling HCT, though this may be reduced by substituting a mammalian target of rampamycin inhibitor for calcineurin inhibitors.[1250] HCT can be extended to additional patients by including umbilical cord blood registries in the donor search, as HLA mismatching is better tolerated in cord blood, possibly due to the naivety/immaturity of the immune cells.[1251,1252] The frequency and severity of the GVHD that develops when extensive HLA barriers are traversed has essentially precluded the routine performance of such transplants from adult donors, though some recent clinical trials using nonmyeloablative conditioning have achieved acceptable GVHD rates.[1206,1253] The establishment of large marrow donor registries and the recognition of common HLA haplotypes has permitted the performance of closely matched transplants from unrelated donors, but these transplants are also associated with a high incidence of severe GVHD, due to the existence of subtle HLA mismatches and more extensive minor histoincompatibilities[13,1251,1254,1255,1256] (see section on Donor Antigens Responsible for Graft Rejection).

The GVL effect of allogeneic lymphocytes, especially T cells, transferred with the donor graft, is due largely to recognition by donor T cells of host alloantigens, which are also expressed on malignant cells. Therefore, while T-cell depletion of the donor graft decreases the incidence of GVHD, this benefit is offset by increased relapse rates[1256] and increased risk of engraftment failure due to rejection.[1246] Graft rejection can be offset by more intensive host conditioning and high doses of donor hematopoietic stem cells, even with extensively (one haplotype) HLA-mismatched stem cell grafts,[1257] but at the expense of delayed

immune reconstitution.[1257,1258] While T cell-mediated GVL effects due to graftversus-host reactivity are greatly diminished with such an approach, this may be compensated for by the ability of NK cells to mediate GVL when the host lacks inhibitory MHC ligands recognized by the donor, at least for acute myelogenous leukemia.[424] Such alloreactive NK cells may also help to promote donor engraftment by eliminating alloresistant host T cells.[424]

A major and elusive goal in the HCT field has been to separate the GVL effect of donor T cells from their potential to cause GVHD. Recently, several new approaches for inhibiting GVHD have been attempted.[1259] The use of costimulatory blockade has been discussed previously. Blockade of proinflammatory cytokines such as TNF-α and IL-1 has shown some efficacy in animal models but were less effective in clinical trials.[386] Many other strategies, such as immune deviation and the use of NKT cells, have been discussed elsewhere in the chapter.

Another approach to separating GVL from the GVHD-inducing capacity of MHC-directed alloreactivity is to separate the HCT and the administration of donor T cells in time, so that the T cells are given after some host recovery from the initial conditioning regimen has occurred. Established mixed hematopoietic chimeras are immunologically tolerant of their original marrow donor's antigens. As expected, a graft-versus-host reaction occurs after administration of nontolerant DLIs, resulting in conversion of mixed hematopoietic chimerism to full donor chimerism. Remarkably, this powerful graft-versus-host alloreaction against lymphohematopoietic cells is not associated with GVHD in mice, even though donor T cells are given in numbers that would cause rapidly lethal GVHD in freshly conditioned recipients.[642,643] Although antihost MHC alloreactivity mediates the most potent GVL effects[268,1260] and GVH-reactive donor T cells can clearly be shown to be activated and proliferating in mixed chimeric recipients of DLI,[268,644] these cells do not migrate to GVHD target tissues (epithelial tissues such as skin, intestines, and liver) unless there are inflammatory signals in those tissues.[644] Such inflammatory signals can be induced by conditioning therapy[645] or by TLR activation,[644] which may be induced by infection or gut translocation of bacteria. The observation that graft-versus-host reactions can be confined to the lymphohematopoietic system suggests an approach to separating GVHD from GVL reactions, as hematologic malignancies reside largely in the lymphohematopoietic system. Proof of principle has been obtained that similar results can be achieved in patients receiving nonmyeloablative BMT with in vivo T-cell depletion of the donor and recipient, followed by delayed DLI for the treatment of lymphomas.[1203,1206] In addition to recovery of epithelial GVHD target tissues from conditioning-induced injury, increasing resistance to GVHD with time may be conferred by recovering T_{reg}-cell populations that downregulate graftversus-host reactions.[1261,1262,1263] Delayed DLI is somewhat variably associated with GVHD in patients, but generally to a lesser degree than would be expected in freshly conditioned recipients of similar cell numbers.[1235,1264]

Graft-versus-host reactions can also be confined to lymphohematopoietic tissues to prevent GVHD by preventing their egress from lymphoid tissues with FTY-720,[1265] preventing attraction to epithelial target tissues by blocking chemokines,[1266,1267,1268] or by reducing tissue inflammation with keratinocyte growth factor,[1269,1270] TLR or MyD88 inhibition, adenosine triphosphate inhibitors, or the nucleotide oligomerization domain/CARD15 axis.[1259]

The surprising protective effect of IL-2 against GVHD[581] may be due in part to its ability to promte T_{reg} expansion, an effect that can be enhanced by administering rapamycin.[1271] Additional approaches to expanding T_{reg}s in vivo include manipulation of DCs with histone deactylase inhibitors,

which results in numerous immunomodulatory effects in addition to T_{reg} expansion.[1259] A clinical trial has been initiated using expanded third-party T_{reg}s in patients receiving cord blood transplantation, but efficacy was not determined in the phase I trial.[1272]

A variety of promising inhibitors of T cells are being explored clinically, such as IL-21 blockade,[1273] protein kinase C theta blockade, and proteasome inhibitors.[1259] Imatinib, a tyrosine kinase inhibitor with strong activity against Philadelphia chromosome-positive leukemias, also inhibits platelet-derived growth factor receptor (PDGF-R) signaling and has promising activity against the fibrosis associated with cGVHD.[1259]

Additional strategies for separating GVHD from allogeneic graft-versus-tumor effects include the transduction of donor T cells with suicide genes so that the alloresponse can be turned off at will, hopefully after residual tumor has been eradicated.[1210,1274,1275] Another approach is to avoid the graftversus-host alloresponse and try to target the donor immune response to tumor-specific antigens.[1276] Minor histocompatibility alloantigens expressed by lymphohematopoietic cells (including leukemias and lymphomas) may also be targeted using in vitro expanded CTLs.[75,1277] Immunization of HCT donors with tumor antigens could help to overcome the very limited frequency of T cells with these specificities,[103] as memory CD4 cells may have reduced GVHD-inducing capacity compared to naïve cells.[1278,1279]

Xenotransplantation

Over the past two decades, the increasing shortage of allogeneic donor organs has evoked a worldwide resurgence of interest in xenotransplantation, that is, the replacement of human organs or tissues with those from a donor of a different species. Routine clinical application of this therapeutic modality is still in the future. However, recent progress, which is reviewed briefly here, offers cause for optimism.

Concordant versus Discordant Xenotransplantation

Xenotransplants have been classified into two groups— “concordant” and “discordant”—on the basis of phylogenetic distance between the species combination, speed of the rejection, and levels of detectable preformed antibodies.[1280] Animals that are evolutionarily closely related and that have minimal or no preformed natural antibodies specific for each other are called “concordant,” whereas animals that belong to evolutionarily distant species and reject organs in a hyperacute manner are termed “discordant.”

Choice of Donor Species for Clinical Xenotransplantation

From a phylogenetic viewpoint, nonhuman primate organs would undoubtedly be the most similar to allotransplants immunologically. However, due to considerations of size, availability, and likelihood of transmission of infectious disease, most investigators have decided against the use of primates as a future source of xenogeneic organs. Instead, the discordant species, swine, has been chosen by many as the most suitable xenograft donor. The pig has

essentially unlimited availability, as well as favorable breeding characteristics, and many of its organ systems are similar to those of humans. Partially inbred miniature swine are a particularly attractive choice, because of their size (adult weights of approximately 120 kg), their physiology (also similar to humans for many organ systems), and their breeding characteristics, which have permitted inbreeding and genetic manipulation.[1281]

Mechanisms of Xenograft Rejection

Xenografts are subject to all four of the rejection mechanisms described previously in this chapter and give rise to more powerful immune responses than allografts, probably for each type of rejection. Primates have large amounts of "natural antibodies," so-called because they are present even though a primate has never been exposed to tissues from pigs. The reason for the presence of these antibodies is that during evolution, at the level of Old World primates, the gene for a particular enzyme was apparently lost due to mutation. This enzyme, α-1,3-galactosyltransferase, puts the sugar αgalactose (αGal) onto cell surface proteins in all species except for Old World primates and humans.[1282] Because the αGal antigen is found on bacteria and other environmental antigens, humans and Old World primates make a large amount of antibody against αGal. It is these anti-Gal antibodies that then react with pig tissues after xenotransplantation, causing vigorous rejection.

In addition, the hyperacute rejection that occurs with pig-to-primate transplantation is more vigorous than in the case of allogeneic blood group disparities. This is true, at least in part, because the complement regulatory proteins expressed by pig endothelium are less efficient in controlling human complement activation than are the human regulatory proteins expressed by human organs. Thus, these molecular incompatibilities also contribute to the increased intensity of the hyperacute rejection mechanism.

Similarly, the factors responsible for accelerated graft rejection are more prominent in xenogeneic than in allogeneic transplantation, probably also because the process is magnified considerably by the failure of regulatory molecules to function effectively with human coagulation factors, thus increasing the tendency toward intravascular thrombosis.[161] The available evidence also suggests that cellmediated immune responses to xenografts are more powerful than those directed to allografts.[1283] Initially, there was some uncertainty about this point as cell-mediated immune responses to xenogeneic stimulating cells were first studied using mouse T cells, for which molecular incompatibilities with human cells lead to weaker direct recognition of xenogeneic than allogeneic stimulators in vitro. In this case, the incompatibilities turned out to involve the accessory molecules that are required for T-cell activation rather than a lack of antigens that stimulate TCRs. Thus, it seemed that cellmediated rejection in vivo might also be weak. However, cell-mediated xenograft rejection, even by mice, has consistently been found to be extremely powerful in vivo, apparently initiated by CD4+ T cells responding to the many additional antigenic peptides through the indirect pathway.

For reasons of potential clinical applicability, greatest attention has been directed at investigation of the

human-antipig cellular response. In contrast to the murine studies, direct responses by human CD4 and CD8 T cells to pig stimulators can be readily measured in vitro.[1284] In addition, the cell-mediated reaction in vitro has been found to include a significant contribution by NK cells that can lyse pig targets. Most of the other molecular interactions involved in cellular immunity that have been examined appear to be at least partially

functional in primate antipig responses. Therefore, human-antipig T-cell responses are likely to be as great or greater than those in allogeneic combinations.

Therapeutic Strategies for Xenotransplantation

There are three main strategies that have been pursued to achieve long-term survival of xenogeneic transplants. The first has been to seek nonspecific immunosuppressive drugs that might prove especially effective for xenotransplantation. Unfortunately, none of the new drugs that have contributed to improved outcomes for allografts have proven sufficient alone to make xenografting possible, and considering the immunologic barriers to xenotransplantation discussed previously, it is unlikely that any such drug exists. Furthermore, the heightened immune response to xenografts compared to allografts suggests that larger amounts of exogenous immunosuppression will be required to achieve xenograft survival comparable to that of allografts. Given the narrow therapeutic window that already exists in allogeneic transplantation, most investigators believe that more than just immunosuppressive drugs will be needed to accomplish widespread clinical application of xenogeneic transplantation. Data so far for long-term survival of functioning pig-to-primate transplants of organs[960] support this impression. However, for islets, recent results with immunosuppression have become sufficiently promising that clinical trials are planned in the United States[1285] and are apparently already underway in New Zealand, although precise details are so far unpublished.

The second therapeutic approach has been to use genetic engineering of donor animals to lessen the immunologic barriers to xenografts. Because the two features that distinguish xenografts from allografts are the larger number of antigens and the molecular incompatibilities between species, these genetic modifications have been aimed primarily at correcting these two disadvantages of xenografts (Fig. 46.13). The first transgenic pigs produced by genetic engineering for xenotransplantation attempted to overcome the species selectivity of complement regulatory proteins. Transgenic pigs were produced that expressed human genes for several of these proteins. Organs from animals expressing one of these molecules (hDAF) have been studied extensively and appear to be more resistant to hyperacute rejection than are those from wild-type pigs,[366] but are nevertheless susceptible to acute humoral rejection.[1286] Numerous other transgenes (see Fig. 46.13) have been tested in attempts to further alter the primate host's humoral response to pig xenografts, but none to date has prolonged the survival of organ transplants beyond the survivals achieved with hDAF organs.[161]

The alternative genetic engineering strategy to the addition of transgenes is the removal or inactivation of genes through knockout technology.[1287] The advent of cloning through nuclear transfer technology, first demonstrated in the famous sheep “Dolly,”[1288] has made knockout technology possible in several large animal species, including pigs. As, as described previously, the major stumbling block in pig-to-primate xenotransplantation has been the large amount of natural antibody in primates directed toward the Gal determinant, investigators have utilized this technology to eliminate this same enzyme from pigs.[1289,1290,1291,1292] These new knockout pigs (called GalT-KO), like humans and Old World primates, do not put αGal on to the surface of their

cells. As a result, xenotransplants can now be performed without the powerful rejection previously caused by natural anti-Gal antibodies. The results have been remarkable, with

increased survivals of both heart and kidney transplants from pigs to baboons.[961,1293,1294] Using immunosuppressive drugs, organ survivals were prolonged using these new Gal knockout (GalT-KO) pigs, but new antibodies soon appeared, causing rejection.[961,1293,1294] However, using a regimen directed toward induction of tolerance (see the following), organ survivals were prolonged markedly, and no rejection was seen.[960] There are still problems to be resolved before such transplants will be attempted in patients, but survivals are now being measured in months rather than in days, as they were only a few years ago.

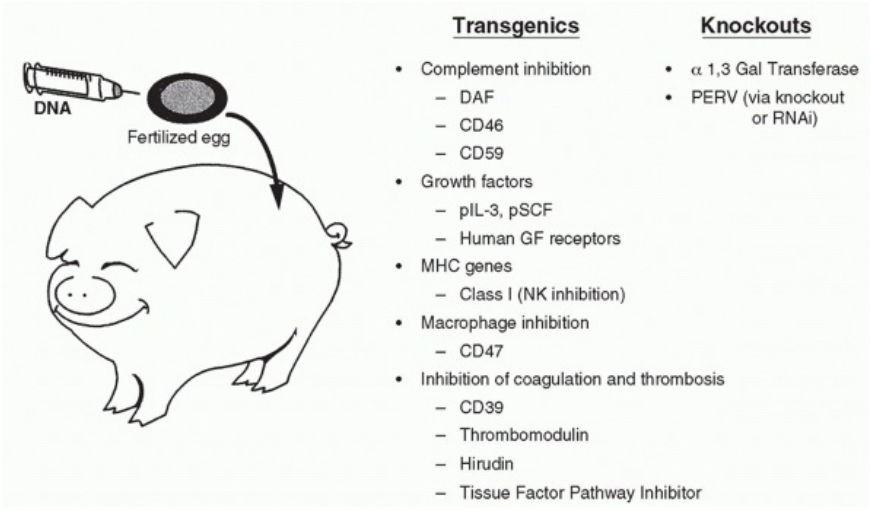

FIG. 46.13. Genetically Modified Pigs as Xenograft Source Animals. GF, growith factors; NK, natural killer; PERV, pig endogenous retroviruses.

The third strategy to achieve successful xenotransplantation is the induction of tolerance of donor antigens. Potential applications of this strategy have been described previously in this chapter, with reference mainly to transplantation in rodent models. There have been attempts to utilize either mixed chimerism or thymic transplantation to induce tolerance across xenogeneic barriers in primates. So far, long-term success by the mixed chimerism approach has been attained only for concordant cynomolgus monkey to baboon renal transplants.[1295] Both mixed chimerism and thymic transplantation approaches had been attempted for the discordant pig to baboon combination before the availability of GalT-KO swine, but with limited success.[1296,1297,1298] However, combining the thymic transplantation approach with the use of the GalT-KO as a source of donor kidneys has extended survivals to over 3 months.[960] Thus, it seems possible that elimination of the natural antibody problem along with tolerance induction could make discordant xenotransplantation as successful as allogeneic transplantation in providing a long-term solution for patients waiting for transplants. Of course, it is possible that when these barriers are overcome, other obstacles, not yet apparent, will still limit the survival of xenogeneic transplants, and additional measures will be required to achieve success.

Nonimmunologic Barriers to Xenotransplantation

In addition to the immunologic mechanisms that prevent successful xenografting, there are two other potentially important obstacles to clinical application. First, molecular

incompatibilities between species may cause physiologic dysfunction of xenogeneic organs. This kind of incompatibility is least likely for the heart, for which the function, albeit vital, is relatively simple. It could certainly become an obstacle, however, for the liver, as the liver is known to produce so many different products, including serum proteins and enzymes, that it is likely that at least some of these products may not function properly in a primate host. On the other hand, if the number of incompatibilities leading to physiologic dysfunction is limited, they could be correctable through knockout and transgenic technology. Thus, the physiologic dysfunction of xenogeneic organs is unlikely to be an insurmountable barrier to xenotransplantation.

The other nonimmunologic barrier to xenotransplantation is the risk of cross-species transfer of infectious agents, potentially creating a health hazard, not only for the recipient, but also for society as a whole. This possibility has gained significant attention, both in the scientific literature and in the lay press, and the issue has become confused by enormous uncertainties about the true risks that are involved. “Zoonosis” is a term that has been used for some time to describe the general process of cross-species infection, and the term “xenozoonosis” has been developed to describe infection transmission that might occur as a result of xenotransplantation.[1299] It is important to realize that from the point of view of the individual recipient, the risk of transmitting infection by xenotransplantation is likely to be less than by current clinical allotransplantation, both because of the natural resistance to cross-species transmission of infectious diseases and because it should be possible to screen for and eliminate the presence of known pathogens from the herd of donor pigs.

The major infectious concern, therefore, is that endogenous retroviral sequences from donor cells might infect the recipient's cells, giving rise to previously unrecognized pathogenic viruses.[1300] The concern has been raised that such new viruses might prove hazardous to other human beings in addition to the xenograft recipient.[1301] However, to date there is no evidence that such cross-species transfer after a pig-to-human transplant would generate a virus that would be infectious or pathogenic. Indeed, studies of humans exposed to pig tissues have not revealed any cases of detectable pig endogenous retroviruses.[1302,1303] Nevertheless, the concern about infections from xenotransplantation involves fear of the unknown, for which it is impossible to assign an accurate level of risk. At this time, therefore, public health agencies and members of the transplant community are attempting to design rational approaches for identifying the true risks of xenotransplantation and detecting untoward events rapidly, while at the same time allowing further progress in this potentially enormously important field of transplantation.[1304]

Clinical Progress in Xenotransplantation

Early clinical efforts in xenotransplantation took place in the 1960s and involved organ transplants from nonhuman primates. One of the patients survived for 9 months with normal renal function provided by the kidney of a chimpanzee.[1305] Additional clinical trials thereafter, using baboon hearts and livers, were considerably less successful. More recent clinical trials have involved fetal pig cells transplanted into the brains of patients with Parkinson or Huntington diseases. Survival of pig tissue 8 months after the transplant was documented in a patient taking only moderate doses of immunosuppression.[1306] These studies suggest that cellular xenotransplantation may be achieved more easily, and thus may be performed sooner, than solid organ transplants, especially because free cellular transplants lack the vascular endothelium that is the target for both hyperacute and accelerated rejection. Indeed, xenogeneic islet transplants have already been performed in

New Zealand (see www.sciencemediacentre.co.nz/2011/03/22/nzbio-the-potential-of-livingcell-therapies/), and the recent long-term successes reported for porcine islet transplants into nonhuman primates[1307] has made it likely that clinical trials will soon be initiated in the

United States. For organ xenotransplantation, most investigators believe that further clinical trials should await a reasonable expectation of success on the basis of pig-to-nonhuman primate experimental studies, a goal that is becoming closer but has not yet been realized.

SOME IMMUNOLOGIC ISSUES IN CLINICAL TRANSPLANTATION

The Effect of Antigen Matching on Organ Graft Survival: Clinical Data

In the absence of transplantation antigen disparities, graft rejection does not occur. However, the importance of antigen matching is one of the controversial issues in clinical transplantation. The evidence from transplantation of kidneys using living related donors provides a clinical demonstration of the importance of HLA antigen matching in subsequent graft survival. Data from a large international database on kidney allograft survival from 1985 to 1999 showed a survival half-life of HLA-identical sibling allografts of 23.4 years, as compared to 12.8 years for haploidentical-related allografts. These data support the basic concept that antigen matching matters and that the use of HLA-matched sibling donors is advantageous. The advantage of complete HLA matching for unrelated donors is also clear, although less compelling than for siblings, and has led to the United Network for Organ Sharing (UNOS)-mandated shipping of kidneys to distant centers for fully matched transplants from deceased donors. Whether or not there are advantages to partial HLA matches over full mismatches remains a subject of controversy, and most surgeons consider the length of the ischemic time necessitated by shipping of deceased donor organs as more important than the degree of HLA mismatch, as long as there is a negative crossmatch (see the following).

Human Leukocyte Antigen in Hematopoietic Cell Transplantation

In contrast to the results described previously for solid organ transplants, the importance of HLA matching for unrelated HCT is unquestioned. Although restriction to HLA-matched donors has severely limited the availability of HCT (only 25% of individuals have an HLA-identical sibling; another 5% has a single antigen-mismatched-related donor), severe GVHD and rejection have been prohibitive limitations in the presence of extensive HLA disparity, as is discussed previously in this chapter. High-resolution, polymerase chain reaction-based HLA typing methods have improved the ability to identify mismatches in unrelated donors, and matching at this level has improved outcomes.[1308,1309] While genotypic matching with unrelated donors is possible for patients with major conserved HLA haplotypes,[13,14] this level of typing reduces the chance of finding a fully matched unrelated donor for patients with uncommon HLA types, even with the availability of large registries such as the National Marrow Donor Program in the United States.[1255] Already, many patients do not succeed in finding an unrelated donor, and thus the ongoing effort to identify “acceptable” mismatches in the unrelated donor setting is important.[1310,1311]

Crossmatch

There are several tests designed to detect preexisting antibodies with specificity for donor antigens in the serum of potential recipients. First, recipients and donors must be matched for

ABO blood type, because, with the exception of organs from donors of the A_2 blood group, transplantation across blood group barriers may cause hyperacute rejection (see previous discussion). Second, immediate pretransplant sera from prospective recipients are tested for reactivity against lymphocytes of potential donors. This "crossmatch" is generally performed by a two-step, antibody-mediated, complement-dependent cytotoxicity assay, although methods utilizing flow cytometry and luminex beads are now becoming more popular in many centers. However, whether a positive crossmatch detected only by the highly sensitive luminex bead assay should be considered in allocation of deceased donor kidneys is controversial.[1312]

"Sensitized" Candidates for Organ Transplantation

Because kidneys and many other vascularized organs cannot be transplanted safely into recipients with preexisting antibodies, the clinical goal is to avoid transplantation of organs that express HLA antigens against which the recipient has been sensitized. Except for blood group antibodies, recipient sensitization to transplantation antigens generally occurs by prior exposure to alloantigens as a result of blood transfusion, previous organ transplantation, or, in women, by exposure to paternal antigens on fetal cells during pregnancy and parturition. The degree of sensitization against a potential kidney donor is measured by testing recipient serum on a panel of lymphocytes expressing a broad representation of HLA antigens, thereby assessing panel reactive antibody, as defined previously. Highly sensitized candidates may wait many years to receive a kidney transplant.

The level of sensitization may decrease over time, leading to a negative crossmatch with recently obtained serum, but a positive crossmatch using previously collected sera. Transplantation in the face of this "historical positive crossmatch" has been performed successfully. Until recently, obtaining crossmatch-negative donors by searching for well-matched organs or waiting for a decline in the level of sensitization represented the primary solutions available for sensitized patients. Recently, however, several centers have begun to transplant kidneys in the face of antidonor antibodies by a variety of "desensitization" procedures, including plasmapheresis,[1313] treatment with anti-CD20 mAb (rituximab),[1314,1315,1316] intravenous immunoglobulin,[1317] and/or bortezamib (Velcade, Millenium Pharmaceuticals, Cambridge, MA),[1318] followed by immunosuppression geared toward preventing antibody responses.[130,158,1319]

The Diagnosis of Rejection

In clinical organ transplantation, the most obvious manifestation of the rejection process is usually diminished function of the transplanted organ, but it is important to confirm the immunologic origin of the event before increasing immunosuppression. The measurement of urinary perforin and granzyme B levels may be useful in this diagnosis.[1320,1321]

Nevertheless, the "gold standard" remains histologic examination of the biopsy of the transplanted organ itself. Pathologists have been able to identify the abnormal lymphocytic infiltrate within grafts, to grade the intensity of the infiltrate, and, for some organs, to describe histologic findings characterizing the effects of immunologic injury.[165] Some pathologic changes, including a lymphocytic infiltrate of the vascular wall, seem to be well correlated with rejection activity. In addition, pathologic changes suggesting nonimmunologic causes of renal dysfunction may be helpful in patient management. The immunohistologic finding of

deposition of the complement component C4d in the peritubular capillaries is generally considered to be indicative of antibody-mediated rejection, especially in the kidney.[1322]

Despite the widespread reliance on the biopsy to define episodes of rejection, however, rejection is sometimes difficult to differentiate from drug toxicity and/or viral infection. Furthermore, when routine "protocol" biopsies of well-functioning transplanted organs have been performed, histologic findings have often revealed cellular infiltrates similar to those of rejection. These results are consistent with several experimental models of tolerance induction that have shown intense lymphocytic infiltrates in organs that go on to survive indefinitely and/or in recipients who develop tolerance to the donor antigens.[1323,1324] These studies suggest that the amount of lymphocytic infiltrate detected pathologically may not be helpful in diagnosing rejection episodes and determining the need for treatment.

How Much Immunosuppression is Enough?

While the majority of transplant recipients respond immunologically to their new organ despite immunosuppression, some patients seem never to generate any rejection activity and maintain their transplanted organ with very small doses of immunosuppressive drugs. Indeed, a few patients have been known to stop all of their medications but have kept their transplant for years without rejection. On the other hand, some patients seem to require and tolerate very high doses of exogenous immunosuppression, while others seem to be severely immunocompromised by low doses of these drugs. These observations make it clear that the amount of immunosuppression that is required or that is safe is not the same for every individual or for all grafts. Unfortunately, there is no well-established assay to determine the amount of immunosuppression an individual requires and can safely tolerate for their particular transplant.

CONCLUSION

The great danger in any textbook chapter is that the need to summarize what we think is known will obscure the much greater amount still left to be learned. For example, we have recently gained important insight into the role of APCs in T-cell sensitization, but we still have not explored adequately the role that indirect presentation of alloantigens plays in graft rejection. During the past two decades, we have learned much about the generation and function of CTLs and about their likely role in some mechanisms of graft rejection and GVHD; however, our understanding of noncytolytic mechanisms of rejection and GVHD, and of the role of B cells and alloantibodies, is much more limited. Finally, this chapter has outlined several techniques for the generation of immunologic tolerance to alloantigens in experimental systems; however, the first human beings have only recently been transplanted with tolerance-inducing regimens that allow the early discontinuation of nonspecific immunosuppression and the mechanisms of tolerance, which involve the kidney graft itself, are incompletely understood. The encouraging initial results raise hopes that routine tolerance induction may soon become a broader clinical reality that can be extended to other organs besides the kidney. It is, of course, the great fascination of transplantation immunology that new insights into basic immunologic issues will likely have important consequences for clinical transplantation in the future.

Chapter 47

Cancer Immunology

Hans Schreiber

INTRODUCTION

The goal of this chapter is to provide foundations and key facts in tumor immunology to students, immunologists, and oncologists in order to stimulate critical thinking and experimentation so that we may better prevent, cure, or at least control cancer. The study of cancer has had a tremendous impact on all fields of science (eg, molecular biology, virology, genetics, and immunology). For example, the discovery of the major histocompatibility complex (MHC) by Peter Gorer[7,8] clearly separated cancer immunity from autoimmunity. His successful search for specificity led subsequent generations of investigators to search for cancer-specific changes (eg, the consistent chromosome translocation in chronic myelogenous leukemia[9]). However, conclusive evidence that rejection antigens on cancer cells are cancer-specific came in 1995 when it was shown that they were encoded by somatic cancer-specific mutations.[10,11,12] Inherent in understanding the field of cancer immunology is the need to understand that immunology and cancer are two very large, different, and rapidly evolving complex fields of research. Thus, in order to make the immune system effective to prevent or treat cancer, an understanding of cancer and cancer models is required. The discussion of the important roles of cytokines in many aspects of tumor immunology is integrated in the various parts of this chapter.

CANCER

Despite all the progress in molecular biology and genetics, the pathologist using histologic or cytologic criteria[13] usually makes the only reliable diagnosis of cancer. Although *tumor* means “swelling,” the term is usually meant to include cancer cells and the stroma supporting the cancer cells; together they are often referred to as *neoplasm*, which literally means “new growth.” A neoplasm is an abnormal mass of cells that persists and proliferates after withdrawal of the stimulus that initiated its appearance. Leukemias are cancers caused by neoplastic proliferations of blood cells, but usually do not form tumor masses. There are two types of neoplasms: benign and malignant. The common term for all malignant neoplasms is *cancer*. Cancers of epithelial tissues (carcinomas) break through the basement membrane to invade adjacent tissues by infiltrative destructive growth. *Invasion* may or may not be followed by cancer cells entering the lymphatics, bloodstream, or fluid of the coelomic cavities to implant at sites discontinuous with the original tumor (*metastasis*; Greek for “emigration”). With extremely rare exceptions, metastasis defines a tumor as malignant; benign tumors do not metastasize. Invasion usually precedes metastases and suffices as diagnostic criterion of cancer, although this criterion cannot be used for leukemia and mesenchymal tumors. With the development of inbred mouse strains many decades ago, transplantability of tumors from one syngeneic animal to another became (and still is) a diagnostic criterion for the malignant phenotype of experimental tumors.

Cancer Cells

Many lines of evidence show that cancer is not a single disease. However, there are important principles that apply to many, if not all, cancers. There is substantial evidence that cancers in mice and humans are the result of multiple sequential mutations. As a result, certain molecules in cancer cells are mutant, up- or downregulated, or no longer expressed.

In addition, most if not all cancers show epigenetic changes in gene expression. An estimated 15% of the worldwide cancer incidence is attributed to infections,[14,15] but chemical and physical carcinogens are involved in the induction of most human cancers in industrialized countries.[16] Many of these carcinogens are mutagens.[17,18,19] While most mutations in cancer cells seem to be acquired (somatic mutations), increasing numbers of germline mutations are being discovered that make individuals prone to develop cancer.[20] A cancer may require as many as 10 or more mutations to develop full malignancy. The first stage of cancer development is called *tumor initiation*,[21] which is generally assumed to be irreversible due to somatic mutations or germline mutations in various oncogene, tumor suppressor gene, or deoxyribonucleic acid (DNA) repair pathways. Initiated cells do not form tumors. However, initiated cells clonally expand to premalignant lesions evolving over many years, often decades. This second protracted stage is driven by *tumor promotion* (ie, exposure to promoting conditions or chemicals[22,23,24] [see Cancer and Inflammation]). The most advanced stage of these premalignant lesions is referred to as intraepithelial neoplasia also *carcinoma in situ*, often abbreviated as, for example, CIN for cervical intraepithelial neoplasia, VIN for vulvar intraepithelial neoplasia, or PIN for prostatic sites. The premalignant process ends with invasion, the appearance of the first cancer cells. Remarkably, however, there is now clear molecular evidence for premalignant cells spreading to distant sites where these cells remain premalignant unless promoted to become malignant.[25,26,27]

A cancer cell that survives treatment may cause recurrence of the entire malignancy. Such cells are referred to as *cancer stem cells* or also tumor-propagating cells.[28,29,30] The elimination of these cancer stem cells is critical to prevent *relapse*. The sweeping assertion that these cells represent an extremely small percentage of the cancer cells in a tumor is not supported by rigorous experimentation or clinical experience. Some of the misconception comes from the observed rarity of only a few human tumor cells able to adapt to growth in a foreign (mouse) milieu.[30] Furthermore, flow cytometric analysis of cancer cells may detect a rare population that results from intraclonal and nonheritable heterogeneity in cancer cell populations.[31,32]

Tumor progression originally meant the change from a benign neoplasm to cancer[33,34] but is now usually used to describe the third phase of the multistep process. Invasive growth of a lesion usually ends with a highly aggressive, widely metastatic cancer that ultimately kills the host.[35,36] There is compelling evidence that most cancers are clonal in origin and that in cancer progression, new subpopulations of cells arise continuously due to Darwinian selection of genetic variants that have a growth advantage, escape homeostatic controls, or resist destruction by defense mechanisms or treatment.[37] During this evolution, sequential mutations result in changes in rate of growth, morphology, hormone dependence, enzyme and cytokine production, and expression of surface antigens. Importantly, by the time cancer is first detected in a patient, it measures usually at least 1 cm in average diameter, contains ~10^9 cancer cells, and has already undergone about 30 generations.[13] Thus, most of the diversity of a cancer has already occurred at time of detection with only 10 generations left before death of the individual unless treatment intervenes.

The term *primary* indicates the tumor from which cancer cells emigrate to *secondary* sites (ie, metastatic growth in tumor-draining [sentinel] lymph nodes or more distant organs). Experimentalists use the term *spontaneous metastases* to describe metastases that occur without experimental manipulations; *artificial metastases* are caused by cancer cells injected into systemic or portal veins of a tumorfree mouse to cause lung or liver metastases, respectively. Cancer cells can disseminate without further cell division (*microdissemination*) or they divide only minimally causing *micrometastases*, conditions that can only be recognized by microscopy and immunohistochemistry but are potential sources of relapse, the central problem of cancer therapy. Similarly, residual microscopic foci of cancer cells may remain at sites of incompletely excised cancer and cause *local recurrence*. Efforts are ongoing to develop sensitive markers and assays for determining the need for additional

therapy or determining the effectiveness of a therapy before relapse is detected clinically.

Cancer Stroma

Definition

Most of the cells in tumors may not be cancer cells but nonmalignant cells, referred to as *stromal cells*. Some of the most aggressive cancers, such as pancreatic cancer, mostly consist of nonmalignant stromal cells.[38] Virchow[39] believed that compression of the growing cancer cells induced a structural fibroblastic framework (now generally referred to as "stroma") in which the cancer cells grew. He thought that cancer cells and stroma both developed from the same primitive precursors. This concept changed with Ehrlich stating clearly that the host provided the stroma of solid tumors.[40] Borst[41,42] was the first to clearly point out the essential mutual relationship between cancer cells and tumor stroma by stating that the question of whether the epithelium or the connective tissue has the leading role in carcinogenesis was difficult to answer, because stroma of tumors is dependent on the presence of cancer cells, and cancer cells are dependent on stromal cells. Thus, cancer cells release factors that attract stromal precursor cells, and stromal cells in turn produce factors that support cancer cell growth.[43,44,45] Interestingly, Rous[46] emphasized the importance of vascularizing stroma for successful tumor transplantation and that immune reaction to nontumor cells led to rejection of the inoculum. Rous, however, was working with noninbred animals. It therefore remained unclear from his experiments whether an immune reaction just to stroma sufficed to cause tumor rejection until 1992[47] when similar experiments done in inbred mice showed that immune reaction to the stroma of transplanted tumor fragments led to the eradication of the inocula.

Components

Willis, in a careful survey of his own studies and published literature,[48] subdivided tumor stroma into just two major components: connective tissue, which usually represents the bulk of stroma, and vasculature, which is usually a smaller fraction. However, we should distinguish at least four critical components: 1) fibroblasts, 2) vasculature, 3) extracellular matrix (ECM), and 4) cells of myeloid and lymphoid lineage, such as macrophages, neutrophils, natural killer (NK) cells, and T and B cells, all derived from hematopoietic stem cells.

Fibroblasts are a prominent cell type in tumor stroma as well as in healing wounds and embryonic connective tissues. Stromal fibroblasts in cancers are metabolically active making matrix substances; the degree of activation of stromal fibroblasts correlates with aggressiveness of the cancer and inversely with survival of patients.[49,50] Unfortunately, we still lack reliable fibroblast-specific immunologic markers for these cells despite repeated assertions to the contrary.[51,52,53,54,55,56,57,58,59,60,61] Therefore, fibroblasts are still mostly defined by morphology and function.[62,63,64,65,66] Characteristically, they synthesize, secrete, and modulate proteins of the fibrous ECM, particularly alpha-collagen.[62,63,67] Macrophages are an essential and prominent part of stroma of every tumor. They lack Gr-1, express low levels of MHC class II, and express F4/80. These macrophages are "alternatively" activated (ie, typically have a tumor-promoting immunosuppressive M2 differentiation phenotype, particularly in hypoxic areas of the tumor[68]). Neutrophil granulocytes, also referred to as neutrophils or polymorphonuclear leukocytes, are an equally pivotal component of tumor stroma. Like the tumor-associated

macrophages, neutrophils in cancers are "alternatively" activated (ie, "N2"[69]). Unlike classically activated neutrophils, N2 do not cause tissue damage. These neutrophils express cluster of differentiation (CD)11b, Ly6-C, high levels of Gr-1 (defined by monoclonal antibody RB6-8C5[70]), and high levels of Ly6-G (recognized by the monoclonal antibody 1A8).[71] RB6-8C5 (anti-Gr-1) recognizes primarily Ly6-G[71] but apparently also binds weakly to Ly6-C,[71] although this is controversial.[72] In any case, RB6-8C5 (anti-Gr-1) not only eliminates

neutrophilic and eosinophilic granulocytes effectively (though only transiently),[43,44,45,70,73,74] but also markedly decreases cells of the subset of blood monocytes that express high levels of Ly6-C but lack Ly6-G.[74] Because of their suppressive effects on cultured T cells,[75] these Gr1+ CD11b+ leukocytes are also referred to as myeloid-derived suppressor cells (MDSCs).[76,77,78,79] MDSCs are increased in the circulation of tumor-bearing individuals but also found in the stroma of autochthonous[80] and transplanted tumors.[68]

Sources

It is presently unknown what percentage of bone marrow-derived stromal fibroblasts originates from hematopoietic versus mesenchymal lineage, what percentage of stromal fibroblasts is derived from circulation rather than local adjacent sources, and whether bone marrow-derived fibroblasts are functionally different.[81] As suggested over a century ago, some cells in the stroma come from progenitor cells entering the site of tumor growth either via the blood circulation or from adjacent normal tissues.[81,82,83,84,85,86,87,88,89,90,91,92,93,94,95,96,97,98,99,100,101,102] The relative contribution of the two sources (circulation or adjacent tissues) is still hotly debated,[103,104] but it is questionable whether circulating endothelial precursors contribute significantly to tumor vasculature in well-established tumors. Similarly, it needs to be determined whether local tissue reservoirs are a major source of alternatively activated M2 macrophages in autochthonous or transplanted cancers (> 2 weeks after transplantation) as it appears to be the case in other pathologic conditions of "type 2 inflammation."[105,106] Type 1 inflammation in tumors is an artifact clearly visible during the first 2 weeks after tumor transplantation.[68,107] An alternative major source of macrophages in tumor stroma may be monocytes or MDSCs from blood circulation.[68]

Function

Lack of tumor stroma drastically reduces tumorigenicity.[47,108,109] All cancers depend on stromal support and establish some type of paracrine loop.[43,44,45,52,110,111,112,113] Signals initiating the loop seem to be intrinsic to the cancer cells (ie, endogenous) and depend on oncogenic mutations in the cancer cells[114,115,116,117] (see Cancer and Inflammation). The proinflammatory mediators attract mesenchymal, endothelial, myeloid, and lymphoid progenitors to the stroma from adjacent and systemic reservoirs; the mediators also induce these cells to make factors that stimulate the growth of the cancer cells.[43,45,118,119,120,121,122,123,124,125] Cytokines released by transfected cancer cells can have powerful local effects on all components of tumor stroma including fibroblasts.[73,126,127,128,129,130,131,132,133,134,135,136,137,138,139,140,141,142,143]

Angiogenesis is a fundamental necessity for tumors to grow by allowing oxygenation and nutrients to diffuse from the blood into the mass. Myeloid cells, including mast cells, neutrophils, eosinophils, Gr-1+CD11b+MDSC/monocytes, and tumor-associated macrophages, can promote tumor angiogenesis.[144] However, cancer cells and tumor-associated fibroblasts can produce proangiogenic as well as growth stimulatory factors such as vascular endothelial growth factor (VEGF) and Bv8.[145] Several studies have shown the importance of neutrophils and granulocyte-colony-stimulating factor (G-CSF) production by cancer cells in causing refractoriness to anti-VEGF therapy.[43,44,45,146,147,148,149] Metalloprotease released from neutrophils and from Gr-1+CD11b+MDSC/monocytes catalyzes the release of preexistent VEGF and transforming growth factor (TGF)-β from the ECM and activates latent TGF-β.[150,151,152,153] Neutrophils are essential for mobilizing various types of stromal progenitor cells including the macrophages from bone marrow and other reservoirs in the body.[154] Finally, neutrophils and Gr-1+CD11b+ monocytes in the tumor stroma themselves can produce large amounts of TGF-β1.[69,80]

ECM is an essential stromal component providing the cancer cells not only with a scaffold for adherence and structure but also with growth and antiapoptotic signals, thereby preventing anoikis.[155,156,157,158,159,160] TGF-β1 stimulates fibroblasts to produce ECM proteins, including collagen, fibronectin, and proteoglycans, and TGF-β1 prevents ECM degradation.[161] Accordingly, transfecting cancer cells to produce TGF-β1 makes them more aggressive.[128] ECM is also a major reservoir for binding and releasing growth factors, chemokines, and cytokines.[162,163] Cancer cells may release the ECM proteoglycan versican that helps attract and activate myeloid cells via toll-like receptors (TLRs) to release interleukin (IL)-6.[164] At later stages, neoplasms often replace paracrine with autocrine loops, notably IL-6 activating signal transducer and activator of transcription (STAT)3.[123,165,166] However, all evidence suggests that even the most aggressive cancers still depend on some factors and ligands provided by tumor stroma.

Knowing how essential stroma is for cancers to grow, it is somewhat surprising that cancer cells would not generate their own stroma. Indeed, epithelial cancer cells can form a "pseudo-stroma" by assuming a mesenchymal phenotype at the invading edges of the cancer.[167,168] However, there is no evidence that this so-called epithelial-to-mesenchymal transition can replace the host-derived stroma (ie, the need of cancer cells to establish paracrine stimulatory loops with nonmalignant stroma[169]). Fusion of cancer cells with stromal cells, particularly macrophages, has been proposed as a major mechanism of cancer development and progression.[170,171,172,173,174,175] However, we still lack conclusive experimental evidence supporting this attractive hypothesis formulated over a century ago.[176,177]

Reaction to Cancer Cell Inoculation

Careful studies showed decades ago that the many cancer cells that die on inoculation play a critical role in the establishment of the cancer. It was found that adding lethally irradiated cancer cells to an inoculum of viable cancer cells at a 100:1 or larger ratio can increase the take of a cancer cell inoculum by more than a 100-fold.[178] The dead cancer

cells have potent thromboplastic activity,[179] and death of the cancer cells is required for this activity to form fibrin at the site of inoculation.[178] In addition, hypoxia induces VEGF-A and CXCL12 (stroma-derived factor [SDF]-1) in many types of cells, but many cancer cells produce VEGF even in normoxic conditions.[180] VEGF-A is a most potent inducer of vascular leakage of plasma proteins, including fibrinogen, that rapidly form a fibrin-fibronectin clot as a provisional tumor stroma.[181] Fibrin deposited at the site of inoculation serves as primitive ECM for cancer cells to escape anoikis. The ECM then undergoes major remodeling during the first 2 weeks after inoculation. Remodeling the ECM microenvironment requires the activity of ECM-degrading enzymes such as matrix metalloproteinases.[182] Thereby, these transplanted tumors acquire later the harder consistency typical for autochthonous tumors that evolve with stroma.

EXPERIMENTAL CANCER

Key Principles

Number of Cancer Cells Targeted

A critical determinant for any cancer therapy is the number of the targeted cancer cells that have proliferative potential ("cancer stem cells"). That number determines the likelihood of recurrence/relapse after most cancer cells have been destroyed by treatment. Even microscopic parts of a cancer left behind by a surgeon often lead to recurrence. Nevertheless, the size of tumor-stem cell population is not the only factor determining the likelihood of relapse as other cancer cells, even when dead or lethally irradiated, can increase the tumorigenicity of the remaining cancer cells by orders of magnitude.[178]

Most human tumors are not detected until they are 0.5 to 1 cm in diameter, have a volume of ~500 mm^3, and contain ~10^9 cancer cells.[13] In leukemia, malignant cells generally do not form tumors, but the patient has also ~10^9 cancer cells when the disease is clinically detected. It is not appropriate to adjust for the difference in host size when comparing cancer in man and mice. Not the size of the species but the size of the cancer cell population determines the chance of relapse because the latter correlates with the number of therapy-resistant variants causing relapse after therapy. Skipper, who pioneered combination chemotherapy of childhood leukemia in the mouse model of L1210 leukemia, targeted 10^9 cancer stem cells as the starting population. This was one major reason why the principles he established in an animal model were clinically relevant and led to the cure of most childhood leukemias. Cellular heterogeneity within a tumor becomes much more relevant when the tumor accumulates 1 billion (10^9) cancer cells, equivalent to a tumor with a diameter of 1 cm.[183,184,185] At this point, the accumulation of so many cancer cell variants makes it improbable that all cancer cells are susceptible to a single chemotherapeutic agent or specific T cell. Cancer cell variants can be considered analogous to drug-resistant bacteria or viruses (ie, the nature of the problem is fundamentally the same in both cases). Unfortunately, in most experimental studies on immunotherapy, almost fivefold smaller populations of cancer cells are being treated[4] (Fig. 47.1).

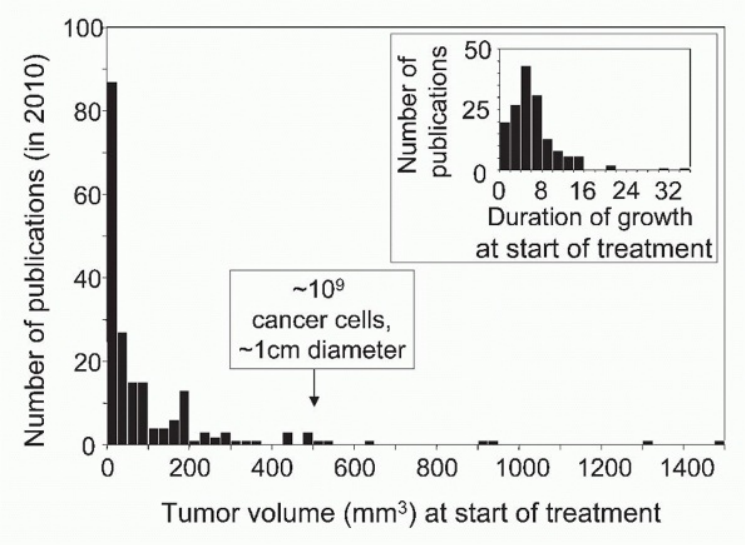

FIG. 47.1. Precipitous Drop in the Number of Publications Reporting the Effects of Experimental Cancer Immunotherapy with Increasing Size or Duration of Growth of Tumors Treated by Immunotherapy. A search of PubMed for year 2010 publications using the keywords "immunotherapy" AND "cancer" recovered 195 experimental studies listing tumor volume or size and 158 studies listing duration of growth at start of treatment. Seventy-five percent of tumors treated in these studies were smaller than 121 mm^3. Only 9 of the 158 tumors had grown for 2 weeks or longer. Modified from Wen et al.[4]

Duration of Growth

Duration of growth of a cancer greatly influences experimental results. Summarizing three decades of studies on immunity to cancer, Woglom concluded in 1929 that immunotherapy is futile against an established tumor, and "nothing may accordingly be hoped for at present in respect to a successful therapy from this direction."[186] Eighty-two years later, the outlook is not quite so grim, but unfortunately, the vast majority of research in animal models is still concentrating at treating malignant cell populations grown for an average of only 5 days after

cancer cell inoculation[4] (see Fig. 47.1). The word “established” is not a scientific term, yet is frequently used to describe neoplastic lesions caused by recently implanted cancer cells,[186] conveying the message that the malignancy being treated does not differ from what would be found in a human cancer patient. Just the opposite is true; transplanted tumors must grow for at least 2 weeks before they are histologically indistinguishable from autochthonous murine or human cancers.[107] Most human cancers have resided in the patient for months if not years before being detected and treated, whether primary, metastatic, dormant, or relapsing. An additional problem of experimental models is that growth of many serially transplanted “standard” cancer lines is so rapid that death may occur so early that treatment has to be started before solid tumors have established a microenvironment even vaguely comparable to that of an autochthonous tumor.

Measuring Growth and Destruction

Tumors are masses and have weight and volumes best approximated by the formula of an ellipsoid (V = πwh/6 or V = 0.5236 lwh or V-½ lwh); length 1, width w, and height h are the orthogonal diameters in the three perpendicular

axes. As was carefully documented, the third dimension, height (or depth), has an inordinately large effect on errors in volume[187] but can usually be determined accurately for subcutaneous tumors.[187,188,189] Describing tumors as areas is incorrect and illogical despite widely practiced misuse. By definition, areas have no volume nor contain a single cancer cell. Area measurements as commonly used by radiologists frequently disagree with volumetric measurements.[187,188,190] Depth of a tumor can greatly vary and determines malignancy and prognosis (eg, in melanoma).

There are important variables when extrapolating the number of cancer cells from a given tumor volume; for example, the human or murine adenocarcinoma of the pancreas usually consists predominantly (˜90%) of nonmalignant stromal cells yet is highly aggressive, whereas in most tumors stromal and cancer cells are more balanced in numbers. Furthermore, while it takes weeks for a tumor to disappear completely even after all cancer cells have been eradicated, it is usually impossible to determine from volume measurements how many viable cancer cells are left. Certain cancers release hormones that have systemic effects such as insulin; even microscopic growth can have major systemic effects.[191] While many experimental models utilize subcutaneous tumors, some cancers, particularly human tumor xenografts, may require transplantation to sites where it is more difficult to assess growth objectively.[192] Cancer cells have been transduced with luciferase to give a signal proportional to the tumor size when substrate is injected; this allows whole body scans with a luminometer, though sensitivity decreases for fewer than 1,000 cancer cells, and there is absorption by overlying tissues.[193]

Cure and Dormancy

The effects of the immune system on cancer can be read out in different ways. Certainly, *cure* of the cancer is the objective. There should be clear prolongation of survival and absence of relapse, but proving that all cancer cells have been eradicated is often difficult. Unfortunately, for most cancers, we lack assays sensitive enough to detect and quantify remaining *dormant* cancer cells. This information would indicate whether or not a patient requires further treatment. Only in a few types of cancers[194,195,196] does a negative diagnostic polymerase chain reaction analysis of the tissue reservoir from where a cancer may relapse suggest —though not prove— complete eradication. Experimental evidence for dormant cancer cells may come from provoking relapse by treating the animal with antibodies neutralizing factors or cells suspected of causing tumor dormancy. Experimentation should include waiting for minimally 30 days after the tumor has disappeared completely (it is best to wait several months or longer). A common unacceptable practice is using the word eradication or cure when there is no follow-up after the cancer becomes undetectable. *Relapse* of cancers may occur within days, weeks, months, or even years after complete disappearance, and is one of

the most important problems of cancer therapy. Nevertheless, experimentalists commonly describe treatments as effective even when followed by rapid relapse.[197] *Eradication* means tearing a tree out with its roots so it cannot regrow, and the term is synonymous with cure. Thus, using the term eradication is only appropriate if the host does not harbor dormant cancer cells, comparable to "sterilizing immunity" in infections.[198,199,200,201]

Inhibition, Arrest, Regression, and Equilibrium

Dependent on the extent and type of destruction as well as when it occurred, tumors may be found to have smaller or larger volumes after treatment compared to controls. It is important to determine whether the rate of tumor growth has been altered or the rate of growth remained unaltered but the onset of growth has changed. Altered rates of growth require an ongoing process, whereas altered onset of outgrowth is usually caused by an event that happened at times of inoculation. Slower growth rates (growth *inhibition*) should be distinguished from shrinkage (*regression*) of a cancer. A steady size of a treated tumor compared to controls is referred to as growth *arrest*, *equilibrium*, or *progression-free survival* in cancer patients, an important goal when cure cannot be achieved.[169,202]

Specificity Controls

It is completely inappropriate yet quite customary to study immunologic therapies specific for a self-antigen on a human cancer in mouse models (human tumor xenograft) when the murine host does not express the same target. These irrelevant models often yield impressive results and mislead the reader that the targeted molecule is tumor-specific when in the real situation it is not.[203,204] If someone subscribes to the widespread highly questionable perception that many, or even most, useful tumor antigens are self-antigens, then this investigator should also use appropriate experimentation. Either a mouse model must be used in which normal tissues express the target molecules closely resembling expression patterns in man or there should be a clear warning to the reader. For example, anti-carcinoembryonic antigen (CEA) immune responses caused toxicity in mice that expressed the target antigen also in normal tissues, as humans do,[205] predicting the severe toxicity later observed in a clinical study.[206] Side effects often become apparent only when the treatment is intense enough to provide clinical efficacy.[207] It is therefore questionable to dismiss results in proper animal models.[208,209]

Selection of Tumor Model

General Considerations

Experimentalists have to be able to translate their findings to clinicians and vice versa. There is no single human cancer, let alone single animal model, that can serve as appropriate model for all human cancers.[28] Organ site as well as histologic type of a cancer may greatly influence the results. Thus the complexity of cancer makes it extremely important that the experimental model used to study cancer immunity be relevant to the question asked; a single model, if carefully chosen, may be appropriate to answer a specific question. Nevertheless, it is essential that we uncover the broader principles underlying cancer-host interactions. For example, the extensive clinical and experimental research on immunotherapy of melanoma has failed to answer the

central question: why are we struggling to make similar advances in the immunotherapy of more common cancers such as breast, colon, prostate, and lung cancers? Weiss argued in 1980 that the failures of clinical immunotherapy were due to using irrelevant laboratory tumor models for extrapolating results for clinical application.[210] One of the major reasons for translating results from animal models to clinical cancer immunotherapy being frustratingly evasive is the disregard of using truly established tumors for experimental therapy (see Fig. 47.1).[4] Current experimentation in cancer immunology mostly uses young hosts to study the effects of the immune system on small, recently implanted inocula of cancer cells derived from tumors once induced in inbred mice (with homozygous genetic loci) and then passed in

vivo for decades from animal to animal, whereas human cancers are already well established when first detected, have a very high probability of heterozygous loci, have never been transplanted, and develop in mostly older individuals.

Modes of Induction

Spontaneous. The term *spontaneous cancer* is defined as cancers arising "in the absence of any experimental manipulation."[211] Spontaneous murine cancers develop without any known exposure to carcinogens or genetic (often transgenic) manipulations introducing oncogenes or eliminating tumor suppressor genes. For example, spontaneous tumors can be observed in many mouse strains with advancing age. All genes have a spontaneous rate of mutation, and genetic instability, though often a consequence, may not be a requirement for tumor development.[212,213] As would be expected from the sporadic occurrence of spontaneous mutations, the occurrence of spontaneous tumors is random and unpredictable.

Carcinogen-Induced (Physical, Chemical, or Viral) . Many of the physical and chemical carcinogens involved in the induction of cancers are mutagens.[16,17] Since repeated application of coal tar was used to induce the first chemically induced cancers,[214] a very large number of chemicals such as polycyclic hydrocarbons and nitroso compounds has been identified with remarkably potent cancer-inducing activity.[215] Cancers have been induced in many tissues and organs and several animal species. Ultraviolet light (UV) has potent skin cancer-inducing activity in man and mice,[216,217] and many well-defined models of UV-induced tumors are now available.[218,219] The potential of ionizing radiation to cause cancer in humans was recognized soon after Roentgen's discovery of x-rays in 1895.[220,221] But study of radiation carcinogenesis in animals mostly occurred after World War II when large-scale tumor-induction studies were carried out in many species over the succeeding three decades in response to the threat of irradiation from nuclear reactors or bombs.[221,222,223] Finally, many models of viral cancer induction have been developed after Rous[224] showed that viruses can also induce cancer in animals.

***Transgene-Induced*.** Experimental cancers are produced artificially by inserting oncogenes into the germline of mice or by manipulating the mouse genome to allow excision of tumor suppressor genes. Genes used for these manipulations are driven by tissue- or cell lineage-specific promoters that are either constitutively active or inducible locally or systemically. While these mice become prone to develop cancer, the tumors they develop are autochthonous but by no means "spontaneous" despite widespread misuse of terminology.

Autochthonous Tumors

Autochthonous tumors originate in the place where they were found (autochthonous, in Greek, means indigenous). The antonym is transplanted tumors. Autochthonous tumors can be spontaneous, carcinogen-induced, or transgeneinduced. Even when induced in the same experiment by the same mode of induction, autochthonous tumors will differ genetically, biologically, and antigenically from one another, because additional but individually differing genetic changes are required for each tumor to develop. Thus autochthonous tumors lack the uniformity of well-defined transplantable models. An advantage of autochthonous over transplanted tumors, however, is that the host's immune system has been neither artificially primed nor altered by an inoculum.

Unlike autochthonous tumors developing after exposure to physical, chemical, or viral carcinogens, transgeneinduced autochthonous tumors have the disadvantage that transgene expression in the thymus during development usually causes systemic tolerance to the transgenic proteins. Nevertheless, several excellent transgenic cancer models have been developed.[225,226] Some models are based on immunologic findings first made in patients.[12] For example, the R24C mutation in the cyclin-dependent kinase 4, first identified as tumor-specific antigen by T cells of a melanoma patient, causes familial melanoma when in the human germline.[227] Introducing this mutation in the germline makes mice highly susceptible

to develop melanoma[225]; tumor development, however, requires additional carcinogenic insults followed by prolonged chemical promotion.

Certain oncogenes such as SV40T are powerful because they inactivate several important suppressor pathways and may therefore require fewer additional mutations. In some transgenic cancer models, the transforming genetic event can be controlled, sometimes reversibly, by topical or systemic application of an inducer such as tamoxifen or tetracycline.[193] Alternatively, systemic or topical application of Cre-recombinase may excise a "floxed" blocking element or attenuator of gene expression.[228] These temporal controls appear to be helpful for answering important questions on tolerance, because expression at birth causes neonatal tolerance to a highly antigenic oncogene such as SV40 T antigen. An approach that more closely mimics the sporadic nature of human cancer relies on a spontaneous mutational event activating an introduced floxed oncogene. The sporadic nature of this event unfortunately also makes time and site of tumor development less predictable.[228]

Transplanted Tumors

Most current experimental work in tumor immunology uses transplantable tumors. However, there are substantial differences among transplantable tumors, and it is

important that the chosen cancer is appropriate for the particular question being asked. It is important to know that 24 hours after inoculation, the majority of the injected cancer cells usually have died,[178] leaving only a shallow outer rim of viable cancer cells at the oxygenated margin.[107] Histology or in vivo imaging reveals pronounced edema at the injection site. In fact, much of the "tumor growth" early after inoculation is due to tissue swelling caused by the inflammatory reaction. Cancer cells may well be invading surrounding normal tissues and be vascularized within 48 to 72 hours after transfer, thereby meeting standard criteria for malignancy. But experienced pathologists will immediately spot the abnormal inflammatory reaction to the transplantation injury and the necrotic center of the early inoculum. Thus, common terms such as "three-day established cancer" or "three-day established metastases" are highly misleading. Such necrosis would not be found in an autochthonous cancer of similar size. The inflammatory reaction progressively decreases with time, and at 14 days, the necrotic material has usually disappeared. The tumor then contains ~10^9 cancer cells, measures ~1 cm diameter, and is histologically indistinguishable from primary autochthonous tumors. Ideally, therapy uses tumors 2 weeks or more after inoculation (see Fig. 47.1).

Even though the terms *tumor transplantation* and *tumor injection* are old and commonly used, they are quite misleading, as they usually refer to inoculation of tumor fragments or a suspension of cancer cells. A common error is the belief that tumors can be injected or "transplanted" like a vascularized organ such as kidney or heart. Instead, much of the inoculum—whether a cancer cell suspension or fragments of a tumor—dies initially and needs about 2 weeks before it becomes histologically indistinguishable for autochthonous tumors.

Tumors can be induced in animals by injecting *cancer cell suspensions* prepared from cultures or by mincing tumors into 1-mm^3 pieces and injecting the *tumor fragments* using a 12-gauge trocar. Cancer cells in fragments are 10- to 100-fold more tumorigenic than stroma-free cancer cell suspensions.[47,108] It had long been known that certain cancers would only grow in mice when transplanted as tumor fragments. This was erroneously thought to be due to more cancer cells being inoculated with fragments.[229] Later analyses revealed that fragments contained fewer cancer cells than injected cell suspensions, yet produced a higher take or larger tumors earlier.[47,108] Another erroneous explanation was that the stroma of tumor fragments provided a physical barrier preventing cancer cells from migrating to draining lymph nodes and priming a protective T-cell response.[108,230] More likely, more cancer cells remain viable when embedded in tumor stroma (by preventing anoikis[160]) and therefore

release less antigen than suspended cancer cells, most of which die. In any case, as long as cancer cells express sufficient levels of antigen, professional antigen-presenting cells in the tumor stroma pick up the antigen and travel to the draining lymph nodes where they present the antigen to naïve T cells.[231]

It is important to know that whether suspensions of cancer cells or tumor fragments are being used, a threshold number of cells or fragments must be inoculated for tumors to develop. The threshold in T cell-deficient mice may be due to innate immunity or nonimmunologic mechanisms.[178,232] The increase in threshold in immunocompetent mice is probably due to adaptive immunity.

***Cell Lines from Tumors Serially Passed in Mice*.** When choosing tumors that have been serially passed in animals for transplantation, it is critical to be aware of how such tumors were altered by the serial transplantation. As was discovered decades ago, even a single in vivo passage of a cancer can select for heritable cancer variants.[45,219,233,234,235,236,237] Even half a century ago, investigators already noted that serial transplantations of these cancers "inevitably result in progression toward more rapid growth rate, loss of functional and histological differentiation, loss of responsiveness to extraneous stimuli"[238(p.522)] and a diminution of strain specificity, a problem shared by B16.[239] These serially transplanted cancers, such as B16, can easily be transferred in mice using cancer cell suspensions rather than tumor fragments. As a result of hundreds of passages in mice,[239] these cancer cells have become resistant to anoikis caused by lack of stroma by acquiring alternate signaling pathways that replace the prosurvival signals of ECM.[240] Many of these tumors grow and kill so fast that they must be treated early before they are truly established. Certainly, many of these tumors no longer resemble primary mouse or human tumors that virtually always grow at much slower rates and have been established for months or years before being treated.

B16 melanoma was derived in C57BL/6J mice in 1954 and is the parent of many available B16 sublines.[239] B16 had been transplanted serially through 328 mice for 13 years before it became available as a standard cancer cell line. Nevertheless, B16 still is arguably the "*Escherichia coli*" of tumor immunology with almost 1,000 entries in PubMed in 2011. The A/J-derived Sa1 originated in 1947 in an A albino mouse and was serially transplanted in A/J mice for 1,017 generations for 19 years. Similarly, the A/J-derived neuroblastoma 1300 derived in 1940 was serially transplanted for decades from mouse to mouse. The Lewis lung carcinoma, isolated by Lewis,[241] arose spontaneously in 1951 at the Wistar Institute in a black C57 mouse (not a C57BL/6 mouse), was serially transplanted extensively, and is still being used in numerous studies as a model for exploring the immune responses to lung cancers and their metastases. When genetically inbred mouse strains became available as sources for murine cancers over half a century ago, serial transplantation was necessary for maintaining a tumor. Dependable long-term cryopreservation did not become available until the late 1960s and early 1970s.[242,243,244] Even after dependable cryopreservation became available, investigators still continued to use serial transplantations to propagate newly derived cancers such as the BALB/c-derived CT26 colon cancer,[245] the C57BL/6-derived MC38 colon cancer,[246] and the BALB/cCr-derived RENCA renal cancer.[247] Many cell lines are renamed sublines of old parental cell lines. Thus, it is often overlooked that RMA, RMA-S, MBL-2, and EL-4 tumors are derived from the same single tumor line,[248] most likely

E.L.4 induced by 9:10-dimethylbenzanthracene in 1945 by Gorer[249] and serially transplanted for many decades from mouse to mouse. Importantly, referring to EL-4 as a C57BL/6 tumor is incorrect as this strain did not exist in 1945. Similarly, Neuro2a is a subline derived in 1969 from the A/J-derived neuroblastoma 1300 derived in 1940. Unfortunately, organizations providing these lines and/or publications often fail to cite the fact of long-term in vivo passage before cryopreservation.

Cell Lines from Autochthonous Mouse Tumors. Autochthonous cancers never need to be serially transplanted. Standard lines can be created by adapting the autochthonous cancer cells to culture and/or by freezing fragments or cells in liquid nitrogen.[218] To prove that antigens expressed by the malignant cancer are truly tumor-specific, nonmalignant cells, tissue and DNA from the host of tumor origin must be available.[218,219] This approach is commonly used by researchers studying the antigenicity and genetics of human cancers. Carefully controlled experimental cancers exist.[218,219]

Human Tumor Xenografts. For certain purposes, human tumor xenografts are useful models. Human cancer cell lines grown in vitro can cause tumors when injected into T-, B-, and/or NK-deficient mice. It is important to remember that the stroma of such cancers is entirely of mouse origin and the cancer cell-stromal loops are defective because of multiple mismatches in ligand-receptor signaling.[250] This problem can be partially alleviated by "humanizing" the recipient mouse. Humanizing usually refers to expressing certain human molecules such as receptors/cytokines in mice that lack murine T, B, and/or NK cells, and/or transferring human mesenchymal and/or hematopoietic cells to such mice. Interestingly, human T- and B-lymphocytes and fibroblasts contained in human tumor fragments may coengraft thereby "humanizing" the mouse[192] (eg, when injecting cell clusters or aggregates from human fresh ovarian cancers into nonobese diabetic-severe combined immunodeficiency IL2γR null mice). Progressive growth of these xenografts leads with great regularity to ascites formation, and pleural metastasis closely simulating classical tumor progression observed in patients with ovarian cancer.[192] Despite continuous improvement, mice can never be completely humanized. Only very few cancer cells of the xenografts may be able to progress in the chimeric milieu.[30] Nevertheless, once a tumor grows, its sensitivity to potential therapeutic agents might reveal the sensitivity of the original cancer growing in the patient.

Selection of Recipient/Host

The vast majority of human cancers develop in later midlife and old age,[251,252,253,254] and there is clear evidence that, at comparable ages, mice have difficulties rejecting immunogenic cancers.[255,256,257,258] Yet most experimental studies use young mice. Mice should have a clinically relevant tumor burden or be selected for treatment when the bulk of cancer cells has been removed to undetectable levels by surgery or chemotherapy, but dormant cancer cells stay behind to cause later relapse. T cell-deficient mice have been used extensively as models for adoptive transfer of T cells.[259] However, cancer patients are usually T cell competent and capable of generating regulatory T (T_{reg}) cells that may not allow an effective "take" of the transferred T cells unless the recipient is lymphodepleted.

CANCER ANTIGENS

No term in cancer immunology is more important and confusing than the term cancer antigen (or tumor antigen). Any molecule detected with T cells or antibody on the surface or within cancer cells is commonly referred to as cancer antigen. The usefulness of a cancer antigen for detection and destruction depends on its specificity (ie, that the antigen is not common to normal cells). The first well-defined tumor antigens encoded by the MHC were discovered by Gorer.[8] Immunity to MHC antigens will kill the cancer cells but also the host because of the ubiquitous expression of MHC on normal cells.

General Aspects

Early History

In the late 1800s,[260,261] it was discovered that in some instances tumors developing spontaneously in experimental animals could be transplanted into other animals of the same species and in this way could be propagated continuously. This finding provided an important experimental tool for cancer research.[40,262] Immediately, scientists began to investigate the

possibility of immunizing against such transplantable cancers. Rodents exposed to a small nonlethal challenge of certain tumors became immune to subsequent challenge with large transplants of the same tumor that regularly killed nonimmunized recipients. Also, complete removal of the transplanted tumors, after initial growth, immunized animals against that tumor. These early results seemed to suggest that immunization against cancer was possible. Furthermore, there were certain other spontaneous tumors that were not readily transplantable, and this was taken as evidence for "natural resistance" or "natural immunity" to the cancers. Many years later, it became clear that no such conclusions could be drawn from these early studies, because outbred, or incompletely inbred, rats or mice had been used. The problem became apparent when it was realized that the immunization with tumor would also immunize the host against normal tissue of the donor and that normal tissues of the donor could also immunize the host against the tumor.[186] These experiments brought the idea of tumorspecific antigens into disrepute but also started the search for antigens that caused rejection of normal transplanted tissue. This research eventually led to the discovery of the MHC and to the development of inbred mouse strains.[8,263,264] Once inbred mouse strains became available, it was found that cancers transplanted within an inbred mouse strain usually grew so well that the existence of tumor-specific antigens seemed very unlikely. In fact, transplantability of tumors in syngeneic animals became (and still is) a diagnostic criterion for the malignant phenotype of an experimental tumor. This criterion was especially useful because many rodent

tumors are cancers of nonepithelial origin (sarcomas) and also because a clear histologic demonstration of local invasive growth can be especially difficult in such cancers.

Proof of Specificity

After discovery of the MHC and the development of inbred mouse strains, the gloom over tumor immunology ended with the discovery that inbred mice could be immunized against syngeneic sarcomas induced by the chemical carcinogen methylcholanthrene (MCA). The first demonstration of induced immunity to a transplantable MCA-induced sarcoma was by Gross in 1943[265]; however, it was not until the 1950s that more complete experiments provided unequivocal evidence for "tumor-specific" rejection of transplanted cancers.[229,266,267,268,269,270] In particular, the experiments of Prehn and Main[268] in 1957 made it likely that the rejection antigens on the MCA-induced sarcomas were functionally tumor-specific, because transplantation assays could not detect these antigens in normal tissues of the mice used. However, irrefutable evidence for the existence of tumorspecific antigens in autochthonous unmanipulated cancers only came after a 50-year-long search[3,5,218,219,236,267,268,269,270,271,272,273,274,275,276,277,278,279,280,281,282] when in 1995, it was proven that tumor-specific antigens on cancer cells were encoded by somatic cancer-specific mutations absent in the normal cells of the host of tumor origin.[10,11,12]

Even though it is clear that cancer-specific antigens are encoded by somatic cancer-specific mutations, the terms "tumor-specific" or "cancer-specific" are frequently used inappropriately, sometimes even used in conjunction as "relatively" tumor-specific. The discussion is far from being semantic. In reality, an antigen either is or is not tumor-specific. Germline controls are absolutely critical for proving mutations are somatic and tumor-specific.[283,284,285,286] Unfortunately, germline controls are missing from virtually all tumors used for experimental work today. Nevertheless, mouse tumors with proper autologous controls have also been used and are available for distribution.[218,219] Notorious problems are genetic polymorphisms. For example, even after 20 backcross generations when a strain is arbitrarily pronounced "inbred" (because it is then more than 99.9% genetically identical), about 373 polymorphic proteinencoding loci remain allogeneic.[287] Any one of these loci could encode a pseudotumor-specific antigen when a tumor is transplanted into a mouse misperceived to be fully syngeneic. Mice respond preferentially to nonself- or mutant-self-antigens whether

caused by genetic polymorphism or tumor-specific somatic mutation.

Peptide Antigens and Major Histocompatibility Complex Affinity

T cell-mediated destruction of cancer cells requires the interaction of T-cell receptor (TCR), peptide, and MHC molecules. In this "three body problem," two affinities simultaneously determine the interaction[288,289]: the peptide to the MHC and that of the TCR to the peptide-MHC complex. Even when the complex cell-cell interaction is reduced to the three molecules interacting in vitro, biochemical analysis is still too complex for analyzing physiologic interactions. TCR affinity to peptide-MHC is therefore usually measured by plasmon resonance in the presence of saturating nonphysiologic amounts of the peptide, and TCR affinities measured this way range between (K_d) 1 to 100 μM.[288,289] This is a narrow range considering that affinities of peptides to the MHC range from 1 to more than 20,000 nM.[290] This difference points at the peptide-MHC affinity probably being the greatest variable and emphasizes the paramount importance of choosing target peptides with highest possible affinity to the presenting MHC. Proper selection is particularly important as the amount of peptide produced by the cancer cell may be relatively small and always must compete for binding with all other peptides naturally present in the cancer or in the cells cross-presenting the antigen. Affinity of a peptide to a given MHC molecule is best measured empirically and many empirical affinities are already available (eg, http://tools.immuneepitope.org or www.syfpeithi.de).[290,291,292] However, even when a peptide binds with high affinity to MHC, it will only be expressed on the cell surface when it is naturally processed and present in sufficient amount.[293,294]

Antigens Revealed by "Reverse Immunology"

"Reverse immunology" is the attempt to predict T-cell epitopes within a given amino acid sequence. Traditionally, "reverse immunology" has focused on finding optimal T-cell antigens, properly referred to as peptide epitopes, on infectious agents for generating vaccines. More recently, self- or mutant proteins recognized by T cells or antibodies from cancer patients have been analyzed in the search for peptide epitopes that may be effective targets of T-cell immunity. Computerized algorithms (eg, http://tools.immuneepitope.org[295,296] and www.syfpeithi.de[297]) have been developed to predict the affinity of peptide-MHC binding, appropriate proteasomal cleavage, and transport by the transporter associated with antigen processing (TAP).[290,291,292,297] Though these algorithms are useful, it appears that these tools cannot replace empirical biochemical measurements. Many of the antigens proposed by reverse immunology have affinities to MHC insufficient to serve as effective targets when tested in appropriate animal models. Together, high peptide-MHC affinity is essential but not sufficient to predict that a given peptide serves as an efficient target.

Complete sequencings of cancer cell genomes from individual patients is becoming increasingly affordable and has revealed up to many thousands of mutations per cancer cell.[298,299,300] However < 1% of these mutations cause amino acid substitutions. For example, of the 33,345 nucleic acid base substitutions found in a human melanoma, most of the mutations were intergenic, intronic, noncoding, silent, or truncating. Only 187 caused amino acid substitutions in coding genes,[300] and only a few of these 187 coding substitutions are expected to lead to mutant peptides that serve as effective targets. To be effective, the mutant peptide 1) must bind with a high affinity (IC_{50} in the nM range) to the particular MHC molecules of that individual and 2) be naturally processed, 3) escape destruction by proteasome cleavage, and 4) be present in sufficient amounts. Only a few of the myriad of tumor-specific mutations identified in human or murine cancers give rise to antigens that fulfill these requirements. However, the frequency of unique tumor-specific targets in

a cancer cell may be larger than predicted when considering only mutations in coding sequences, because mutations in intron sequences can be translated and also encode tumorspecific antigens.[11] These mutations are over 50-fold more frequent than those in

protein-encoding loci.

Antigens Recognized by Patients' T cells

In the search for the best antigens to eradicate the cancer, T cells infiltrating tumors (TILs) have been recovered, expanded, and used therapeutically. However, TILs are removed from cancers that have not been destroyed. It is, therefore, a widespread misperception that the TILs were necessarily fighting cancer growth. Three questions become obvious: 1) Are strong antigens retained because the host has been tolerized during very early stage of cancer growth? 2) Can T cells specific for the strongest antigens be recovered from the TILs? 3) Can T cells specific for weak antigens promote rather than inhibit tumor growth?

It is possible that 1) potent rejection antigens are retained because they tolerize the host very early during cancer development,[228,301] 2) a few T cells have not been tolerized and can be propagated for therapy, and 3) tolerization is reversible, and competent effector cells can be obtained from TILs. Clinically, the patients who fare best have T cells in their peripheral blood that are specific for antigens encoded by somatic tumor-specific mutations.[12,302,303] Whether the same T cells were infiltrating these cancers as TILs is unknown. In any case, it is likely that only a few (if any) of an endless array of antigens recognized on cancer cells by antibodies or tumor-infiltrating T cells may have significance as targets or diagnostic markers.

Cancer-Specific Antigens (Encoded by Mutant Genes)

Prevalence

All cancers in man and mouse that have been analyzed carefully express bona fide tumor-specific antigens that could be targeted by T cells. Because tumor-specific antigens arise from mutations,[10,11,12] they are usually unique. Each patient's cancer seems to have a unique set of mutations, and unique antigens can provoke powerful immune responses. In mice, immunization with one tumor protects only against the same tumor (Fig. 47.2).[5,274] Shared cancer-specific antigens do exist when the same mutations occur in several cancers, but by comparison, such antigens are relatively rare. Most cancer-specific mutations affect intracellular proteins that may be recognized by T cells as mutant peptide-MHC complex on the surface of viable cancer cells. Very few cancer-specific mutations affect surface proteins, such as the mutant epidermal growth factor receptor (EGFR), a shared tumor-specific antigen on glioma cells.[304,305]

Oncogenicity

A major misconception is that unique cancer-specific antigens are caused by random mutations and are incidental to the oncogenic process. For example, a group of experts

stated in 2009[306(p.5326)] that unique antigens come “from random mutations presumed to be present in all patients,” implying mutations encoding unique tumor antigens have no functional significance in the malignant process. Nothing is further from the truth. Of course, all mutations caused by chemical and physical carcinogens are random, but virtually all of them are lost during cancer evolution except those that promote the neoplastic process. When it was first shown in 1995 that cancers harbor cancer-specific antigens caused by somatic tumor-specific mutations,[10,11,12] every one of the three antigens represented a mutation in a tumor suppressor locus.[307,308,309,310,311] For example, the mutation in the cycline-dependent kinase 4 reduces the binding to its inhibitor and tumor-suppressor protein p16INK4a,[12] and the same mutation is found in the germline in cases of familial melanoma.[227] The fact that selection for a tumorspecific antigen commonly represents a mutation in genes with functional significance in the malignancy of that cancer (oncogenes or tumor suppressor genes) has been shown in many other studies.[219,312,313,314,315] Remarkably, T cells against unique tumor antigens identify mostly novel, functionally important tumor-specific mutations and oncogenic proteins that would not have been easily

detected by other technologies.[10,11,12,219,307,308,309,316] Importantly, several of these unique tumor-specific antigens are excellent targets because they cannot be lost by immune selection. The reason is that some of these mutant proteins are not only oncogenic but are also needed to provide an essential household function no longer provided by the second allele due to Knudson-type loss[317] or mutational inactivation.[302,307,308,309]

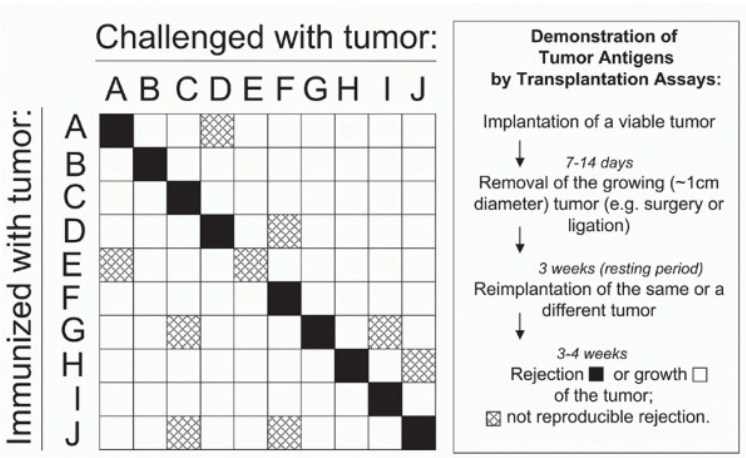

FIG. 47.2. Demonstration of the Individual (Unique) Specificity of Rejection Antigens on Independently Derived Methylcholanthrene-Induced Tumors in Transplantation Experiments. For details, see Basombrio.[3] Modified from Basombrio and Prehn.[5]

Therapeutic Significance

Another misperception surrounding unique tumor-specific antigens is that they have remained unexploited clinically, because truly personalized therapy would be required. Again, nothing is further from the truth. One of the most effective immunologic treatments of cancer today is the adoptive cell transfer of autologous tumor-infiltrating lymphocytes from patients with metastatic melanoma: response rates are in the range of 50% to 70% of the patients, and a few of these patients are cured.[318] This truly personalized therapy involves reinfusion of the patients' own lymphocytes isolated from the patients' own melanomas and expanded in vitro. Because the TILs response is dominated by T cells to unique tumor-specific antigens,[303] it is likely that the success of the reinfused T cells depends on their reactivity to unique tumor-specific antigens. Similarly, clinical studies show that therapeutic vaccinations with autologous cancer cells are likely to be much more effective,[319,320] confirming decades of experimental work.[229,234,268,269,271,321,322] Self-antigens may serve as useful and effective targets in a very few instances (eg, CD20 and CD19), but industry supported by government panels and organizations focuses almost exclusively on self-antigens,[306,323,324] so far with very modest results.[325] Finally, it is a misperception that immunizing each patient to the unique antigen of the individual's tumor is impractical because of cost and should not be pursued. This is incorrect compared with other highly individualized treatments such as those used in renal transplantation. Thus, individualizing cancer therapy could be affordable as other strategies used in the clinics.

Shared Tumor-Specific Antigens

Ideally, antigens targeted on cancers would be expressed exclusively on malignant cells but be shared by cancers of the same type or at least subtype. Several cancer-specific mutations have been identified that are shared between cancers,[9,304,326,327] but very few of them have so far been found to be an effective immunologic target. The main reason probably is that, aside from specificity, additional requirements for effective recognition by T cells are 1)

high-affinity binding to the patients' MHC molecules and 2) expression of the protein at sufficient amounts to compete with other peptide for presentation. Unique tumor-specific antigens must fulfill the same requirements but, because these unique mutations are more abundant, chances are much higher to yield an effective antigen. A few examples of shared tumor-specific antigens are discussed in the following.

Mutant Epidermal Growth Factor Receptor **.** See further under Immunotherapy.

Fusion Proteins. Fusion proteins found in cancer cells are the result of internal deletions (see mutant receptor EGFRvIII under Immunotherapy) or chromosomal translocations.[9,326] New antigenic determinants can result from the juxtaposition of previously distant amino acid sequences, resulting in a mutant peptide sequence at the breakpoint and possibly a change in conformational structure. The same chromosomal breakpoints consistently recur in different individuals with the same cancer, therefore result in shared tumor-specific antigens. Fusion proteins encoded by these translocations are usually essential for cancer maintenance, making them ideal targets for pharmacologic and immunologic intervention because tumor cells may not easily escape therapy by losing expression of the fusion proteins.[328] Pharmacologic approaches are exemplified by the drug imatinib targeted to the fusion protein of the 9;22 translocation in chronic myelogenous leukemia.[9,294,329] The antikinase drug imatinib does not selectively inhibit the catalytic activity of the BCRABL fusion protein, and this results in toxicity to normal cells in the patient. The intracellular BCR/ABL fusion proteins can be recognized specifically by antibody but only in fixed cells.[330] BCR/ABL fusion peptides can also be recognized by human CD4+ T cells in the context of MHC class II[331] and serve as targets for CD8+ human cytolytic T cells.[332] Why do we then still lack effective immunologic therapies for targeting this and other fusion proteins? As explained previously, the predicted epitopes may 1) not be generated naturally by cells,[293] 2) lack sufficient affinity to the particular MHC of that patient, or 3) not be produced in sufficient amounts.

Mutant RAS**.** Point mutations in oncogenes can also be shared by several cancers and could encode useful antigens. For example, a valine for glycine substitution at position 12 of RAS is one of the most common mutations in human cancers and can be recognized by human CD4+ T cells.[333] The region of the mutant RAS protein from which

the peptide was derived is identical for all the three members of the *RAS* proto-oncogene family, namely, H-RAS, K-RAS, and N-RAS, which have different prevalence in different cancers. In addition, about 90% of pancreatic adenocarcinomas, a very aggressive human cancer, have one of three to four different single amino acid substitutions in codon 12 of the cellular Kirsten *RAS* gene.[334] Despite remarkable clinical and experimental efforts,[335,336,337,338,339,340] targeting mutant RAS-derived epitopes has so far met with little if any success, the likely reasons being the same as those mentioned under the section titled Fusion Proteins. Immunizing cancer-prone mice harboring “initiated” mutant ras-expressing cells with mutant ras peptide resulted in mutant ras-specific CD4+ T cells, antibodies to the mutant ras protein, and more tumors and faster tumor development.[341] Possibly, the antibody, produced in response to antigen, activated myeloid cells via FcR-γ to become tumor-promoting, and/or antibody carrying TGF-β downregulated CD8+ effector responses.[342,343]

Self-Antigens (Encoded by Normal Genes)

All antigens listed in this section are encoded by nonmutant cellular genes and expressed not only by cancer but also by at least some normal adult cells. Therefore, these antigens are not tumor-specific and are commonly referred to as *tumor-associated* antigens. The level of expression of these antigens can vary from widespread expression to restriction to a small population or a subset of normal cells. However, self-antigens should not be called “quasi-tumor-specific” because even very low levels and/or selective expression of a self-antigen may cause severe even lethal toxicity when targeted.[204,206]

Self-antigens expressed by tumor cells are used for destruction, inhibition, or detection of cancerous growth. When used as targets for destruction, T cells or antibodies must eliminate the cancer cells while not destroying normal cells expressing the same self-antigen, or destruction of selfantigen -expressing cells must be tolerated. Thus, no serious toxicity must occur even when the immunity is strong enough to destroy the cancer cells.[195,196] Antibodies against growth factors or their receptors can inhibit growth of cancer cells without destroying them. When self-antigens are used for diagnosis, background levels of antigen generated by normal cells complicate use of these antigens for early detection of cancer. However, changes in the amount of circulating self-antigens may indicate relapse of cancer after therapy.

All normal individuals have so-called natural autoantibodies as well as T cells to a wide spectrum of self-antigens without causing pathology, but those B-cell receptors and TCRs have usually very low affinity. In fact, any immune receptor binds with some affinity to any particular antigen[344] and immune receptors may bind to several molecularly unrelated structures,[345] making the discussion of specificity seemingly useless. However, the antibody response of an individual to self- and nonself-antigens differs in affinity by many orders of magnitude, and therapeutically effective antiself-antibodies or TCRs are commonly raised in a nonself, usually xenogeneic, setting. Whether removing natural mechanisms that prevent autoimmunity is a general approach to achieve truly effective antitumor immunity needs to be substantiated.

The problem of B-cell unresponsiveness can be overcome by immunizing mice with xenogeneic human antigen. Misleadingly, these high-affinity antixenogeneic antibodies are usually advertised as “fully human” when they were made in mice in which the murine immunoglobulin (Ig) gene locus had been inactivated and replaced with the human Ig gene locus.[346] The toxicities of such “fully human” antibody will still be those of high-affinity antiself antibody: severe to lethal toxicity. These reactions may occur when the variable region of such antibodies (eg, anti-CEA or anti-human epidermal growth factor receptor [HER]-2[204,206]) is fused with the transmembrane and signaling domains and then transduced as chimeric antibody receptors (CARs) into T cells.[347]

T-cell tolerance to self can be overcome by making T cells in a host that is allogeneic to the MHC class I molecule presenting the targeted peptide.[348] However, recent studies exposed that such allo-human leukocyte antigen (HLA)-restricted high-affinity T cells can have severe “off-target” reactivity likely to cause toxicity when used in patients.[349] T cells transduced with these TCRs kill each other (fratricide) when the self-antigen (eg, wild-type p53 or survivin) is expressed by the T cells.[350,351] High-affinity TCR cells can also be generated in knockout mice lacking the targeted selfpeptide (eg, wild-type p53 peptide sequences[352]), but T cells expressing these TCRs are lethal when given to normal mice because wild-type p53 is expressed in bone marrow and can also be expressed by most other normal cells.[350]

Overexpressed Molecules

***Growth Factors and Their Receptors*.** See Immunotherapy.

Survivin. Although survivin is overexpressed in many cancer cells, it is a problematic antigen particularly as a vaccine because it is widely expressed on lymphocytes causing fratricide.[351] Not surprisingly, this antigen has been ineffective in vaccine trials.

p53. Research using p53 as target for immunotherapy is exemplary of the problems and persistent misconceptions of research on tumor-specific (unique or shared) and selfantigens. Mutations in the p53 suppressor gene are among the most common found in human and experimental cancers.[353,354] These mutations tend to cluster in evolutionarily conserved regions of the gene, but the exact locations are highly diverse in individual cancers.[355] Targeting these mutations would require an individualized therapy considered by many impractical. Therefore, researchers have attempted to exploit the fact that mutant p53 is

usually overexpressed in cancers. Thus, major efforts have been made to target conserved, nonmutated regions of the p53 protein hoping for “relative tumor specificity” based on the usual belittlement for low-level expression of this protein by every normal cell including lymphocytes. As a result, T cells expressing highaffinity anti-p53 TCRs commit fratricide unless the anti-p53 TCRs are transduced into T cells from p53 knockout mice.

However adoptive transfer of these T cells causes lethal hematopoietic ablation in normal mice.[350] Mortality can be prevented by reconstitution of the recipients with bone marrow from p53 knockout mice,[350] an option unavailable in humans. Not surprisingly, there is no evidence for clinical efficacy of targeting wild-type p53 in humans.

***Prostate-Specific Membrane Antigen*.** Prostate-specific membrane antigen (PSMA) is a type II transmembrane glycoprotein more correctly referred to as glutamate carboxypeptidase II. PSMA is an inappropriate misnomer because it is anything but specific for prostate; it is also expressed by duodenal mucosal cells, proximal renal tubule cells, and a subpopulation of neuroendocrine cells in colonic crypts,[356] and has important functions in the brain.[357] Vaccination of mice with human PSMA induces antitumor effects without causing toxicity but because the mouse model lacks expression of human PSMA on normal tissues, the findings in this inappropriate model are meaningless.[358] Similarly, a “fully humanized” anti-PSMA antibody had potent antitumor xenograft activity in mice that lacked expression of this antigen on normal cells.[359] Therefore, this antibody may have severe, possibly lethal, toxicity in patients.

Differentiation/Lineage-Specific Molecules

Some antigens expressed on tumor cells are also expressed during at least some stage of differentiation on nonmalignant cells of the lineage from which the tumor developed. Differentiation antigens may therefore help to determine the organ or cell type of origin (lineage) of a cancer.[360] For example, B-cell tumors express surface Ig, and T-cell leukemias can be separated into helper and suppressor cell leukemias using T-cell subset-specific monoclonal antibodies to surface and intracellular antigens including transcription factors. For metastatic cancer of unknown origin, differentiation antigens can be important indicators of the histologic and organ site of the primary tumor.[361] Careful diagnostic delineation of different subtypes of cancer is important because different tumor subtypes may have different prognoses and may be susceptible to different therapies. However, the use of differentiation markers for histologic or cytologic tumor classification has pitfalls.[361] Lineage-specific antigens represent a very diverse group of proteins: glycoproteins (including mucins) and glycolipids (carbohydrate, peptide, glycopeptide, or glycolipid epitopes). Several of these antigens are being explored as potential immunotherapeutic targets. However, the normal cell types that express these antigens will determine toxicity and usefulness of any antibody or agent for which these are targets.

Cluster of Differentiation 20 and Cluster of Differentiation 19 **.** CD20 is a signature B-cell differentiation antigen targeted by a genetically engineered monoclonal antibody that is relatively effective in the treatment of B-cell lymphoma. Lineage restriction of this marker limits the cytocidal effects to long-term depletion of normal B cells. This depletion is usually well tolerated because patients can be protected by intravenous administration of IgG. While antibodies to CD20 antibodies are therapeutically effective, relapse is common. CD19, but not CD20, appears to be expressed on the more immature malignant cells causing the relapse. Therefore, anti-CD19 Fv has been used in the killing of these cancer cells, either as a fusion protein with an anti-CD3 Fv to engage T cells[195] or as chimeric antibody receptor inserted into the patient's T cells.[196] These treatments may prevent relapse.

***Melanocyte-Specific Differentiation Antigens*.** Several differentiation antigens (such as tyrosinase, the related brown locus protein or tyrosinase-related protein 1 (Trp-1), gp100, and Melan A/MART-1[362,363]) appear to be restricted to melanocytes, and all of them are being explored as immunotherapeutic targets in melanoma.[364,365,366] Immune recognition of the

melanocyte differentiation antigens can lead to rejection of a tumor challenge but this self-antigen-specific immunotherapy not only targets the tumor cells but also normal cells expressing the shared antigens,[365,367] resulting in the depigmentation of normal skin (vitiligo) and possibly other, more serious toxicities (see following discussion). For example, mice immunized with syngeneic Trp-1 in various adjuvant settings fail to produce a T- or B-cell response.[368] Xenogeneic or altered Trp-1, however, induces responses that cause vitiligo and protect against challenge with melanoma cells.[368] Passive transfer of Trp-1-specific antibodies from these mice causes vitiligo and protects against metastatic spread of melanoma cells in mice when given at the time of seeding of the malignant cells.[367] Similar antibodies may have analogous beneficial effects in human melanoma patients,[369] but evidence is lacking for such antibodies eliminating bulky human melanoma. Trp-1-deficient mice respond to Trp-1 as a foreign antigen and Trp-1-specific CD4+ T cells from these mice can eradicate large B16 melanoma 10 to 14 days after inoculation,[370,371] cause autoimmune vitiligo, and damage the retina.[370] Designating these T cells as “tumor-specific” when they are clearly not is incorrect and misleading.[370] Trp-1 is expressed in all neurocrest-derived pigmented cells, not only those of the skin but also those of the eye (uvea), inner ear, and brain (substantia nigra, forebrain, and midbrain).[372,373,374,375] Other targets include gangliosides GD2 and GD3 that are also not only overexpressed in melanoma but are also found in other cells of neurocrest origin and in other tissues.[376,377]

***Prostate-Specific Antigen*.** Prostate-specific antigen (PSA), also called kallikrein-3, is a chymotrypsin-like protease that digests semenogelin I and II to release motile sperm.[378] Elevation of PSA above the normal range occurs in inflammation (prostatitis) and benign hypertrophy of the prostate as well as in prostate cancer. Using PSA levels for early detection of prostate cancer is controversial. The U.S. Preventive Services Task Force no longer recommends this test in healthy man.[379] However, detection of any PSA following complete surgical removal of the prostate indicates residual tumor cells and/or recurrence.[380] Prostate-specific phosphatase is selectively expressed and secreted by the epithelial cells of the prostate gland.[378,381] Sipuleucel-T, a vaccine targeting prostate-specific phosphatase

and approved by the U.S. Food and Drug Administration for the treatment of castration-resistant prostate cancer, results in only a very modest improvement in overall survival.[323] Furthermore, a recent analysis of internal documents that became available after the U.S. Food and Drug Administration approval questions the adequacy of the trial and correctness of the conclusions drawn.[382]

***Epithelial Cell Adhesion Molecule*.** Normal and malignant cells of epithelial origin express the transmembrane glycoprotein epithelial cell adhesion molecule (Epcam).[383] Anti-Epcam antibody 17-1A[384] showed promising results in patients with colon cancer in several early studies,[385] whereas subsequent randomized clinical trials consistently failed to show any benefit.[386] A high-affinity engineered anti-Epcam antibody caused cases of acute pancreatitis and was discontinued.[387] Other anti-Epcam antibodies in the form of bi- and trifunctional constructs may be more effective, but finding efficacy while keeping lethal toxicity under control presents a major hurdle.

Tumor Antigens Caused by Altered Glycosylation

Aberrant glycosylation and the overexpression of certain carbohydrate moieties is a consistent feature of cancers,[388,389] and tumor-associated oligosaccharides are actively investigated as targets for immunotherapy.

***Mucins*.** Mucins are normally heavily glycosylated glycoproteins (ie, containing complex O-glycans) that protect the luminal mucous epithelial surfaces. Mucins of cancer cells often show decreased expression of the complex O-glycans and increased expression of short

oligosaccharides, the TF, sialyl-Tn, and Tn antigens[390] (see following discussion). Thus, human adenocarcinomas of the pancreas, breast, and colon express mucins[391] that can be recognized on cancer cells by MHC-unrestricted cytolytic T cells. These T cells apparently react specifically with repeated epitopes on the protein core of the mucin molecules,[392] exposed because of deficient glycosylation in the malignant cells.[393] The epitopes are expressed at high density, do not require processing, have a stable conformation, and can directly bind to certain TCRs without being presented by MHC molecules.[394] Hypoglycosylated MUC1 is expressed on about two-thirds of newly diagnosed cancers. However, multiple types of vaccines using the nonglycosylated tandem repeat peptides or tumor-associated saccharide antigens conjugated to carriers failed to immunize effectively.[395,396] This finding is consistent with multiple lines of evidence that humans and MUC1-transgenic mice are tolerant to the unglycosylated long MUC1 peptide. Numerous approaches have been developed capable of overcoming this tolerance such as using short and long synthetic glycopeptides or plant-expressed MUC1.[397,398,399,400] Many different mucin genes have been identified[401] and antigens have been defined, but evidence for clinical efficacy with controllable toxicity is lacking.

***T and Tn Antigens*.** Tn antigen on human erythocytes, first described by Moreau et al. in 1957,[402] is the cause of a hemolytic autoimmune disorder, Tn syndrome.[403] Tn ("T antigen nouvelle") is a Ser/Thr-O-linked *N* -acetylgalactosamine monosaccharide distinct from the disaccharide T (or TF) antigen galactose-β1-3-N-acetylgalactose O-linked to a Ser or Thr (Galβ1-3GalNAcα1-Ser/Thr) described earlier by Huebner, Thomsen, and Friedenreich.[404] Human cancers very frequently express TF and Tn antigens.[405,406] Recently it was shown that the Tn syndrome is caused by somatic mutations in the chaperone COSMC.[407] While TF antigen is an oncofetal antigen highly expressed in the embryo and fetus,[390] there is no evidence that Tn is also an oncofetal antigen.[404] Mutational deletion of the chaperone COSMC leads to expression of the Tn antigen on virtually every embryonic cell and leads to early embryonic death.[408] Most adults naturally have anti-Tn as well as anti-TF antibodies due to antigenic stimulation by Tn and TF antigens expressed on the bacterial flora.[409,410] Tn antigen is also expressed on human immunodeficiency virus-1 and pathogenic parasites. Thus, evidence is lacking for any expression of Tn antigen on adult or embryonic human or murine cells except by patients suffering from Tn syndrome and cancers that may or may not show a tumor-specific deletion of COSMC. There is no evidence that Tn is an effective therapeutic target. This may be due to anti-Tn antibodies being usually IgM or IgA of very low affinity, though recently developed IgG antibodies reduced slightly the growth rate of human cancer cells in vitro and in vivo.[411]

***Glycopeptide Antigens Resulting from Tumor-Specific COSMC Mutations*.** The remarkable characteristic of this new class of antigens is the exquisite tumor specificity of the antigen[412,413,414] even though it is encoded by normal genes. Appearance of the antigen, however, depends on a tumor-specific somatic mutation that destroys the chaperone COSMC that is essential for any functioning of the core 1β (1-3) galactosyl-transferase, T-synthase. COSMC protects the newly synthesized T synthase from aggregation and subsequent endoplasmic reticulum-associated degradation.[404] T-synthase is essential for extending O-linked glycosylation beyond a single O-linked *N*-acetylgalactosamine (ie, Tn antigen). Importantly, the antigen recognized by the high-affinity, tumor-specific antibody does not bind Tn alone but contains the Tn hapten (ie, the single O-linked *N*- acetylgalactosamine on a threonine or serine). X-ray crystallography shows that the antibody completely envelops the carbohydrate moiety while interacting with the unique sequence of the peptide moiety in a shallow groove.[413] Because Tn does not exist on normal embryonic or adult human or murine cells, there is no central or peripheral tolerance to these antigens allowing high-affinity destructive immune reactions to occur. This also explains the severity of the autoimmune disease associated with the Tn syndrome caused by somatic (not germline) mutations of the

COSMC gene.[407] Importantly, somatic tumor-specific mutations disabling the X chromosome encoded COSMC gene (for which one copy is naturally silenced) seem to be more common than originally assumed and occur in a wide variety of spontaneous or virally induced human and murine cancers.[415] Nevertheless, it must be shown that high-affinity receptors when used as CARs on T cells or linked to anti-CD3 are effective against tumors but have little if any toxicity to

normal tissues. This may be expected from the fact that the epitopes depend on somatic tumor-specific mutations.

Oncofetal, Carcinoembryonic, and Cancer-Germline Antigens

Over 50 years ago, human cancer cells were found to express antigens that serologically cross-react with normal embryonic tissue.[416] Since then, it has been postulated repeatedly that certain normal genes that are completely silent in all nonmalignant cells may be activated exclusively in malignant cells.[417] Alternatively, it has been postulated that cancer cells may express proteins (or immature forms of a protein) that are only expressed in fetal but not in nonmalignant adult cells.[418] There certainly is profound hope for finding a universal tumor rejection antigen that can be used for vaccination, prevention of cancer, and antitumor therapy. However, repeated claims of selective activation of normal genes or selective expression of immature forms of these proteins in cancer cells leading to tumor-specific antigens have not been substantiated. Expression of the same antigen by at least one normal cell type in the adult was later often discovered.[419,420,421,422]

***Cancer-Germline/Cancer-Testis Antigens*.** Changes in gene methylation lead to the expression of a large number of genes encoding a group of antigens referred to “cancer-testis,” “cancer-germline,” or “cancer-spermatogonal” antigens. Many cancer-testis antigens have been described in humans such as MAGE, BAGE, GAGE, LAGE/NY-ESO-1, SAGE, HAGE, and BORIS.[422,423,424,425,426,427,428,429,430] All cancer-testis antigens are expressed at high levels in spermatocytes in the testis. And most, if not all, are also expressed in the thymus.[430,431,432] Many, but not all, cancer-testis antigens are encoded on the X chromosome.[433] Most of cancer-testis antigens can be recognized by autologous cytotoxic T-lymphocyte (CTLs), but there is no evidence for these antigens being generally effective targets for cancer cell destruction in human.[434,435] P1A was the first cancer-testis antigen to be identified in the mouse mast cell tumor line P815.[436,437] P1A can be induced in a broad range of tumors of diverse histologic origins with the demethylating agent 5-aza-2′-deoxycytidine.[438] Various normal tissues including thymus and premeiotic spermatocytes also express P1A.[437,439] While active immunization has only modest protective effects against cancer cell inoculation,[440] adoptively transferred T cells (monoclonal or polyclonal) targeting only the P1A antigen shrink large tumors (>1 cm in diameter) for several weeks followed by relapse caused by epitope-loss variants.[441] For eradication, cancer cells must first be transfected to express costimulatory molecules, which probably leads to the induction of T cells to recognize other tumor antigens.[442] Remarkably, autoimmunity has not been reported to be associated with a response to this antigen. In humans, the HLA-A2-restricted NY-ESO1 peptide has very poor affinity to its presenting MHC class I molecule, but high-affinity TCRs to this antigen have been generated and their efficacy in therapy is being explored.[443] While many cancer-testis antigens have been described and studied extensively for two decades, their usefulness as targets eradicating human cancers still remains to be shown. Despite these uncertainties, occasional successes have been observed. The hypothetical explanation: the relatively few T cells induced against the cancer-testis antigen served to elicit additional antitumor T-cell clones directed against other antigens that are actually responsible for the tumor regression by a poorly understood phenomenon referred to as epitope spreading.[434,444]

Numerous cancer-testis antigens have been detected using sera of cancer patients for

identifying antigens by recombinant expression cloning (SEREX). Importantly, sera from mice infected with cytopathic or noncytopathic viruses or injected with tumor cell lysates also show an autoantibody response of broad specificity, and intriguingly the majority of the identified autoantigens have been previously described as autoantigens in humans.[445,446] This suggests that human SEREX antigens may have to be regarded as afterglows of infection-associated immunopathology and/or tissue damage. This is consistent with the assumption that the human adult IgG autoantibody repertoire is the result of lifelong encounters with bacterial and viral agents and tissue damage. Together, usefulness of the SEREX-defined selfantigens remains to be demonstrated.

***Carcinoembryonic Antigen*.** CEA is a 200-kDa membraneassociated glycoprotein that is expressed not only in fetal but also in adult nonmalignant tissues such as normal colonic mucosa, lung, and lactating breast tissue.[447,448] It is released into surrounding fluids. At one time, it was hoped that CEA could be used as a marker for early diagnosis of gastrointestinal and other malignancies[449]; however, elevated serum levels of CEA are also found in the absence of malignancy (eg, in smokers and in inflammatory bowel diseases such as ulcerative colitis). Though serum levels of CEA are not useful for detecting early cancer, the level of CEA in the blood can be used to monitor the effects of therapy to indicate whether a cancer has been successfully eradicated or has recurred.[450] Using CEA as immunotherapeutic target is highly problematic because of severe toxicity. Mice expressing the target antigen in normal tissues closely resembling expression in humans showed severe toxicity from anti-CEA T-cell responses,[205] a result that predicted the severe adverse effects later observed in patients treated with anti-CEA CARs.[206]

***Alpha-Fetoprotein*.** Alpha-fetoprotein (AFP) was the first defined oncofetal protein.[451] Though produced by fetal liver and yolk sac cells, it is also present in small amounts in cells and the serum of normal adults. The amount of this protein is elevated in some patients with cancer of the liver or testis and also in some patients with various nonmalignant liver diseases. Therefore, similar to CEA, using AFP as a marker for the early diagnosis of cancer is of questionable use.[452] Nevertheless, assays of AFP can detect primary liver cancer at a time when the cancer is treatable, and AFP assays are also used for monitoring patients after therapy.[452] The use of AFP as target for active or passive immunotherapy is complicated by lack of specificity.[417,453]

Clonal Antigens

Clonal antigens are expressed only on the clone of cells from which the cancer originated.[454] Except for idiotypes of surface Ig-positive B-cell and T-cell malignancies, there

are presently no candidates for other clonal antigens. Immunization of animals against the idiotype induces an idiotype-specific transplantation immunity against the growth of cancers (myeloma, lymphoma, and leukemia) expressing the idiotype.[455,456] Furthermore, idiotype-specific antibodies prevented the growth of surface idiotype-positive murine malignant B cells in mice and guinea pigs in vivo and in vitro,[457,458,459,460] and occasionally induced the cancers to go into a long-lasting dormant state.[461] Finally, idiotypespecific monoclonal antibodies have caused several partial remissions and one complete remission in patients with B-cell lymphoma,[462] and targeting the idiotype on B-cell malignancies continues to be explored.[463,464,465] It is necessary to generate different monoclonal antibodies or idiotypic vaccines for each individual cancer to be treated, but the advantage of using such clonal antigens over less restricted tumor-associated antigens is that eliminating the few normal cells bearing the same antigen would probably not adversely affect the patient.

Viral Antigens (Encoded by Viral Genes)

Cancer-causing tumor viruses such as SV40, polyoma viruses, human papillomavirus (HPV), hepatitis B virus, hepatitis C virus, human T-lymphotropic virus 1, Epstein-Barr virus (EBV),

and other herpes viruses and their antigens are discussed in other parts of the chapter. For discussion of a 70-kDa glycoprotein (gp70)[419,420,466,467] and other important antigens[468,469,470] encoded by ribonucleic acid (RNA) tumor viruses (eg, murine leukemia virus, maize streak virus,[471,472,473,474] and mouse mammary tumor virus[475]), see Coffin[476] and Schreiber.[477]

IMMUNOGENICITY OF AUTOCHTHONOUS CANCERS

There is the widely held misconception that human cancers are usually less immunogenic than are murine tumors.[478] However, convincing evidence indicates that many, probably all, human cancers are antigenic. Similarly, even the most antigenic murine UV-induced "regressor" tumors grow progressively and invariably kill the primary host[218,479] (Fig. 47.3). Only transplantation of primary murine tumors into young, syngeneic, immunocompetent, tumor-free recipients reveals their antigenicity and immunogenicity. UV-induced regressors are so immunogenic that they are rejected by naïve immunocompetent hosts. Many experimental cancers require preimmunization to be rejected upon transplantation, and the degree of *immunogenicity* usually refers to the relative strength of antigen-specific protection a tumor can induce against rechallenge with that tumor. Obviously, the resistance of the host to its autochthonous tumor cannot be great at the time it is clinically apparent and progressively growing.[228] Only weak reactions can be detected[321] because resistance of the autologous host depends on vaccinations

with the autochthonous tumor following complete tumor removal.[269] *Antigenicity* refers to the antigens on a cancer cell. However, a cancer may have strong antigens yet fail to induce a response (ie, lack immunogenicity). A cancer may also be antigenic and immunogenic but resistant to destruction by the immune response it induces. Thus immunogenicity, antigenicity, and *immunosensitivity* must be distinguished.

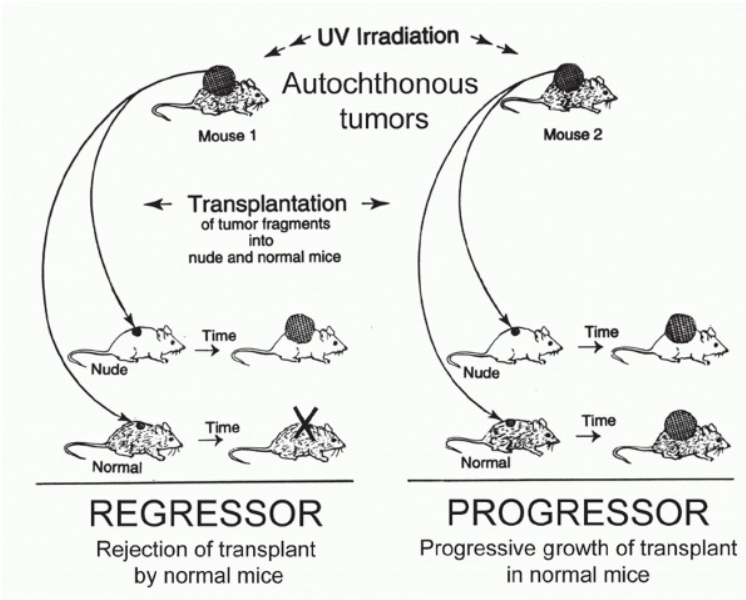

FIG. 47.3. Autochthonous Cancers are Indistinguishable in the Primary Host Regardless of Whether They are Highly Antigenic or Not. Only subsequent transplantation into young syngeneic immunocompetent hosts defines these tumors as regressors or progressors, and shows their antigenicity and immunogenicity.

Progressively growing autochthonous cancers differ greatly in immunogenicity as determined by responses of syngeneic, tumor-free hosts. Autochthonous tumors induced in mice with UV are among the most immunogenic cancers; transplantation resistance to these so-called

regressor tumors appears to be absolute rather than relative. Rejection by normal syngeneic mice is observed without prior immunization, even when the largest testable doses of tumor cells or fragments are used.[275] Most MCA-induced fibrosarcomas, unless induced in immunodeficient mice (see following discussion),[480] display an intermediate degree of immunogenicity in normal mice.[268,269,481] This is shown by the fact that induction of immunologic resistance to most chemically induced tumors requires prior immunization because the initial graft of the tumor generally produces progressive lethal growth.[268] Importantly, failure of a cancer to induce a tumor-destructive immune response does not mean it lacks either antigenicity or immunogenicity. (See below discussion of sporadic SV40-induced tumors under Immune Surveillance of Cancer[228,301].)

Age and Latency

Experimentally, the length of the latency period of a tumor is usually inversely proportional to the dose of carcinogen. In humans, the doses of (ie, the levels of unintentional exposure to) carcinogens and promoters are believed to be usually relatively low. This means usually a long time is needed for the initiated cells to accumulate the multiple genetic events essential for a premalignant or cancerous lesion. Once the neoplastic cells have reached sufficient numbers to stimulate a response, the host may be too old to respond vigorously. The overwhelming majority of human cancers arise in individuals past 60 years of age,[254] and it has been shown repeatedly in humans and mice that the immune response to new antigens declines with age[258,482,483,484]; this should include antigens on the developing tumors. Thus we do not know the extent of which cancers arising in old individuals may have been selected or retained antigenicity and immunogenicity. In stark contrast, most experimental cancers are induced at an age correlating to that of young middle-aged humans. If 2 years of mouse life roughly correlate to 60 years of human life, then most experimental cancers mirror cancers developing in humans 30 years old or less. Tumors induced by MCA or transgenic oncogenes are usually produced in mice less than 1 year old.[485,486,487,488,489] The length of the latency period of these MCA-induced tumors correlates inversely with the degree of immunogenicity.[229,490,491,492] There is no such correlation in UV-induced tumors[275,479] that begin to develop past 9 months of age, mostly in mice more than 1 year old. Old mice beginning at about 9 months of age fail to reject various types of highly antigenic cancer cells that are regularly rejected by young mice.[255,256,257,258] Even though UV irradiation is immunosuppressive, young UV-irradiated mice remain immunocompetent long enough to select for antigen loss variants.[235] This indicates that advanced age must contribute to allowing the developing cancers to remain immunogenic. An intriguing question is how many of the tumors that spontaneously arise in older animals would grow in younger syngeneic hosts.[480] Considerable but only indirect evidence makes it very unlikely that all tumors would grow.

Spontaneous versus Induced

“Spontaneous” cancers that develop without any known exposure to carcinogens tend to be less immunogenic than cancers induced by DNA tumor viruses or by deliberate exposure to carcinogen.[266,267,493,494,495] Unfortunately, serially transplanted tumors were used for most of these comparisons, and transplantation may have selected for less immunogenic variants, thereby confusing the results. If spontaneous murine cancers more closely resembled human cancers, this could suggest that human cancers are poorly immunogenic.[495] However, most human cancers are not “spontaneous” but induced by environmental carcinogens, have never been transplanted, and develop mostly in old individuals that may not select for cancer variants. Most, if not all, carcinogens are mutagens[17] and probably always cause the expression of tumor-specific antigens. However, it is not clear why tumors induced with the same dose of chemical or physical carcinogen may exhibit quite different degrees of immunogenicity.[268,479] One reason might be that the actual

local dose of carcinogen that is delivered to a particular target cell or target tissue may vary greatly from animal to animal. Another reason might be that mutations are selected that favor malignant behavior irrespective of the degree of immunogenicity of that mutant protein. This is consistent with the observation that considerable differences in immunogenicity of primary UV-induced tumors only become apparent *after* transplantation into secondary hosts[218,479] (see Fig. 47.3).

"Regressors" from Immunocompromised Hosts

Immunocompetence of the host may not affect the cancer incidence but still influence the immunogenicity of the developing tumor. Conversely, immunosuppression or immune deficiency of the host during carcinogenesis should allow growth of highly immunogenic tumors in the absence of such selection.

Clinical Evidence

Clinical support comes from the appearance of highly antigenic EBV-associated lymphomas in immunosuppressed transplant recipients that are virtually unknown to occur in immunocompetent humans.[502] In addition, renal transplant patients experience a reduced risk of developing UV-induced skin cancer after immunosuppressive medications are stopped.[503] It is tempting to suggest that many of these

cancers developing in transplant patients are actually "regressor" tumors that have arisen only because host defenses were damaged.

Experimental Evidence

In normal adult mice, Moloney sarcoma virus[496] induces tumors larger than 2 cm in diameter that then regress while tumors continue to grow and kill immunodeficient adult or newborn mice.[497,498,499] The first experimental evidence for UV-induced regressors came from Kripke in 1974,[275] showing that UV irradiation made mice immunodeficient and induced cancers that were often "regressors," meaning that they were rejected with any testable size inoculum by naïve syngeneic immunocompetent mice. Tumor transplants will grow for about a week and then disappear, though small numbers of the same tumor cells will grow and kill athymic nude mice. The same regressors grew after inoculation of few cancer cells in UV-irradiated mice. So, it may be highly relevant that some carcinogens are immunosuppressive.[500,501] Repeated exposures of mice to UV induce persistent immune suppression,[502,503,504] leading to the development of highly immunogenic regressor tumors. In contrast, the single injection of MCA induces tumors in 100% of mice and only a short-lived state of immune suppression,[501] thus allowing a fully immunocompetent host to select for less immunogenic variants. The concept that immunocompetence of a host influences the immunogenicity of the developing tumor has been tested experimentally by Roberts and Daynes[480] comparing the MCA-induced tumors occurring in immunodeficient UV-irradiated mice with cancers induced in normal mice. Indeed, cancers induced with MCA in mice immunosuppressed with UV were frequently regressor tumors, whereas none of tumors induced with MCA in immunocompetent mice were regressors.[480] Decades later, this concept was confirmed with tumors induced with MCA in nude, severe combined immunodeficiency, or Rag-/- mice.[487,505,506]

Selection by the Immunocompetent Host

Immunocompetent hosts can select for cancer variants. Thus, when regressors are transplanted into normal immunocompetent hosts, heritable progressor variants can escape. Some of these variants show antigen loss,[218,219,507,508,509] but many others retain their antigenicity and grow faster than the parental tumor when their growth is compared in T, B, or NK cell-deficient hosts,[43,45,218,307,505,508,510] suggesting that mechanisms other than antigenicity must participate determining the differences in growth behavior between

regressors and progressors.

"Regressors" from Immunocompetent Hosts

Human cancers are sporadic (ie, occur at irregular times and locations); this is in part due to the occasional genetic events that can cause malignant transformation in a single cell that expands to become a detectable tumor. A murine model of sporadic genetic events is the recombinational activation of a normally silenced transgene encoding the strongly oncogenic and strongly antigenic molecule SV40 T, thereby causing sporadic appearance of cancers.[228,301] These tumors are regressors. The tumors "snuck" through immune surveillance and immunoselection despite expressing such a powerful antigen and oncogene, but not unnoticed. The developing cancers did induce antibodies and proliferation of antigen-specific T cells during their early dormant phase of growth, but developing tumor-specific T cells were anergized in that they failed to produce interferon (IFN)γ and kill tumor cells in vivo. In contrast, titers of the T antigen-specific IgG response increased with progressive tumor growth.

EFFECTOR MECHANISMS IN CANCER IMMUNITY

Because cancer is not a single disease, it is not surprising that findings using one tumor model may not apply to other tumor models. Considering the antigenic diversity found in tumors, it is also not surprising that different types of innate and adaptive, humoral and cell-mediated immunity have been shown to play different roles in the destruction or enhancement of malignant cells in one or another of the numerous tumor models.

Assays to Study Effector Mechanisms in Vivo

In principle, five different assays have been used to evaluate the importance of different effector mechanisms in vivo. The first type of assay involves transfer of effector cells, cytokines, or antibodies into sublethally irradiated, cyclophosphamide-pretreated, or normal animals challenged with tumor cells. There are certain limitations of this assay. Effector cells or molecules may not reach or localize in the tumor unless both the effector cells and cancer cells are injected intravenously, and both may be trapped in the lungs. Furthermore, if transferred cells or reagents are effective, the assay does not rule out that other effector mechanisms of the host may have been activated by the procedure. In a second procedure, called the *Winn assay*,[229,269,511] tumor cells are mixed with effector cells or serum in vitro; the mixture is injected subcutaneously into an animal to determine whether tumor growth in vivo is prevented. Tumor cells may be killed within minutes before or shortly after the injection, though the readout takes much longer. Therefore, the Winn assay is, in part, an in vitro cytotoxicity assay, even though the host is used as a readout for viable cancer cells. A third method involves elimination of specific lymphocyte subsets or cytokines in vivo by treatment with antibodies specific for different lymphocyte subsets or cytokines. Failure of the host to resist a tumor challenge indicates that the particular subsets or cytokines are an essential component of the host resistance. A fourth method is to use mice genetically deficient in a certain effector mechanism, cell, or cytokine. An analysis of tumor variants that have escaped tumor destruction by the host provides a fifth way for determining the importance of immunologic effectors in vivo.[43,44,45,218,235,236,507,512] The phenotypic changes observed in these variants may indicate which effector mechanism was responsible for the selection. Therefore, the type of phenotypic change

may give insight into the relative importance of a naturally occurring defense mechanism that may function in immunocompetent mice (analogous to deducing the action of an antibiotic from the type of change found in the bacterium that has become drug resistant). Host-selected variants from experimentally induced regressor tumors are used extensively for this approach.

Antibodies and B Cells

The role of B cells in regulating tumor immunity continues to be studied extensively yet remains poorly understood. In a tumor model of leukemia in which CD4+ helper T cells were

required for successful treatment, B cells were necessary for efficient T-cell priming.[513] Conversely, in other tumor models, elimination of CD4+T cells promoted tumor rejection by CD8+ cells, and an absence of B cells improved CTL responses and tumor rejection.[514,515,516] Antibodies and B cells have been associated with enhanced papilloma formation and autochthonous cancer development.[341,489,517,518,519] The mechanism recently postulated is that regulatory B cells help the macrophage become tumor-promoting,[520,521] or that they suppress surveillance by T cells that normally eliminate neoplastic cells with oncogenic mutations.[519] There are other possible mechanisms.[342,343] Also, none of these experiments identified the antigens involved, except one study showing that induction of mutant-ras specific-antibodies correlates with much more effective papilloma development in an autochthonous tumor model.[341]

Human antisera and monoclonal antibodies reactive with autologous tumors have been isolated.[420,522] However, a strong humoral response to tumor antigens does not correlate with demonstrable resistance of the host to the tumors. TL+ leukemias induce high titers of TL-specific antibodies that are cytotoxic to TL+ leukemia cells in vitro in the presence of heterologous complement,[420] but TL+ leukemias grow equally well in immunized mice having high titers of TL antigen-specific antibody and in nonimmunized mice.[523,524] Similarly, humoral immune response to MCA-induced sarcomas does not provide protective immunity against a tumor transplant.[525] Obviously, the presence of antibodies for these kinds of tumors has no relevance in predicting whether the host will reject the tumor.

Normal or malignant cells of hematopoietic origin are generally lysed quite effectively by antibody and heterologous complement in vitro; however, normal cells such as fibroblasts or malignant cells derived from solid tissues may be much less affected, even when expressing high levels of antigen. The reasons for this striking difference are still unclear. In vitro, some tumor cells are killed by a process involving coating with antibody, opsonization, and subsequent phagocytosis by macrophages; this process may be enhanced by the presence of heterologous complement. Alternatively, antibody-coated tumor cells may be killed in the absence of phagocytosis by antibody-dependent cell-mediated cytotoxicity when cocultured with macrophages, NK cells, or neutrophils. The general relevance of these mechanisms for killing tumor cells in vivo is unclear. Exogenous antibodies that block growth factors and/or their receptors or activate costimulatory molecules are useful for some kinds of immunotherapy (see Immunotherapy).

T-Lymphocytes

It has been demonstrated convincingly that T cell-mediated immunity is critical for rejection of virally[526,527,528] and chemically induced tumors,[229,269,529] or for the rejection of allogeneic[530] and UV-induced tumors.[218,275,503,508] For example, in the model of murine MCA-induced tumors, it was shown that intravenous injection of immune cells, but not of immune serum, could transfer systemic tumor-specific immunity into sublethally x-irradiated mice.[229] These findings were consistent with earlier work with allogeneic tumors showing that lymphocytes not serum were effective in transferring transplant resistance.[531,532,533] In another study, transfer of immunity to a plasma-cell tumor was abolished by pretreatment of the immune cells by anti-T-cell antibodies and complement.[529]

The relative importance of various T-cell subsets in tumor rejection (ie, T_C1 [type I CD8+ cytotoxic T cells]; T_C2 [type II CD8+ cytotoxic T cells]; T_H1 [type I CD4+ helper T cells]; T_H2 [type II CD4+ helper T cells], T_C17 [IL-17-producing CD8+ T cells], etc.) have been the subject of repeated, and probably unnecessary, controversies.[534,535] Different tumors are dissimilar enough so that differences would be expected in T-cell subset requirements. Also different therapeutic settings may require different subsets (eg, to prevent cancer development or destroy premalignant lesions), established solid cancers, malignant effusions, microdisseminated cancer cells, or leukemic cells. Dependent on their subtype, T cells

produce and induce various cytokines and chemokines that may destroy tumors by direct effects on tumor vasculature or recruit neutrophils, macrophages, and NK and other innate effector cells that are needed for tumor eradication.[536] Many recent studies employ overexpressed model antigens and TCR-transgenic T cells not available in humans; thus, results need to be confirmed using non-TCR-transgenic models and genuine tumor-specific antigens. Interestingly however, adoptive transfer of TCR-transgenic CD8+ T cells specific for a model antigen can eliminate large established tumors[536,537,538,539,540] or artificial pulmonary metastases[541] without the T cells needing perforin.[536,541] Release of IFNγ and tumor necrosis factor (TNF) by the T cells seems to be critical; receptors for both cytokines must be expressed on bone marrow- and non-bone marrow-derived tumor stroma to kill T cell-resistant cancer variants as bystanders or relapse may occur.[537,538,540,542] CD4+ T-cell subsets can influence antitumor immunity, and truly tumor-specific CD4+ T cell-recognized tumor antigens exist.[10] CD4+ T cells seem to be critical at the effector phase of CD8+ T cells for cancer cell destruction in vivo,[543,544] for sustaining CD8+ T-cell memory,[545] and for the survival of adoptively transferred CD8+ T cells.[546,547] However, CD4+ T cells do not necessarily require recruitment of CD8+ T cells for eliminating cancer cells in vivo,[10,371,548,549,550,551] even when the cancer cells are MHC class II negative and killing as well as presentation must be indirect.[10,549,552,553] Destruction of the cancer cells

in vivo requires IFNγ, but occurs even when cancer cells lack the receptor for it.[552] Thus the effects of CD4+ T cell-released IFNγ must be on stroma, most likely tumor vasculature.[554,555]

Certain CD4+ subsets may also suppress tumor rejection, because elimination of the CD4+ T-cell subset may increase tumor resistance in certain tumor models.[514,556] Now termed T_{reg} cells, these Foxp3+CD25+ T cells mostly suppress the induction of immune response to new antigens, reduce anticancer immunity particularly to self-antigens, and suggest poor prognosis when prevalent in excised cancers.[557] However, it is uncertain whether these T_{reg}s can prevent adoptively transferred tumor-specific memory T cells from eradicating cancers.

Natural Killer, Lymphokine-Activated Killer, and Natural Killer T Cells

NK cells are distinct subpopulations of lymphocytes that, without prior sensitization and without the requirement for MHC restriction, can kill some cancer cells, particularly while circulating in the bloodstream, as well as nonmalignant nonself cells[558,559,560,561,562,563,564,565] (see Chapter on NK cells in this book). NK cells occur as 1) "resting" NK cells that nevertheless kill very sensitive targets such as YAC, 2) "activated NK" cells induced within hours by IFNαβ to become cytolytic but without proliferation (many conditions and microbial agents rapidly induce IFNαβ), and 3) lymphokine (IL-2)- activated killer (LAK) cells developing after days of *culture* in high doses of IL-2 and requiring proliferation.

NK cells can "recognize" the absence of self[566] (ie, the missing MHC allele fails to provide an inhibitory signal to prevent the activation of NK cells to kill the target[567]). Therefore, cancer cells that fail to express at least one of the MHC class I alleles of the host are killed more effectively.[568,569] Transformed cells often have decreased or lost MHC class I surface expression or have induced expression of ligands for activating receptors on NK cells and thus are targets of NK cells. In vivo, NK cells or NKG2D-mediated effects inhibited autochthonous and transplanted tumor formation and tumor recurrence, and reduced metastatic dissemination of intravenously injected cancer cells.[570,571,572,573,574] However, NK cells were effective usually only at incipient stages.[575,576] In patients, intratumoral NK cells may reduce metastatic seeding, thereby leading to longer survival,[577]

and NK cells may be a key factor in the occasional cure of acute myeloid leukemia and childhood acute lymphoblastic leukemia by allotransplantation.[578]

Activation of peripheral blood cells in vitro with high doses of IL-2 induces LAK cell.[579] Cancer cells, even when resistant to NK cells, are usually susceptible to killing by LAK cells in vitro, whereas most nonmalignant target cells have been reported to be resistant to killing by LAK cells.[580] Intravenous injection of LAK cells early after intravenous seeding of cancer cells into mice reduces the metastatic tumor cell growth in the lungs; however, with this procedure, both LAK and cancer cells are trapped in the lungs.[581,582] Antitumor responses have also been reported in humans after adoptive transfer of LAK cells in patients with renal cell carcinoma and melanoma.[583] This selectivity is difficult to explain, considering the general susceptibility of cancer cells to LAK cells in vitro. In more recent studies, adoptive transfer of NK cells activated in vitro with IL-2 failed to cause tumor regression in patients with melanoma.[584] The cells that mediate the killing in vitro of a broad range of malignant cells are more than 90% activated CD16+/CD3- NK cells,[585,586] but which cells have antitumor activity in vivo is not fully established. Even though murine LAK cells can be generated from nude mouse spleen cells,[587] it has not been demonstrated that LAK cells from nude mice or normal mice have similar therapeutic effects against tumor cells in vivo. Other cell types, such as CD3+ lymphocytes, which are regularly present in every preparation of LAK cells, may contribute significantly to the killing of tumor cells in vivo, particularly because activated CD8+ T cells express the stimulatory lectin-like NKG2D receptor and can kill tumor cells expressing the ligands for the receptor.[588]

Many surface receptors originally discovered in NK cells are expressed by subsets of T cells such as NKT cells, defined by the invariant Vα14/24Jα18 TCR α chain.[589] NKT cells, when treated with IL-12 at the time of cancer cell inoculation or after 1 day, inhibited tumor development and metastasis.[590,591] Also, the development of tumors induced by MCA was found to be reduced in some but not other studies.[486,489,592] In any case, clinical studies are exploring the usefulness of NKT cells in certain cancers.[593,594,595,596] NKT cell infiltration of neuroblastoma is associated with a favorable outcome; NKT cells may target the tumor-promoting stromal macrophages rather than the neuroblastoma cells directly.[597]

Together, previous studies have failed to provide evidence that NK, LAK, or NKT cells can eliminate well-established solid tumors casting continuing skepticism about the clinical usefulness of these cells in the therapy of advanced solid tumors.[575,576,598] A recent study, however, shows even very large solid tumors being eradicated by NK cells alone when the NK cells are properly activated by IL-15 in vivo at the site of the tumor.[599]

Macrophages and Granulocytes

Neutrophils rapidly appear at the site of injury and respond very rapidly to diverse chemotactic and inflammatory stimuli.[200] Furthermore, neutrophils often appear to pave the way for the influx of inflammatory monocytes that then mature to “angry” classically activated macrophages (or M1 macrophages) (eg, after “classical” activation by intraperitoneal/pleural injection of thioglycolate[105,106,600,601,602]). However, such inflammatory stimuli are usually absent in cancers. As a result, neutrophils can be relatively rare (0.1% to 0.4% of the total cells in solid tumors).[603] Macrophages, however, are regularly found in the microenvironment of solid tumors and are usually at least 10 times more abundant than neutrophils,[604] sometimes a third or more of the tumor mass. These tumor-associated macrophages differ from “angry,” tissue-destructive, “classically activated” macrophages (or M1) but are “alternatively” activated macrophages (M2).

“Alternatively” activated macrophages seem to be derived from resident tissue macrophages that proliferate.[105,106] Cancers may not recruit tissue-destructive inflammatory cells (N1 neutrophils and M1 macrophages); apparently, cancer cells lack the signals necessary for

activating innate immunity,[605] but cancer cells transfected to express CD95L induce cancer cell-destructive neutrophils.[606] Therapeutic interventions may aim at converting cells of innate immunity to a tumor-inhibitory “type 1” response pattern. IL-4, the prototypical “type 2” cytokine, can inhibit growth of cancer cells transfected to produce this cytokine by activating granulocytes[73,127,137,138] and can activate macrophages to kill cancer cells in vitro,[607] but may also interfere with eventual clearance leading to outgrowth of escape variants.[142] IL-4-secreting tumors are heavily infiltrated by eosinophils,[73,127] and many clinical and experimental studies reported eosinophilic tumor infiltrates.[535] Nevertheless, the contribution of eosinophils to tumor destruction and tumor growth is still incompletely understood.[138,535,608]

Macrophages and neutrophils from normal donors are generally not cytotoxic to tumor cells or normal cells in vitro; however, macrophages and neutrophils can be activated by bacterial products and IFNγ (or other cytokines) in vitro to cause selective cytolysis or cytostasis of malignant cells.[609,610,611,612,613,614,615,616,617] Fully activated macrophages require long-term 16- to 72-hour assays to demonstrate in vitro tumoricidal activity in isotope-release assays or cytostatic activity in growth-inhibition assays. Some of the cytolytic or cytostatic effects of macrophages on tumor cells involve cell contact and/or the secretion of various cytotoxic substances, but phagocytosis may also play an important role.[618] TNF-α[619,620] produced by thioglycolate-activated macrophages can account for all of the classical tumoricidal effects of macrophages against some cancer cells in vitro.[621,622,623,624] However, as might be expected because of the plethora of cytotoxic molecules that can be released by activated macrophages,[200,625] other mechanisms such as reactive nitrogen intermediates can also be important mediators of killing of cancer cells in vitro.[626,627] Systemic activation of macrophages reduces metastatic seeding,[628] while a (nonactivated) colony-stimulating factor 1-dependent macrophage subset seems to help metastatic seeding.[629] Because of the rather selective cytotoxicity of thioglycolate-activated macrophages against malignant cells, numerous studies have considered the potential role of this cell type in cancer (see Cancer and Inflammation, Immunotherapy, Factors Limiting Tumor Immunity for discussion of myeloid-derived suppressor cells). As would be expected, these in vitro-activated leukocytes mixed with cancer cells and injected into an animal prevent cancer development from the inoculum “in vivo” (a Winn assay, see previous discussion).[630] Interestingly, dependent on the role neutrophils have in a particular cancer model, their transient elimination in vivo can either abrogate or enable T cell-mediated transplantation resistance.[44,631] However, there is a major difficulty of effectively eliminating macrophages or neutrophils long-term in vivo. Therefore, there is, at present, no critical evidence to establish or refute the idea[632] that macrophages and or granulocytes activated in vivo destroy nascent tumors and therefore play a role in immune surveillance.

FACTORS LIMITING CANCER IMMUNITY

Various mechanisms allow cancers to escape innate or adaptive host immunity, principally by 1) inducing a protective and supportive stromal microenvironment, 2) increasing resistance to direct attack, and 3) inducing T-cell anergy. Often, cancer cells seem to use a combination of the three, but numerous lines of evidences indicate that the first is key and virtually always part of tumor progression and escape. Unfortunately, most experimental tumor immunology depends on observations using cancers serially transplanted for decades. This is surprising, knowing that a single transplantation of an autochthonous tumor into an immunocompetent host dependably results in heritable variants that avoid destruction by the host[43,44,45,218,219,508] (see above under Experimental Cancer, Key Principles, and Selection of Tumor Model).

Tumor Microenvironment

Many escape variants keep their antigens but induce a stroma more effectively than the

parental cells for better support of growth and protection against destruction by the host (also see Cancer Stroma). Experiments have shown that stroma is critical for preventing or permitting immunologic destruction of cancer,[47] and it is likely that cancer stroma is also an important factor in causing very early cancers to resist therapeutic immunization.[633] Local factors must explain why tumor-bearing mice, while failing to reject a primary tumor transplant, reject a later implant of small numbers of the same cancer cells at second sites, a phenomenon called concomitant immunity (see discussion below under Cancer and Inflammation, Facilitation of Inhibition of Metastasis). Local factors particular to the tumor environment must also explain why mice bearing malignant grafts fail to reject the established tumors but reject nonmalignant grafts expressing the same rejection antigen[634]; T cells in these tumorbearing mice are neither clonally exhausted nor systemically anergic.[635] Antigenic stroma, as it exists in nonmalignant allografts[635] or when strong tumor-specific antigens are crosspresented by tumor stroma,[537,538,539,540,542] can help T cells to eradicate cancers. In addition, recent work in two tumor models suggest that lack of “help” at the site of cancer growth may be an important reason for the failure of cancer cells to be rejected by CD8+ T cells, thereby stressing the importance of CD4+ T cells cooperating with CD8+ T cells in the effector phase.[543,544] The situation might be somewhat analogous to transgenic mice that express allo-MHC class I molecules as self-antigen on islet cells and have autoreactive T cells that infiltrate the islets,[636] but even after priming, the autoreactive cells fail to destroy the islet cells unless local help is provided in the form of IL-2.[636] Antigen-specific T cells can infiltrate even tumors growing in immunologically privileged sites, but proper differentiation of the infiltrating T cells is prevented.[301,637,638,639] Several different models have shown that the

milieu of large tumors can inhibit the function of adoptively transferred T cells.[640,641,642,643,644,645,646] Lack of costimulatory molecules or expression of Fas ligand by the cancer cells may lead to peripheral anergy.[647,648,649] Suppression in the tumor microenvironment may also be the result of macrophages long known for abrogating immune responses when prevalent in culture.[650] In the stroma, the macrophages are alternatively activated and produce indolamine-2,3-dioxygenase, inducible nitric oxide synthetase, lactate dehydrogenase-A, and myeloid cell-derived arginase.[651,652,653] Autochthonous cancers transplanted once and reisolated are usually heritable variants that grow more progressively, more effectively attract macrophages and neutrophils that are pro-angiogenic (see Cancer Stroma), and more rapidly induce a protective and supportive stromal microenvironment.[43,44,45] Treatment with RB6-8C5 allows mice to reject a lethal tumor cell inoculum,[43,44,45] thereby indicating the profound role that Gr1+ CD11b+ leukocytes have in helping tumors to escape. The significance of tumor-infiltrating T_{reg} cells is discussed separately in the following. Finally, tumor-bearing mice and cancer patients may have alterations in the signal-transduction machinery in T cells, particularly in those infiltrating the tumors but also in T cells from draining lymph nodes or, at later stages, even in circulating T cells.[654,655,656] NK cells can be similarly affected.[654] A decrease in NF-κB p65 at an early stage is followed by loss of TCRζ chain and p56 lck after continued tumor growth.[657,658,659,660,661,662] Activated macrophages can secrete substances that induce these structural abnormalities.[663] As another example of subversion of host defenses in the tumor microenvironment, tumors are a privileged site for bacterial growth.[664,665] Together, numerous immunosuppressive mechanisms have been shown to be functioning in the tumor microenvironment and the tumor draining lymph node. Their relative significance is difficult to judge because there is rarely a real “positive control” (ie, destruction of a truly long established large solid tumor in the absence of the implicated mechanism).

Resistance to Direct Attack

Cancer variants can become resistant to direct attack by T cells by 1) loss/downregulation of

MHC class I and II molecules, 2) losing expression of the rejection antigens, or 3) increased resistance to the killing pathways.

Selective loss or downregulation of MHC class I molecules or the associated antigen-processing machinery allows cancer cells to resist direct attack by T cells.[237,666,667,668,669,670,671,672,673,674,675,676,677,678,679,680,681,682,683,684,685,686,687,688,689,690,691,692] These mechanisms allow cancer cells to escape while retaining the antigen that might be essential for cancer cell survival and malignant behavior.[10,302,307,693] As noticed already decades ago, MHC-heterozygous F1 tumors can escape destruction when transplanted into either parent by loss of the mismatched MHC antigens.[694,695] This agrees with the commonly observed loss of the mismatched HLA after haploidentical hematopoietic stem cell transplantation.[696,697] MHC homozygous tumors rarely lose MHC antigens and require MHC compatible strains for serial transplantation, and they were therefore an essential tool to define the MHC.[698] Two cancers are known to be naturally transmitted within a species as cells.[699] The devil facial tumor disease, first observed in 1996, is a lethal cancer cell line serially transmitted by facial bites during fights among Tasmanian devils.[700,701] These marsupial carnivores in Tasmania have very little MHC diversity and are in rapid decline due to spread of the cancer. Canine transmissible venereal tumor, first described in 1876,[260] is passed between dogs through coitus and bites.[702,703,704] The tumor cells express very little β2-microglobulin and MHC class I during the progressive growth phase followed by regression after ˜6 months unless the dog is immunosuppressed. Some cancer cells express low levels of MHC, but levels can be upregulated by cytokines. At least some of these changes seem to be due to epigenetic mechanisms.[705,706] In other cancer cells, irreversible loss of MHC class I expression is caused by several molecular mechanisms, including mutations in the gene coding for β2-microglobulin.[672,674,675,707] Loss of a single HLA class I allele was found more commonly than loss of all class I alleles.[706] The E1A gene of the adenovirus (Ad) strain Ad12 suppresses MHC class I expression in transformed cells that are tumorigenic and escape T cell-mediated destruction,[708] but there was no correlation between the level of MHC class I expression and tumorigenicity of Ad2 and Ad5 transformed cells. Oncogenes such as myc can cause locusspecific suppression of MHC class I antigen expression.[709] Importantly, MHC class I molecules have now been shown to act as tumor suppressor genes.[710] Thus, some of the observed changes in MHC expression may not be the result of immunoselection.

Cancers also escape by loss of expression of the rejection antigens.[218,219,236,507,508] Even when the antigen is necessary for cancer cell survival,[10,302,307,693] point mutations might preserve the oncogenic potential while rendering the protein nonantigenic. Mutations in SV40 large T that preserve the transformed phenotype in vitro have been selected for with CTL clones, but, in vivo, evidence is lacking for tumorigenicity or selection of such clones.[711] Interestingly, mutational changes in E6 and E7, the transforming genes of HPV, have not been observed in cervical cancer while total or allelic loss of HLA class I expression is commonly observed in this cancer.[712] Immune selection has been reported in patients at later stages of malignancy and after therapy.[713,714,715] Partial immune suppression may lead to a higher yield of antigen loss variants.[235,716] UV-irradiated mice show a partial immune deficiency so that the generation of cytolytic T cells is delayed.[235,717] Incomplete therapy of bacterial infections with antibiotic drugs also favors the outgrowth of variant bacterial strains that show heritable resistance to these drugs; by analogy, partial or incomplete immunotherapy of cancer-bearing individuals may lead to selection of antigenloss variants. When targeting cross-presented tumor antigen on tumor stroma only, T cells do not select for cancer cell variants.[169] Thus, direct (or very short-range) cell-cell interactions appear to be essential for selecting antigen or MHC-loss variants. Antigenic modulation, a reversible antibody-induced loss of surface antigen,[523,524,718,719] and cellular resistance

to perforin/granzyme,[720] FAS/CD95,[721] and other pathways to evade destruction are not discussed.

Anergy/Unresponsiveness/Neonatal Tolerance

Antigens newly expressed on cancers in the adult may be ignored at the earliest stages of autochthonous cancer development because of insufficient amounts of antigen.[191,228,301,722] But once the tumor grows and the amount of antigen increases, the host responds.[723] Thus, immunologic ignorance is unlikely in cancer patients. Tumor transplantation induces acute inflammation that may influence the immune response to the transplanted tumors.[724,725] By contrast, the antigens on sporadic autochthonous tumors fail to induce tumor destruction.[228,301] Importantly, these cancers grow progressively though they are not resistant to direct immune attack (eg, by adoptively transferred T cells). Furthermore, tumor antigen-specific CD8+ T cells are remarkably increased in number in mice bearing autochthonous cancers but failed to lyse antigen-specific targets in vivo and the production of IFNγ was low whereas the production of TGF-β1 was increased and high titers of IgG antibody specific for the rejection antigen were observed.[228,301] Thus, antigen-specific B and T cells in mice bearing the autochthonous tumors responded to the rejection antigen but in a way that resulted in failure to reject the cancers. This altered responsiveness[726,727] must be distinguished from "peripheral" or "extrathymic" tolerance that occurred under certain conditions when an antigen was presented to an adult in highly immunogenic form with the consequence of temporary expansion of mature T cells followed by clonal elimination.[728] The important distinction is that clonal deletion would require adoptive T cell transfer whereas retention of antigen-specific T cells in the host bearing autochthonous cancers may allow rescue or induction of a tumor-specific destructive T-cell response.

Thymic tolerance to self may explain why oncofetal and carcinoembryonic or oncospermatogonal self-antigens, all expressed in the thymus, induce weaker protection than is found in animals immunized with tumor-specific antigens.[364,453,729,730] Nevertheless, at least certain cancers seemingly do not follow the rules that prevent immune recognition of normal self-tissues. Thus, some tumor-bearing hosts may readily recognize normal differentiation antigens on certain cancers such as melanomas. In this type of cancer, it appears to be possible to uncouple the mechanisms of autoimmunity from tumor immunity.[731,732] However, it is unclear how effectively these T cells can control tumor growth.[733] Epigenetic memory can prevent self-reactive CD8+ T cells from escaping their tolerant fate.[734] Because the thymus "selects the useful, neglects the useless and destroys the harmful" T cells,[735(p.57)] only self-antigen-reactive T cells with too low avidity to cause destruction escape deletion and prominently infiltrate tumors.[736,737]

Age

As already discussed (see Immunogenicity of Autochthonous Tumors), most cancers developing in older individuals may be fully sensitive to tumor-specific T cells but for age-related reasons fail to induce an effective immune response. Immunotherapy in older individuals may require rescuing the age-dependent immune deficiencies of the host environment[738] as well as the T cells[484] because adoptively transferred lymphocytes from young, but not old, immunized mice eradicate large solid tumors.[258]

Regulatory T Cells/B Cells/Antibodies/Blocking Factors

Passively administered antibody can prevent the rejection of tumor allografts (homografts).[739,740,741] These antibodies are also referred to as "enhancing antibodies." "Blocking factors" are complexes of antigen and antibodies that can suppress cell-mediated immunity in vitro.[742,743] Complexes of tumor antigen and antibody can induce suppressor T

cells[744] (now generally referred to as T_{reg}s) that can suppress specific immune responses in vivo. Treatments of recipients with donor-type cells as antigen and homologous antibody to donor-type cells enhances acceptance of rat renal allografts.[745,746] The mechanisms responsible for these findings are incompletely understood. The induction of T_{reg}s required active TGF-β; latent TGF-β linked to IgG causes the suppression of sensitization/proliferation of CD8+ effector T cells. Recent and earlier experiments have pointed at a joint role of CD4+ T cells and B cells/antibodies in preventing the rejection of transplanted tumors[514,515] and enhancing the development of autochthonous cancers in mice.[341,517,520] Eliminating B cells or CD4+ T cells can have virtually identical effects in preventing tumor rejection in the same tumor model,[514,515] pointing at the fact that B cells are required for multiple functions of CD4+ T cells and vice versa[747,748,749,750] and that T_{reg}s may not necessarily be generated or act independent of B cells and antibodies.[751,752] "Suppressor T cells" can suppress tumor rejection.[514,556,753,754,755] Residual cancer cells remaining after incomplete tumor removal can be sufficient for continuing the suppression.[756] However, unlike what has been reported,[756] suppression is short-lived after complete tumor removal and may give way to specific immunity without further immunization.[757] Unlike CD4+ helper T cells, T_{reg}s usually express CD25 and Foxp3.[758,759,760,761,762] The Foxp3+ CD25+ T cells are essential in preventing autoimmune destruction of the host[759] and suggest, as discussed previously, poor prognosis when prevalent in excised cancers.[763] T_{reg}s are sensitive to low-dose gamma irradiation and cyclophosphamide pretreatment.[764,765] Preirradiation, cyclophosphamide pretreatment, T-cell deficiency, or CD4+ T-cell depletion of the tumor-bearing host facilitates tumor destruction by adoptively transferred immune T cells.[766,767] However, these treatments also cause homeostasis-driven expansion and activation of the transferred T cells,[768] which may be sufficient or at least synergize with the effects of T_{reg}s depletion. However, whether T_{reg}s can suppress memory T cells needs further study. In any case, these proposed mechanisms and observed effects confirm the early pivotal discovery that low dose whole-body x-irradiation and/or chemotherapy are an essential adjunct to adoptive tumor immunotherapy in mice.[766,767] "Nonmyeloablative lymphodepleting chemotherapy" is now standard treatment in melanoma patients before adoptive T-cell transfer.[769]

Myeloid-Derived Suppressor Cells

MDSCs[75,76,77,78,79] are a subset of monocytes[68] that express CD11b and Ly6C (resulting in intermediate levels of Gr-1 (RB6/8C5) staining), but lack Ly6G (defined by 1A8) (see Components, under Cancer Stroma). They differ from alternatively activated tumor-associated M2 macrophages in well-established tumors 3 weeks after transplantation and from neutrophils. Neutrophils express high levels of Ly6G and Gr-1 and intermediate levels of Ly6C. Cells of myeloid origin are increased in numbers in the peripheral blood of tumor-bearing mice and cancer patients, especially in later stages. In the mouse, MDSCs come from bone marrow as well as spleen, which is a natural extramedullary blood-forming organ in this species. MDSCs and blood monocytes seem to be the predominant precursors of intratumoral macrophages not only in transplanted but also autochthonous tumors.[68,770] A vast number of studies indicate that MDSCs isolated from the peripheral blood of cancer-bearing individuals are profoundly immunosuppressive in vitro. How this correlates to immune suppression in vivo remains an open question.[77,78]

IMMUNE SURVEILLANCE OF CANCER

Types of Surveillance Mechanisms

The term surveillance should be restricted to its meaning (ie, protection from cancer

development[771]). Early in the last century, Ehrlich wrote, “I am convinced that the development of aberrant [mutant] cells occurs very frequently during the extremely complicated fetal and postnatal development but that these foci luckily remain completely latent in most humans because of protective mechanisms in the host. If these mechanisms were not existent, cancer would probably develop with an incredible frequency. „261(p.95),262(pp.289-290) Ehrlich's statement was based on experimental and clinical findings which included *Xeroderma pigmentosum*, an inherited defect in repair of DNA damage caused by UV leading to countless skin cancers. Ehrlich distinguished two basic types of surveillance: 1) immunologic responses (acquired or natural) and 2) cellular (cell-intrinsic) resistance. The latter, attributed by Ehrlich to deprivation of nutrients (athrepsia), is now best explained as cell-intrinsic controls such as DNA repair, checkpoint functions, programmed cell death, and epigenetic controls. With great foresight, Ehrlich emphasized his “firm conviction” that cell-intrinsic protective mechanisms were critical for resistance to cancer development, but discussing these cell-intrinsic mechanisms[772,773,774] is beyond the scope of this chapter.

Today, the microenvironment produced by stroma should be added as third important type of surveillance. Numerous cytokines and cell-cell interactions in the stromal microenvironment can be highly effective in preventing tumor development from transformed cells.[139,555,775,776,777,778,779] Diet, host microbial flora, and chemicals affect stroma and microenvironment, and can thereby promote or prevent cancer development depending on the agent and the condition. However, these factors have little or no effect once full-blown cancer has developed. This means therapy directed at stroma to prevent cancer or to cure cancer must be fundamentally different, though recent reviews do not make this distinction.[780] Of the three principle types of surveillance mechanisms, focus here is on the immune system that can be a powerful restraint against the development of certain cancers.

Adaptive Immunosurveillance

The concept of surveillance by adaptive immunity was especially attractive in the 1950s and 1960s because it provided evolutionary significance to T cell-mediated cellular immunity, which previously seemed to have no use other than to cause rejection of experimental allografts.[781,782,783] Thus, Burnet's hypothesis of immunologic surveillance suggested that the primary reason for development of T cell-mediated immunity during the evolution of vertebrates was defense against altered self- or neoplastic cells.[784] We now know that T cell-mediated immunity is necessary for resistance to many viral and other infections and therefore may be important in the host response to cancers induced by these agents.

Congenital Immunodeficiency Diseases

Patients with certain congenital immunodeficiency diseases may have a markedly (several thousand-fold) increased incidence of cancer,[785] but mostly of lymphopoietic and reticuloendothelial or certain virally induced cancers (Table 47.1).[786,787] Most common forms of cancer (eg, lung, breast, colon, and prostate) do not occur earlier or at a significantly higher rate than in the general immunocompetent population. It is therefore possible that the congenital abnormality itself contributed to the high incidence of lymphopoietic and reticuloendothelial cancers. Mice with congenital immunodeficiency diseases also have a higher incidence of cancers of hematopoietic origin.[788,789,790,791]

Virally Induced Cancers

While gene-targeted mice have demonstrated the influences of innate immunity on tumor induction,[792] these defects are usually absent in human transplant patients that therefore have intact innate immunity to exert cancer surveillance. This would also explain why patients do not show an increased incidence of nonvirally related cancers, and we need more information how innate effector mechanism might influence cancer incidence in humans.

It is important to realize that resistance to tumor induction by oncogenic viruses is also

genetically determined, as illustrated by the example of the lymphotropic herpes virus saimiri.[793] In its natural host, the Old World squirrel monkey, the virus is an innocuous inhabitant probably due to Darwinian selection. However, some New World monkeys (such as the marmoset or owl monkey) do not harbor the virus, and experimental inoculation of the virus regularly causes malignant lymphomas. The susceptible monkeys do respond immunologically to the virally encoded antigens but too late and only at a time when lymphoma development has already occurred. These results suggest that viruses with oncogenic potential survive because lethal tumors would eliminate the virus along with the host. A further example is lymphotropic EBV, which causes a self-limiting lymphoproliferative disease called mononucleosis in humans, the natural host of EBV.[771] Infection usually occurs at very early age usually without any symptoms or, rarely, at later ages (10 to 35 years old) when it may cause disease (mononucleosis). After infection, EBV becomes latent. About 90% of adults are latently infected. Only immunosuppressed individuals appear to develop EBV-associated lymphoproliferative disease and malignant lymphomas. EBV-encoded, CTL-recognized antigens must be important for host recognition and tumor rejection because lymphomas expressing these antigens in immunocompetent individuals have not been found. Instead, EBV-associated lymphomas express the full array of CTL-recognized antigens only in immunosuppressed patients.[794]

TABLE 47.1 Cancers with Increased Incidence in Patients with Immunodeficiency

Type of Immunodeficiency	Cancer	Cause/Carcinogen	Reference
Primary (inherited)	B-cell lymphoma	EBV[a]	786,1100
	Hepatocellular carcinoma, biliary tumors	HBV	787,1101
	Gastric cancer*	*Helicobacter pylori*	1102
	Hematologic malignancies	Germline	785,786,1103
Secondary (drug-induced) (patients with or without allograft)	B-cell lymphoma	EBV	909,1103,1104
	Kaposi sarcoma	HHV-8	1105
	Skin cancer (nonmelanoma)	HPV, UV	806,808,818,819
	Vulvar, oral, or anal carcinoma	HPV	1106
	Merkel cell carcinoma	MCV	796,1107,1108

	Cervical carcinoma	HPV	909
Acquired immunodeficiency syndrome	B-cell lymphoma	EBV	909
	Kaposi sarcoma	HHV-8	909
	Hodgkin lymphoma	EBV	
	Anal, vulvar, or oral carcinoma	HPV	909
	Merkel cell carcinoma	MCV	796,1108,1109
	Cervical carcinoma	HPV	909
	Hepatocellular carcinoma	HBV, HCV	909
	Skin cancer (nonmelanoma)	HPV, UV	909

EBV, Epstein-Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HHV, human herpesvirus; HPV, human papillomavirus; MCV, Merkel cell polyomavirus; UV, ultraviolet light.

* Patients with primary hypogammaglobulinemia.

In principle, adaptive T cell-mediated immunity may protect against the development of primary virus-associated cancers by either preventing or shortening the duration of infection with the oncogenic viruses or by eliminating virally transformed cells expressing the virus. As example for the latter, cells malignantly transformed by oncogenic DNA viruses often do not produce (in contrast to oncogenic RNA viruses) viruses; only the tumor formation, not infection by these viruses, may be prevented by the immune system. Such a resistance to tumor induction by DNA tumor viruses is consistent with the fact that polyomavirus is a common harmless passenger virus in adult mice and is commonly found in wild mice without inducing malignancies.[795] But even a generally harmless polyomavirus when it integrates and acquires the mutations needed to inactivate viral production may induce cancer, as in the Merkel cell carcinoma in immunosuppressed humans.[796] By contrast, in the case of high-risk human papilloma viruses 16 and 18, T cell-mediated responses may prevent or at least shorten the duration of viral infection. This may reduce the chance that the initially mostly episomal virus integrates its oncogenic E6/E7 sequences into the host's epithelial cells[15,797,798] (also see Immunoprevention).

Cells transformed by certain DNA or RNA viruses can be very immunogenic.[771] For example, SV40 and polyomaviruses usually do not induce tumors in adult animals[799] or humans[800] because the viruses induce rejection antigens on the transformed cells that are immunogenic

enough to elicit rejection without prior immunization. Therefore, the use of immunoincompetent animals, such as neonatal animals or nude mice, is required for tumor induction, a finding that led to a breakthrough in studying the tumorigenicity of viruses and of cells transformed by viruses in vitro. It is important to note that this immunologic resistance of the natural host is directed against the oncogenes expressed by the virally transformed cells, not against the virus itself. Interestingly, when the oncogenic SV40 large-T antigen is expressed as a sporadic extremely rare event in single cells (rather than as part of a systemic infection alerting the host to respond), this strongly antigenic and oncogenic protein can cause cancer in mice.[228,301] Transplants of these autochthonous cancers are regularly rejected by naïve syngeneic normal hosts, indicating that during development, the autochthonous cancers managed to sneak through all host controls in the euthymic normal individual without losing their highly antigenicity and immunogenicity.[228,301] Even a progressor tumor may be highly antigenic, immunogenic, and sensitive to immune destruction (immunosensitive), yet induce, for example, a strong T_{reg} cell and B cell "type 2" immune response that downregulates destructive T-cell responses and promotes tumor growth.

MHC genes may regulate immune responses to cancer cells or cancer-causing viruses, and since the discovery that the MHC profoundly influences the susceptibility of mice to leukemia caused by Gross virus,[801,802] investigators have searched for a possible association between MHC type and cancer susceptibility in humans and mice.[803] However, no firm association between HLA haplotype and the occurrence of any major human cancer has been established except for virally induced nasopharyngeal, cervical, and liver cancers.[804,805]

Ultraviolet Light-Induced Cancers

Renal transplant patients show a 65- to 250-fold increase in skin cancers virtually restricted to UV-exposed sites of the body.[806,807] The increase is independent of whether the immunosuppressive agent is mutagenic or not,[808] although cyclosporine enhances transformation in vitro.[809] Skin cancers in transplant patients are often more aggressive with a mortality of 7% to 9% due to metastases.[810] The increased incidence in transplant patients could be in part due to an increase of mutations due to impaired repair of DNA damaged by UV.[811,812] Immunosuppressive drugs can decrease local production of IFNγ ,[813] and this decrease may favor tumor development.[555,814,815,816,817]

UV-signature mutations in oncogenes and suppressor genes play a critical role for skin cancer development. Nevertheless, viruses of the beta HPV group may play an essential role as cocarcinogens.[818,819] This would make these cancers virally related and more similar to the other cancers increased in transplant patients. In any case, two-thirds of these transplant patients experience reduced skin cancer development after immunosuppressive medications are stopped[820]; it appears that, similar to murine UV-induced tumors,[218,479] many human UV-induced cancers are actually "regressor" tumors and have arisen only because host defenses had been damaged.

Chemically Induced Cancers

We lack evidence that the incidence of chemically induced cancers is increased in immunosuppressed humans.[821,822] Experimentally, loss of adaptive immunity increases the incidence of virally induced cancers in virtually all studies and all species tested; however, the increased incidence or a shortened latency of chemically induced cancers due to lack of T cells has been found only in some experiments and not in others.[487,488,489,506,792,823,824,825,826,827,828] Transporter associated with antigen processing-deficient mice are defective in presenting intracellular mutant peptides (the key targets of adaptive immunity to nonviral cancers) to αβ TCR-bearing T cells (the key effectors of adaptive T-cell immunity). Nevertheless, transporter associated with antigen processing

knockout mice do not have an increased or accelerated incidence of chemically induced cancers whether or not these mice are also nullizygous for p53.[829] Clearly, immunosurveillance by adaptive T-cell immunity is effective against the development of several virally induced cancers, but it is still uncertain how effectively adaptive T-cell immunity prevents the development of forms of cancers that are induced by chemical or physical carcinogens.

Innate Immunosurveillance

The innate immune system uses nonrearranging germline receptors to trigger responses of cellular effectors that can recognize and kill cancer cells or normal cells. Many studies using gene-targeted mice have demonstrated the important influence of various components of innate immunity on tumor induction.[792] When it comes to the mechanisms of protection against cancer, the effects of innate immunity are not easily delineated from cancer cell-intrinsic and/or microenvironmental/stromal control mechanisms mentioned briefly at the beginning of this section. For example, mice lacking the transcriptional activator interferon regulatory factor (IRF)-1 show several immunologic disorders, most notably a severe defect in the development of NK cells,[830] but the tumor-prone phenotype of these mice was shown to be directly attributable to the cell-intrinsic lack of protective IRF-1.[815] IRF-1 regulates DNA repair and is also an activator of IFNα and IFNβ transcription, and is required for double-stranded RNA induction of these genes. Many cell types secrete IFNα and IFNβ. Furthermore, IFNα/β signaling contributes to p53-mediated tumor suppression.[831] Thus, cooperation between innate and cell-intrinsic mechanisms is likely to be common. IFNγ induces the IRF-1 that functions as a tumor suppressor,[139,814] and mice with a defective IFNγ signaling pathway (IFNγ receptor- or STAT1-deficient mice) have an increased incidence of MCA-induced tumors.[485,487,777] The spontaneous[485,487] but not MCA-induced[777] tumor incidence was increased when these mice also lacked p53. Thus, the IFNγ pathway may help eliminate somatic cells harboring spontaneous DNA damage. Stimulation of the IFNγ pathway by IL-12 reduces oncogene-driven tumor development in HER-2/neu transgenic mice.[832] This surveillance effect of IFNγ may be complemented by cytolytic γδ T cells or NKT cells. These cells may use their NKG2D receptors to eliminate somatic cells exposed to the initiating chemical carcinogen followed by the tumor promoter TPA.[573,574,827]

While gene-targeted mice have demonstrated the influences of innate immunity on tumor induction,[792] these defects are usually absent in human transplant patients that therefore have intact innate immunity to exert cancer surveillance. This would also explain why patients do not show an increased incidence of nonvirally related cancers; we need more information about how innate effector mechanism might influence cancer incidence in humans.

CANCER AND INFLAMMATION

Key Principles

Rudolf Virchow was among the first to stress the importance of local irritation for neoplastic proliferation, but central parts of his “Reiztheorie” (irritation theory) were incorrect.[833,834] Instead Virchow's contemporary, Carl Thiersch, may have been the first to state clearly that epithelial cancer cells invaded adjacent tissues and were not derived from connective tissue or inflammatory cells.[835] (An exception may be gastric cancer induced in *Helicobacter felis*-infected mice and proposed to originate from bone marrow-derived

cells recruited to sites of injury and inflammation[836].) In this section, we will discuss the evidence that local inflammatory reactions can stimulate or destroy cancerous growth, and that stroma plays an integral role in permitting or forbidding these interactions.

It seems confusing that in one and the same organ (eg, urinary bladder), inflammation can promote cancer development in humans as well as prevent cancer relapse. Schistosomiasis,

a parasitic helminth infection, increases the incidence of cancer whereas instillation of live Bacille Calmette-Guérin (BCG) prevents relapse of superficial bladder cancer. Schistosomiasis causes a chronic, growth-promoting, IL-4-driven "type 2" inflammation characterized by tissue repair and angiogenesis, alternatively activated neutrophils (N2) and macrophages (M2), and T_H2 and T_{reg} leukocytes driven by active TGF-β and STAT3 signaling. In contrast, BCG causes an acute, bacteriocidal, tissue-destructive "type 1" inflammation with classically activated neutrophils (N1) and macrophages (M1), and T_C1, T_H1, T_H17, and other killer leukocytes driven by STAT1, IFNγ, TNF, and IL-17. Dependent upon the antigen, cell, and cytokine involvement, the result may be either inhibition or stimulation of growth of the premalignant or malignant cells by acquired and/or innate immunity (Fig. 47.4). There is little knowledge of how differences in amount, kinetics, and local concentration of cytokines determine these different biologic outcomes.[619,837,838,839,840,841,842]

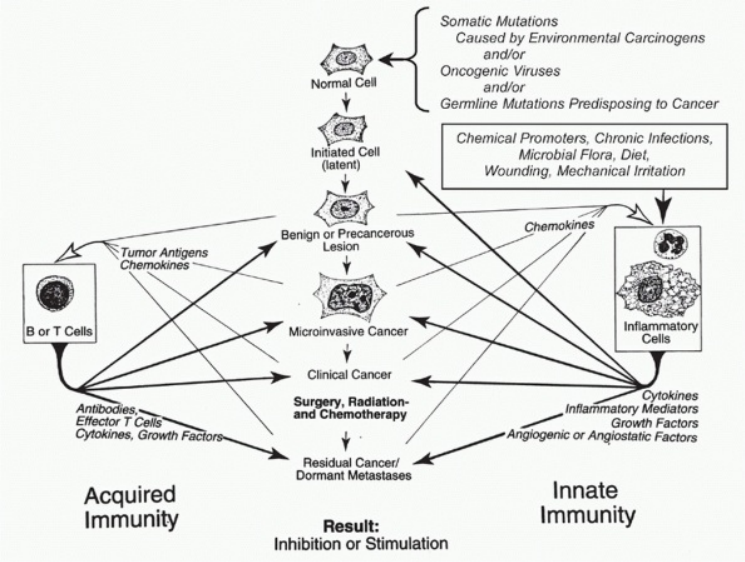

FIG. 47.4. Both Acquired and Innate Immunity can Stimulate or Inhibit All Stages of Cancer Development and Progression.

Exogenous Promotion

It is generally assumed that most human and animals harbor initiated mutant cells from exposure to low levels of chemical or physical carcinogens. Experimentally, this can be mirrored by exposing a small area of mouse skin to very small doses of the polycyclic hydrocarbon carcinogen 7,12-dimethylbenz[*a*]anthracene. No cancers develop over the life of the animal unless this site is exposed to prolonged inflammation caused by wounding or a nonmutagenic proinflammatory promoter[23,34,843,844,845] (eg, croton oil, a now obsolete laxative,[21,22] or its active component, phorbol ester [12-*O*-tetradecanoylphorbol-13-acetate, also referred to as phorbol-12-myristate-13-acetate][846]). Phorbol esters are strong inducers of NF-κB in keratinocytes and many other cell types. NF-κB, as a crucial communicator of innate

immunity and inflammation, normally receives exogenous signals from the proinflammatory cytokines TNF-α and IL-1β, TLRs signaling tissue damage and microorganisms. The major force opposing NF-κB is p53 that is upregulated by sensing DNA damage caused by the carcinogens (Fig. 47.5).[119] Upregulated p53 induces apoptosis and blocks cell proliferation and the replication of cells with damaged DNA. Evasion from p53-induced cell death is essential for mutant cells to survive and for cancers to develop.[774] The prosurvival signal

exerted by NF-κB is therefore essential for the premalignant cells to escape apoptosis-mediated cell death.[119] Wounding, used by Rous,[844] also seems to be effective if there is a prolonged healing.[847,848,849] Tumors have been compared with “wounds that do not heal.”[850(p.1650)] Mouse strains that have low or poor inflammatory reaction to wounding or phorbol esters are more resistant to tumor promotion.[851]

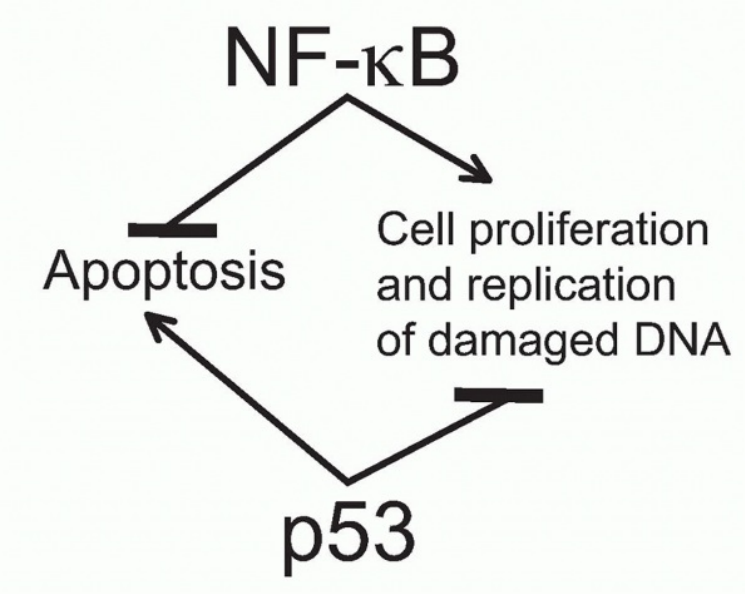

FIG. 47.5. Opposing Effects of p53 and NF-kB. p53 not only inhibits cell cycle progression, cellular proliferation, and the replication of deoxyribonucleic acid, but also leads to apoptosis. By contrast, NF-κB promotes cellular proliferation and blocks apoptosis. Thus, any substance that chronically upregulates the NF-κB pathway may promote cancer development and therefore be dangerous.

Until recently, few experimental studies have critically examined whether the microbial flora and chronic infections can exert substantial tumor-promoting effects, as suggested by clinical evidence. In one early study, the sensitivity to chemical carcinogen of germfree or specific pathogenfree rats was compared with that of chronically infected animals.[852] It was shown that chronic respiratory infection enhanced cancer development. Clearly, the microbial flora is a major regulator of innate and adaptive immunity,[853] and certain bacteria that are part of the normal gut flora exert a protective effect against inflammatory bowel disease that is strongly associated with the development of colon cancer.[854,855]

Switch to Paracrine Loops

When the chronic application of an exogenous chemical promoter is stopped during experimental skin carcinogenesis, some papillomas regress spontaneously while others persist and continue to grow.[848] Tumor persistence and progression appears to depend on heritable changes in premalignant and cancer cells to establish a “paracrine stimulatory loop”[43,44,45]: cancer cells producing chemokines that attract and activate leukocytes. These leukocytes in turn produce cytokines and growth factors that stimulate tumor angiogenesis or the growth of the cancer cells.[110,629,856] Thus, several experiments have shown that, during tumor progression, cancer cells can switch from being inhibited to being stimulated by inflammatory cells[43,44,45] or cytokines (eg, TGF-β or IL-6).[857,858,859,860,861] It has also now become clear that cause of the heritable switch is cancer cell-intrinsic (ie, the expression of mutant oncoproteins that causes an activation of NF-κB signaling pathways).[114,115,862,863] This allows the neoplastic cells not only to escape apoptosis-

mediated cell death but also to produce proinflammatory signals that initiate the paracrine loop.[80,114,115,116,862,864,865,866,867,868,869,870] Interestingly, the signals coming from the same oncogenic mutation can diverge into separate proinflammatory NF-κB and transforming RAS/PI3K signaling cascades.[862] The K-RAS pathway can lead to the secretion of MCP-1 (CCL2), KC (CXCL-1), MIP-2 (CXCL-2), and IL-8 (CXCL-8).[864,870] These more recent insights give a mechanistic basis for much earlier data showing that cancer cells release numerous inflammatory mediators and growth factors such as MCP-1 (CCL2), KC (CXCL-1), MIP-2 (CL-2), SDF-1 (CXCL12), IL-1β, IL-6, IL-8 (CXCL-8), IL-10, MIF, CXCL5, NFκB, TGF-β, osteopontin, versican, PDGF, FGF-2, VEGF, G-CSF, and granulocyte-macrophage colony-stimulating factor (GM-CSF).[164,780,869,871,872,873,874,875,876,877,878,879,880,881,882,883,884]

Regression Following Acute Inflammation

By the mid-1800s, physicians observed that occasional cancer patients who developed erysipelas, a serious acute bacterial infection of the skin, had remarkable regression, sometimes cures, of cancers that would have been inoperable today.[885] This led to intentional infection of patients,[886,887] later with cloned *Streptococcus pyogenes*, the causative agent of erysipelas.[888,889] Stunning successes occurred, in some cases regression,[888,889] and a decade later in 1893, the work was confirmed in the United States.[890] The variability of success was suspected to be a function of the different types of cancers treated, and the successes in occasional patients were marred by serious complications including death in the preantibiotic era. Today, topical use of live bacteria remains restricted to treating residual superficial bladder cancer, which typically recurs following surgery.[891,892] Repeated instillation of the live BCG mycobacteria into the bladder by a catheter after surgery has become a treatment of choice for this cancer. The repeated local infection with BCG leads to prolonged acute inflammation in the bladder wall. This is invariably associated with local production of type I and type II IFNs and a significantly reduced cancer recurrence. Consistent with this idea, topical application of imiquimod, a TLR7 agonist, can induce immunologic destruction of premalignant actinic keratoses and basal cell and squamous cell carcinomas.[893,894] Imiquimod also enhances IFNγ production and T-cell effector function when topically applied to UV-induced skin cancers in transplant recipients.[895]

Increased Incidence Following Chronic Inflammation

Chronic “type 2” inflammation by infectious agents is associated with development of some kinds of cancers[896] (eg, hepatitis B and C virus and hepatocellular carcinoma, *Helicobacter pylori* and gastric cancer, HPV infection and cervical cancer, and schistosomiasis and bladder cancer). Also, chronic tissue damage caused by physical or chemical agents is associated with development of some cancers (eg, reflux esophagitis and esophageal cancer), chronic pancreatitis and pancreatic carcinoma and inflammatory disorders of unknown etiology (such as ulcerative colitis or Crohn disease), and colon cancer.[118,780,897] Substantial clinical, epidemiologic, and preclinical data indicates that nonsteroidal anti-inflammatory drugs (eg, aspirin) are effective in reducing colorectal polyps and colon cancer.[898,899] Western diet is another highly significant risk factor to developing colon cancer.[900,901] Diet has major effects on shaping the intestinal microbiome[902] and may be associated with chronic inflammation,[853] but the mechanisms of this important link remain to be discovered. Chronic inflammatory responses to impaired glycosylation of intestinal mucosa has been suggested to be tumor promoting.[903] At least some patients with ulcerative colitis have impaired glycosylation due to lost T synthase function as a result of somatic mutations in COSMC in colonic Tn antigen-positive crypt cells.[904] Such mutations have also been found in human colon cancer.[412] Mice selectively deficient in T synthase in colonic

mucosa express the Tn antigen and develop massive inflammatory infiltrates and abscesses in their distal colon, similar to patients with the cancer-predisposing ulcerative colitis.[904]

Prognostic Significance of Tumor Infiltrates

Melanoma

Despite some claims,[905] the infiltration of lymphocytes into melanoma remains a histopathologic variable of unproved prognostic significance. In a recent study, absence of TILs in melanomas was associated with a sixfold higher probability of metastases in the sentinel lymph nodes[906]; however, depth of invasion of the primary melanoma, not the TILs status, was prognostic of survival of the patients.

Colorectal and Ovarian Cancers

Relapse of colorectal cancer (stage Duke B or C) ranges between about 25% to 70% in patients who had the cancer surgically removed. Histopathologic and gene expression analysis of leukocyte infiltrates in primary colorectal cancers can apparently predict recurrence as well as survival. Cancers with dense CD45R+ CD8+ T-cell infiltrates have a better prognosis at any stage, whereas patients with low numbers of T cells regardless of stage have more recurrences.[907] Inflammatory cells, such as macrophages or lymphocytes, may look morphologically identical, but secrete different cytokines that have opposite effects on tumor growth. This may be the reason why gene expression analyses can serve as a better indicator of the functional properties of immune infiltrates in cancers.[908] Current work suggests that these analyses may provide better prognostic indicators in colorectal cancers than conventional TNM staging. Different expression profiles may reflect differences in cancer cell-intrinsic oncogenes/regulatory pathway usage. This may result in different cytokines, chemokines, and other factors being released that attract different types of lymphocytes and innate immune cells. The incidence of primary colon cancer virtually remains unchanged in renal transplant patients compared to virally related cancers.[909]

In ovarian cancers, the presence of intratumoral T cells is correlated with delayed recurrence of cancer and delayed death.[910] Absence of intratumoral T cells is correlated with increased levels of VEGF. Furthermore, recruitment of T_{reg} cells predicts reduced survival.[557,763] Again, differences between different ovarian cancers could be due to the use of different oncogenes/regulatory pathways resulting in different aggressiveness. Ovarian cancers are not increased in immunosuppressed organ transplant patients.[909]

Prognostic Significance of "Regression" and Vitiligo

Much research continues to be stimulated by the observation that regression of melanomas can occur, spontaneously fostering the idea that immunosurveillance or immunologic destruction is responsible.[911,912] However, regression of a melanoma is usually partial, rarely total, and usually involves its horizontally growing (radial), intraepidermal part while the major predictor of survival is the extent of vertical growth (ie, depth of invasion). The prognosis is excellent for melanomas <1 mm in depth (thickness) but much worse if the cancer is ≥1 mm in thickness. In a recent analysis of over 2,000 melanomas, regression neither predicted the likelihood of lymph node metastases nor survival of the patient.[913] Possibly, partial destruction of a malignant lesion may result from infiltrative growth into the surrounding tissue and destruction of that part of the tumor's blood supply.

Vitiligo (a depigmentation of normal skin) has many causes including an autoimmune etiology.[914] Though vitiligo is frequently induced experimentally or clinically as during treatment targeting melanocyte differentiation antigens,[364,731,733,915,916] it is not predictive nor needed for success of eradicating the melanoma.[917,918]

Inflammatory Responses to Tumor Growth

Experimental as well as clinical studies are now producing a rather coherent mechanistic

picture of the significance of systemic inflammatory responses in tumor growth. About 30% of patients with solid tumor have elevated granulocytes in their peripheral blood (> 8,000/μl), and granulocytosis is common in tumor-bearing mice.[871,883,919,920,921,922,923,924,925] It is long known that systemic effects, such as splenic enlargement,[926] frequently accompany local growth of autochthonous or transplanted murine tumors. Although many tumors commonly used in experiments have been serially passed hundreds or more times through euthymic mice,[239] a similar enlargement is also observed in response to growth of primary autochthonous tumors in nontransgenic mice.[927] Enlargement is mostly caused by increased myeloid hematopoiesis with macrophages, monocytes, and neutrophils accounting for more than half of the splenocytes.[770,928] G-CSF,

GM-CSF, and/or IL-6,[871,876,878,883,929,930] released by cancers, may be particularly important in inducing the systemic effects. STAT3 is persistently activated in many types of cancers, particularly in cancer cells at the invasive edge of tumors adjacent to inflammatory cells.[849] IL-6 preferentially activates STAT3,[931] causing cancer cells to resist apoptosis, sustain angiogenesis, and suppress acute STAT1-driven inflammation[849,931,932] and destructive T-cell responses.

G-CSF plays a central role in neutrophil production. Importantly, G-CSF also induces stem cell mobilization by upregulating CXCR4 and decreasing its ligand SDF-1 (CXCL12) in the bone marrow,[154,933] spleen, and local[86,88] reservoirs for progenitors. Degradation of SDF-1 in the progenitor/stem cell reservoirs is probably a result of G-CSF-induced granulocytosis that causes an increase of the neutrophil-derived proteases (TIMP-free matrix metalloproteinase-9 and neutrophil elastase, specific products of neutrophils that degrade SDF-1[934,935,936]). Mobilization of progenitors expressing CXCR4, the receptor for SDF-1, includes the mesenchymal, hematopoietic, and angiopoietic progenitors and T_{reg} cells.[146,937] Attraction of these cells into the tumor stroma of a neoplastic lesion occurs along a chemotactic gradient and depends on high local concentrations of SDF-1 produced by cancer cells[879,880,938] and tumor-stromal myofibroblasts.[939,940]

Given these mechanisms, it is not surprising that elevated neutrophil blood counts, neutrophil/lymphocyte ratio, matrix metalloproteinase-9, and plasma levels of C-reactive protein have been described as prognostic indicators of recurrence and reduced survival.[941,942,943,944,945] However, systemic responses to cancer vary greatly between individuals depending on stage and type of cancer. Even when they are not detectable, the mechanistic loops outlined previously are likely needed locally for every malignant growth.

Facilitation or Inhibition of Metastasis

A systemic increase in circulating factors such as IL-6 and progenitor cells may facilitate metastasis by creating “metastatic niches” (ie, a stroma in which disseminated cancer cells can successfully engraft).[629,946,947,948,949,950,951,952,953,954] Experimentally, there is little evidence that facilitation of metastasis (or secondary tumors developing at distant sites) is antigen-specific.[757,884,955] However, a primary transplanted tumor may suppress the growth of a second inoculation with the same tumor.[261] The phenomenon can be caused by immunologic as well as nonimmunologic mechanisms. The phenomenon is therefore properly referred to as “concomitant tumor resistance.”[956] Following surgical removal of the primary tumor, accelerated seeding and/or growth of metastases will occur, obviously a troubling observation for patients undergoing cancer surgery. This phenomenon, first described a hundred years ago,[957] occurs in different species and in several tumor models.[958] As would be expected, the primary tumor during its growth must inhibit metastasis possibly by usurping most available progenitor cells and/or consuming growth factors and nutrients (similar to what Ehrlich described nutrient deprivation or athrepsia[261]) and/or by producing antimitotic factors.[959] There is little evidence whether or not cancer patients inhibit metastasis by

antigen-specific immunity. Concomitant immunity refers to the observation that an individual bearing a primary transplanted tumor may be resistant to secondary challenge with the same tumor at a different location because of an antigen-specific immune response.[958] However, this old extensively studied observation[958,960,961,962] may well be the result of artificially priming the host by tumor transplantation.

IMMUNOPREVENTION

There is convincing evidence that immunosurveillance can prevent or reduce the incidence of cancers associated with certain viruses. Therefore, active immunization against viral capsid proteins may prevent infection and thereby cancer induction. While this is expected, it is still too early to confirm this with results. However, a federally funded, extensive vaccination program began in Australia in April of 2007 with a quadrivalent HPV vaccine to provide protection against the high-risk HPV types 16 and 18, which cause cervical cancer, and also low-risk types 6 and 11, which cause genital warts.[963,964] There has been a highly significant decline in the diagnoses of genital warts and a significant decrease in high-grade cervical abnormalities only 3 years after implementation of the program.[963] The latency period for cervical cancer is 15 to 25 years; therefore, evidence for a decline in cancer incidence cannot be expected until about 2027. Furthermore, only 70% of cervical cancers are caused by the HPV types that are in the present vaccine; thus, this vaccine can be expected to prevent only about 70% of cervix cancers. The effect might be somewhat higher because of cross-reactivity with the other HPV types, which may provide cross-protection with viral types 31, 33, and 45. Therapeutic HPV vaccines for treating already existent persistent infections or advanced cervical lesions are needed.[965] The current vaccine has no effect against HPV infection once it has been acquired and must therefore be given before onset of sexual activity. Remarkably, there is a therapeutic vaccine that seems to be effective against HPV-induced vulvar preneoplastic lesions.[966] The same vaccine has not been shown to be effective against high-grade premalignant cervical lesions. In general, premalignant lesions often persist for a very long time; destroying these lesions should prevent the development of cancer.

After introduction of hepatitis B virus vaccines, a decline in the incidence and prevalence of hepatitis B virus infection occurred[967]; this should eventually lead to a decline of chronic hepatitis and hepatocellular carcinoma. Several strategies for vaccination against hepatitis C virus, human T-lymphotropic virus 1, and human herpesvirus 8 are being developed. Also, developing vaccines against *Helicobacter pylori* and *Schistosoma* infections remains extremely important. The major influences of diet and microbial flora on the incidence of colorectal cancer and probably other cancers suggest new approaches for immunoprevention of these cancers.

It will be important to determine whether cancer can also be prevented by active immunization of cancer-prone individuals with predisposing inherited or acquired antigens resulting from mutation (eg, in K-ras[968]). An ever-increasing

number of predisposing inherited or acquired mutations are being identified; however, inducing immune responses against them may be problematic. For example, active immunization against an oncogenic viral protein became ineffective in preventing cancer when the immunization was begun in the later part of the latency period[228,799,969,970] or after the oncogenic protein was expressed in premalignant host tissues[301,722,971] for reasons that are poorly understood. Finally, we need to avoid stimulating cancer development when vaccinating cancer-prone individuals.[341]

IMMUNOTHERAPY

General Aspects

Multiple immunotherapeutic strategies involving innate or acquired immunity have been developed to control cancer; they include 1) local application of a live bacterial vaccine, BCG

(see discussion under Cancer and Inflammation); 2) use of cytokines; 3) active immunization; 4) passive therapy with antibodies; and 5) adoptive transfer of effector cells. Some of these strategies are being combined with other forms of cancer treatment. It is important to realize that chemo- and radiation therapy can synergize with or antagonize innate or adaptive immunity dependent on timing and sequence of the treatments. These important issues have been described and discussed elsewhere[539,972,973,974,975,976] and previously in this chapter. But why are so few immunotherapies effective or the treatment of choice, except for melanoma and superficial bladder cancer? Extensive recent reviews of immunotherapy of cancers expose some complementary but several differing viewpoints.[306,323,324,977,978,979,980] There is also an astounding repetition of findings made decades ago, and a tendency of overstating the translational potential of new findings.[4,143] As already discussed (see Fig. 47.1), the focus of current experimental research remains treating very small transplanted lesions in mice < 2 weeks after cancer cell inoculation.[4,633,981] Very few publications report immunotherapy in animals with cancers of clinically relevant size (≥ 10^9 cancer cells and ~1 cm average diameter) and duration of growth (> 14 days). Adoptive T-cell therapy and anti-CD20 antibody treatments were singled out as experimental therapies effective in causing regression at this stage (Fig. 47.6). Indeed, adoptive transfer of T cells (with endogenous or transduced TCRs) may be effective with longer established tumor loads.[977,982,983] Because both of these therapies can also be effective in humans, there is no "disconnect" between preclinical models and clinical experience.[4,107] Relapse after therapy, the main problem of cancer treatments, is rarely

considered; in fact, most animal studies break off before relapse could occur.

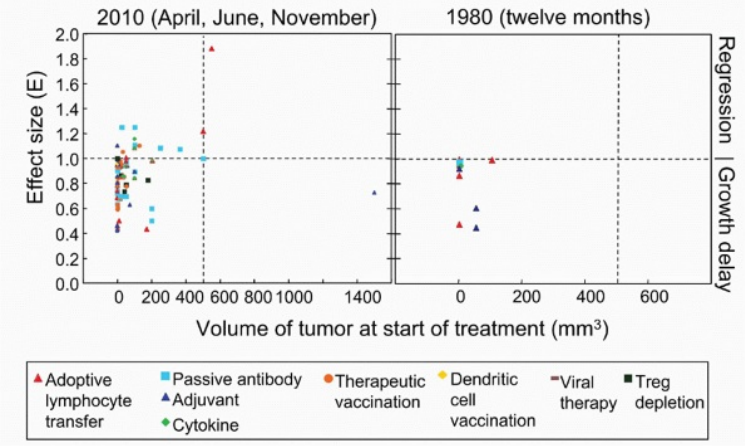

FIG. 47.6. Analysis of All Experimental Cancer Immunotherapy Publications Listed in PubMed for April, June, and November of 2010 and of the Entire Year 1980. Most experimental immunotherapies published treat small tumors (< 500 mm^3) yet succeed only at slowing or delaying tumor growth. In several 2010 reports, larger tumors are being treated than in 1980, and a few reports indicate tumor regression. An effect size (E) of 1 indicates the treatment arrested tumor growth. An E < 1 indicates that the treated tumor still grew progressively but slower than control. An E > 1 indicates tumor regression. Regression of tumors > 200 mm^3 is observed only after passive antibody or adoptive T-cell therapy. Modified from Wen et al.[4]

Therapeutic Vaccinations

Active immunization of cancer-bearing mice or humans is a heroic approach that was abandoned in the clinical management of infectious diseases, except for rabies, which has very long incubation period.[984,985] Cancer cells have a much slower generation time than

most infectious organisms, and most of the bulk of the tumor load can usually be removed by other therapy (eg, surgery). At the time when the antigen load is lowest, the suppressive environment may be removed, and conceivably active immunization might lead to an effective immune response. However, persistent antigen appears to be a major reason why cancers and chronic infectious diseases are ineffectively treated by therapeutic vaccination. Possibly, combining active immunization with blockade of immunoinhibitory pathways may lead to more effective therapeutic vaccinations.[965]

Certain cancer cells may be fully sensitive to tumor-specific T cells but for various reasons fail to induce a response. The reasons for the poor immunogenicity may vary; therefore, different methods must be used for different cancers to immunize effectively.[492] Currently, most methods have been developed in tumor-free mice (preventive/prophylactic vaccination).[986] Immunization with small numbers of viable tumor cells may cause cancer, but, if not, it can stimulate solid long-lived memory immunity that prevents growth. Dead and disrupted tumor cells, membrane fractions, or cell extracts may enhance the growth of the cancer, although they stimulate “immune” (ie, lymphocyte) responses. Destroying the proliferative potential of the tumor cells, while leaving the cells viable and metabolically active, may result in a prolonged exposure to the antigen that allows T-cell immunity to develop.[987] There are no general rules for accomplishing this, but exposing cancer cells to gamma radiation or certain cytostatic chemicals, such as mitomycin C, can work. However, chemotherapy makes cancer cells more immunogenic when they can undergo autophagy.[986] In any case, chemotherapy of transplantable tumors is more efficient in immunocompetent than in immunodeficient mice.[988]

Because these methods alone are often insufficient to elicit a cytolytic T-cell response to cancer cells, many strategies including genetic engineering have been designed to increase the immunogenicity of the tumor-cell inoculum and/or stimulate innate immunity at the site of vaccinations by the use of chemical and/or bacterial agents. However, irrespective of which particular genetic engineering of the tumor cells is used, rejection of the modified tumor cells is often followed by T cell-mediated immunity against the unmodified tumor cells. Methods include infecting cancer cells with certain viruses[989,990,991]; somatic cell fusion with various nontumorigenic cells[992,993,994]; transfection of self- or foreign MHC class I or class II molecules[995,996,997]; hapten conjugation[998,999]; exposure to mutagens[1000]; transfection of tumor cells to express the B7 ligand that can provide a costimulating signal to T cells[1001,1002]; attracting secondary lymphoid structures to the cancer[1003]; targeting herpesvirus entry mediator pathways[965]; combining tumor cells with killed bacteria, such as *Corynebacterium parvum*[1004]; recombinant vaccines of antigen expressed by vaccinia, listeria, or virus-like particles[2,1005]; transfection of tumor cells to produce certain cytokines such as IL-2, IFNγ, IL-4, IL-6, IL-7, G-CSF, GM-CSF, or TNF-α[134,138,141,535,1006]; injecting naked DNA constructs encoding the tumor antigen (whereby the gene for GM-CSF may also be used to recruit dendritic cells)[456,1007,1008,1009]; vaccination with anti-idiotypic antibodies, which bear the internal image of a tumor antigen[1010]; inhibiting extracellular adenosine triphosphate-degrading enzymes to increase autophagy[986]; transfection of tumor cells to express antisense RNA of a required growth factor thereby inducing terminal differentiation[1011]; peptide vaccines combined with blocking IFNγ action[1012,1013] with peptides long enough not to tolerize[987,1013,1014]; loading peptides to heat-shock protein[1015]; siRNA-mediated inhibition of nonsense-mediated messenger RNA decay,[1016] which may trigger innate immunity[1017] or the expression of new epitopes to which the host is not tolerant; and finally dendritic cells[323,1018,1019] that can be loaded with 1) synthetic antigenic peptides, 2) recombinant proteins, 3) native peptides stripped from tumor cell surfaces, 4) tumor-derived, peptide-loaded heat-shock proteins, 5) tumor-derived messenger RNA, or 6) by fusion of tumor cells. One advantage of the latter three strategies is that immunity to (unique) individually distinct tumor antigens, as well as tumor-associated antigen

may be induced without having to identify the antigens. The limitation is that the antigen dose cannot be standardized. Vaccines are also being used that target the mutant epidermal growth factor receptor EGFRvIII, a truly tumor-specific antigen on the surface of human malignant glioma cells capable of inducing strong B- and T-cell responses. The goal is to prolong patients' relapse-free survival because this cancer, the most common primary brain malignancy, is untreatable by conventional therapy.[305] The mutation in the EGFRvIII occurs in about 40% of the glioblastomas and represents an internal deletion in the gene encoding the receptor.[1020] About half of the patients with this variant receptor have the same deletion, which generates a new amino acid at the fusion point of the resulting fusion protein and new antigenic determinant recognized specifically by a monoclonal antibody.[304]

A healthy skepticism is needed to stimulate experiments determining whether therapeutic effects of active immunization are found when the experimental tumor is not in early stages of malignant growth (see Figs. 47.1 and 47.7). Until then, it remains uncertain whether any of these procedures will be effective against longer established or advanced stages of cancer including microdisseminated cancer cells.[382,985]

Therapy with Engineered Antibodies

Targeting Cancer Cells Directly

General Considerations. The major alternatives to therapeutic vaccinations are antibody therapy and adoptive transfer of tumor-specific T cells. As already mentioned, there is little evidence that antibody produced by the host

in response to autochthonous or transplanted cancers has any beneficial effects on the growing tumor. However, B-cell tolerance to self-antigens on human cancers can be overcome by immunizing mice with xenogeneic human antigen.[1021] Thus, high-affinity antixenogeneic antibodies to self-antigens such as human Epcam, FAP, CD20, CD19, HER-2, and various other receptors and growth factors have been made.[1022] Misleadingly, some of these high-affinity antixenogeneic antibodies are usually advertised as “fully human” when they were made in mice in which the murine Ig gene locus had been inactivated and replaced with the human Ig gene locus.[346] The toxicities of such “fully human” antibodies will still be those of high-affinity anti-self-antibody. Severe toxicity and lethal reactions may only occur once the destructive capabilities of the antibody are increased further by engineering (see following discussion).[204,206]

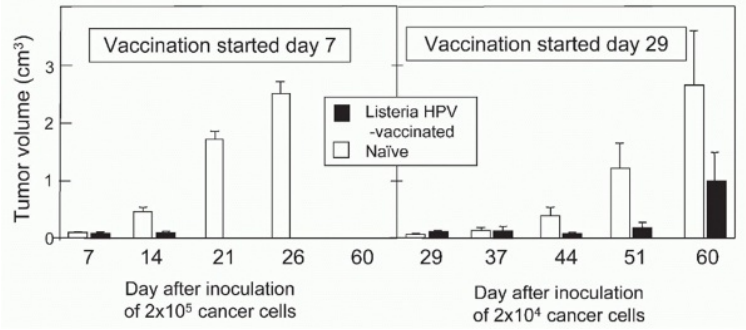

FIG. 47.7. Tumors can Escape from Therapeutic Vaccinations Once Truly Established. Then, therapeutic vaccinations become ineffective even against small tumors. Note the volumes of the tumors at start of therapeutic vaccinations, at day 7, or at day 29, respectively, are virtually the same size. However, only when vaccinations against were started early after TC1 cancer cell inoculation, tumors are eradicated and outgrowth prevented. †, mice in the naïve group were sacrificed. For human papillomavirus-16 E7 listeria, vaccine LLO-E7 leads to production of a fusion protein containing the complete E7 sequence.[1,2] TC-1 cancer cells are HPV16 E6 and E7 and

Ha-Ras transduced cell.[6] Unpublished; courtesy of Zhen-Kun Pan and Yvonne Paterson, University of Pennsylvania, Philadelphia, PA, USA.

Some antibodies can be relatively effective and useful in the therapy of selected human cancers, but rarely curative. To increase the clinical efficacy, scientists have searched to combine the specificity conferred by antibodies with the destructive potential of T cells. Two ideas, published decades ago,[347,1023,1024] led to reagents that are in clinical use[195,196,1025] and have little toxicity, but only if appropriate targets are used.

The first approach makes bispecific molecules linking the cancer-reactive antibody (or its variable regions) with an antibody (or its variable regions) binding to and activating T cells (eg, anti-CD3).[1023,1024] The second approach uses CARs consisting of the cancer-reactive variable region fused with transmembrane and signaling domains that are then transduced into T cells.[347]

Considerable technologic efforts are being made to enhance the ability of antibodies to kill tumor cells by using them as carriers for cytokines or cytotoxic agents, such as radiochemicals or natural toxins.[1026,1027,1028,1029,1030,1031] The recombinant antibody-cytokine or antibody-toxin fusion proteins may be useful to concentrate these agents in the stroma surrounding the tumor cells, but some of these coupled antibodies may have serious toxicity unless selective delivery of the conjugates to the tumor is achieved,[1032] a problem shared with bispecific or trispecific antibodies that bind effector cells as well as tumor antigens.[1033]

Cluster of Differentiation 20 and Cluster of Differentiation 19 **.** Monoclonal antibodies against B-cell lineage-specific differentiation antigens such as CD20 or CD19 are highly effective in preclinical models and can destroy large established B-cell lymphomas in patients,[1034] though relapse is common. However, when anti-CD20 or anti-CD19 are combined with anti-CD3 antibody or their variable regions are chimerized and used as CARs, patients with chronic lymphocytic leukemia or other B-cell malignancies may be cured.[195,196] Depletion of normal B cells occurs regularly but can be tolerated by giving intravenous Ig to the patient. Unfortunately, the antigens CD20 and CD19 are currently the exceptions rather than the rule. Other self-antigens exclusively expressed on cancer cells and only dispensable normal cells of the patient have not been identified.

HER-2. Anti-HER-2 antibodies are effective and useful in the therapy of some cancers (see following discussion). Treatment may be tolerated relatively well because the most

important effect may be inhibition by blocking signaling rather than destruction of cells.[1035,1036] Thus, antibodies to HER-2 (anti-HER-2/erb-B2/neu antibody; trastuzumab) can inhibit tumor growth independent of perforin or FasL in mice but inhibition requires type I and II IFNs released by NK and CD8 T cells.[1037] The role of antibody-dependent cell-mediate cytotoxicity in the trastuzumab efficacy in HER2-positive breast cancer patients is unclear, because a recent large study[1038] failed to confirm the previously published association between therapeutic effectiveness of anti-HER-2 antibodies and FcR genetic polymorphisms reflecting high- or low-affinity Fc receptors. In mice, the effects of anti-HER-2 antibodies seem to depend also on the participation of innate and adaptive immunity of the host that may be abrogated when the antibody is combined with chemotherapy[1039]; the relevance of this finding for the clinic is still unknown. However, HER-2 is expressed at low levels in several vital human tissues, and severe toxicity and death have occurred when the antibody receptor was inserted as antigen-receptor for T cells as CARs.[204]

GD2 and Carcinoembryonic Antigen **.** Some therapeutic effects have also been observed in patients treated with other murine monoclonal antibodies,[1040,1041] and anti-GD2 ganglioside-specific CARs had moderate antitumor effects in patients with

neuroblastoma.[1042] GD2 is expressed in the human cerebellum and peripheral nerves; serious toxicity as observed with anti-HER-2 CARs may have not been observed with anti-GD2 CARs because of a lesser therapeutic potency of the latter. Certainly, another CAR targeting CEA expressed on cancers and normal epithelium of the gut caused severe toxicity in patients.[206]

Other Receptors and Growth Factors. Antibodies to the IL-2 receptors can cause tumor regression in patients with cutaneous T-cell lymphoma.[1043] Other examples of overexpressed growth factors and their receptors are VEGF and receptors and epidermal growth factor and its receptor-1 (EGFR-1). Treatments with antibodies to these factors and receptors are fraught with complications (eg, anti-VEGF [bevacizumab] therapy for example has been linked to cardiac failures, digestive tract perforations, and bleedings in the lungs[1044]).

Targeting Immunoregulatory Molecules

Major clinical and preclinical efforts utilize monoclonal antibodies specific for regulatory and activation molecules expressed on T cells (anti-CTLA4, anti-PD-1 and anti-CD137 [4-1BB][1045,1046,1047]) and on cancer and normal host cells (eg, antibodies to ligands of PD-1, PD-L1, and L2[1048]). Monoclonal antibodies to the regulatory molecule CTLA-4 counteract tolerance and have antitumor effects in some but not in all tumor models.[1045,1049,1050] Severe autoimmunity may be a complication of this treatment. This subject is extensively reviewed elsewhere.[980,1051,1052]

Cytokines

The action of cytokines is essential for immunotherapy. Cytokines act in diffusion-limited spaces, but, when they act systemically, they may be toxic or lethal as in the Shwartzman-like shock reaction caused by systemic release of TNF-α[837,1053,1054] Mice surviving systemic TNF-α show a remarkable necrosis in the center of very large solid tumors of many different types of cancers.[619] Unlike the tumor neovasculature, the preexisting vessels at the tumor margin are resistant to TNF-α, and residual cancer at the viable margins gives rise to relapse. “Cytokine storm” caused by systemic high-dose anti-CD3 antibodies is mediated largely by TNF-α and can be lethal. Intratumoral injections of genetic vectors encoding TNF-α or other cytokines have some restricted applicability.[1055] Intravenous infusions of high doses of IL-2 induce clinical responses in a very small number of patients with a few types of cancers but have substantial side effects that need close medical supervision.[1056] Infusions of IL-2 are also used to amplify the effects of adoptively transferred T cells; the effect of IL-2 is indirect through action on T cells, NK cells, endothelial cells, and by inducing other cytokines. IL-2 effects on endothelial cells may cause vascular leakage syndrome that may allow better extravasation of transferred T cells into tumors. Clinical trials with another powerful cytokine, IL-15, are beginning in patients with cancer and human immunodeficiency virus.[1057]

Adoptive T-Cell Therapy

Seminal studies by Mitchison showed adoptive transfer of lymphocytes, not serum, produced resistance to allogeneic tumor transplants.[531,532,533] This was confirmed using syngeneic tumor transplants.[229,269,321,1058] Lymphocytes, either injected systemically or mixed with the cancer cell suspension and inoculated subcutaneously (Winn-type assay; see Assays to Study Effector Mechanisms in Vivo), protected against outgrowth of cancers while serum was ineffective. However, lymphocytes were as ineffective as serum in a therapeutic setting. Adoptive T-cell therapy of cancers was pioneered by Fefer, later working with Cheever, Greenberg, and Gillis, using established maize streak virus-induced tumors or Friend leukemia as a models.[471,766,767,1059,1060,1061,1062] Critical for the advance was recognizing the need for transient lymphodepletion of the recipient and transiently culturing and expanding the T cells in vitro with the help of IL-2 before transfer to recipients.

The use of TILs for adoptive T-cell therapy was pioneered by Rosenberg and coworkers at the National Institutes of Health.[1063] In preclinical models, TILs were effective even when given about 2 weeks after intravenous cancer cell inoculation.[1063] Adoptive cell transfer of autologous tumor-infiltrating lymphocytes was effective in ~50% of the patients with metastatic melanoma, but only few of the patients qualified for the treatment.[318,1064] Melanomainfiltrating lymphocytes were expanded in vitro with IL-2 and then infused into patients who receive IL-2 as well. Because the TIL response is dominated by T cells to unique tumor-specific antigen,[303] it is likely that the success of the reinfused T cells depends on their reactivity to unique tumor-specific antigens. Unfortunately, it is unclear how effective this personalized therapy is in patients with cancers other than melanoma.

Allogeneic EBV nuclear antigen-specific T cells sharing major MHC allele restriction with the patient can be used

to treat successfully posttransplant lymphoproliferative disease[1065] and EBV-positive lymphomas.[1066,1067] Such antigen-specific allogeneic T cells proved to be safe[1068] and effective.[1069] However, detailed knowledge of the molecular biology and immunology of EBV were critical to establish procedures that drive out EBV-specific T cells while losing alloresponsiveness.[1070] The donors did not need to be immunized with the patient's cancer cells. Instead, donor T cells containing EBV-specific precursors were primed specifically to EBV antigens using autologous EBV antigen-positive stimulators in vitro. Thus, donor T cells were never primed to the patient's alloantigens and were exclusively EBV-specific, although, as mentioned previously, donors and recipients need to be partially matched so that the EBV-specific T cells will be appropriately restricted. However for other cancers, immunization of the donor with the patient's cancer cells will be essential but not acceptable until proven to be without hazard to the donor and recipient. Much more work remains.

Rather than immunizing T-cell donors or cancer patients, current preclinical and clinical research focuses on the transfer of TCR or CAR genes into a patient's own T cells.[1071,1072,1073] These gene-modified T cells thereby gain specificity for cancer antigens and are reinfused. Recent studies in humans and mice are promising but also raise serious concerns.[204,208,1074,1075,1076,1077]

Preventing Relapse and Targeting Variants

As mentioned previously, experimental and human tumors have multiple tumor-specific CTL-recognized epitopes that are lost independently by selection with T cells in vitro.[218,278] However, in vivo, the host fails to recognize all antigens simultaneously on a cancer cell.[716,1078,1079] Recognition of a second antigen occurred only after the first antigen was lost by most of the tumor cells,[716,1079] even though the subdominant antigen can serve as effective target.[1080] This suggested that an immunodominant antigen prevents sensitization to other tumor antigens.[237,716,1079] A hierarchy in the immune response to multiple independent antigens has also been described in the study of immune responses to multiple minor histocompatibility antigens expressed on a single cell.[1081] The mechanism for the priority of the first response is unclear.[342,1082] However, understanding how to break the hierarchy could help prevent immune selection and tumor escape. For example, studies in vitro using CTL clones suggest that the rate of mutation resulting in the loss of a single antigen from the tumor cells is less than 10^{-6}. Even if the frequency were as high as 10^{-4}, only one tumor cell that had lost four independent antigens would be expected in 10^{16} tumor cells (ie, in a tumor larger than the human body).[278,1083] Thus, if the immune response of the host could be manipulated so that multiple antigens were attacked simultaneously, no escape of tumors should occur. Experimental evidence suggests that immunization with tumor-cell variants, selected in vitro and expressing selective antigenic components, can overcome immunodominance and prevent tumor escape.[1084] This will be important for

constructing vaccines.[1085]

Targeting Tumor Stroma and Bystander Killing

When complete surgical excision is no longer feasible, cancers usually contain variants resistant to numerous types of therapy. Whether killing of the overwhelming majority of antigen-positive cancer cells will result in the death of the few antigen-negative tumor cells "as bystanders" was studied over three decades ago with contradictory results.[1086,1087,1088] It is now clear that bystander killing of cancer variants can occur through stromal destruction and lead to the eradication of well-established solid tumors. This requires targeting tumorspecific antigens released from the cancer cells in the form of exosomes, microvesicles, and membrane fragments[1089,1090] that are cross-presented by stromal cells in the immediate tumor microenvironment. Antigen-specific, adoptively transferred T cells eradicate large tumors including variants by also targeting and destroying the tumor antigen cross-presenting stroma.[169,537,538,540,542] Pretreatment of the cancer by chemo-or radiotherapy can temporarily increase stromal loading and thereby increase the efficacy of cross-presentation and tumor eradication by subsequent adoptive T-cell therapy.[539] Thus, the therapy-resistant variants "caught" in the destroyed stroma are killed or die as bystanders in the necrotic stroma. Because cross-presentation depends on vicinity of stroma to the cancer cells, systemic toxicity has not been observed. No other antigens or molecules exist that are specific for stromal cells in cancers and not present on normal cells in the rest of the body. In contrast, other most intriguing and diverse approaches targeting antigens on stroma that are not cancerspecific[1091,1092,1093,1094,1095,1096] must overcome likely limitations in terms of toxicity and/or efficacy.[143]

EPILOGUE

Cancer immunology is at the interphase of two extraordinarily complex fields of research. Few fields of immunology have stimulated more emotional discussions. A healthy skepticism about the validity and relevance of experiments and concepts stimulates more experiments.[800] Differences in opinion do not harm scientific progress and should not be branded as attempts to "destroy the field." Any scientific field can only be strengthened by experiments in the search for truth.[1097] Opinions, but not truth, can be refuted.[1098] Many perceived "truths" have been refuted in the past, and this will likely also apply to parts of what is said in this chapter. The value of a scientist depends not on possessing real or perceived truth but his or her honest search for a better resolution of questions asked. Possession acquiesces and makes us proud and insensitive to opposing views of colleagues, but search for truth increases our strength to perfect our knowledge[1099] and find answers to the many important questions remaining in tumor immunology.

Chapter 48

Inborn Errors of Immunity

Jean-Laurent Casanova

Mary Ellen Conley

Luigi D. Notarangelo

INTRODUCTION

Louis Pasteur established the germ theory of infectious diseases whilst working near Alès, between 1865 and 1870, following his discovery that the two most prevalent diseases of silkworm were caused by different microbes.[1] This groundbreaking discovery apparently settled a long discussion between two conflicting theories. The first, in which diseases were considered to be intrinsic, had long held sway over the second, in which diseases were considered to be extrinsic. It rapidly became clear, with the successive identification of numerous microbes, culminating in Koch's discovery of *Mycobacterium tuberculosis* in 1882,[2] that this new paradigm accounted for the heavy burden of childhood fever and death that had prevailed throughout human history. About half the children born died of fever before the age of 15, and this death toll could be attributed to microbes.[3] This theory did not explain why rare children survived infectious diseases and assumed that healthy children had remained free from infection. However, the edifice on which this theory was constructed collapsed between 1905 and 1915, with the gradual realization that most infected individuals remained asymptomatic, often throughout their lifetime. Asymptomatic individuals were found to harbor latent microbes—nonreplicating microbes in a dormant state— such as *M. tuberculosis*.[4] Even more strikingly, actively replicating microbes were found to cause silent infections in other individuals, such infections being termed “unapparent infections” by Charles Nicolle.[5] The question of interindividual variability in the course of infection therefore became, and has since remained, a key question in the fields of infectious disease and immunology, and is, arguably, one of the most important questions in biology and medicine. The problem in itself suggests that there are, after all, some intrinsic determinants of disease. The first explanation put forward followed on naturally from another ground-breaking discovery by Pasteur in 1880 to 1881: the prevention of infectious diseases and the foundations of immunology, with the use of attenuated microbes to vaccinate against fowl cholera and sheep anthrax.[6] This led to the hypothesis that related, less virulent microbes or smaller amounts of the same microbes had previously immunized the individuals who remained healthy in the course of infection with a microbe virulent enough to kill other individuals. This powerful idea can be seen as an immunologic or somatic theory of infectious diseases. We now know that this acquired immunity (often referred to as adaptive immunity) emerged twice in the evolution of vertebrates, by convergent evolution, that it is lymphoid, and that it involves both genetic and epigenetic components. However, although this theory was considered plausible in adults, and perhaps in teenagers, especially during secondary infections or reactivation from latency, it was less convincing for primary infections in early childhood, which comprised the majority of cases. In this context, a few human geneticists looking at the problem from the complementary standpoints of clinical and population genetics, including Archibald Garrod and Karl Pearson in particular, collected evidence between 1910 and 1930 for strong, germline, genetic determinism, controlling innate immunity against microbes.[7,8] As stated by Garrod, “It is, of necessity, no easy matter to distinguish between immunity which is inborn and that which has been acquired.”[7]

The development of new vaccines and the discovery of sulfonamides and antibiotics during the 1930s rendered these questions obsolete; it became less pressing to understand a problem that everyone thought would soon be resolved. Paradoxically, antibiotics themselves triggered renewed interest in the question in the early 1950s, when a small group of pediatricians in Europe and America noted that rare children suffered from multiple, recurrent infectious diseases, each of which was treated with antibiotics, lacked a major leukocyte subset or gammaglobulins, and shared this phenotype with relatives, consistent with an inheritable trait.[9,10,11,12,13,14] This was the birth of the field of primary immunodeficiency (PID), a term apparently first coined in 1971[15,16] that remains more frequently used than inborn errors of immunity, which was first used in 1966.[16,17] These children had major immunologic abnormalities, such as neutropenia,[11,14] alymphocytosis,[12,13] or agammaglobulinemia.[9,10] Moreover, their infectious and immunologic phenotypes often

followed a Mendelian pattern of segregation within their families. It is, however, important to bear in mind that the definition of PID established in the 1950s was based on an artificial, as opposed to natural phenotype, because these children with multiple life-threatening infections would have died during their first episode of infection before the advent of antibiotics. Moreover, although the infectious phenotype of these patients led to their investigation and the pattern of inheritance was suggestive of a Mendelian trait, PIDs were classified and defined solely on the basis of the immunologic phenotype. There had been previous descriptions of inherited disorders associated with infectious diseases, such ataxia-telangiectasia in 1926 and 1941,[18,19] Wiskott-Aldrich syndrome in 1937,[20,21] and epidermodysplasia verruciformis in 1933[22] (and its viral etiology in 1946[23]), but

these disorders were not recognized as PIDs until 1964,[24,25] 1959,[26,27] and 2002,[28] respectively. They were long considered from other angles, in the absence of detectable immunologic abnormalities. Autoimmune polyendocrinopathy syndrome with mucocutaneous candidiasis was probably first described clinically between the 1920s and 1940s, but the autoantibodies involved were not described until the 1970s.[29,30] More surprisingly, Chediak-Higashi syndrome (CHS) was first described as an inherited predisposition to infections with detectable leukocyte abnormalities in 1943 to 1954,[31,32,33] but was not recognized as a PID until 1962.[34]

Severe congenital neutropenia (SCN) and CHS were among the first PIDs to be described, but these and other inborn errors of myeloid cells, such as chronic granulomatous disease (CGD), which was first described in 1966, and complement defects, first described in 1963 (hereditary angioneurotic edema due to an absence of C1 esterase inhibitor),[35] were not included in the first classifications of PIDs, which were restricted to the lymphoid arm of immunity, in 1968,[36] 1970,[37,38] 1971,[15] 1972,[39] 1973,[40] and 1974.[41] Over this period, the fields of immunology and PIDs evolved in parallel, focusing on acquired or adaptive immunity, which is sometimes referred to as adaptive or lymphoid immunity. The lymphoid imprint was so strong that the first report on PIDs even distinguished explicitly between these disorders and myeloid abnormalities. Unsurprisingly, given that these PIDs affected the development or function of B- and/or T-cell immunity, these patients displayed multiple, recurrent infectious diseases that were often opportunistic (ie, not seen in patients with apparently intact immunity). Patients with T- and B-cell PIDs also displayed noninfectious, autoimmune, allergic, and in some cases, cancer phenotypes. Despite the broad infectious phenotypes of the patients with complement and phagocyte disorders identified, the first mention of quantitative and qualitative disorders of phagocytes did not occur until 1974, when it appeared, somewhat amusingly, in a preliminary report,[42] but not in the official report[43] of the second World Health Organization (WHO) international workshop on PIDs. The weaknesses of this definition and classification of PIDs were apparent to some investigators, including Gatti, who ironically compared this system to the ancient Chinese classification for animals.[44] The classification nonetheless evolved, as complement disorders were mentioned in 1976 but phagocyte defects were not,[45] and qualitative phagocyte disorders (including CGD and CHS) appeared in the third (1978),[46] fourth (1983),[47] fifth (1986),[48] sixth (1989),[49] and seventh (1992)[50] WHO classifications, although SCN did not. The full range of PIDs was not covered until the eighth WHO classification in 1999,[51] and has since been dealt with in the 10th (2003),[52] 11th (2004),[53] 12th (2006),[54] 13th (2007),[55] 14th (2009),[56] and the most recent (15th[57]) WHO International Union of Immunological Societies reports. Meanwhile, two prominent reviews published in 1984 and 1995 made no reference to phagocyte defects.[58,59,60] Some aspects of the history of the field have been covered in at least two reviews.[61,62]

The common PID classification and the underlying definition of PIDs proved increasingly inadequate and unable to describe the situation in reality, which extended well beyond phagocytic disorders, from the 1990s onwards. The definition and classification of PIDs have always been engaged in an eternal game of catch-up with the reality of the situation on the ground, and this gap between the conservative words used to describe these conditions and the continual discovery of new PIDs, ever increasing the known spectrum of these diseases, has been maintained.[63,64] Phenotypic studies in this field have progressed in at least two ways. First, multiple and diverse new phenotypes have progressively been attributed to PIDs, including, of course, autoimmunity,[30] malignancy,[65] and allergy,[66] but also various other phenotypes, such as autoinflammation,[67] angioedema,[68] hemophagocytosis,[69] and thrombotic microangiopathies.[70] The underlying mutations involve multiple circuits affecting both myeloid and lymphoid cells. Second, patients with a single infectious disease, and often with a single infectious episode, have been shown to display PIDs.[71] Again, the underlying mutations affect both lymphoid and myeloid cells, but they may also, in some cases, concern nonhematopoietic cells. PIDs were initially associated with multiple, recurrent, and often

opportunistic infections with an early onset and fatal outcome. They were familial, recessive traits. Exceptions to these rules gradually emerged, beginning with the description of patients with autosomal recessive (AR) defects in the terminal components of complement (C5 to C9), who are specifically susceptible to *Neisseria*,[72] patients with X-linked recessive (XR) lymphoproliferative syndrome, who are susceptible to Epstein-Barr virus (EBV),[73] and patients with AR epidermodysplasia verruciformis, resulting in a selective predisposition to infection with skin-tropic, oncogenic papillomaviruses.[74] These studies paved the way for the discovery of new PIDs underlying particular infectious diseases in children who were otherwise healthy and normally resistant to other infectious diseases. Children with mycobacterial diseases were found to carry inborn errors of interferon (IFN)γ immunity.[75] Mutations in the toll-like receptor (TLR) and interleukin (IL)-1R pathway are associated with pyogenic bacterial diseases, whereas mutations in the TLR3 pathway are associated with herpes simplex encephalitis.[76] Finally, inborn errors of IL-17 immunity underlie chronic mucocutaneous candidiasis.[77,78] These discoveries indicated that otherwise healthy children with a single infectious disease can display inborn errors of immunity to primary (in cases of acute disease) or recurrent/latent (for chronic disease) infection.[71,79]

The definition of PIDs is evolving, thanks largely to the clinical delineation and genetic dissection of new phenotypes. These advances are also leading to changes in the classification of PIDs. PIDs were initially classified into two groups (defects of humoral and cell-mediated immunity), then into four major groups (T, B, complement, and phagocyte disorders). The 2011 WHO classification includes up to 10 (somewhat overlapping) categories of PIDs, despite the contentious omission of certain types of PID.[79a] However, there is no consensus about the definition and classification of PIDs.[16] The classification of PIDs principally on the basis of immunologic phenotypes entails a risk of clinical and genetic overlap and of some disorders being ignored. A classification based on clinical phenotype would be more useful at the patient's bedside, and a classification based

on genotype would be more useful at the research bench. However, the apparent lack of a solution to this problem is not a major concern. Hopefully, the classification will improve with the characterization of more PIDs, the deciphering of their genotypes, the dissection of their molecular, cellular, and immunologic phenotypes. and the description of their clinical phenotypes. Like a jigsaw puzzle, every piece should start to fit into place as we approach the solution. This task may not be as vast as it might initially appear, as there are no more than 25,000 genes for 7 billion individuals reproducing every two or three decades. However, we may never reach the asymptote, as there is no such thing as a distinct disease entity, precisely because of the tremendous germline and somatic genetic variability that makes each disease in each patient unique: there are only patients. There is therefore unlikely to be any satisfactory definition and classification of inborn errors of immunity in the near future. This does not matter so long as rapid progress is made in this field, in terms of awareness, diagnosis, treatment, and above all, in explorations of the genotype and intermediate phenotypes of known and new clinical phenotypes.

Why is it so important for the field of PIDs to thrive? This progress is above all important for the patients. As in other areas of medicine, strategies improving our understanding of pathogenesis constitute the only rational approach to improving the clinical management of patients, in terms of the quality of diagnosis, prognosis, and treatment. The availability of blood samples has made it possible to carry out very careful analyses of the relationships between genotypes, cellular phenotypes, immunologic phenotypes, and clinical phenotypes, as for inborn errors of erythrocytes and platelets, perhaps more thoroughly than in other fields of human genetics and pediatrics. For example, the discovery of new PIDs over the last two decades has made it clear that the 10 conventional warning signs used in PID awareness campaigns are completely out of date and require revision.[80] Another clinical lesson learned in the last 50 years is that most PID-causing genes are associated with high levels of clinical heterogeneity. Remarkable examples include mutations in the *NEMO* gene, the effects of which range from death in utero to mild immunodeficiency in adults, reflecting the severity of the biochemical deficit caused by the morbid alleles,[81] and mutations in *RAG* genes, the impact of which ranges from life-threatening severe combined immunodeficiency in infancy to combined immunodeficiency in adults.[57] Several genes have even been found to harbor loss-of-function (LOF) and gain-of-function (GOF) mutations. These genes include *WASP*, LOF mutations, which underlie Wiskott-Aldrich syndrome (WAS), and GOF mutations, which underlie SCN,[82] and *STAT1*, LOF mutations, which underlie mycobacterial or viral diseases, and GOF mutations, which underlie chronic mucocutaneous candidiasis (CMC).[78] Similarly, most, if not all of the known clinical phenotypes are associated with high levels of locus and allelic genetic heterogeneity. For example, several agammaglobulinemia-causing autosomal genes were identified following the discovery of *BTK* mutations in boys with XR agammaglobulinemia.[83] A large proportion of the patients with each PID, particularly for the most recently described conditions, do not carry mutations in known morbid genes. It is

therefore highly likely that new genetic etiologies will be discovered in the future. The clinical implications of research in this field actually extend well beyond diagnosis and pathogenesis, as the first cases of successful immunoglobulin (Ig) substitution,[9] bone marrow transplantation,[84] transfusion-based enzymatic replacement,[85] and gene therapy[86] all concerned children with PIDs. These children were also among the first to benefit from PEGylated enzymatic replacement[87] and treatment with recombinant cytokines.[88]

Perhaps of greater relevance to this book, this field has had extraordinary immunologic implications. One of the pioneers in this field, Robert Good, often referred to PIDs as "experiments of nature," reviving a line of investigation that began with Harvey and was followed by Osler, Garrod, McQuarrie, and Burnet, among others.[89,90] Indeed, physicians and scientists can learn much by deciphering the enigmas posed by the experiment of nature represented by each patient with a PID. No matter how rare a disorder, it can provide considerable insight into the fundamental laws operating in living organisms. More conventional experiments, designed by humans and carried out in animal models, benefit from being carefully thought out and executed in a controlled manner. However, they suffer from the limitations inherent to their experimental nature. Experimental protocols differ from natural processes in many ways (inbred animals, conditions of infection, microbes). Human genetics provides us with a unique opportunity to define the function of host genes in natural, as opposed to experimental, conditions: in a natural ecosystem governed by natural selection.[91,92] Immunity *in natura* can be defined by the careful dissection of PIDs and by other related approaches, such as epidemiologic and evolutionary genetics. The differences between mice and humans are often discussed, and rightly so, as these two species differ in many ways, despite the similar architecture of their immune systems. Beyond these multiple, and in some cases large, differences between humans and mice, there may be major differences between the processes used to study phenotypes, infectious and otherwise, in the two models. For example, experimental infections in mice generally involve inoculation with microbes that have not coevolved with these rodents, via artificial routes of infection and at high doses. By contrast, most human infections are natural, although some experimental infections, such as those caused by live vaccines, have played an important role in the development of this field. The experimental triggers of autoimmunity in mice are also different from those operating in natural conditions in humans. The genetic dissection of PIDs thus provides us with a unique opportunity to cast new light on the function of human genes in a natural ecosystem. Over the years, these observations have provided invaluable insights sometimes at odds with the mouse model.

It will not be possible to cover the entire field in this chapter. More than 200 inborn errors of immunity have been characterized genetically.[57,93] Many other PIDs have been described clinically but have no known genetic etiology. Doctors in this field also know that a large fraction of the patients under their care suffer from exceedingly rare

disorders, sometimes apparently limited to a single family, not reported in the medical literature. Moreover, many phenotypes might be due to new PIDs. These phenotypes form a large reservoir for the future dissection of new inborn errors of immunity, as previously illustrated by autoinflammation, hemophagocytosis, angioedema, thrombotic microangiopathies, and isolated infectious diseases.[64] Finally, we know that most known PIDs are associated with tremendous locus and allelic heterogeneity. With about 25,000 known genes and only 8000 known inborn errors, including about 300 PIDs, we can predict that 10,000 inborn errors of immunity, defined by a specific causal relationship between a genotype and a phenotype, currently await discovery. An estimate of 1000 to 2000 PID-causing loci is not unrealistic. Even with the only 300 or so known PIDs, it is clear that we cannot cover even a substantial fraction of these diseases here. We will therefore focus our review on seven topics, focusing in more detail on a specific syndrome or disease for each and discussing its genetic basis. We will pay particular attention to the immunologic lessons that can be drawn from these experiments of nature.

INBORN ERRORS OF T-CELL DEVELOPMENT OR FUNCTION

In 1950, Glanzman and Riniker described two infants who presented with severe infections, diarrhea, failure to thrive, and disseminated candidiasis, leading to early death. Severe lymphoid depletion tissue was found at the postmortem examination.[94] Similar cases of early death due to severe infection (often with weakly virulent microbes), lymphopenia, and agammaglobulinemia were reported a few years later in Switzerland.[95] Both male and female patients were affected by this disease, which was named "Swiss-type agammaglobulinemia "[96] to distinguish it from Bruton agammaglobulinemia, which affects principally male patients and is characterized chiefly by recurrent bacterial infections.[97] The cases described by Glanzman and Riniker[94] and by Hitzig et al.[95,96] constitute the first description of humans with severe combined immunodeficiency (SCID), a group of conditions characterized by a lack of autologous T cells and extreme susceptibility to infections caused by a broad range of pathogens, including weakly virulent agents. The genetic heterogeneity of SCID became

apparent in the 1960s, with the identification of families in which the disease was inherited as an X-linked trait.[98] In the 1970s and 1980s, the immunologic phenotype of SCID was shown to be heterogeneous, through the demonstration that all patients had low levels of autologous T-lymphocytes but that only some of these patients displayed an associated decrease in the numbers of B and/or natural killer (NK) lymphocytes.[99] This has led to the identification of various immunological subtypes of SCID: a) with a complete absence of T, B, and NK lymphocytes (T-B- NK- SCID); b) T- B+ NK- SCID; c) T- B+ NK+ SCID; and d) T- B- NK+ SCID. Finally, genetic studies over the last three decades have shown that SCID is also highly heterogeneous in terms of its genetics[57,100] (Table 48.1; Fig. 48.1).

SCID has a prevalence of 1:50,000 to 1:100,000 live births. The study of SCID has played an essential role in the identification of the key mechanisms governing human T-cell development. In several cases, SCID-causing gene defects were identified in patients before the generation of animal models. Moreover, comparison of humans and mice with mutations in orthologous genes associated with SCID has often revealed differences in the immunologic phenotype in these two species, indicating the existence of speciesspecific differences in the mechanisms governing lymphoid development. Finally, the heterogeneity of mutations in individual SCID-causing genes is associated with variability of the clinical and immunologic phenotype, which may include manifestations other than SCID, such as various forms of immune deficiency and immune dysregulation, particularly in patients with hypomorphic mutations allowing residual development of T- and/or B-lymphocytes.[101]

Molecular Mechanisms Accounting for Severe Combined Immunodeficiency

Defective thymus organogenesis is associated with a profound impairment of T-cell development. The genetic defects affecting the development of the thymic epithelium are extrahematopoietic in nature, but they may greatly disturb T-cell development, in some cases leading to a clinical and immunologic SCID phenotype. *DiGeorge syndrome* (DGS) results from defects of the third and fourth branchial pouches and is characterized by impaired thymic development, congenital heart disease, hypoparathyroidism, and facial dysmorphisms. Most patients carry a heterozygous interstitial deletion of chromosome 22q11.[102] The molecular mechanism by which haploinsufficiency for the genes of the DGS critical region underlies defective thymic development remains unclear. The severity of the thymic development defect varies considerably between patients. Most patients with DGS have moderate T-cell lymphopenia, but a few have complete thymic aplasia (complete DGS) and no circulating T-lymphocytes.[102,103,104,105] Another PID in which thymogenesis is impaired is caused by mutations of the gene encoding FOXN1, a transcription factor required for the development and maturation of the thymus stroma and eccrine glands.[106,107] Biallelic *FOXN1* mutations cause an AR SCID phenotype in which a lack of circulating T-lymphocytes is associated with alopecia.[108,109,110] This disease is the human equivalent of the *nude* phenotype in mice, for which the underlying gene was identified before the discovery of human patients.[111]

The proliferation and survival of lymphoid progenitor cells are also essential for the generation of a normal number of mature lymphocytes. Some forms of SCID are associated with high rates of apoptosis. In 1972, while investigating polymorphic enzymes as genetic markers, Giblett discovered that the erythrocytes of two infants with SCID displayed no adenosine deaminase (ADA) activity.[112] ADA converts adenosine to inosine (and deoxyadenosine to deoxyinosine).[113] In patients with AR *ADA deficiency*, the accumulation of toxic phosphorylated derivatives of deoxyadenosine causes cell death, resulting in extreme lymphopenia, with an almost total absence of T, B, and NK lymphocytes.[112,114,115] A few years after describing ADA deficiency, Giblett discovered

that a deficiency of another enzyme involved in purine metabolism, purine nucleoside phosphorylase, was also associated with impaired lymphoid development.[116]

TABLE 48.1 Inborn Errors of T-Cell Development

Disease	Gene Defect	T Cells	B Cells	NK Cells	Inheritance	Pathogenesis	Associated Features Other than Immunodeficiency
FOXN1 deficiency	*FOXN1*	↓↓↓	N	N	AR	Defective maturation of thymic	Alopecia

						epithelium	
DiGeorge syndrome	22q11del*	↓↓	N	N	Sporadic	Defective thymus organogenesis	Hypoparathyroidism, congenital heart disease
Reticular dysgenesis	*AK2*	↓↓↓	N or ↓	↓↓	AR	Increased apoptosis	Neutropenia, sensorineural deafness
Adenosine deaminase deficiency†	*ADA*	↓↓	↓↓	↓↓	AR	Increased apoptosis	Bone abnormalities, neurologic problems, liver and lung involvement
Nucleoside phosphorylase deficiency	*PNP*	↓↓	N	N	AR	Increased apoptosis	Neurologic problems, autoimmunity
X-linked SCID†	*IL2RG*	↓↓↓	N	↓↓↓	XL	Defective signaling through gc	
JAK3 deficiency	*JAK3*	↓↓↓	N	↓↓↓	AR	Defective signaling through gc	
IL-7R deficiency†	*IL7R*	↓↓↓	N	N	AR	Defective signaling through IL-7R	
RAG1 deficiency†	*RAG1*	↓↓↓	↓↓↓	N	AR	Defective V(D)J recombination	
RAG2 deficiency†	*RAG2*	↓↓↓	↓↓↓	N	AR	Defective V(D)J recombination	
Artemis deficiency†	*DCLRE1C*	↓↓↓	↓↓↓	N	AR	Defective V(D)J recombination	Developmental defects, radiation sensitivity
DNA ligase IV deficiency†	*LIG4*	↓↓	↓↓	N	AR	Defective V(D)J recombination	Microcephaly, dysmorphisms, radiation sensitivity
Cernunnos/XLF deficiency	*NHEJ1*	↓↓	↓↓	N	AR	Defective V(D)J recombination	Microcephaly, radiation sensitivity
DNA-PKcs deficiency	*PRKDC*	↓↓↓	↓↓↓	N	AR	Defective	V(D)J recombination
CD3γ deficiency	*CD3G*	N or ↓	N	N	AR	Defective TCR signaling	Most often, autoimmunity
CD3δ deficiency	*CD3D*	↓↓↓	N	N	AR	Defective signaling through pre-TCR	
CD3ε deficiency	*CD3E*	↓↓↓	N	N	AR	Defective signaling through pre-TCR	

CD3ζ deficiency	*CD3Z*	↓↓↓	N	N	AR	Defective signaling through pre-TCR	
CD45 deficiency	*CD45*	↓↓↓	N	N	AR	Defect of signaling	
ZAP-70 deficiency†	*ZAP70*	↓↓↓ of CD8+ cells	N	N	AR	Defect of signaling (impaired positive selection of CD8+ cells)	
MHC class II deficiency	*CIITA, RFX5, RFXANK, RFXAP*	↓↓ of CD4+ cells	N	N	AR	Defect of positive selection of CD4+ cells	
Coronin-1A deficiency	*CORO1A*	↓↓↓	N	N	AR	Defect of thymocyte egress, impaired T lymphocyte survival	
ORAI1 deficiency	*ORAI1*	N (but defective function)	N	N	AR	Defective calcium flux	Autoimmunity, myopathy
STIM1 deficiency	*STIM1*	N (but defective function)	N	N	AR	Defective calcium flux	Autoimmunity, myopathy
MAGT1 deficiency	*MAGT1*	↓↓ of CD4+ cells, reduced proliferation	N	N	XL	Defective magnesium flux	Chronic viral infections, lymphoma
DOCK8 deficiency	*DOCK8*	↓	↓	↓	AR	Defective activation	Severe atopy, severe cutaneous viral infections
CD40L deficiency	*CD40LG*	N	N	N	XL	Impaired CD40L-mediated costimulation of B and dendritic cells by activated CD4+ cells	Neutropenia, *Cryptosporidium* infection, biliary tract disease, neuroectodermal tumors; IgM levels are often elevated

AR: autosomal recessive; CD, cluster of differentiation; DNA, deoxyribonucleic acid; gc, germinal center; Ig, immunoglobulin; IL, interleukin; MHC, major histocompatibility complex;

N, normal; NK, natural killer; PNP, purine nucleoside phosphorylase; RAG, recombinase-activating gene; SCID, severe combined immunodeficiency; TCR, T-cell receptor; XL,

X-linked; XLF, XRCC4-Like factor.

* DiGeorge syndrome is most often associated with 22q11 chromosomal deletion; however, other cytogenetic and genetic abnormalities have been also reported in a minority of cases.

† Hypomorphic mutations in these genes have been associated with Omenn syndrome or other conditions with immune dysregulation.

SCID may also be caused by impaired cytokine signaling by T-cell precursors in the thymus. In 1993, two groups demonstrated that the newly cloned *IL2RG* gene encoding the γ chain of the IL-2 receptor was mutated in male patients with XR SCID, the most common form of SCID in western countries.[117,118] XR SCID is characterized by a T-B+ NK- phenotype, indicating that *IL2RG* mutations are deleterious to the development of both T- and NK lymphocytes. This was a surprising discovery, because disruption of the *Il2* gene in mice had been shown to be associated with immune dysregulation rather than SCID.[119] It soon became clear that the IL-2Rγ chain was also common to other cytokine receptors, including those for IL-4, IL-7, IL-9, IL-15, and IL-21,[120,121,122,123,124,125] leading to its being renamed the common γ chain, γc. In all these receptors, the γc is coupled to the intracellular kinase JAK3, allowing intracellular signaling.[126] These discoveries have helped define the molecular basis of XR SCID and to identify other genetic defects causing SCID in humans. In 1995, two groups established that an AR variant of T- B+ NK- SCID (a phenocopy of XR SCID) was due to mutations of the *JAK3* gene.[127,128] Furthermore, the observation of severely impaired T-cell development in *Il7*$^{-/-}$ and *Il7r*$^{-/-}$ mice[129,130] led to the discovery of *IL7R* mutations in patients with AR T- B+ NK+ SCID.[131,132] IL-7 provides important signals for the survival and proliferation of thymocytes and peripheral T cells and regulates the rearrangement of T-cell receptor (TCR) genes,[133] thus accounting for the absence of circulating T cells in patients with SCID due to *IL2RG*,*JAK3*,and *IL7R* mutations. Interestingly, B-cell development is unaffected in these forms of SCID, but abolished in *Il2rg*$^{-/-}$, *Jak3*$^{-/-}$, and *Il7r*$^{-/-}$ mice.[134,135,136,137] These data highlight significant species-specific differences in the molecular mechanisms governing lymphoid development. Circulating NK lymphocytes are absent in patients with XR SCID and with JAK3 deficiency, but not in those with IL-7R deficiency, suggesting that impaired signaling through another γc-dependent cytokine may occur. The cytokine concerned is probably IL-15, because IL-15-mediated signaling is essential for human NK cell development in vitro[138] and *Il15*$^{-/-}$ and *Il15r*$^{-/-}$ mice lack NK cells in vivo.[139,140]

SCID can also result from impaired TCR gene rearrangement due to abnormalities in VDJ recombination, a process essential for the expression of both the pre-TCR and the mature TCR.[141,142] The lymphoid-specific recombinaseactivating gene (RAG) 1 and RAG2 proteins initiate VDJ recombination by recognizing recombination-specific sequences flanking the variable (V), diversity (D), and joining (J) elements of the TCR and introducing deoxyribonucleic acid (DNA) double-strand breaks.[143,144] These breaks are eventually repaired through the ubiquitously expressed nonhomologous end-joining (NHEJ) pathway.[145,146] RAG1, RAG2, and the NHEJ pathway are also involved in the rearrangement of Ig genes, which is required for expression of the pre-B-cell receptor (BCR) and the BCR.[141,143] Mutations of the *RAG1* and *RAG2* genes,[147] and of the genes encoding Artemis,[148] DNA ligase IV,[149,150,151,152] and DNA-PKcs[153] (all components of the NHEJ pathway) result in T- B- NK+ SCID. Mutations of Cernunnos/XLF, another component of the

NHEJ pathway, severely impair, but do not completely abolish T- and B-cell development.[154,155] The genes encoding Artemis[148] and Cernunnos/XLF[154] were cloned from humans before they were cloned from mice, the availability of fibroblastic cell lines from SCID patients being essential to this achievement. NHEJ is involved in general mechanisms of DNA repair, including those occurring in nonlymphoid cells. Thus, patients with defects of this pathway also display an unusually high level of cellular sensitivity to radiation, have a higher than normal risk of malignancy, and may present with neurologic problems.[146,156] Finally, hypomorphic mutations of genes involved in V(D) J recombination and NHEJ have been identified in patients with “leaky” forms of SCID, in whom the residual development of T- (and in some cases, B-) lymphocytes was associated with autoimmunity and a high risk of lymphoid malignancies.[157,158,159]

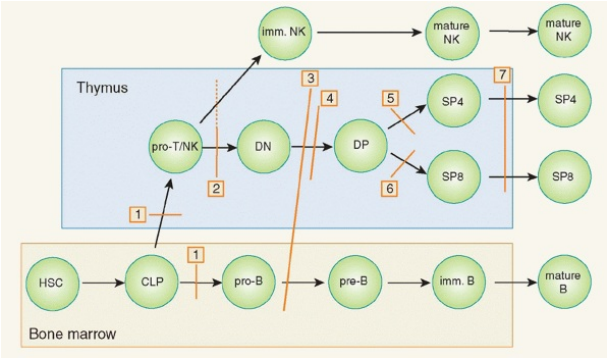

FIG 48.1. Schematic Representation of Developmental Blocks in Combined Immunodeficiencies. Discrete stages in T-, B-, and natural killer (NK)-cell development are shown. *Red bars* identify stages at which developmental arrests are caused by specific gene defects. *Numbers in boxes* identify the molecular defects accounting for the developmental blocks. In particular: 1): adenosine deaminase deficiency; 2) defects of cytokine-mediated signaling (*IL2RG*, *IL7R*, *JAK3* deficiency); 3) defects of V(D)J recombination (*RAG1*, *RAG2*, *Artemis*, *LIG4*, *Cernunnos*, and *DNA-PKcs* deficiency); 4) defects of pre-T-cell receptor signaling (*CD3D*, *CD3E*, *CD3Z* deficiency); 5) defects of positive selection of cluster of differentiation (CD)4+ thymocytes (major histocompatibility complex class II deficiency); 6) defects of positive selection of CD8+ thymocytes (ZAP-70 deficiency); and 7) defects of thymocyte egress from the thymus (Coronin-1A deficiency). The *hatched bar* indicates that NK-cell development is affected by mutations of *IL2RG* and *JAK3* gene (that interfere with interleukin-15-mediated signaling) but not by *IL7R* mutations. Not shown is severe combined immunodeficiency due to *FOXN1* mutations (that impair thymus organogenesis) and reticular dysgenesis, due to mutations of the *AK2* gene, in which the exact stage at which T-cell development is blocked is not known. CLP, common lymphoid progenitor; DN, double negative; DP, double positive; HSC, hematopoietic stem cell; imm., immature; SP4, single positive CD4; SP8, single positive CD8.

Signaling through the pre-TCR is essential to promote the progression from cluster of differentiation (CD)4-CD8- double-negative (DN) thymocytes to CD4+ CD8+ double-positive cells. This signaling is mediated by the CD3 complex, mimicking the requirement of this complex for TCR signaling in mature T cells. Null mutations of the *CD3D*, *CD3E*, and *CD3Z* genes interfere with this process and result in AR SCID.[160,161,162,163] By contrast, *CD3G* mutations are more often associated with a milder phenotype including autoimmunity.[164]

Other Combined Immune Deficiencies Due to Late Defects in T-Cell Development and Function

The positive selection of CD4+ and CD8+ thymocytes requires the interaction of thymocytes expressing a functional TCR with thymic epithelial cells (and dendritic cells) expressing self-antigens bound to human leukocyte antigen (HLA) class II and class I molecules, respectively.[165,166] Several gene defects account for *HLA class II deficiency* in humans,[167,168,169,170] a condition characterized by severe CD4+ lymphocyte depletion and normal CD8+ T-cell development.[171] Conversely, mutations of *ZAP-70*, a tyrosine kinase that binds to the CD3ζ chain and promotes TCR-mediated signaling,[172] cause immunodeficiency with a lack of CD8+ cells.[173,174,175] The CD4+ lymphocytes of affected patients develop normally but are nonfunctional and fail to

proliferate in response to mitogens and antigens. ZAP-70 deficiency in humans results in a phenotype different from that of *Zap70*$^{-/-}$ mice, which lack both CD4+ and CD8+ lymphocytes.[176] The prolonged expression of SYK in human (but not in mouse) double-positive thymocytes seems to compensate for the lack of ZAP-70 protein, allowing the generation of CD4+ T cells.[177,178] However, mature CD4+ lymphocytes from ZAP-70-deficient patients have no SYK and are therefore functionally impaired.

The egress of mature thymocytes from the thymus to the periphery requires rearrangement of the actin cytoskeleton. Coronin-1A is involved in this process.[179] Accordingly, *Coronin-1A deficiency* causes the retention of mature thymocytes and a failure to generate peripheral T cells, although impaired survival of newly generated T lymphocytes is probably another very important mechanism of disease.[180,181]

Finally, mature T cells in the periphery respond to mitogenic signals by releasing calcium from

endoplasmic reticulum stores and opening calcium release-activating channels on the cell membrane, allowing calcium influx to occur.[182] Mutations of *STIM1* (which encodes a sensor of endoplasmic reticulum calcium stores) and of *ORAI1* (which encodes calcium release-activating channels) cause a severe immunodeficiency in which T-lymphocyte generation in the thymus is not affected, but the function of peripheral T cells is impaired.[181] Both conditions are also characterized by myopathy and the impairment of immune homeostasis, with autoimmunity.[183,184]

Clinical and Immunologic Features and Treatment

Infants with SCID are susceptible to severe infections from shortly after birth. Infections may be due to bacteria, viruses, or fungi. Infections with weakly virulent microorganisms (eg, *Pneumocystis jiroveci*, cytomegalovirus) are common and frequently cause interstitial pneumonia and chronic diarrhea, leading to failure to thrive.[101,185,186]

Lymphopenia is present in 60% to 70% of affected infants.[186] T-cell lymphopenia is even more common. In 30% to 50% of cases, a variable number of T-lymphocytes of maternal origin (that have crossed the placenta and not been rejected by the fetus with SCID) are detected.[187] Maternal T-lymphocytes may cause alloreactive signs resembling graft-versus-host disease, with infiltration and damage to the liver, the skin, the gut, and the bone marrow.[187,188] All patients lack autologous T cells.

Alternatively, less severe (hypomorphic) mutations in SCID-causing genes may be permissive for residual T-cell development, but result in a lower level of TCR diversity in circulating T cells.[101] The oligoclonal expansion of these T-lymphocytes is often associated with tissue damage, as in infants with Omenn syndrome.[189] This damage resembles the severe inflammatory lesions resulting from the homeostatic proliferation of a few T-cell clonotypes in mice.[190] In other patients, the mutations may underlie milder forms of combined immunodeficiency.[159,191] However, the severity of the clinical and immunologic phenotype is not determined solely by the nature of the mutation, because different phenotypes (eg, SCID and Omenn syndrome) have been reported in different individuals harboring the same mutation and even in individuals from the same family.[192]

Lymphocyte and lymphocyte subset counts are the mainstay of SCID diagnosis and may provide useful information about the underlying genetic defect.[101] The presence of T cells does not exclude a diagnosis of SCID, as the T cells detected may be of maternal origin. However, the maternal T cells have a very limited in vitro proliferative response to mitogens (eg, phytohemagglutinin).[186] Infants with SCID are unable to mount specific antibody responses.[186] Genetic diagnosis is guided by the NK- and B-cell phenotype and the mode of inheritance. A SCID screening test for neonates has recently become available. This test is based on the polymerase chain reaction-mediated amplification of TCR excision circles (TRECs) from a dried blood spot collected at birth.[193,194] TRECs are a byproduct of TCRα rearrangement that persist in newly developed T-lymphocytes expressing the αβ form of the TCR,[195] but are diluted out during the subsequent proliferation of cells in the periphery. TREC quantification therefore provides important information about thymic function.

Infants with SCID require the regular administration of Igs and antimicrobial prophylaxis. When indicated, blood products should be irradiated before transfusion to prevent transfusional graft-versus-host disease, and should be obtained from cytomegalovirus-negative donors to prevent the risk of transmission. The diagnosis and treatment of infection should be prompt and aggressive. However, in the absence of prophylaxis, SCID is inevitably fatal within a few months, and patients do not survive beyond a few years in the absence of transplantation.[185] Indeed, hematopoietic stem cell transplantation (HSCT) is the mainstay of SCID treatments, and optimal results (> 90% survival) are obtained if the donor is an HLA-matched sibling.[196,197] If no such donor is available, HSCT can be performed with a matched unrelated donor or with a haploidentical parent as the donor. However, if a haploidentical parent acts as the donor, mature T-lymphocytes must be removed from the graft to prevent graft-versus-host disease. Excellent results (> 95% survival) have been reported for SCID patients treated by HSCT before the age of 3.5 months,[197] highlighting the importance of neonatal screening for SCID. HSCT results are less satisfactory for combined immunodeficiency with the residual presence of autologous T-lymphocytes, because there is a risk of graft rejection and of treatmentrelated toxicity, due to the need for chemotherapy for ablation of the immune system of the host.[196] In particular, the outcome of HSCT is far from good in patients with major histocompatibility complex (MHC) class II deficiency, because the transplantation of hematopoietic stem cells does not correct the lack of MHC class II antigen expression on thymic epithelial cells.[198] Enzyme replacement therapy may lead to detoxification and immune reconstitution in infants with ADA deficiency.[199,200] Finally, gene therapy has been successfully used in infants with SCID due

to ADA deficiency[201] or to a γc defect.[85,202,203] However, 5 of 20 infants with X-linked SCID treated by gene therapy developed leukemic proliferation due to insertional mutagenesis (ie, insertion of the transgene near an oncogene, mostly LMO2, leading to transcriptional activation of the oncogene).[204,205]

Thus, studies of patients with SCID have laid the foundations for an understanding of the molecular and cellular mechanisms governing lymphoid development in humans. Identification of the molecular basis of SCID in humans has preceded the generation of gene-targeted mice on a number of occasions. Furthermore, important differences have emerged between the immunologic phenotypes of humans and mice, with mutations in orthologous genes associated with SCID. Finally, the early identification of SCID patients with molecular and immunologic tools has important clinical implications, optimizing survival after HSCT. Despite these advances, the gene responsible for disease remains unidentified in most cases of combined immunodeficiency and a small minority (< 5%) of infants with SCID. The deep sequencing of human exomes and genomes should lead to the identification of still more genes causing T-cell deficiencies in humans.

INBORN ERRORS OF B-CELL DEVELOPMENT OR FUNCTION

Antibody deficiencies constitute the largest group of currently recognized PIDs (Table 48.2).[206,207,208] This is partly because these disorders were among the first to be recognized to cause inborn errors in immunity and because they are among the easiest to detect with routine laboratory studies. Antibody deficiencies, regardless of their etiology, are associated with recurrent or persistent infections with encapsulated bacteria, particularly *Streptococcus pneumoniae* and *Haemophilus influenzae*. Patients develop infections typical of these organisms, including otitis, sinusitis, and pneumonia, but they are also likely to experience more severe, invasive infections, such as sepsis, meningitis, joint infections, and cellulitis. Other infections and clinical findings are more specific to particular antibody deficiencies.

X-linked Agammaglobulinemia

X-linked agammaglobulinemia (XLA), sometimes called Bruton agammaglobulinemia or congenital agammaglobulinemia, was first described in 1952, when Colonel Bruton reported the case of an 8-year-old boy with recurrent pneumococcal sepsis and no globulin fraction on serum electrophoresis.[209] The patient's clinical course was improved by treatment with exogenous gammaglobulin. Once techniques had been developed for the evaluation of B cells in the peripheral blood, it became clear that patients with XLA had very few or no B cells in the bloodstream.[210,211,212,213] This is the most consistent feature in patients with XLA. Although 10% to 15% of patients have higher than expected serum Ig concentrations, all patients have < 2% CD19+ lymphocytes in the peripheral blood (normal range 5% to 20% CD19+ cells). Patients are treated by gammaglobulin replacement and the aggressive use of antibiotics.

In addition to infections caused *S. pneumoniae* and *H. influenzae*, patients with XLA are more vulnerable to enteroviral infections, particularly enteroviral encephalitis and vaccine-associated polio.[214,215,216,217,218] Mycoplasma and ureaplasma infections are also more common and may cause arthritis, prostatitis, and meningitis, as well as pneumonia.[219,220] The incidence of *Giardia* infection is also high in patients with XLA; some of these patients have protein-losing enteropathy and low serum IgG as the first sign of infection.[221] Although significant complications and early death are still sometimes reported for patients with XLA,[216] many patients now survive into adulthood.[222]

In 1993, two groups, using two separate approaches, showed that XLA was due to mutations in a previously unrecognized cytoplasmic tyrosine kinase, now called Bruton tyrosine kinase (BTK).[223,224] One group identified the gene on the basis of linkage analysis[223]; the other isolated a cDNA encoding a tyrosine kinase from B-cell precursors.[224] This gene mapped to the XLA critical region on the long arm of the X chromosome, making it an excellent candidate gene.[224] BTK is an enzyme specific to hematopoietic cells that is expressed throughout B-cell differentiation.[225] It is found in the platelets and myeloid cells, but not in T cells or plasma cells.[226] However, the clinical effects of BTK deficiency appear to be limited to the B-cell lineage. Severe neutropenia is seen in some patients with XLA, particularly those who are very young.[218,227] However, very low neutrophil counts are also seen in patients with defects specific to the B-cell lineage, such as μ heavy chain deficiency.[228] This neutropenia may be due to bone marrow suppression by viruses in the absence of natural antibody.

BTK has an amino-terminal pleckstrin homology domain, a proline-rich region, and an SH3 domain, followed by an SH2 and a carboxy-terminal kinase domain.[224] It is activated and phosphorylated within minutes of pre-BCR or BCR activation.[229,230] Activated BTK and

PLCγ2 then bind to the scaffold protein BLNK, allowing BTK to phosphorylate PLCγ2, resulting in biphasic calcium flux.[231]

Over 600 different mutations have been identified in the BTK gene,[232,233] most of which result in an absence of detectable BTK in monocytes and platelets.[234,235,236] Amino acid substitutions, particularly those that do not affect the stability of the protein, tend to result in a milder phenotype characterized by an older age at diagnosis, higher serum Ig concentrations, and the presence of B cells in small, but detectable numbers.[237,238,239] However, the genotype/phenotype correlation is not strong.

Mutations of the BTK gene account for 85% of cases of early onset of infection and isolated defects in B-cell development.[240] A similar clinical phenotype is seen in patients with mutations in genes encoding components of the pre-BCR and BCR, including the μ heavy chain,[228,241,242,243] the surrogate light chain protein λ5,[244] the signal transduction molecules Igα and Igβ (also called CD79a and CD79b),[242,245,246] and the downstream scaffold protein BLNK.[243,247]

Bone marrow studies have shown B-cell development to be blocked at the pro-B cell to pre-B cell transition, the stage at which the pre-BCR is first expressed, in patients with mutations affecting BTK, the μ heavy chain, λ5, Igα, Igβ, or BLNK. BTK gene mutations cause a leaky defect in B-cell differentiation. Most patients with XLA have a small number of both pre-B cells in the bone marrow and immature

B cells in the bloodstream.[248,249,250] As in healthy controls, the number of B cells produced decreases with age,[251] and most adults with XLA have less than 0.02% B cells in the blood. Mutations in the other genes cause a more severe block in B-cell development. Null mutations in the μ heavy chain, Igα, and Igβ genes result in a complete absence of CD19+ lymphocytes from the blood (< 0.01%). A patient with a hypomorphic mutation in Igβ and young children with mutations in λ5 or BLNK have been reported to have a small number of B cells (< 0.1% CD19+ cells). By contrast, mice with BTK, λ5, or BLNK defects have been reported to have 50%, 20%, or 10%, respectively, the normal number of B cells in the blood.

TABLE 48.2 Antibody Deficiencies

Disease	Gene Defect	B cells	T cells	Serum Igs	Inheritance	Pathogenesis	Associated Features or Comments
Agammaglobulinemia with absent or very low B cells							
X-linked agammaglobulinemia	*BTK*	↓↓↓	N	All isotypes decreased	XL	Defective signaling through the BCR	Detectable serum Igs in some patients
μ heavy chain deficiency	*IGHM*	↓↓↓↓	N	All isotypes decreased	AR	Defective signaling through the BCR	
λ5 deficiency	*IGLL1*	↓↓↓↓	N	All isotypes decreased	AR	Defective signaling through the BCR	
Igα deficiency	*CD79A*	↓↓↓↓	N	All isotypes decreased	AR	Defective signaling through the BCR	
Igβ deficiency	*CD79B*	↓↓↓↓	N	All isotypes decreased	AR	Defective signaling through the BCR	
BLNK deficiency	*BLNK*	↓↓↓↓	N	All	AR	Defective	

				isotypes decreased		signaling through the BCR	
Hypogammaglobulinemia with normal or low B cells							
CVID	*Multifactorial*	N or ↓	N or ↓	↓IgG and IgA; IgM may be normal	Usually sporadic	variable	Autoimmune cytopenias; granulomatous disease; lymphoma
IgA deficiency	*Multifactorial*	N	N	↓ IgA; normal IgG and IgM	Usually sporadic	variable	Sometimes assoicated with IgG subclass deficiency
ICOS deficiency	*ICOS*	N	N	↓ IgG and IgA; IgM may be normal	AR	Defective T-cell activation	
CD19 deficiency	*CD19*	N	N	↓ IgG; ↓ or normal gA and IgM	AR	Poor amplification of BCR signal	May have glomerulonephritis
CD81 deficiency	*CD81*	N	N	↓ IgG; ↓ or normal gA and IgM	AR	Poor amplification of BCR signal	May have glomerulonephritis; coreceptor with CD19
CD20 deficiency	*MS4A1*	N	N	↓ IgG; normal IgA and IgM	AR	Defective B-cell activation	Poor antibody response to T cell-independent antigens
TACI	*TNFRSF13B*	N	N	variable	AD or AR	Defective B-cell activation and survival	Susceptibility gene not diseasecausing; associated with autoimmunity
BAFF-R	*TNFRSF13C*	↓	N	↓ IgG and IgM; normal IgA	AR	Defective B-cell activation and survival	
Class switch recombination defects							
X-linked hyper-IgM syndrome	*CD40LG*	N	N	↓ IgG and IgA; IgM may be normal or ↑↑↑	XL	Impaired CD40L-mediated costimulation of B and dendritic cells by activated CD4+ cells	Neutropenia, *Cryptosporidium* infection, biliary tract disease, neuroectodermal tumors
CD40 deficiency	*CD40*	N	N	↓ IgG and IgA; IgM may be normal or ↑↑↑	AR	Impaired CD40L-mediated costimulation of B and dendritic cells by activated CD4+ cells	Neutropenia, *Cryptosporidium* infection, biliary tract disease, neuroectodermal tumors
AID deficiency	*AICDA*	N	N	↓ IgG and IgA; IgM	AR or AD	Defective initiation of	Lymphadenopathy, increased

				↑↑↑		somatic hypermutation and class switch recombination	incidence of autoimmune disease
UNG deficiency	*UNG*	N	N	↓ IgG and IgA; IgM ↓↓↓	AR	Defective somatic hypermutation and class switch recombination	Lymphoid hyperplasia

AD, autosomal deficient; AID, activation-induced cytidine deaminase; AR, autosomal recessive; BCR, B-cell receptor; CD, cluster of differentiation; CVID, common variable immunodeficiency; Ig, immunoglobulin; N, normal; UNG, uracil-DNA glycosylase; XL, X-linked.

Hyperimmunoglobulin M Syndromes/Class Switch Recombination Defects

Hyper IgM syndrome is characterized by normal or high serum IgM concentrations, with IgG and IgA either present at very low concentrations or undetectable.[216,252,253] However, with the identification of the genetic etiologies of the most common forms of hyper-IgM syndrome, it has become clear that not all patients have high IgM concentrations. This has led to the suggestion of "class switch recombination defects" as a more appropriate designation for this group of disorders.[253] We will use these terms interchangeably here. Approximately 65% of patients with hyper-IgM syndrome have the XR form of the disease, which is caused by mutations in the gene encoding the tumor necrosis factor (TNF) family member CD40 ligand (CD40L).[254,255,256] These patients tend to have more severe illness than patients with XLA.[216,252] The median age at diagnosis is 12 months, and patients generally have little or no detectable IgA and IgG in the serum, frequently accompanied by neutropenia and/or opportunistic infections. The numbers of T cells and B cells are usually within normal limits. Infections with encapsulated bacteria, *Pneumocystis*, cytomegalovirus, parvovirus, *Cryptosporidium*, and *Histoplasma* are problematic in patients with CD40L deficiency. Sclerosing cholangitis secondary to *Cryptosporidium* infection[252] and neuroendocrine or hepatobiliary carcinomas[257,258] have been reported in a significant number of patients. Treatment consists of gammaglobulin replacement, the aggressive use of antibiotics, granulocyte-colony stimulating factor (G-CSF) in cases of persistent neutropenia and, in some patients, HSCT.[259]

CD40L (also called CD154, gp39, TRAP, and TNFSF5) is a type II transmembrane protein transiently expressed on the surface of activated T cells[260,261,262] and platelets. The binding of CD40L to its cognate receptor on B cells, CD40, induces B-cell activation, short- and long-term B-cell proliferation, and in the presence of cytokines, isotype switching[260,262,263,264] through the induction of activation-induced cytosine deaminase (AID) production. By deaminating cytosine residues in VH and switch regions, AID performs the first step in both class switch recombination and somatic hypermutation.[265,266] However, CD40 is also expressed on monocytes,[267] dendritic cells,[268] activated platelets,[269] epithelial cells,[270] and endothelial cells.[271] The stimulation of these target cells via CD40L elicits an inflammatory response, with release of cytokines, including IL-12 in particular.[267,272] The failure to elicit this inflammatory response accounts for the viral, fungal, and parasitic diseases seen in patients with CD40L deficiency.

Several other genetic disorders resulting in hyper-IgM syndrome have been reported. A small number of patients with AR defects in CD40 have been described.[273] These patients have a clinical phenotype identical to that seen in patients with mutations in CD40L. Approximately 10% to 15% of patients with class switch recombination defects have mutations in *AICDA*, which encodes the B cell-specific protein AID described previously.[266,274,275] Defects in UNG, an enzyme responsible for eliminating the uracil molecules generated by AID activity, also account for a small number of cases.[276] Patients with mutations affecting AID or UNG do not have the viral, parasitic, and fungal infections or neutropenia seen in patients with CD40L deficiency, but they are more likely to have lymphadenopathy and autoimmune disease.[277]

Common Variable Immunodeficiency

Shortly after Bruton described the first case of agammaglobulinemia in a young boy, other authors reported adult patients, of both sexes, with severe

hypogammaglobulinemia.[278,279,280] Many of these patients appeared to have acquired, rather than congenital immunodeficiency, and both clinical and

laboratory findings were highly variable.[281,282] This disorder therefore came to be called acquired hypogammaglobulinemia or common variable immunodeficiency (CVID). Hypogammaglobulinemia can be seen in other immunodeficiencies and may result from infections, drug reactions, protein-losing conditions, or cancers, and it is therefore important to rule out these other possibilities before diagnosing CVID.[283]

Patients of any age may be diagnosed as having CVID, but onset occurs most frequently between the ages of 10 and 40 years.[284,285,286,287,288,289] Respiratory tract infections, diarrhea, and autoimmune disorders are the most common findings on presentation. Laboratory analyses show low serum IgG and IgA concentrations, but IgM concentration may be low or within the normal range. B cells are easily detected in the blood of most but not all patients.[290] However, most patients lack CD27+ memory B cells.[291,292] About 10% of patients have a family history of immunodeficiency or autoimmune disease.[286] Patients with CVID or IgA deficiency are more likely to have certain uncommon MHC haplotypes.[293,294,295] The precise gene within this locus responsible for susceptibility remains unclear.[296] Recent genome-wide association studies have suggested that some copy number variants are more common in CVID.[297]

In the last 10 years, several genetic disorders resulting in clinical signs consistent with CVID have been reported. A small number of CVID patients with homozygous mutations in *ICOS* have been identified.[298,299] Heterozygous and homozygous mutations affecting TAC1, which belongs to the TNF receptor family (also known as TNFRSF13B), have been reported in 10% of patients with CVID and 1% of healthy controls.[300,301,302,303,304] CVID patients with TACI alterations are more likely to have autoimmunity and splenomegaly than other patients with CVID.[300,304] Homozygous mutations of the gene encoding another TNF receptor family member, BAFF-R, have been described in a brother and sister in whom immunodeficiency was first recognized after the age of 50 years.[290] Homozygous mutations of the genes encoding CD19 or another component of the CD19 complex, CD81, have been reported in fewer than 10 patients.[305,306,307,308] A child with a homozygous mutation of the gene encoding CD20 and a low serum IgG concentration has been reported.[309] The clinical and laboratory findings for all the individuals with these mutations are highly variable, and it is not clear that any of these genetic alterations are sufficient to cause clinical symptoms when present on their own. In most patients, a combination of genetic and environmental factors is likely to play a role.

INBORN ERRORS OF PHAGOCYTE DEVELOPMENT OR FUNCTION

A number of inborn errors affect the polymorphonuclear or mononuclear phagocytes of the myeloid lineage (Table 48.3). Granulocyte disorders mostly affect neutrophils, whereas mononuclear phagocyte disorders affect monocytes, macrophages, or dendritic cells. Some disorders affect phagocytes and other leukocytes; they may also sometimes affect nonhematopoietic cells. Some of these disorders will be covered elsewhere in this chapter. The disorders mostly or exclusively affecting phagocytes have traditionally been grouped together under the umbrella of “phagocyte disorders.” We will not review all these disorders here, as this group is rapidly expanding. Instead, we will focus on two of these disorders that have played an important role in the history of this field, in which considerable progress has been made in recent decades. These two disorders—severe congenital neutropenia (SCN) and chronic granulomatous disease (CGD), first described by Rolf Kostmann, and CGD, first described by Robert Good— elegantly illustrate the quantitative and qualitative defects of phagocytes. Studies of these disorders have also provided substantial immunologic insight into granulocyte function and the respiratory burst of phagocytes. Many other equally fascinating quantitative defects, such as AR IRF8 deficiency, in which circulating monocytes and dendritic cells do not develop, have been described but will not be discussed here.[310] Similarly, we will not consider qualitative disorders here, such as specific granule deficiency, which is characterized by a lack of specific granules, making it impossible to distinguish between neutrophil, basophil, and eosinophil granulocytes, and is caused by AR C/EBP-ε deficiency.[311] A list of phagocyte disorders is provided in Table 48.3, under the caveat that the classification of these disorders is imperfect.

SCN is characterized by absolute neutrophil counts of < 500/μl from early infancy, often falling below 200/μl, with normal counts of other leukocytes.[312,313,314,315] Patients with SCN have normal counts of basophil and eosinophil granulocytes. Myeloid maturation in the bone marrow is arrested at the promyelocyte or myelocyte stage of development. Differential diagnoses include complex and often syndromic PIDs with neutropenia, such as warts, hypogammaglobulinemia, immunodeficiency, and myelokathexis syndrome, cartilage hair hypoplasia, CHS, dyskeratosis congenita, Fanconi anemia, reticular dysgenesis, and

Schwachman-Diamond syndrome. Several other inborn errors of immunity do not affect the myeloid lineage directly but often result in transient or chronic neutropenia, due to infections or the use of particular drugs. Cyclic neutropenia (CN) is characterized by regular oscillations of the number of peripheral neutrophils, with a nadir at about 200/μl and a period of about 21 days. SCN is also known as Kostmann syndrome, and CN is sometimes referred to as cyclic hematopoiesis. Both disorders were long absent from PID classifications, principally because patients with diseases of myeloid cells were seen by hematologists, whereas patients with lymphoid diseases were seen by immunologists. CN is marked by fever, oral ulcers, and bacterial infections during the nadir. The prognosis on G-CSF treatment is excellent[316]; these patients do not develop myelodysplasia or acute myeloid leukemia (AML).[315] The clinical features of SCN are more severe, with mucocutaneous and deep-seated bacterial and fungal infections. The bacterial infections are caused by various Gramnegative and Gram-positive species, including staphylococci in particular. The fungi responsible for infections are equally diverse and include *Candida albicans*. Without treatment, the outcome in infancy or early childhood is poor. Before the advent of G-CSF treatment, half the patients died from sepsis in the first year of life, the other half dying during early childhood. Myelodysplastic syndromes (MDSs) and AML were rare. Antibacterial and antifungal prophylaxis cannot provide long-term protection. HSCT has been successful in some patients. Spectacular progress was achieved in 1989, with the discovery that recombinant G-CSF could restore normal counts of circulating granulocytes, in at least some patients.[87] G-CSF treatment should be tailored to the individual patient. Most SCN patients and almost all CN patients respond to G-CSF treatment, although SCN patients require higher doses. It was subsequently shown that a substantial fraction of SCN patients treated with G-CSF developed MDS or AML, these conditions now constituting a more common cause of death in these patients than sepsis.[317,318] No such effect was observed in CN patients. The cumulative incidence of MDS/AML is about 20% after 10 years on G-CSF treatment. Somatic mutations of the G-CSF receptor and monosomy 7 often precede MDS/AML. It is unclear whether G-CSF treatment itself favors these complications or whether treatment reveals natural complications of the underlying disorders. Patients who do not respond to G-CSF, or are undergoing malignant transformation, should be treated with HSCT.[319,320,321]

TABLE 48.3 Inborn Errors of Phagocytes

Disease	Affected Cells	Affected Function	Associated Features	Inheritance	Genetic Defect/Presumed Pathogenesis	OMIM Number
1. Defects of neutrophil differentiation						
a. Severe congenital neutropenia 1 (ELANE deficiency)	N	Myeloid differentiation	Subgroup with myelodysplasia	AD	*ELANE:* misfolded protein response	202700
b. SCN2* (GFI 1 deficiency)	N	Myeloid differentiation	B/T lymphopenia	AD	*GFI1*: loss of repression of ELANE	613107
c. SCN3 (Kostmann disease)	N	Myeloid differentiation	Cognitive and neurologic defects in some patients	AR	*HAX1*: control of apoptosis	610738
d. SCN4 (G6PC3 deficiency)	N + F	Myeloid differentiation, chemotaxis, O_2^- production	Structural heart defects, urogenital abnormalities, and venous angiectasias of trunks and limbs	AR	*G6PC3*: abolished enzymatic activity of glucose-6-phosphatase, aberrant glycosylation, and enhanced apoptosis of N and F	612541
e. Glycogen storage disease type	N + M	Myeloid differentiation, chemotaxis,	Fasting hypoglycemia, lactic acidosis, hyperlipidemia,	AR	*G6PT1*: Glucose-6-phosphate transporter 1	232220

1b		O_2^- production	hepatomegaly			
f. Cyclic neutropenia	N	?	Oscillations of other leukocytes and platelets	AD	*ELANE*: misfolded protein response	162800
g. X-linked neutropenia*/ myelodysplasia	N + M	Mitosis	Monocytopenia	XL	*WAS:* Regulator of actin cytoskeleton (loss of autoinhibition)	300299
h. P14 deficiency*	N + L Mel	Endosome biogenesis	Neutropenia Hypogammaglobulinemia ↓CD8 cytotoxicity Partial albinism Growth failure	AR	*ROBLD3*: Endosomal adaptor protein 14	610389
i. Barth syndrome	N	Myeloid differentiation	Cardiomyopathy, growth retardation	XL	Tafazzin (*TAZ*) gene: Abnormal lipid structure of mitochondrial membrane	302060
j. Cohen syndrome	N	Myeloid differentiation	Retinopathy, developmental delay, facial dysmorphisms	AR	*COH1* gene: Pg unknown	216550
k. Poikiloderma with neutropenia	N	Myeloid differentiation, O_2^- production	Poikiloderma, MDS	AR	*C16orf57* gene: Pg unknown	604173
2. Defects of motility						
a. LAD type 1	N + M + L + NK	Adherence, chemotaxis, endocytosis, T/NK cytotoxicity	Delayed cord separation, skin ulcers Periodontitis Leukocytosis	AR	*INTGB2*: Adhesion protein (CD18)	116920
b. LAD type 2*	N + M	Rolling, chemotaxis	Mild LAD type 1 features plus hh-blood group plus mental and growth retardation	AR	*FUCT1*: GDP-Fucose transporter	266265
c. LAD type 3	N + M + L + NK	Adherence, chemotaxis	LAD type 1 plus bleeding tendency	AR	*KINDLIN3*: Rap1-activation of β1-3 integrins	612840
d. Rac 2 deficiency*	N	Adherence, chemotaxis O_2^- production	Poor wound healing, leukocytosis	AD	*RAC2*: Regulation of actin cytoskeleton	602049
e. β-actin deficiency*	N + M	Motility	Mental retardation, short stature	AD	*ACTB*: Cytoplasmic Actin	102630
f. Localized juvenile periodontitis	N	Formylpeptide-induced chemotaxis	Periodontitis only	AR	*FPR1*: Chemokine receptor	136537
g. Papillon-Lefèvre syndrome	N + M	Chemotaxis	Periodontitis, palmoplantar hyperkeratosis in some patients	AR	*CTSC*: Cathepsin C activation of serine proteases	245000
h. Specific granule deficiency*	N	Chemotaxis	Neutrophils with bilobed nuclei	AR	*C/EBPE*: Myeloid transcription factor	245480

i. Shwachman-Diamond syndrome	N	Chemotaxis	Pancytopenia, exocrine pancreatic insufficiency, chondrodysplasia	AR	*SBDS:* Defective ribosome synthesis	260400
3. Defects of respiratory burst						
a. XL CGD	N + M	Killing (faulty O_2^- production)	McLeod phenotype in patients with deletions extending into the contiguous Kell locus	XL	*CYBB*: Electron transport protein (gp91phox)	306400
b-e. Autosomal CGDs	N + M	Killing (faulty O_2^- production)		AR	*CYBA*: Electron transport protein (p22phox) *NCF1*: Adapter protein (p47phox) *NCF2*: Activating protein (p67phox) *NCF4*: Activating protein (p40 phox)	233690 233700 233710 601488
4. MSMD						
a. IL-12 and IL-23 receptor β1 chain deficiency	L + NK	IFNγ secretion	Susceptibility to *Mycobacteria* and *Salmonella*	AR	*IL12RB1*: IL-12 and IL-23 receptor β1 chain	601604
b. IL-12p40 deficiency	M	IFNγ secretion	Susceptibility to *Mycobacteria* and *Salmonella*	AR	*IL12B:* subunit of IL-12/IL-23	161561
c. IFNγ receptor 1 deficiency	M + L	IFNγ binding and signaling	Susceptibility to *Mycobacteria* and *Salmonella*	AR, AD	*IFNGR1*: IFNγR ligand binding chain	107470
d. IFNγ receptor 2 deficiency	M + L	IFNγ signaling	Susceptibility to *Mycobacteria* and *Salmonella*	AR	*IFNGR2*: IFNγR accessory chain	147569
e. STAT1 deficiency (AD form)*	M + L	IFNγ signaling	Susceptibility to *Mycobacteria, Salmonella*	AD	*STAT1*	**600555**
f. Macrophage gp91 phox deficiency*	Mf only	Killing (faulty O_2^- production)	Isolated susceptibility to mycobacteria	XL	*CYBB:* Electron transport protein (gp 91 phox)	**306400**
g. IRF8 deficiency (AD form)*	CD1c+MDC	Differentiation of CD1c+MDC subgroup	Susceptibility to *Mycobacteria*	AD	*IRF8:* IL12 production by CD1c+MDC	**601565**
5. Other defects						
a. IRF8 deficiency (AR form)*	Monocytes peripheral DC	Cytopenias	Susceptibility to *Mycobacteria*, *Candida*, myeloproliferation	AR	*IRF8*: IL-12 production	
b. GATA2 deficiency (mono MAC syndrome)	Monocytes peripheral DC + NK + B	Multilineage cytopenias	Susceptibility to *Mycocbacteria*, papillomaviruses, histoplasmosis, alveolar proteinosis, MDS/AML/CMML	AD	*GATA-2*: loss of stem cells	137295
c. Pulmonary alveolar	Alveolar macrophages	GM-CSF signaling	Alveolar proteinosis	Biallelic mutations in	*CSF2RA*	306250

proteinosis*	pseudoautosomal gene

ACTB, Actin beta; AD, autosomal dominant inheritance; AML, acute myeloid leukemia; AR, autosomal recessive inheritance; B, B lymphocytes; CD, cluster of differentiation; CEBPE, CCAAT/Enhancer-binding protein epsilon; CGD, chronic granulomatous disease; CMML, chronic myelomonocytic leukemia; CTSC, cathepsin C; CYBA, cytochrome b alpha subunit; CYBB, cytochrome b beta subunit; DC, dendritic cell; ELANE elastase neutrophil-expressed; F, fibroblasts; FPR1, formylpeptide receptor 1; FUCT1, fucose transporter 1; GATA2, GATA binding protein 2; GFI1, growth factor independent 1; GM-CSF, granulocyte macrophage-colony stimulating factor; HAX1, HLCS1-associated protein X1; IFN, interferon; IFNGR1, interferon-gamma receptor subunit 1; IFNGR2, interferon-gamma receptor subunit2; IL-12B, interleukin-12 beta subunit; IL-12RB1, interleukin-12 receptor beta 1; IFR8, interferon regulatory factor 8; ITGB2, integrin beta-2; L, lymphocytes; LAD, leukocyte adhesion deficiency; M, monocytes-macrophages; MDC, myeloid dendritic cell; MDS, myelodysplasia; Mel, melanocytes; Mf, macrophages; MSMD, Mendelian susceptibility to mycobacterial disease; N, neutrophils; NCF1, neutrophil cytosolic factor 1; NCF2, neutrophil cytosolic factor 2; NCF4, neutrophil cytosolic factor 4; NK, natural killer; OMIM, Online Mendelian Inheritance in Man; ROBLD3: roadblock domain containing 3; SBDS, Shwachman-Bodian-Diamond syndrome; STAT, signal transducer and activator of transcription; XL, X-linked inheritance.

* Ten or fewer unrelated cases reported in the literature.

P.1250

Multiple genetic etiologies of SCN have been identified. The first was responsible for autosomal deficient (AD) SCN, whereas more recent genome-wide linkage approaches have discovered causes of AR SCN. Heterozygous mutations of *ELA2* are responsible for about 60% of SCN cases and most cases of CN.[322,323,324] Penetrance appears to be complete. In most, but not all cases, the mutations cause either SCN or CN, although both phenotypes have been observed in a few rare kindreds. The mechanism of disease remained unclear for many years, as *ELA2* encodes a cytoplasmic neutrophil elastase, a serine protease synthesized at the promyelocyte stage and stored in the primary granules of neutrophils. ELA2-deficient mice are not neutropenic but they do have impaired host defenses.[325] By contrast, humans with heterozygous *ELA2* mutations display impaired neutrophil granulocyte differentiation, due to high levels of intramedullary apoptosis. These mutations were recently shown to activate unfolded protein responses (UPRs) due to the detection of misfolded ELA2 proteins in the secretory pathway, resulting in cellular apoptosis.[326,327] Thus, dominant-negative *ELA2* mutations seem to cause SCN or CN not because ELA2 is involved in granulocyte differentiation, but simply because the resulting misfolded proteins, which are selectively expressed in granulocytes, activate the apoptosis-inducing UPR pathway in a “normal” manner. The degree of UPR activation seems to depend on the *ELA2* mutation, possibly determining the type of phenotypic expression: CN (mild mutations) or SCN (more severe mutations). Rare cases of SCN are due to heterozygous dominant-negative mutations of the gene encoding GFI1,[328] which encodes a transcriptional repressor of myeloid genes. GFI1 knockout mice are severely neutropenic and display an accumlulation of immature monocytes in the blood.[329,330] A mouse model of the human mutation also displays specific neutropenia.[331] However, the molecular mechanisms by which *GFI1* mutations cause AD SCN remain unclear.[314] Interestingly, GOF mutations in the WASP gene have been shown to cause X-linked dominant SCN.[81] The underlying mechanism involves unregulated actin polymerization, leading to defects of mitosis and cytokinesis that result in the apoptosis of granulocyte precursors.[332] Some of the patients with these mutations have platelet and lymphocyte abnormalities.

The original kindred described by Kostmann displayed AR inheritance.[11,14,333] The underlying genetic defect was not identified until 2007, when causal mutations were discovered in the *HAX1* gene, which encodes a mitochondrial protein.[334] This is the most common genetic etiology of AR SCN. The mutations concerned are LOF and cause the mitochondrial membrane potential to dissipate, leading to the release of proapoptotic molecules into the cytoplasm, potentially accounting for SCN pathogenesis.[335] However, the mechanism underlying SCN in HAX1-deficient patients remains unclear.[314] Apoptosis rates are high in the neurons and lymphocytes of HAX1-deficient mice.[336] HAX1-deficient patients from the kindred originally studied by Kostmann also displayed some neurologic signs.[333] Moreover, *HAX1* mutations affecting only isoform A were found to underlie SCN, whereas mutations affecting isoforms A and B (lacking part of exon 2 and expressed in neurons) were found to cause both SCN and various forms of neurologic impairment.[337,338] Another genetic etiology of AR SCN has been identified in a few kindreds with mutations of the *G6PC3* gene, encoding a member of the endoplasmic reticulum-resident glucose-6-

phosphatase family.[339] As in patients with *ELA2* mutations, these patients display signs of endoplasmic reticulum stress and UPR pathway activation, possibly due to impairment of the glycosylation of proteins transported in the secretory pathway. The knockout mice also display neutropenia.[340] As this enzyme is ubiquitous, the other clinical features recorded in patients, including developmental defects of the heart or urogenital tract, are not particularly surprising. Overall, what have we learned from these experiments of nature? A number of genes cause CN and SCN, and there are probably multiple mechanisms of disease, converging on the apoptosis of myeloid precursors of neutrophil granulocytes. These studies have identified key players in neutrophil differentiation, in some cases even before the description of their impact in mice (HAX1), which differs for at least the two most common genetic etiologies of SCN (HAX1- and ELA2-deficient mice do not display neutropenia). These studies also identified the first gene for which LOF and GOF mutations underlie two different immunologic disorders: XR WAS and X-linked dominant SCN. These investigations are not yet complete, not only because the pathogenesis of SCN remains unclear for several genetic defects (HAX1, G6PC3), but also because no genetic etiology has yet been discovered for some patients with SCN, suggesting that new morbid genes remain to be discovered.

CGD has also played an important historical role, as it was the first functional defect of phagocytes to be identified. It is also the most common and best characterized functional defect of phagocytes. It was first described clinically in individual patients in the late 1950s,[341,342,343,344] and the first series of affected boys was studied in 1965.[344] The phagocyte

phenotype was demonstrated in 1966, in a study showing the impaired killing of staphylococci by granulocytes,[17,345] in which the terms “CGD” and “inborn error” were first used. Granulocytes from CGD patients were found to kill streptococci normally, these bacteria posing no particular threat to these patients.[346] Shortly thereafter, in 1967, a lack of respiratory burst in the granulocytes of patients was reported.[347,348] The concomitant identification of a respiratory burst phenotype in the mothers of affected boys confirmed that most known cases resulted from XR inheritance.[349] The nitroblue tetrazolium reduction assay was soon developed,[350] and an AR form of CGD was discovered.[350,351] A deficiency of phagocyte nicotinamide adenine dinucleotide phosphate activity was then demonstrated.[352] The first review on CGD, an insightful and comprehensive paper, was published by Good et al. in 1968.[353] These early studies led to the demonstration that patients lacked a particular enzyme, phagocytic nicotinamide adenine dinucleotide phosphate oxidase (abbreviated to Phox). This discovery preceded the identification of the underlying genetic lesions, as reviewed in detail elsewhere.[354,355,356,357,358,359] Phox has five components, including membrane-bound gp91 and p22, which form the flavocytochrome b558. The other three components are cytosolic, and the complex forms after phagocyte activation, as occurs during phagocytosis. This complex is more potent in granulocytes than in other phagocytes. Upon formation of the Phox complex, reactive oxygen species, including superoxide and hydrogen peroxide (the levels of which can be assessed in various assays, including the nitroblue tetrazolium reduction assay) are released into the phagosomes, where they directly and indirectly contribute to the killing of ingested microbes. The patients have an abolished (CGD) or impaired (variant CGD) granulocyte respiratory burst. Mutations in any of the five components of Phox can be found in patients with XR or AR CGD. Mutations of the X-linked *CYBB* (encoding gp91, two-thirds of patients), *CYBA* (encoding p22), *NCF1* (encoding p47, the most common AR form), and *NCF2* (encoding p67) genes were identified in the 1980s, and it was not until 2010 that a patient with p40 deficiency was discovered.[360] The *CYBB* gene, encoding one of the two membrane-bound components, was the first human morbid gene to be identified, based on its chromosomal location.[361] Also interesting from a genetic standpoint, most, if not all mutations of *NCF1* result from a rare gene conversion event between the gene and a nearby homologous pseudogene.[362]

CGD affects about 1/100,000 individuals. Typically, it is symptomatic in early childhood, whereas variant CGD may manifest later in life.[363,364,365,366] Affected children display bacterial and fungal infections, but with different frequencies of the causal microbes. Most, but not all pathogens causing infections in CGD patients produce catalase, which was long thought to be an essential virulence factor in this setting.[367] Some bacteria, such as *Staphylococcus* and *Serratia*, are major threats, whereas closely related bacteria, such as *Streptococcus* and *Klebsiella*, which pose a threat to many other PID patients, are almost completely innocuous in CGD patients. *Aspergillus* species pose a major threat to CGD patients, whereas other fungi, such as *Candida*, are rarely pathogenic in these patients. The defect in host defense is profound, as illustrated by the occasional detection of very weakly virulent microbes that appear to pose a threat only to CGD patients.[368] Patients with AR CGD have a residual respiratory burst, albeit weaker than that of variant CGD patients, and

this may account for their somewhat milder clinical phenotype and better prognosis.[369] Interestingly, an impaired respiratory burst has been demonstrated in the macrophages and B cells, but not in the monocytes and granulocytes, of two kindreds with unique missense mutations in *CYBB*.[370] These two kindreds display a pure Mendelian susceptibility to mycobacterial disease (MSMD) phenotype, consistent with the susceptibility of CGD patients to Bacillus Calmette-Guérin and *M. tuberculosis*.[371] The results obtained for these two kindreds suggest that the respiratory burst in macrophages is essential for protective immunity against tuberculous mycobacteria. They also suggest that the respiratory burst in other phagocytes contributes to other manifestations of CGD, whether infectious or otherwise. Indeed, CGD patients also have inflammatory lesions, consisting of granulomas, that can affect almost all tissues and organs. The treatment of these lesions with steroids may precipitate the development of new infections. The prevention of infection in CGD patients has gradually been improved, initially by the use of oral trimetoprim-metronidazole, then by the subcutaneous administration of IFNγ,[372] and finally by the addition of oral itraconazole to the treatment regimen.[373] Most patients now survive until adulthood, provided that inflammatory and infectious complications are treated aggressively. The course of the disease is heterogeneous in CGD patients. Some patients do very well and survive without infection throughout adulthood, thanks to antibacterial and antifungal prophylaxis. Others experience invasive fungal disease and chronic inflammation, which may require transfusions of leukocytes and steroids, respectively, or, in some cases, HSCT. The success of HSCT has raised questions as to whether this procedure should be proposed to a larger number of patients early in life.[359] Gene therapy trials were initiated but were stopped early due to insertional mutagenesis precipitating myeloid transformation in some cases.[366,374] In any case, the investigation of CGD as an experiment of nature has resulted in the dissection of a fundamental mechanism by which phagocytes control microbes. The respiratory burst has been dissected in human phagocytes, largely through studies of patients with CGD. Mice lacking one or other of the components of Phox were engineered in the 1990s and their biochemical and infectious phenotypes matched those of human patients. There is little doubt that other functional defects of phagocytes will be discovered in the near future. Indeed, CGD patients are normally resistant to a large number of microbes, implying that other microbicidal pathways also operate in phagocytes.

SYNDROMIC IMMUNODEFICIENCIES

There are several PIDs in which physical or laboratory findings unrelated to the greater susceptibility to infection are

a prominent part of the clinical picture (Table 48.4).Some of these disorders are caused by mutations in genes that are broadly expressed and others are caused by defects affecting hematopoietic cells alone but involving processes not specific to immune defense. Interestingly, defects in the same signal transduction pathway or biologic process may cause different clinical manifestations.

Wiskott-Aldrich Syndrome and Defects in Cytoskeletal Organization

The first cases of WAS were reported in 1937 by Wiskott, a German physician who described three brothers with bloody diarrhea, draining otitis, and severe eczema.[21] In 1954, Aldrich et al. described a family in which 17 affected males had symptoms similar to those of the patients reported by Wiskott, with an XR pattern of inheritance.[20] All the patients reported by both Wiskott and Aldrich died before the age of 3 years. Over time, it became clear that a low platelet number (thrombocytopenia) and unusually small platelets were the most frequent findings in WAS.[375,376] The immune deficiency consists of recurrent infections, low serum IgM and high serum IgA and IgE concentrations, and impaired antibody production in response to carbohydrate antigens, particularly pneumococcal polysaccharides. Eczema is the least consistent component of the disease. Autoimmune disease and malignancies, such as EBV-related B-cell lymphoma in particular, are also more common in patients with WAS.[377,378]

In 1994, the gene responsible for WAS, a previously unknown gene, was identified by positional cloning. This gene encodes a hematopoietic cell-specific cytoplasmic protein, WASP, that acts as a scaffold, promoting rearrangement of the actin cytoskeleton in response to cell activation and assembly of the proteins involved in signal transduction.[375,379,380] The carboxy-terminal VCA domain (verprolin homology, cofilin homology, acidic region) is the most strongly conserved domain in protein family members. Other recognized domains of WASP include the amino-terminal WH1 domain, which is followed by the GTPase-binding domain (GBD) and a proline-rich region proximal to the VCA domain. In resting cells, WASP is in an autoinhibited conformation in which the VCA domain binds to a hydrophobic pocket within the GBD.[381,382] When a GTPase, generally CDC42, binds to the GDB domain, the VCA domain is released and WASP forms a dimer in which a pair of VCA domains bind the

actin-related proteins 2 and 3 complex.[380] The actin-related proteins 2/3 complex recruits monomeric actin and stimulates the assembly of branched actin filaments.[383]

WASP forms part of the immune synapse in activated T cells, B cells, and dendritic cells.[384,385,386,387,388] It participates in the recruitment of downstream signaling molecules and cell

motility. In the absence of WASP, T-cell proliferation, differentiation, and survival are impaired, and the number of T cells tends to decrease with age.[389] WASP is also important for maintenance of the function and normal numbers of circulating invariant NKT cells and regulatory T cells.[390,391,392,393]

TABLE 48.4 Syndromic Immunodeficiencies

Disease	Gene Defect	B Cells	T Cells	Serum Igs	Inheritance	Pathogenesis	Associated Features or Comments
Wiskott-Aldrich syndrome	*WASP*	Progressive ↓	N	↓ IgM, ↑ IgA and IgE, IgG variable	XL	Defective cytoskeletal response to activation	Thrombocytopenia with small platelets; eczema; autoimmunity; lymphoma
AT	*ATM*	May be ↓	May be ↓	↓ IgA and IgE; IgG and IgM variable	AR	Defective phosphorylation of targets required for DNA repair	Ataxia; telangiectasia; malignancy; progeria
AT-like disease	*MRE11*	May be ↓	May be ↓	Variable	AR	Defective repair of DNA double-strand breaks	
Nijmegen breakage syndrome	*NBS1*	May be ↓	May be ↓	Variable	AR	Defective repair of DNA double-strand breaks	Microcephaly; bird-like facies; growth failure
Nijmegen breakage-like disease	*RAD50*	↓↓↓↓	N	All isotypes decreased	AR	Defective repair of DNA double-strand breaks	Microcephaly; bird-like facies; growth failure
Hyper-IgE syndrome	*STAT3*	N	N	Elevated IgE	AD	Impaired response to cytokine and activation signals	Eczema; staphylococcal abscesses; delayed shedding of primary teeth

AD, autosomal dominant; AR, autosomal recessive; AT, ataxia telangiectasia; DNA, deoxyribonuclec aicd; Ig, immunoglobulin; N, normal.

Lymphocytes with normal WASP expression have a strong selective advantage in proliferation and survival over WASP-negative cells. This has been demonstrated in heterozygous carriers of a WASP mutation (the mothers of affected boys),[394,395] in chimeric mice treated with a mixture of wildtype and WASP-deficient bone marrow,[396] and in patients with WAS with a second mutation of the WASP gene.[397,398,399,400] In as many as 11% of patients with WAS, there is evidence of either a reversion of the primary mutation to the wild-type sequence, or of a second mutation compensating for the disease-causing mutation in at least some cells.[400,401] Gene reversion is seen most frequently in T cells, but it has been detected in NK cells and B cells. The first example of somatic gene reversion improving the clinical course of an inherited disorder was documented in 1994 for another PID, ADA deficiency.[402,403] Such reversion now appears to be less rare than initially thought, at least in WAS patients.

A wide diversity of *WASP* mutations has been observed in affected patients, with some

genotype/phenotype correlation.[404] However, this correlation is not strong enough to predict clinical outcome. Amino acid substitutions and some splice variants are more likely to be associated with mild disease, particularly if some WASP protein is detectable on western blots. A subset of patients with mutations in WASP have thrombocytopenia or even intermittent thrombocytopenia as the only manifestation of their disease.[405,406] These patients usually display alterations to the WHI domain. The WHI domain binds a protein called the WASP-interacting protein (WIP), which stabilizes WASP and contributes to actin polymerization.[407,408] A nonsense mutation in *WIP*, introducing a premature stop codon, has been identified in a single patient with no WASP protein in monocytes and a clinical phenotype very similar to that of patients with WAS.[409]

Activating mutations in WASP have been reported in a small number of patients with severe congenital neutropenia but not thrombocytopenia.[81,410,411] Additional clinical manifestations vary in the 17 reported patients: some displayed low levels of proliferation in response to CD3 cross-linking, some had small numbers of monocytes, and one patient had large platelets. Several had low CD4+ T-cell counts. The activating mutations result in amino acid substitutions in the GBD of WASP, preventing the autoinhibitory binding of the VCA domain to the GBD and resulting in the disorganization of actin polymerization.[332] These mutations led to the first description of two unrelated phenotypes caused by GOF and LOF mutations in a gene responsible for immunodeficiency.

Another two immunodeficiencies resulting in abnormal regulation of the actin cytoskeleton have recently been described. DOCK8 is a GTP exchange factor that binds to CDC42. Homozygous or compound heterozygous mutations in the gene encoding this protein result in a syndrome with some similarities to both hyper-IgE syndrome (HIES) and WAS.[412,413] Patients with DOCK8 deficiency have low serum IgM and markedly high IgE concentrations, like patients with WAS. However, one of the most striking characteristics of their immunodeficiency is severe viral infections of the skin caused by herpes simplex virus (HSV), varicella virus, molluscum contagiosum virus, and papillomaviruses. The incidence of cancer is also higher than normal in these patients. Thrombocytopenia is not reported in this syndrome.

Heterozygous dominant-negative mutations of *Rac2*, which encodes a GTPase similar to CDC42, have been reported in three patients with an early onset of severe bacterial infections, high neutrophil counts, impaired respiratory burst, and poor chemotaxis.[414,415,416] One of these patients was identified during newborn screening for SCID based on low levels of T cell.[416]

Ataxia Telangiectasia and Defects in the Deoxyribonucleic Double-Strand Break Response

An unusual combination of ocular telangiectasia and cerebellar ataxia was first described in French medical journals in 1926 by Syllaba and Henner[19] and then in 1941 by Louis-Bar.[18] In the mid-1950s, Broder and Sedgwick named this disorder ataxia telangiectasia (AT) and noted the high incidence of pulmonary infections in affected patients.[24] AT is a complex, highly variable, progressive disorder characterized by the onset of an unsteady gait after the first year of life, telangiectasia first noted when the child is 2 to 8 years old, unusual eye movements, drooling, recurrent respiratory infections, premature aging, infertility, an affable personality, and a high risk of cancer.[25] Patients are usually wheelchair-bound by adolescence and often die from cancer or pulmonary disease before the age of 20 years.[417] Lymphocytes from patients with AT are particularly susceptible to radiation damage and display frequent translocations involving chromosomes 7 and 14, involving the sites encoding the antigen receptor genes.[418,419,420]

AT is caused by homozygous or compound heterozygous mutations of *ATM* (ataxia telangiectasia mutated),[421,422] a large gene consisting of 66 exons. Most of the mutations in patients with classical AT are premature stop codons or frameshift mutations resulting in a null phenotype.[423] The protein encoded by *ATM* consists of 3056 amino acids, the 350 most carboxy-terminal residues displaying sequence similarities to the catalytic domain of phosphatidylinositol 3-kinases. However, ATM functions as a serine/threonine kinase. The amino-terminal end of ATM binds to several substrates, including BRACA1 and p53.[424] ATM is predominantly a nuclear protein that responds rapidly to doublestrand DNA breaks and oxidative stress.[425,426]

In response to double-strand DNA breaks, a complex consisting of Mre11, Rad50, and Nbs1 (MRN complex) binds to DNA ends and recruits ATM.[427] ATM is then able to phosphorylate Rad50, which acts as a scaffold for downstream targets. ATM also phosphorylates a wide array of target proteins involved in DNA double-strand break repair, cell cycle control, and stress responses.[425] ATM is also activated, in a pathway independent of the MRN complex,

by high levels of reactive oxygen species production.[426]

Mutations of the genes encoding each of the components of the MRN complex are associated with clinical disorders with some, but not all, of the features of AT. Homozygous mutations in *Nbs1* (also called nibrin) cause Nijmegen breakage syndrome,[427,428,429] a disorder associated with profound microcephaly, chromosomal breakage, and a high risk of cancer, but not ataxia or telangiectasia.[430] A syndrome that has been referred to as AT-like disorder is caused by hypomorphic mutations of the Mre11 gene.[431,432,433] Affected patients have ataxia and some have microcephaly, but no telangiectasia is observed. A single patient has been reported with microcephaly and hypomorphic mutations of the Rad50 gene.[434] All three disorders are associated with abnormally high sensitivity to ionizing radiation.

Hyperimmunoglobulin E Syndrome

Autosomal dominant HIES, also called Job syndrome, is a multisystem disorder characterized by eczema-like skin rashes, recurrent skin and pulmonary abscesses, pneumonia, hyperextensible joints, a high incidence of bone fractures and scoliosis, late shedding of primary teeth, and markedly high serum concentrations of IgE with eosinophilia.[435,436,437,438] Heterozygous dominant-negative mutations of the gene encoding the (signal transducer and activator of transcription) STAT3 are responsible for this disorder.[439,440]

Like other members of the STAT family, STAT3 is activated by various cytokines and growth factors using the JAK-STAT pathway. The receptors containing the widely expressed ligand binding chain gp130, including receptors for IL-6, IL-11, IL-27, OSM, CNTF, and cardiotrophin-1 all activate STAT3. These receptors activate STAT3, which forms dimers that enter the nucleus and enhance the transcription of genes encoding mediators of inflammation and immunity.[441] Paradoxically, STAT3 may have both pro- and anti-inflammatory effects, depending on the cell type and activating signal.[442] In mice, homozygous null mutations of *STAT3* are lethal early in embryogenesis.[443] In patients with autosomal dominant HIES, the mutations of *STAT3* cluster in the regions of the gene encoding the SH2 and DNA-binding domains.[444]

Homozygous mutations of the gene encoding the JAK Tyk2 may also result in an immunodeficiency characterized by rashes, unusual susceptibility to viral and fungal infections, and high serum IgE concentration.[445] However, the phenotype of patients with *Tyk2* mutations is variable, and one patient was found to be particularly susceptible to mycobacteria and viruses but to have none of the cardinal features of HIES: high serum IgE concentration, rashes, and staphylococcal disease.[446] As noted previously, mutations in *DOCK8* also result in high serum IgE concentration and susceptibility to infections.

INBORN ERRORS OF IMMUNITY TO A NARROW RANGE OF INFECTIONS

PIDs were originally defined by the identification of immunologic phenotypes. As the first immunologic abnormalities detected were profound, such as neutropenia and agammaglobulinemia, PIDs were, unsurprisingly, initially associated with multiple, recurrent, and often opportunistic infections. The first exception to this rule was provided by the description of XR lymphoproliferative disease (XLP), which manifests as various EBV-driven clinical phenotypes in previously healthy individuals (Table 48.5). The clinical features of this disease, including hemophagocytosis, lymphoma, and agammaglobulinemia, were described between 1974 and 1976, and all were attributed to an XR inheritance of susceptibility to EBV in a large kindred.[447,448,449,450] The variety of phenotypes triggered by EBV was confirmed by studies of additional kindreds.[451] The morbid gene, *SAP*, was identified in 1998 and shown to be specifically expressed in T cells.[452,453] A related XR disorder associated principally with hemophagocytosis was found to be due to mutations in *XIAP*.[72,454,455] The pathogenesis of XLP was fully deciphered only recently, with the discovery that SAP-deficient cytotoxic T cells from healthy female carriers could not respond to EBV-infected B cells.[456] Moreover, somatic reversion of SAP mutations in cytotoxic CD8+ T cells was documented in XLP patients with the mildest forms of disease.[456a] Other well-known examples of narrow vulnerability to infection are provided by AR deficiencies of any component of the complement membrane attack complex (C5 to C9), and XR deficiencies of properdin and factor H. Patients with these conditions display selective susceptibility to recurrent, invasive *Neisseria* infections. The first AR deficiencies of C6, C7, and C8 were reported in 1974 to 1976,[457,458,459,460,461] whereas the first XR properdin deficiency was not reported until 1982,[462] and AR deficiencies of factors I[463] and D[464] were reported even later. Properdin and factors I and D act by stabilizing the alternative pathway. Remarkably, alternative and terminal complement defects are almost exclusively associated with

gonorrheal and meningococcal diseases.[71,465,466] A third example, although it should really be considered the first in terms of chronology, is provided by epidermodysplasia verruciformis (EV), a rare, lifelong disorder characterized by an abnormal and selective susceptibility to disseminated and persistent warts following the infection of keratinocytes with weakly virulent skin-tropic human β-papillomaviruses.[73] EV is also associated with an increase in the risk of nonmelanoma skin carcinomas, with no other clinical signs in most patients.[467] The viral etiology of EV was demonstrated between 1946 and 1959, and specific human papillomavirus genotypes were implicated in this disease in 1978.[23,468] EV-causing human papillomaviruses are now known to cause asymptomatic infections in the general population. Cockayne first suggested in 1933 that EV could be inherited as an AR condition.[22] EV may therefore be seen as one of the first PIDs described, although the lack of a detectable immunologic phenotype long prevented this disease from being considered as such. The first genetic etiologies of EV were identified in 2002, with the identification of mutations in *EVER1* (*TMC6*) and *EVER2* (*TMC8*).[28] Both *EVER1* and *EVER2* are strongly expressed in circulating lymphocytes, including CD4+ and CD8+ T cells, B cells, and NK cells. These two genes are also expressed in keratinocytes, in which the EVER proteins form a complex with the zinc transporter ZnT1. Inactivating

P.1255

P.1256

mutations in *EVER1* or *EVER2* affect intracellular zinc distribution and the activity of transcription factors stimulated by zinc.[469] The remaining 25% or so of patients with EV and no demonstrated mutations in *EVER1* or *EVER2* include patients from families displaying AR,[470] XR,[471] and AD inheritance.[472] A third genetic etiology, with mutations in *RHOH* underlying a specific T-cell deficiency, was recently discovered, suggesting that the pathogenesis of EV in EVER-deficient patients might involve T cells.[472a] These pioneering studies together set the stage for the discovery of new inborn errors of immunity underlying life-threatening infections in previously and otherwise healthy children.

TABLE 48.5 Inborn Errors of Immunity Against a Single Infection

Disease	Affected Cell	Functional Defect	Associated Features	Inheritance	Genetic Defect/Presumed Pathogenesis	OMIM Number
1. Anhidrotic EDA-ID						
a. EDA-ID, XL (NEMO deficiency)	Lymphocytes + monocytes	NF-κB signaling pathway	Anhidrotic ectodermal dysplasia + specific antibody deficiency (lack of Ab response to polysaccharides) + various infections (mycobacteria and pyogens)	XL	Mutations of NEMO (*IKBKG*), a modulator of NF-κB activation	300291, 300584, 300301
b. EDA-ID, autosomal-dominant*	Lymphocytes + monocytes	NF-κB signaling pathway	Anhidrotic ectodermal dysplasia + T-cell defect + various infections	AD	Gain-of-function mutation of *IKBA*, resulting in impaired activation of NF-κB	612132
2. IRAK4 deficiency	Lymphocytes + monocytes	TIR-IRAK signaling pathway	Bacterial infections (pyogens)	AR	Mutation of *IRAK4*, a component of TLR- and IL-1R-signaling pathway	607676
3. MyD88 deficiency	Lymphocytes + monocytes	TIR-MyD88 signaling pathway	Bacterial infections (pyogens)	AR	Mutation of *MYD88*, a component of the TLR and IL-1R signaling pathway	612260
4. Warts, hypogammaglobulinemia, infections, myelokathexis syndrome	Granulocytes + lymphocytes	Increased response of the CXCR4 chemokine	Hypogammaglobulinemia, reduced B-cell numbers, severe reduction of neutrophil count,	AD	GOF mutations of *CXCR4*, the receptor for CXCL12	193670

		receptor to its ligand CXCL12 (SDF-1)	warts/HPV infection			
5. Epidermodysplasia verruciformis	Keratinocytes + leukocytes		HPV (group B1) infections and cancer of the skin	AR	Mutations of *EVER1*, *EVER2*	226400
6. HSE*						
a. TLR3 deficiency*	CNS resident cells and fibroblasts	TLR3-dependent IFNα, -β, and -l induction UNC-93B-dependent	HSE	AD	Mutations of *TLR3*	613002
b. UNC93B1 deficiency	CNS resident cells and fibroblasts		HSE	AR	Mutations of *UNC93B1*	610551
c. TRAF3 deficiency	CNS resident cells and fibroblasts	IFNα, -β, and -l induction TRAF3-dependent	HSE	AD	Mutation of *TRAF3*	
7. Predisposition to fungal diseases*	Mononuclear phagocytes	IFNα, -β, and -l induction CARD9 signaling pathway	Invasive candidiasis and peripheral dermatophytosis	AR	Mutations of *CARD9*	212050
8. CMC						
a. IL-17RA deficiency*	Epithelial cells, fibroblasts, mononuclear phagocytes	IL-17RA signaling pathway	CMC	AR	Mutation in *IL17RA*	605461
b. IL-17F deficiency*	T cells	IL-17F-containing dimers	CMC	AD	Mutation in *IL17F*	606496
c. STAT1 GOF	T cells	GOF STAT1 mutations that impair the development of IL-17-producing T cells	CMC	AD	Mutations in *STAT1*	Not in OMIM yet
9. Trypanosomiasis*		APOL-I	Trypanosomiasis	AD	Mutation in *APOL-I*	603743

AD, autosomal dominant inheritance; AR, autosomal recessive inheritance; CMC, chronic mucocutaneous candidiasis; EDA-ID, anhidrotic ectodermal dysplasia with immunodeficiency; GOF, gain-of-function; HPV, human papilloma virus; HSE, HSV-1 encephalitis; IFN, interferon; IL, interleukin; OMIM, Online Mendelian Inheritance in Man; STAT, signal transducer and activator of transcription; TIR, toll and interleukin-1 receptor; TLR, Toll-like receptor; XL, X-linked inheritance.

* Ten or fewer unrelated cases reported in the literature.

The idea that PIDs may underlie infectious diseases in patients normally resistant to most other microbes gained ground from the mid-1990s onwards, with the identification of AR IFN-γR1 deficiency as the first genetic basis of MSMD (Fig. 48.2).[473,474] Mutations in two X-linked (*NEMO*, *CYBB*) and six autosomal (*IFNGR1*, *IFNGR2*, *IL12B*, *IL12RB1*, *STAT1*, *IRF8*) genes have since been discovered.[74,310,370,475] MSMD was first described in the 1950s, as unexplained infections caused by the Bacillus Calmette-Guérin vaccine.[476,477,478] The high levels of locus and allelic heterogeneity have resulted in the definition of 15 different disorders, accounting for only about half the known cases. These defects are physiologically related, as they all result in an impairment of IFNγ immunity. Mutations affecting *IFNGR1*, *IFNGR2*, and *STAT1* impair cellular responses to IFNγ. Mutations affecting *IL12B* and *IL12RB1* impair the IL-12-dependent induction of IFNγ, accounting for MSMD, and the IL-23-dependent induction of IL-17, accounting for the mild CMC documented in some of these patients.[479,480] MSMD-causing mutations in *NEMO* impair the T cell- and CD40L-dependent induction of IL-12 by dendritic cells.[481] MSMD-causing mutations in *CYBB* impair the respiratory burst in macrophages.[370] In both these cases, subtle mutations in genes for which null alleles are known to cause more complex PIDs—anhidrotic ectodermal dysplasia with immunodeficiency (EDA-ID) and CGD, respectively—have highlighted the effects of specific alleles on a specific signaling pathway (*NEMO*) or a specific cell (*CYBB*).[482] Heterozygous mutations in the IRF8 gene prevent the development of IL-12-producing CD1c+ CD11c+ dendritic cells.[310] Patients with MSMD display clinical disease caused by weakly virulent mycobacteria, such as Bacillus Calmette-Guérin vaccines and environmental mycobacteria. They also often suffer from nontyphoidal, extraintestinal salmonellosis. They are highly prone to tuberculosis upon exposure to *M. tuberculosis*. AR IL-12Rβ1

deficiency was the first genetic etiology of the severe forms of pediatric tuberculosis to be identified.[483,484,485,486] Such identification of the defects underlying MSMD has been very beneficial to patients. Poor producers of IFNγ, due to IL-12 deficiency, for example, benefit from preventive or curative treatment with recombinant IFNγ. Conversely, patients whose cells do not respond to IFNγ, such as those with complete IFNγR1 deficiency, should undergo HSCT. These studies have also had important immunologic implications. These experiments of nature have shown that IFNγ is essential for immunity against mycobacteria and a few other intracellular bacteria, fungi, and parasites that infect macrophages. Surprisingly, however, these patients are not prone to infections with other intracellular agents, including most viruses, in particular. The rare viral illnesses occurring in these patients may have been favored by mycobacterially induced immunosuppression. IFNγ plays a more important role as a macrophage-activating factor than as an antiviral molecule.[487] The "Th1" arm of immunity, if such a lineage exists in humans, is not as broadly potent in host defense as reported for the mouse model. The dissection of MSMD has, therefore, revealed the narrow role of the "Th1" branch of T helper cell immunity. These studies have also suggested that mycobacterial diseases in other medical settings may result from the impairment of IFNγ immunity. Finally, these studies lend weight to the idea that otherwise healthy children with other infectious diseases may suffer from single-gene inborn errors of immunity.[70]

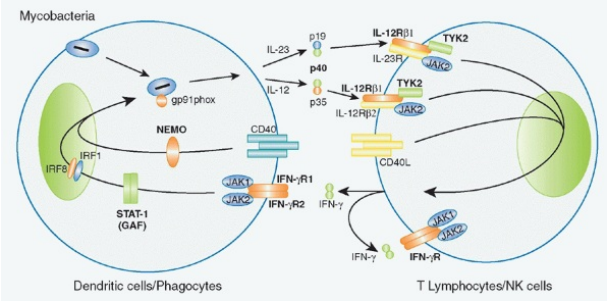

FIG 48.2. Inborn Errors in the Interleukin (IL)-12/23-Interferon (IFN)γ Pathway Underlie Mendelian Susceptibility to Mycobacterial Diseases (MSMD). Schematic diagram of cytokine production and cooperation between phagocytes/dendritic myeloid cells and natural killer/T lymphocytes. The IL-12/IFNγ circuit, the CD40/CD40L pathway, and the oxidative burst (mediated in part by CYBB-encoded gp91, a component of the nicotinamide adenine dinucleotide phosphate phagocyte oxydase) are crucial for protective immunity against mycobacterial infection in humans. Mutations in IFNGR1 or IFNGR2, encoding the ligand-binding and associated chains of the IFNγR, impair cellular responses to IFNγ. Likewise, heterozygous dominant-negative mutations in STAT1 impair IFNγ but not IFNα/β responses. Mutations in IL-12p40 or IL-12Rb1 impair IL-12-dependent induction of IFNγ. Mutations in CYBB that selectively impair the respiratory

burst in monocyte-derived macrophages are associated with MSMD. Heterozygous dominant-negative mutations in IRF8 impair the development of IL-12-producing CD1cCD11c dendritic cells. Proteins for which mutations in the corresponding genes have been identified and associated with MSMD are shown in *red*. The allelic heterogeneity is described in Table 48.1.

No germline mutation affecting the "Th2" arm of immunity has yet been identified, but mutations impairing the recently described "Th17" arm of immunity have been identified during investigations of CMC disease (CMCD), which was clinically described in the late 1960s and shown to display AR or AD inheritance in the early 1970s.[488,489,490] CMC is characterized by persistent or recurrent infections of the nails, skin, and oral and genital mucosae with the fungus *C. albicans*. It is common in patients with various inherited or acquired T-cell deficits that are also associated with other infections.[491] In patients with AD HIES caused by dominant-negative *STAT3* mutations, the two principal infectious threats are CMC and staphylococcal diseases.[65,492] These patients have a small proportion of IL-17-producing T cells.[479,493,494] However, this does not formally demonstrate a role for impaired IL-17 immunity in the CMC observed in these patients, as this immunologic phenotype may be silent or even be responsible for other phenotypes, infectious or otherwise. Interestingly, however, patients with autoimmune polyendocrinopathy type I suffer from a single infectious disease, CMC, which is accompanied by numerous autoimmune signs.[495] They have high titers of neutralizing auto-Abs against IL-17 cytokines.[496,497] Again, this observation alone does not prove that impaired IL-17 immunity underlies CMC in such patients, as the auto-Abs may be clinically silent or may attenuate autoimmune signs. However, these clinical observations, together with the results of studies in mice, suggest that impaired IL-17 immunity may generally underlie CMC.[491] These studies paved the way for the discovery of patients with isolated CMC (CMCD) due to inborn errors of IL-17F or IL-17RA immunity.[76] These patients were otherwise healthy and normally resistant to other infections, with the exception of a few cutaneous staphylococcal infections. One patient displayed AR complete IL-17RA deficiency, whereas patients from another kindred displayed AD partial IL-17F deficiency. These findings provided the first genetic etiologies of CMCD and suggested that IL-17A and IL-17F were essential for mucocutaneous immunity against *C. albicans*, but otherwise largely redundant in host defense, at odds with findings for the mouse model. Moreover, the use of a genome-wide approach led to the discovery of GOF mutations of *STAT1* in other patients with CMCD, some of whom also displayed features of autoimmunity.[77,498] Previously described *STAT1* mutations were LOF (null or hypomorphic) and associated with AD or AR predisposition to viral and/or mycobacterial diseases.[499,500,501] By contrast, the CMCD-causing *STAT1* mutations are GOF. They prevent the nuclear dephosphorylation of activated STAT1-containing complexes, thereby increasing transcriptional activity in response to IFNγ, IFNα/β, IFNλ, and IL-27, the biologic functions of which are highly dependent on STAT1. Cytokines that activate STAT3 predominantly and STAT1 to a lesser extent, including IL-6, IL-21, and IL-23, also trigger enhanced STAT1-dependent responses in these patients. Patients with GOF mutations in *STAT1* have small proportions of IL-17 T cells, because IFNγ, IFNα/β, IFNλ, and IL-27 are inhibitors of IL-17 T-cell differentiation via STAT1, or because IL-6, IL-21, and IL-23 are inducers of IL-17 T cells via STAT3 but not via STAT1, or both.[77] Impaired IL-17 immunity therefore underlies CMCD in these patients. Surprisingly, some CMC patients with *STAT1* mutations were recently reported to suffer from reactivations of viral disease.[501a] This situation is reminiscent of the observation that patients with HIES that are heterozygous for *STAT3* develop shingles due to impaired T-cell memory.[502] Overall, *STAT1* LOF alleles underlie viral diseases that occur during primary infection due to the impairment of antiviral IFN activity. By contrast, GOF *STAT1* mutations may confer a predisposition to the reactivation viral diseases (including some caused by the same herpes viruses) due to insufficient T-cell memory. In any case, studies of CMCD revealed that the "Th17" arm of immunity is apparently redundant for host defense against most microbes in humans, at odds with findings for the mouse model. Studies of MSMD and CMC have indicated that helper T-cell immunity is unlikely to be restricted to the "Th1" and "Th2" arms, even with the addition of the third partner "Th17." Indeed, mutations of IFNγ and IL-17 immunity underlie predispositions to only a few of the millions of microbes in the environment, including hundreds of known pathogens.

Another step forward came with the investigation of children with invasive pneumococcal disease (IPD). Patients with inborn errors of IL-17 or IFNγ immunity typically display recurrent or persistent infectious diseases, consistent with the production of these cytokines principally by T cells. Only patients with IL-12 and IL-12R deficiencies

seem to display a single episode of mycobacterial disease, implying that these cytokines are necessary for immunity against primary infection with mycobacteria but not for immunity to

latent or secondary infection.[78] IPD was long known to be favored by inborn errors of pneumococcal opsonization, such as defects of the classical complement pathway or of antibody responses to capsular glycans, and asplenia.[503] Patients with any of these PIDs are actually susceptible to a wide range of encapsulated bacteria. Interest in the investigation of IPD was stimulated in 2001 by the genetic dissection of a rare PID, known as EDA-ID.[504,505] IPD is, by far, the most common infection in these patients, but susceptibility to other pyogenic bacteria, mycobacteria, and some fungi and viruses has been recorded. Inflammation is weak or delayed in the course of infection. The only consistent immunologic abnormality is a lack of antibodies directed against glycans. This finding is consistent with the observation that IPD is often recurrent in these patients, with recurrences in some cases even being caused by the same serotype. Inborn errors of NF-κB were identified as responsible for the disease: patients with XR-EDA-ID carry hypomorphic mutations in *NEMO*,[506] whereas patients with AD-EDA-ID carry hypermorphic mutations in *IKBA*.[507] The key role of NF-κB in developmental processes accounts for the developmental features of the disease in affected children. Impaired immunity has a broad basis, consistent with the broad role of the multiple TNF, IL-1, and TLR receptors downstream from NF-κB. The *NEMO* mutations underlying EDA-ID are hypomorphic; null alleles cause the death in utero of male embryos and incontinentia pigmenti in women.[508] These hypomorphic mutations are associated with immunologic and infectious clinical phenotypes, some underlying IPD[509] and others underlying mycobacterial diseases[481] in otherwise healthy patients. *NEMO* mutations probably define the broadest phenotypic diversity in the field of PIDs, ranging from death in utero or lifethreatening neonatal disease to a mild and transient B-cell deficiency in adults. The mechanisms underlying IPD and other infections in patients with *NEMO* or *IKBA* mutations are progressively being deciphered through the identification of patients with germline mutations in genes encoding products acting upstream or downstream from NEMO. Children with isolated IPD provide the best example, as some have been shown to suffer from IRAK-4 or MyD88 deficiency.[510,511] These children have no developmental phenotype and are normally resistant to viruses, fungi, and mycobacteria. They suffer from IPD and, more rarely, from invasive staphylococcal diseases. Gram-negative infections are rare, with the exception of those caused by *Pseudomonas* and, more rarely, *Shigella*.[512,513,514] The patients display weak, delayed biologic and clinical signs of inflammation during infection. The patients' cells do not respond to agonists of most TLRs (other than TLR3 agonists) and IL-1Rs (including IL-1, IL-18, and IL-33). Surprisingly, these patients are susceptible to a few pyogenic bacteria, but normally resistant to other bacteria and parasites, fungi, and viruses. The clinical status of patients improves spontaneously from adolescence onwards, with no deaths or invasive infections observed in the absence of prophylaxis. This implies that TLRs and IL-1Rs are not required for protective T- and B-cell immunity to these infectious agents. This experiment of nature has not only confirmed that IPD may have a genetic basis, as previously shown in patients with inborn errors of opsonization, but has also revealed that TLR and IL-1R immunity is largely redundant in host defense. This is at odds with theoretical models attributing a broad role in host defense to TLRs, as microbial sensors or pathogenassociated molecular pattern receptors, and with experiments conducted in MyD88-deficient mice, which were found to be susceptible to more than 35 of the pathogens tested.[75] However, this finding is entirely consistent with evolutionary genetic studies, which have shown surfaceexpressed human TLRs to be subject to weaker selection pressure than intracellular TLRs.[515] Impaired TLR immunity may even play no more than a modest role in the development of infections in MyD88- and IRAK-4-deficient patients. It is not inconceivable that impaired IL-1 immunity alone accounts for the development of the few pyogenic bacterial infections observed in these patients.

TLR3, the only TLR that does not signal via MyD88 and IRAK-4 but instead uses TRIF as its sole adaptor, was serendipitously found to be essential for protective immunity against HSV-1 in the central nervous system (CNS), in the course of primary infection, in at least some children (Fig. 48.3).[75] The other intracellular TLRs—TLR7, TLR8, and TLR9—which are stimulated by nucleic acids and generally thought to play an important role in antiviral defense, were found to be redundant in humans against most viruses.[512] However, the strong purifying selection operating on these genes suggests that past pathogens or other physiologic processes have exerted selection pressure on these four receptors.[515] The role of TLR3 in host defense was deciphered by investigations of children with HSV-1 encephalitis (HSE).[516] This disease is the most common sporadic viral encephalitis in western countries. In this terrible disease, the virus is restricted to the CNS. It is absent from the bloodstream and does not spread to other organs. HSE is neurotropic in terms of both the route it follows and its destination: it reaches the CNS via cranial nerves. Patients with the most severe myeloid and lymphoid PIDs, including children with no T cells, display no particular susceptibility to HSE. The disease is sporadic in the vast majority of cases, with only four multiplex kindreds reported in 60 years, but there is a high frequency of parental consanguinity (14% in the French survey) in these cases, suggesting that HSE may be due

to single-gene inborn errors of immunity displaying incomplete clinical penetrance.[516] The first genetic etiology of HSE was identified as AR UNC-93B deficiency, resulting in an impairment of cellular responses to the four intracellular TLRs, including TLR3.[517] Involvement of the TLR3 pathway was then suspected, because IRAK-4- and MyD88-deficient patients, whose cells do not respond to TLR7-9, are not prone to HSE. TLR3 was formally implicated in the disease when AD and AR TLR3 deficiencies were discovered in other patients with HSE.[518,519] The subsequent identification of children with AR or AD TRIF deficiency confirmed the role of TLR3-TRIF and further suggested that childhood HSE might result from a collection of highly diverse

but immunologically related single-gene lesions.[520] HSE-causing heterozygous mutations of TRAF3 further highlighted the potential role of subtle mutations in pleiotropic genes in narrow clinical phenotypes. In AD TRAF3 deficiency, the mutation is dominant-negative and impaired TLR3 responses account for HSE, whereas the other cellular phenotypes, such as impaired responses to members of the TNF receptor superfamily, are clinically silent.[521] There is a broad immunologic phenotype but a narrow infectious phenotype, because the thresholds for clinical consequences differ between cellular phenotypes. Patients with *NEMO* mutations are broadly susceptible to viral infections, including HSE, reflecting the impairment of antiviral IFN production in response to the stimulation of multiple receptors, including TLR3, in their cells.[522] The target genes involved in HSE, downstream from TLR3, were identified as antiviral IFN genes in 2003, when patients with LOF mutations of *STAT1* were found to be prone to multiple viral diseases, including HSE.[500,523,524] All these genetic etiologies display complete penetrance at the cellular level (in fibro-blasts) but incomplete clinical penetrance, accounting for the sporadic nature of HSE. Interestingly, these defects also predispose subjects to childhood HSE, in the course of primary infection, but do not seem to impair immunity against latent HSV-1 infection, in the CNS and elsewhere. The molecular dissection of HSE also led to its cellular dissection. The TLR3 pathway was recently shown to be largely redundant for poly(I:C) responses in keratinocytes and leukocytes, whereas it is essential in CNS-resident cells, including astrocytes, neurons, and oligodendrocytes.[524a] However, anti-HSV1 immunity has been shown to be critically dependent on the TLR3-dependent production of IFNα/β in neurons and oligodendrocytes only. These findings strongly suggest that HSE results from a CNS-intrinsic defect of antiviral immunity. HSE probably results from a collection of single-gene inborn errors of TLR3 intrinsic immunity operating in CNS-resident cells, including neurons and oligodendrocytes in particular. Overall, the genetic dissection of HSE has shed new light on host defenses, revealing that the TLR3 pathway is responsible for ensuring CNS-intrinsic

protective immunity against HSV-1 during primary, but not latent infection.

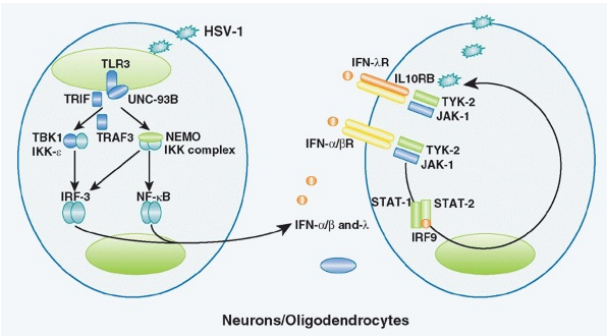

FIG 48.3. Inborn Errors of Toll-Like Receptor (TLR)3-Dependent, Interferon (IFN)α/β and -l Immunity Underlie Childhood Herpes Simplex Virus (HSV) 1 Encephalitis (HSE). Schematic representation of the production of and response to IFNα/β and IFNλ in anti-HSV-1 immunity in the central nervous system, based on the genetic dissection of children with HSE. Like most viruses, HSV-1 produces double-stranded ribonucleic acid (dsRNA) intermediates during its replication. TLR3 is an endosomal transmembrane receptor for dsRNA. The recognition of dsRNA by TLR3 induces activation of the IRF-3 and NF-kB pathways via TRIF, leading to IFNα/β and/or IFNλ production. TLR3, UNC-93B, TRIF, TRAF3, TBK1, and NEMO deficiencies are all associated with impaired IFNα/β and/or IFNλ production and predisposition to HSE in the course of primary infection by HSV-1. The binding of IFNα/β and IFNλ to their receptors induce the phosphorylation of JAK1 and TYK-2, activating the signal transduction proteins signal transducer and activator of transcription (STAT)-1, STAT-2, and IRF9. This complex is translocated as a heterotrimer to the nucleus, where it acts as a transcriptional activator, binding to specific deoxyribonucleic acid response elements in

the promoter region of IFN-inducible genes. STAT-1 and TYK2 deficiencies are associated with impaired IFNα/β responses and, for STAT1, impaired IFNλ responses and predisposition to HSE. Proteins for which genetic mutations have been identified and associated with susceptibility to isolated HSE are shown in *blue*. Proteins for which genetic mutations have been identified and associated with susceptibility to mycobacterial, bacterial, and viral diseases, including HSE, are shown in *green*. Proteins for which genetic mutations have been identified but not associated with susceptibility to infectious diseases are shown in *red*. This figure will be revised as new results are obtained with the genetic and immunologic dissection of children with HSE and other viral diseases.

INBORN ERRORS OF TOLERANCE

The second most common phenotype associated with PIDs is autoimmunity (Table 48.6). The random process of assembling V, D, and J elements of TCR and Ig genes through the process of VDJ recombination inevitably generates TCRs and BCRs recognizing self-antigens. Tonal signaling in response to self-antigens is essential to promote the progression of T- and B-cell development in the thymus and bone marrow, respectively. However, the prevention of autoimmunity requires T- and B-lymphocytes with high affinity for self-antigens to be deleted or kept in check. The mechanism underlying immune tolerance in the T-lymphocyte compartment include deletion of self-reactive clones,[525,526] conversion of autoreactive T-lymphocytes to self-antigen-specific regulatory T (T_{reg}) cells, and the apoptosis of self-reactive T cells. Autoreactive B-lymphocytes are eliminated from the bone marrow through receptor editing (whereby the reexpression of *RAG* genes promotes sequential rearrangements of the immunoglobulin genes, thus modifying antigen specificity).[527] Furthermore, B cellactivating factor levels regulate the survival of autoreactive B-lymphocytes in the periphery.[528] These processes define central and peripheral mechanisms of tolerance, depending on the developmental stage at which they occur.

As discussed previously, autoimmune manifestations have frequently been reported in patients with combined immunodeficiency and residual T- and B-cell development, but not in infants with SCID. In addition, some rare monogenic disorders associated mostly, if not exclusively, with autoimmunity highlight the critical role played by tolerogenic mechanisms in immune homeostasis and function (see Table 48.6).[92]

Autoimmune-polyendocrinopathy-candidiasis-ectodermal dystrophy (*APECED*, also known as autoimmune polyglandular syndrome type 1) is an AR disorder characterized by multiple autoimmune endocrine manifestations (hypoparathyroidism, Addison disease), CMC, and nail dystrophy. The syndrome was probably first described in the 1920s to 1940s.[30] In 1981, Neufeld et al. collated information for 295 patients with autoimmune Addison disease as a component of polyglandular autoimmune syndrome, and established that APECED/autoimmune polyglandular syndrome

type 1 consisted of a combination of at least two of the following three featurs: Addison disease, hypoparathyroidism, and CMC.[529] Other autoimmune manifestations are also common (hepatitis, ovarian failure).[530]

TABLE 48.6 Inborn Errors of Tolerance

Disease	Gene Defect	Inheritance	Immunologic Phenotype	Pathogenesis	Associated Features
APECED	*AIRE*	AR	None	Defect of central tolerance	Autoimmune endocrinopathies, candidiasis
IPEX	*FOXP3*	XL	↓↓↓ FOXP3+ T_{reg} cells	Defect of T_{reg}	Autoimmune enteropathy, IDDM, skin rash
ALPS					
ALPS-FAS	*FAS (TNFRSF6)*	AD, rarely AR	↑ TCRαβ+CD4-CD8- cells (DN T)	Impaired apoptosis via FAS	Splenomegaly, adenopathies, autoimmunity, increased risk of

					lymphoma
ALPS-FASLG	*FASLG (TNFSF6)*	AD, AR	↑ TCRαβ+ CD4-CD8- cells (DN T)	Impaired apoptosis via FAS	Splenomegaly, adenopathies, autoimmunity, SLE
ALPS-CASP10	*CASP10*	AD	↑ TCRαβ+ CD4-CD8- cells (DN T)	Impaired apoptosis (intrinsic pathway)	Splenomegaly, adenopathies, autoimmunity
Caspase-8 deficiency	*CASP8*	AD	Slight ↑ of DN T cells	Impaired apoptosis (intrinsic pathway)	Recurrent infections, splenomegaly, adenopathies
N-RAS defect	*NRAS*	Sporadic	DN T cells are ↑ or N	Activating N-RAS mutations that impair apoptosis	Splenomegaly, adenopathies, lymphoma
K-RAS defect	*KRAS*	Sporadic	DN T cells are ↑ or N	Activating N-RAS mutations that impair apoptosis	Splenomegaly, adenopathies, lymphoma
FADD deficiency	*FADD*	AR	↑ DN T cells	Impaired apoptosis	Recurrent infections, liver dysfunction, encephalopathy
CD25 deficiency	*IL2RA*	AR	T cells ↓ or N	Impaired homeostasis of T cells	Recurrent infections, autoimmunity (IPEX-like)
ITCH deficiency	*ITCH*	AR	None known	Not known	Autoimmunity, developmental delay, microcephaly, lung disease

AD, autosomal deficient; ALPS, autoimmune lymphoproliferative syndrome; APECED, autoimmune-polyendocrinopathy-candidiasis-ectodermal dystrophy; AR, autosomal recessive; CD, cluster of differentiation; DN, double negative; FADD, Fas-associated protein with death domain; IDDM, insulin-dependent diabetes mellitus; IPEX, immune dysregulation polyendocrinopathy enteropathy X-linked; N, normal; SLE, systemic lupus erythematosus; T_{reg}, regulatory T; XL, X-linked.

Although it was obvious that identification of the gene underlying APECED could shed light on the mechanisms governing immune tolerance, it was not until 1997 that two groups independently and simultaneously established that the disease was due to mutations of the autoimmune regulator (*AIRE*) gene.[531,532] This discovery constituted a major breakthrough in the understanding of central T-cell tolerance and led to fundamental studies in mice. AIRE is a transcription factor expressed by terminally differentiated medullary thymic epithelial cells, in which it regulates the expression of tissue-specific antigens.[533] AIRE-dependent tissue-specific antigens associated with HLA molecules are presented to developing T cells. Through this mechanism, self-reactive T-lymphocytes are deleted from the thymus.[534] Consistently, mutations of *AIRE* cause autoimmunity that is not restricted to endocrine glands and other tissues, but also includes the production of autoantibodies against various cytokines, including IL-17A, IL-17F, and IL-22, which play a key role in defense against *Candida* spp.[535,536] This accounts for the occurrence of CMC in patients with APECED. The autoimmune phenotype of autoimmune polyendocrinopathy type I patients might well be both broader and more profound in the absence of neutralization of these cytokines, which have been shown to play an important role in autoimmunity in the mouse model. Conversely, it is remarkable that the most severe autoimmune disorder known occurs despite the neutralization of these cytokines, indicating the IL-17-independent nature of at least a few

autoimmune diseases in humans.

In 1959, Russell et al. described a naturally occurring mutant mouse strain (the "scurfy" mouse) with an XR phenotype characterized by enteropathy, runting, dermatitis, and early lethality.[537] In 1982, Powell et al. described a large family in which 19 male subjects presented early-onset enteropathy, dermatitis, and endocrine abnormalities. Most of the affected male subjects died before the age of 3 years.[538] Other kindreds with a similar phenotype were subsequently described and the disease was named *immune dysregulation polyendocrinopathy enteropathy X-linked* (*IPEX*) syndrome. Linkage analysis mapped the *scurfy* locus in mice and the IPEX locus in humans to the same syntenic region of the X chromosome.[539,540] The demonstration that disruption of the *Foxp3* gene is responsible for the *scurfy* phenotype in mice[541] led to a candidate gene approach culminating in the identification of *FOXP3* gene mutations in patients with IPEX.[542] FOXP3 is a transcription factor required for the development and function of T_{reg} cells.[543,544] In patients with IPEX, activated autoreactive T-lymphocytes infiltrate target tissues and secrete cytokines, causing tissue damage. The patients lack CD4+ $CD25^{hi}$ FOXP3+ (T_{reg}) cells. T_{reg} cells may be generated in the thymus (natural T_{reg}) or in the periphery (induced T_{reg}), and these cells have suppressive activity.[545] Patients with IPEX require immune suppression, but the only definitive treatment currently available is allogeneic HSCT.[546]

Inborn Errors of Interleukin-2 Responses

T_{reg} cells express the high-affinity IL-2R. IL-2 plays an important role in both T-lymphocyte proliferation and immune homeostasis, by increasing *FOXP3* expression and enhancing the suppressive activity of T_{reg} cells.[547] Mutations of the *IL2RA (CD25)* gene, which encodes the α chain of the IL-2 receptor, are inherited as an AR trait and cause IPEX-like signs of immune dysregulation and lymphoproliferation (lymphadenopathy, hepatosplenomegaly), associated with susceptibility to severe infections.[548,549] The presence of circulating FOXP3+ T_{reg} cells in CD25-deficient patients[549] indicates that CD25 is dispensable for the generation of natural T_{reg} cells, for which a low IL-2R signaling threshold may suffice.[550] However, signaling through the high-affinity IL-2R is important for the generation of Foxp3+-induced T_{reg} lymphocytes from naive peripheral T-lymphocytes.[551] Moreover, CD25 deficiency leads to an impairment of the survival and fitness of mature natural T_{reg}s in mice.[547,552]

The binding of IL-2 to IL-2R activates the JAK-STAT signaling pathway, resulting in STAT5B phosphorylation, dimerization, and nuclear translocation, with the expression of IL-2-dependent genes, including FOXP3, Bcl-2, and CD25.[553] Furthermore, STAT5B is also activated in response to signaling through the growth hormone receptor, inducing the expression of insulin growth factor-1, a critical growth mediator.[553] In 2003, Kofoed et al. described a patient with short stature and growth hormone insensitivity, severe infections due to viruses and *P. jiroveci*, and lymphoid interstitial pneumonitis with a homozygous missense mutation of *STAT5B*.[554] Additional patients with a similar phenotype combining short stature, immunodeficiency, and autoimmunity have been reported,[555] thus substantiating the role of STAT5B-mediated signaling in immune function and homeostasis.

Inborn Errors of Apoptosis

A syndrome consisting of generalized lymphadenopathy, autoimmune cytopenia, and hypergammaglobulinemia was described in 1967 by Canale and Smith.[556] In 1992, Sneller et al. reported other patients with this constellation of symptoms and showed that these patients had larger than normal numbers of circulating T cells expressing the αβ form of TCR, but lacking the expression of CD4 and CD8 on their surface.[557] These cells have since been named DN T cells, and the disease (originally named Canale-Smith syndrome) has been renamed *autoimmune lymphoproliferative syndrome (ALPS)*. Sneller et al.[557] recognized the similarity of the ALPS phenotype to a mouse model of genetically determined lymphoproliferation (*lpr/lpr* mice) shown to result from mutations of the *Fas* gene.[558]

The apoptosis of autoreactive lymphocytes plays an important role in the preservation of immune homeostasis. Interactions between FAS ligand, produced by activated lymphocytes, and FAS (CD95) trigger an intracellular signaling pathway that ultimately results in the activation of caspases and cell death.[559] *FAS* mutations are the leading cause of ALPS in humans.[560,561,562] These patients have a higher

than normal risk of developing cancers (especially B-cell lymphomas), which are observed in 10% of patients with *FAS* mutations.[563]

ALPS is mostly inherited as an AD trait and is due to dominant-negative mutations inhibiting FAS-mediated signaling and caspase activation.[560] ALPS may more rarely be AR and due to biallelic *FAS* mutations completely abolishing the production or function of FAS. Furthermore, somatic mutations in the *FAS* gene may also cause ALPS.[564] Finally, combination of a germline *FAS* mutation affecting one allele and somatic mutations affecting the other allele have recently been reported in some patients with progressive development of the disease phenotype.[565] Other rare causes of ALPS include mutations of the gene encoding the FAS-associated death domain protein,[566] FAS ligand,[567,568] caspase-8,[569] and caspase-10.[570] The apoptosis of chronically activated T-lymphocytes can also be induced through a FAS-independent mechanism involving the release of cytochrome *c* and the activation of caspase-9.[571] This "intrinsic" (or mitochondrial) pathway of apopotosis is elicited in response to cell damage and cytokine (eg, IL-2) deprivation. GOF mutations of *N-RAS* may disrupt this pathway and cause ALPS.[572] Somatic mutations of *K-RAS* may also cause ALPS,[573,574] but this variant does not result in an increase in the number of DN T-lymphocytes.

ALPS is diagnosed on the basis of clinical features, the demonstration of a larger than normal number of DN T cells, and defective apoptosis in response to FAS stimulation or activation of the intrinsic pathway.[562,575] Treatment is based on the use of immunosuppressive drugs and surveillance for lymphoma.[561,563]

The study of patients with ALPS has provided an important confirmation that mechanisms for controlling T-cell survival are important in immune homeostasis. However, it has also raised interesting questions that remain unanswered: why do patients with ALPS suffer principally from autoimmune cytopenia, whereas AIRE and FOXP3 defects are mostly associated with organ-specific autoimmunity? Why is the phenotype of *lpr* mice (increased in the risk of kidney disease) different from that of FAS-mutated patients? Deep sequencing of the exomes and genomes of patients with unexplained autoimmunity will undoubtedly shed new light on the mechanisms governing central and peripheral tolerance in B cells and T cells.

INBORN ERRORS OF LYMPHOCYTE CYTOTOXICITY UNDERLYING HEMOPHAGOCYTOSIS

In 1952, Farquhar and Claireaux described the cases of a brother and sister who presented with high fever, progressive pancytopenia, hepatosplenomegaly, and bruising.[576] Unfortunately, a rapid progression to death was observed in both cases. Postmortem examination revealed a prominent infiltrate of lymphocytes, plasma cells, and histiocytes in the liver, spleen, and bone marrow. Other similar cases were subsequently reported. In some cases, the disease occurred in multiple family members and was thought to be intrinsic, whereas the sporadic presentation in other patients was thought to be a consequence of infections or cancers. This led to a distinction being made between primary and secondary forms of hemophagocytic lymphohistocytosis, although it is now clear that many sporadic cases are actually genetic in origin and that episodes of familial cases can be triggered by infection (Table 48.7; Fig. 48.4).

Familial hemophagocytic lymphohistiocytosis (FHL) is a genetically determined condition characterized by impaired lymphocyte-mediated cytotoxicity.[577,578,579,580,581] In patients with FHL, an inability to clear viral infections results in the persistent activation of CD8+ and NK lymphocytes, high levels of IFNγ production, macrophage activation, and the uncontrolled release of proinflammatory cytokines (TNFα, IL-6).[582] Clinical features of FHL include episodes of high fever, pancytopenia, liver and spleen enlargement, and neurologic signs. The study of patients with hemophagocytic lymphohistiocytosis has made an important contribution to definition of the role of lymphocyte cytotoxicity in immune homeostasis.

The elimination of virus-infected cells is dependent on CD8+ cytotoxic T-lymphocytes (CTLs) and NK lymphocytes, which release cytotoxic proteins (granzyme B, granulolysin) into target cells through cell membrane pores formed by perforin multimers, causing the activation of caspases and apoptosis.[583] The cytotoxic proteins are contained in endosomal lytic granules. Following the interaction of CTL or NK cells with the target cell, rearrangement of the cytoskeleton guides the transport of the lytic granules toward the immunologic synapse.[584] During this process, the small GTPase Rab27a promotes docking of the lytic granules, Munc 13-4 induces priming of the cytolytic granules, and syntaxin-11 and Munc 18-2 (also known as syntaxin-binding protein) promote the fusion of the lytic granules with the cell membrane. The lytic proteins are then released by exocytosis through pores formed by perforin (see Fig. 48.3).[583]

Mutations in the genes encoding Rab27a, Munc13-4, syntaxin-11, Munc 18-2, and perforin cause AR FHL. In addition, patients with Rab27a deficiency (also known as Griscelli syndrome type 2) show partial albinism, because the Rab27a protein is also important for melanin transport in melanocytes, as seen in patients with CHS (see following discussion).

An important step in the diagnosis of FHL is the demonstration of defective cell-mediated cytotoxicity.[585,586] NK cells present in peripheral blood mononuclear cell preparations from healthy controls kill ^{51}Cr-labeled K562 erythroleukemic cells; a profound defect in this killing is observed in FHL patients. Moreover, during cytotoxic processes, degranulation is accompanied by the surface expression of proteins (such as CD107a) that are normally sequestered in endosomal granules. FHL-associated defects in the docking, priming, and fusion of cytolytic granules impair the expression of CD107a in response to the in vitro activation of CTLs and NK lymphocytes.[587] Finally, flow cytometry can be used to detect defects of perforin expression.[585,586]

FHL is fatal in the absence of treatment, which is based on the prompt recognition and specific therapy of underlying

infections associated with chemotherapy and immunosuppressive regimens.[588] However, although such treatment may induce remission, relapses are the rule. The only curative approach to FHL is thus HSCT. Optimal results have recently been obtained with reduced-intensity conditioning regimens.[589]

TABLE 48.7 Inborn Errors of Lymphocyte Cytotoxicity

Disease	Circulating T Cells	Circulating B Cells	Serum Ig	Associated Features	Inheritance	Genetic Defect/Presumed Pathogenesis	OMIM Number
1. Immunodeficiency with hypopigmentation							
a. Chediak-Higashi syndrome	Normal	Normal	Normal	Partial albinism, recurrent infections, late-onset primary encephalopathy, increased lymphoma risk;n eutropenia, giant lysosomes, low NK and CTL activities, elevation of acute-phase markers	AR	Mutations in *LYST*, impaired lysosomal trafficking	214500
b. Griscelli syn-drome, type2	Normal	Normal	Normal	Partial albinism, elevation of acute-phase markers, encephalopathy in some patients; low NK and CTL activities	AR	Mutations in *RAB27A* encoding a GTPase that promotes docking of secretory vesicles to the cell membrane	607624
c. Hermansky-Pudlak syndrome, type 2	Normal	Normal	Normal	Partial albinism, increased bleeding; neutropenia, low NK and CTL activity	AR	Mutations in the *AP3B1* gene, encoding for the b subunit of the AP-3 complex	608233
2. FHL syndromes							
a. Perforin deficiency, FHL2	Normal	Normal	Normal	Severe inflammation, persistent fever, cytopenias, splenomegaly; hemophagocytosis, decreased to absent NK and CTL activities	AR	Mutations in *PRF1*; perforin, a major cytolytic protein	603553
b. UNC13D (Munc13-4) deficiency, FHL3	Normal	Normal	Normal	Severe inflammation, persistent fever, splenomegaly, hemophagocytosis, decreased NK and CTL	AR	Mutations in *UNC13* (as named in OMIM) required to prime vesicles for fusion; note	608898

				activities		that also in OMIM the “official” name is UNC13D deficiency with the alternative title of MUNC13D deficiency	
c. Syntaxin 11 deficiency, FHL4	Normal	Normal	Normal	Severe inflammation, persistent fever, splenomegaly; hemophagocytosis, decreased to absent NK activity	AR	Mutations in *STX11*, required for fusion of secretory vesicles with the cell membrane and release of contents	603552
d. STXBP2 (Munc 18-2) deficiency, FHL5	Normal	Normal	Normal or low	Severe inflammation, fever, splenomegaly, hemophagocytosis possible bowel disease; decreased NK and CTL activities with partial restoration after IL-2 stimulation	AR	Mutations in *STXBP2*, required for fusion of secretory vesicles with the cell membrane and release of contents	613101
3. Lymphoproliferative syndromes							
a. SH2D1A deficiency, XLP1	Normal	Normal or reduced	Normal or low	Clinical and immunologic abnormalities triggered by EBV infection, including hepatitis, hemophagocytic syndrome, aplastic anaemia, and lymphoma Dysgammaglobulinemia or hypogammaglobulinemia, low to absent NKT cells	XL	Mutations in *SH2D1A* encoding an adaptor protein regulating intracellular signals	308240
b. XIAP deficiency, XLP2	Normal	Normal or reduced	Normal or low	Clinical and immunologic abnormalities triggered by EBV infection, including splenomegaly, hepatitis, hemophagocytic syndrome, colitis	XL	Mutations in *XIAP* encoding an inhibitor of apoptosis	300635

AR, autosomal recessive; CTL, cytotoxic T-lymphocyte; EBV, Epstein-Barr virus; FHL, familial hemophagocytic lymphohistiocytosis; Ig, immunoglobulin; IL, interleulin; NK, natural killer; OMIM, Online Mendelian Inheritance in Man; XL, X-linker; XLP, XR lymphoproliferative disease.

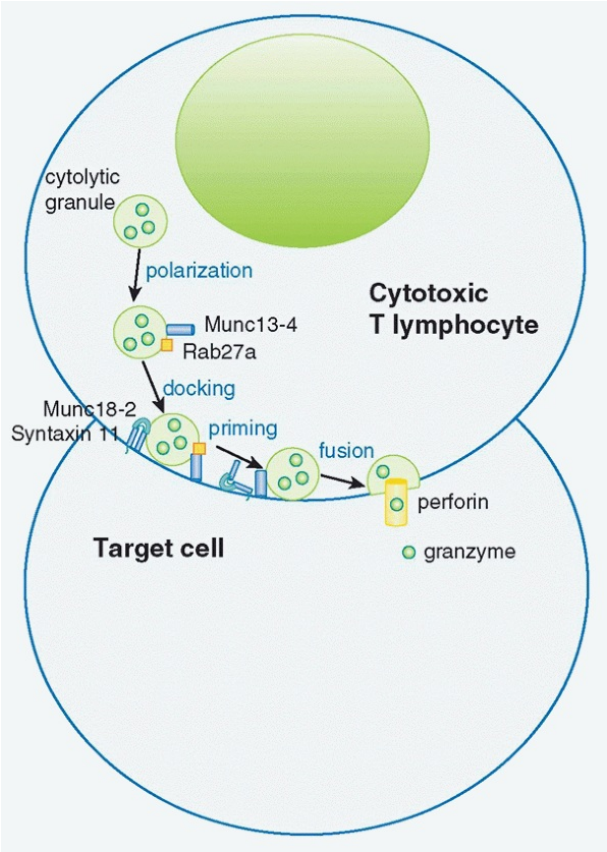

FIG 48.4. Schematic Representation of Cytolytic Granules Trafficking and Release. Upon recognition of target cells, cytotoxic T-lymphocytes mobilize cytolytic granules toward the point of contact with the target cell. The Rab27a protein mediates docking of the cytolytic granule; the syntaxin-11/Munc18-2 complex also participates at this process. Then, Munc13-4 favors priming of the granule, allowing a shift of syntaxin-11 from a closed to an open conformation. Eventually, the membrane of the cytolytic granule fuses with the cell membrane and granzyme, contained in the cytolytic granules is delivered to the target cell through pores formed by perforin.

CHS associates features of FHL with partial albinism, peripheral neuropathy, and the presence of giant lysosomes, which are easy to identify in leukocytes.[590] In this disease, the defect lies in the sorting of proteins to secretory endosomes.[591,592] This defect affects not only cytotoxic lymphocytes (accounting for FHL-like clinical features), but also melanocytes, which are unable to transfer melanin to keratinocytes and other epithelial cells, thus accounting for albinism.

X-Linked Lymphoproliferative Disease

In 1975, Purtilo et al. described a large family in which 6 of 18 male subjects died from a lymphoproliferative disease; infectious mononucleosis due to EBV infection preceded clinical signs of the disease and death in at least three of these cases. At the postmortem examination, lymphocytic and histiocytic infiltration was apparent in multiple organs.[448] This constituted the first report of XLP in humans.

In normal individuals, EBV causes a self-limiting disease: infectious mononucleosis. The virus establishes a latent infection in B-lymphocytes, salivary glands, and some epithelial cells, but is kept under control by CD8+ CTL and NK lymphocytes.[593] By contrast, EBV infection may lead to life-threatening complications in patients with genetic defects in affecting the mechanism controlling EBV infection. Male subjects with XLP are uniquely susceptible to EBV,[594] although EBV is also a common trigger of the acute disease phenotype in patients with FHL. Most male subjects with XLP carry mutations in the *SH2D1A* gene encoding a small adaptor molecule: SLAM-associated protein (SAP).[595,596,597,598] Various molecules of the SLAM family are expressed on the surface of CTL and NK cells. Through SAP, they trigger activatory signaling pathways that ultimately lead to the killing of EBV-infected cells.[597] In the absence of SAP, these activatory pathways are inhibited, and EBV infection remains uncontrolled.[599] The persistence of the virus within B-lymphocytes triggers the continuous activation of virus-specific CD8+ CTLs, which display hyperproliferation and

release large amounts of IFNγ. This ultimately leads to a macrophage activation syndrome, as described for patients with FHL. Alternatively, EBV may cause neoplastic degeneration of the infected B-lymphocytes (lymphoma). SAP is also important for the function of follicular helper T cells (T_{FH}), which interact with B-lymphocytes in secondary lymphoid organs and secrete IL-21, promoting B-cell activation, germinal center reaction, memory B-cell development, and plasmablast differentiation.[600] Consistent with these findings, male subjects with XLP and SAP defects often develop hypogammaglobulinemia with a lack of memory B-lymphocytes. Finally, SAP is also important for the development of NKT lymphocytes, which are typically absent in SAP-deficient patients.[601] The cellular pathogenesis of XLP in SAP-deficient patients was recently clarified by two studies. First, CTL from female carriers expressing the mutant SAP were shown not to recognize and kill EBV-infected target cells, whereas CTL from the same individuals expressing the wild-type SAP did.[456] Second, somatic reversions of the germline SAP mutations in CTL from affected male subjects were associated with the control of EBV infection.[456a] These data therefore implicate CTL, as opposed to other lymphocytes that also normally express SAP, in the pathogenesis of XLP.

A minority of patients with XLP carry defects in another gene (*BIRC4*) encoding the X-linked inhibitor of apoptosis.[602] Consistently lymphocytes from patients with *BIRC4* mutations are particularly susceptible to apoptotic stimuli. However, unlike SAP deficiency, X-linked inhibitor of apoptosis defects are not associated with lymphoma and are more often present with hemophagocytic lymphohistiocytosis, even in the absence of EBV infection.[455]

XLP is a severe disease. Most patients die from fulminant hepatitis or B-cell lymphoma, and survivors often display

hypogammaglobulinemia.[594] XLP is diagnosed on the basis of an analysis of SAP expression[603,604] and is ultimately confirmed by mutation analysis. HSCT is the only curative treatment available and should probably be attempted before primary EBV infection, if possible, in genetically affected individuals.[605]

It should be stressed that we owe our full appreciation of the consequences of SAP deficiency to the study of XLP patients, because mice are not susceptible to EBV infection. XLP demonstrates the importance of studying human disease in natura. *Sap*$^{-/-}$ mice have been generated by gene targeting,[606] but they cannot fully replicate the human disease, because EBV does not infect murine cells. Other viruses, such as lymphocytic choriomeningitis virus in particular, have been used to model XLP in mice. This has made it possible to show that CD4+ and CD8+ lymphocytes proliferate in an unrestrained manner in *Sap*$^{-/-}$ mice infected with lymphocytic choriomeningitis virus and that this proliferation is associated with a marked increase in the production of IFNγ.[606] These are important observations, but they fall short of the broad and dramatic phenotype of XLP patients following EBV infection.

CONCLUSION

We have attempted to cover the diversity of inborn errors of immunity by highlighting disorders affecting different branches of the host response and resulting in various phenotypes, infectious and otherwise. The field is so large and diverse that we could easily have selected other topics. For example, we did not review the inherited disorders of complement, despite their recently discovered surprising association with hemolytic uremic syndrome and related disorders.[607] It is also clear that the rapidly expanding and fascinating group of autoinflammatory disorders merits more attention.[66] Patients with these diseases do not display autoimmunity, in the classical sense of the term, because they have no detectable autoreactive T cells and B cells. Most patients suffer from enhanced IL-1- or TNF-mediated inflammation. Similarly, we did not discuss the inborn errors of enhanced IFNα/β production, resulting in Aicardi-Goutière syndrome and systemic lupus erythematosus.[608] This chapter focuses on pediatric PIDs, discussing only briefly the most common form of PID in adults, common variable immunodeficiency, which has taken much longer to dissect than anticipated, possibly because patients with this disease have more than one genetic lesion.[82] The possibly polygenic basis of some immunologic diseases is not reviewed here, and we have not even touched on autoimmune diseases that are almost Mendelian, such as type I diabetes, which is closely associated with HLA-II alleles, such as HLA-DQ8, in particular.[609] Finally, we do not consider here the ground-breaking discoveries of Mendelian resistance to certain infectious diseases.[610] Patients with AR DARC, CCR5, or FUT2 deficiencies are intrinsically resistant to *Plasmodium vivax*, human immunodeficiency virus, and norovirus, respectively. Individuals carrying at least one functional allele at any of these loci therefore display AD susceptibility to the corresponding pathogen. In these cases, the PIDs are represented by the wild-type alleles, which are currently more common, but the

selective pressure exerted by the pathogens may gradually inverse the allele frequencies.[611] These are only some of the topics not covered here due to space constraints. We have undoubtedly omitted many other fascinating lines of research in the field of PIDs and we apologize to our colleagues for these omissions. The field of PIDs is one of the most rapidly expanding fields of research in immunology. New phenotypes are continually being explored. As host defenses are mediated not only by leukocytes, but by almost all cells and tissues, a myriad of diseases, infectious and otherwise, may result from genetic lesions affecting host defense genes. We anticipate that thousands of PIDs will be deciphered in the future.

In any case, we have attempted to highlight the main clinical and immunologic implications of these studies. Over the last 60 years, more than 200 disorders have been clinically described, immunologically deciphered, and genetically dissected. New therapeutic approaches have been pioneered in patients with PIDs, including IgG substitution, enzyme replacement, recombinant cytokine, HSCT, and gene therapy. This field has, arguably, been one of the most successful in pediatrics and clinical immunology. The immunologic lessons learned from these experiments of nature are also of considerable interest. Some ground-breaking immunologic discoveries have resulted directly from the dissection of PIDs, such as the discovery that AIRE was responsible for autoimmune polyendocrinopathy type I.[612] Many other genes first discovered in patients with PIDs, only some of which have been discussed here, have paved the way to new avenues of immunologic investigation. PIDs have also provided considerable insight in situations in which the morbid genes were first described in the mouse model. Indeed, whether identified by genome-wide or candidate gene approaches, these genes have, in some cases, been assigned a new function, or at least had their known function redefined, in the human model. There are grounds for optimism, as the increasingly careful and widespread clinical care of 7 billion patients will provide an extraordinary wealth of phenotypic description. Moreover, spectacular technologic progress in genetics is making it possible to study the genome of these patients rapidly, searching for morbid lesions at high speed. Finally, tremendous progress in basic immunology, in the mouse model in particular, has provided investigators with the concepts and tools they require to connect PID genotypes and phenotypes experimentally. The identification of causal relationships between gene lesions and clinical phenotypes is based on the molecular and cellular dissection of immunologic pathogenesis. These studies will be of benefit to patients, while providing new insight into the function of host defense genes. We like to think that PIDs is a new frontier in basic immunology and that some of the most extraordinary, paradigm-shifting, immunologic discoveries in the near future will be generated by the investigation of human patients.
