Chapter 33

Regulatory/Suppressor T Cells

Ethan M. Shevach

INTRODUCTION

T cells are crucial in the immune response because they can function as both effector cells in cell-mediated responses and as helper cells in both humoral and cell-mediated responses. Most biologic systems are subject to complex regulatory controls, and the immune system is not an exception. In addition to T cells that upregulate (help), other populations that downregulate (suppress), the immune response must exist. Once a normal immune response is initiated by antigenic stimulation, mechanisms must be in place to control the magnitude of that response and to terminate it over time. Downregulation should contribute to the homeostatic control of all immune responses serving to limit clonal expansion and effector cell activity in response to any antigenic stimulus. An active mechanism of T-cell suppression is also needed to control potentially pathogenic autoreactive T cells. The primary mechanism that leads to tolerance to self-antigens is thymic deletion of autoreactive T cells, but some autoreactive T cells may escape thymic deletion or recognize antigens that are expressed only extra-thymically. T-cell anergy[1] and T-cell ignorance/indifference[2] have been proposed as the primary mechanisms used to control autoreactive T cells in the periphery, although these “passive” mechanisms for self-tolerance may not be sufficient to control potentially pathogenic T cells.

It was proposed more than 40 years ago that a distinct subset of T cells is responsible for immune suppression.[3] A suppressor T cell is functionally defined as a T cell that inhibits an immune response by influencing the activity of another cell type. Although a strong theoretical basis exists for T cell-mediated suppression, this area of immunologic research has been plagued by controversy. The past decade has seen a resurgence of interest in the concept of T-cell suppression mediated by a distinct subset of T cells that are uniquely equipped to mediate suppressor activity.

HISTORICAL PERSPECTIVE

Gershon and Kondo[3,4] first identified suppressor T cells during studies designed to understand the process of “highzone” tolerance. Injection of supraoptimal doses of an antigen including sheep red blood cells (SRBCs) resulted in specific tolerance or nonresponsiveness to subsequent challenge with that antigen. It was believed at that time that the antibody-producing B cell was rendered nonresponsive by exposure to the high concentration of antigen. To investigate whether B-cell tolerance was dependent on the

presence of T cells, Gershon and Kondo injected high doses (2.5×10^{10}) of SRBCs into thymectomized (Tx), irradiated, bone marrow-reconstituted mice and then assayed the functional status of B cells from these mice by a secondary challenge with SRBCs in the presence of added thymocytes as a source of T-cell help. Surprisingly, nonresponsiveness as measured by deficient antibody production was only induced in the B cells of animals that had received thymocytes as well as bone marrow cells during the initial exposure to high dose antigen, but not in mice that received bone marrow alone (Fig. 33.1). This result fulfilled Gershon's prediction that under certain conditions, antigen seen by T cells can induce not only helper and effector cells, but also cells that are able to suppress immune responses. Furthermore, when spleen cells from tolerized animals were transferred into secondary recipients together with normal thymocytes and bone marrow cells, they were capable of suppressing the otherwise competent response of these animals to SRBCs. This suppression, or “infectious tolerance” as it was originally termed, was antigen-specific, as the immune response to an unrelated antigen, horse red blood cells, was not inhibited.[4] T cells were necessary for the induction of B-cell tolerance, and these T suppressor cells were assumed to be a distinct cell population with a fully differentiated gene program that allowed them to perform a very specialized function. Other studies[5,6,7] during the 1970s supported the existence of T cell-mediated suppression.

Most of the early studies in these models demonstrated that the T cells mediating suppression were distinct from T cells mediating help because the former were cluster of differentiation (CD)8+, while the latter were CD8-. The finding that T suppressor effector cells were CD8+ distinguished them from helper cells, but did not allow them to be distinguished from cytotoxic cells, which are also CD8+. It remained possible that suppressor T cells were actually cytotoxic cells that killed the helper or effector T cells. A cell surface marker that seemed to identify a suppressor cell-specific antigen was discovered in 1976. It was found that an antiserum raised by immunizing the congenic strains B10. A(3R) with cells from B10. A(5R) mice or vice versa gave rise to an antiserum that seemed to react exclusively with suppressor cells.[8] CD8+ suppressor cells were also shown to bind antigen in the absence of major histocompatibility complex (MHC) molecules. These experiments suggested that the suppressor effector cells differed from other T cells in that they were capable of binding antigen directly and did not recognize processed antigenic peptides in association with

products of the MHC on the surface of antigen-presenting cells (APCs). Soon after the existence of T cell-mediated suppression was appreciated, some studies suggested that interactions among multiple distinct T-cell subpopulations might be involved. A CD4+ cell was described that appeared to induce CD8+ suppressor cells and was called the suppressor inducer cell. Contrasuppressor T cells had no independent helper, suppressor, or cytotoxic activity on an immune response, but enhanced immune responses by preventing the downregulation mediated by suppressor cells.

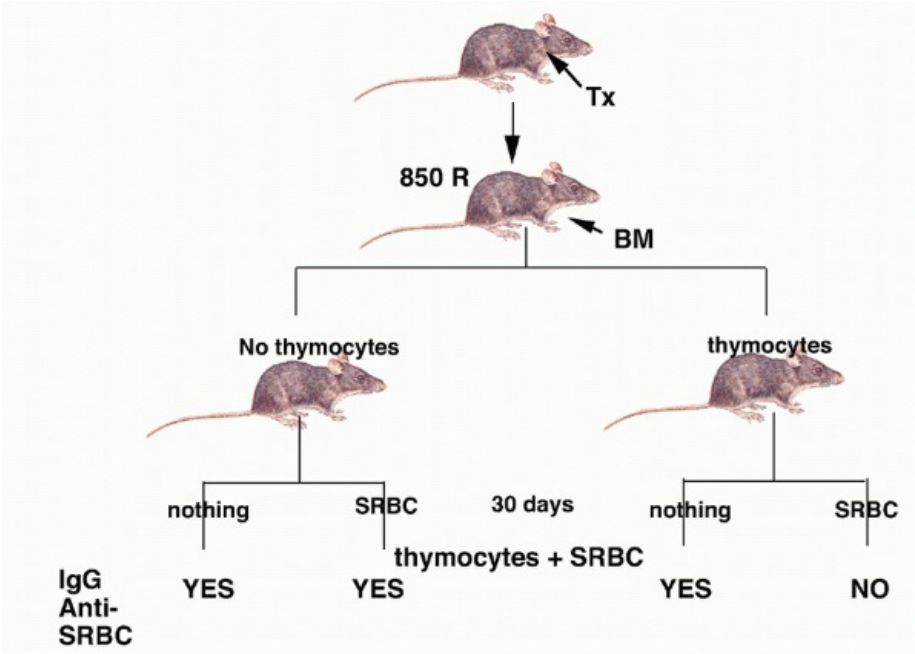

FIG. 33.1. First Demonstration of Suppressor T Cells. Adapted from Gershon and Kondo.[3]

Research in this area rapidly shifted from studies of the function of intact T cells to studies of their soluble products.[9] By the late 1970s, soluble factors produced by T suppressor cells were described by several groups, and cloned T-cell hybridomas that produced such factors were generated. T-cell suppression was regarded as being mediated by numerous soluble antigen-specific and nonspecific factors that comprised a functionally unique network.[10,11,12] The cascade involved antigen-specific, I-J-restricted CD4+ suppressor inducer cells (Ts1 cells), CD8+ anti-idiotype-specific cells (Ts2 cells), and CD8+ antigen-specific effector cells (Ts3 cells), whose suppressor function was not restricted by the MHC. Some of these cells were capable of binding directly to immobilized antigen in the absence of MHC molecules. Connectivity in this cellular cascade was mediated by a series of soluble factors: TsF1 was idiotypic and antigen-specific and immunoglobulin (Ig) heavy chain variable (V_H) region restricted. TsF2 was anti-idiotypic and required delivery by a macrophage. TsF3 acted totally nonspecifically. TsF1 and TsF2 required APCs, but TsF3 did not. Most of these factors were composed of two polypeptide chains, one of which was capable of binding native antigen and the other which bore a determinant recognized by anti-I-J antibodies.

These elaborate highly convoluted suppressor cell pathways and circuits fell out of favor in the mid-1980s for a number of important reasons. The existence of I-J was called into question by the finding that the region of the MHC complex to which I-J mapped did not contain a gene that could encode a unique I-J polypeptide.[13] When the genes encoding the T-cell receptor (TCR) were isolated, they were completely unrelated to the genes encoding Ig heavy chains, thereby calling into question the existence of T-cell factors that expressed Ig V region products. Many of the suppressor T cell hybridomas that produced antigen-specific suppressor factors were found either to have unrearranged genes for the α- or β- chains of the TCR or to have deleted genes for TCR β-chain.[14] No studies were ever performed that

convincingly characterized at the molecular level any of the suppressor

T cell factors. These studies, together with the inability to identify a marker specific for suppressor T cells and the inability to purify suppressor T cells, raised considerable doubts about the existence of a distinct functional lineage of suppressor T cells.

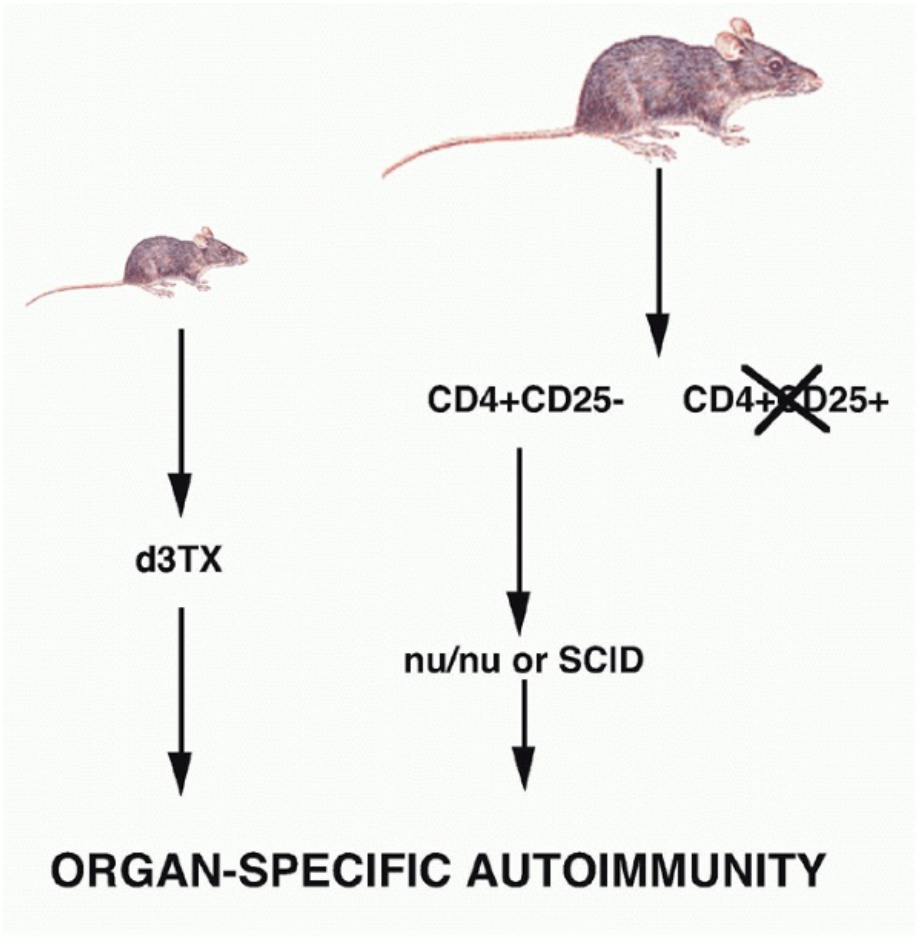

FIG. 33.2. Depletion of CD4+ CD25+ T Cells Results in Organ-Specific Autoimmunity. Adapted from Nishizuka and Sakakura[15] and Sakaguchi et al.[21]

Two completely different approaches to the demonstration of the importance of regulatory or suppressor T cells in the prevention of organ-specific autoimmunity were also developed in the 1970s. In one, mice that were Tx on the third day of life (d3Tx) were shown to develop organ-specific autoimmune diseases (Fig. 33.2). The specific disease that developed varied with the strain of mouse under study; more than one organ could be involved in a given mouse. Most importantly, autoimmunity was not seen if the mouse was Tx on day 1 or day 7 of life, and disease could be completely prevented if the d3Tx mouse received a thymus transplant between days 10 and 15 of life.[15] These observations led to the hypothesis that autoreactive T cells were exported from the thymus during the first 3 days of life and that somewhat later in ontogeny a population of suppressor cells emigrated from the thymus that controlled the autoreactive T cells. Removal of the thymus before the suppressor cells reached the periphery resulted in autoimmune disease. A number of other protocols (Table

33.1) that induced a lymphopenic state also resulted in the development of organ-specific autoimmunity. It was believed that these procedures resulted in a selective depletion of suppressor T cells, while leaving the autoreactive effector populations intact. Subsequent studies demonstrated that the effector cells in this model were CD4+ T cells. The suppressor T cells were also CD4+ cells, and the development of autoimmune disease could be prevented by reconstitution of the d3Tx animals with peripheral CD4+ T cells from normal adult mice.[16]

A second approach to define the role of regulatory T (T_{reg}) cells in the control of autoimmunity was described by Penhale and coworkers in the 1970s.[17,18] They devised a procedure to deplete Tregs from adult animals, while leaving

the helper population responsible for autoantibody production intact. The disease model was autoimmune thyroiditis because circulating antibody to thyroglobulin was believed to play an important pathogenic role. Spontaneous thyroiditis and circulating IgG autoantibodies developed in 60% of rats following the selective depletion of T cells by adult Tx followed by irradiation. Tx was performed between 3 and 5 weeks of age, and the rats were then given four to five repeated doses of 200 rad at 14-day intervals (Fig. 33.3). No evidence of thyroiditis was seen in rats that received only local irradiation to the thyroid region, indicating that irradiation itself did not induce pathologic changes. The conclusion drawn from these studies was that in the normal animal, B cells that recognized thyroid antigens were prohibited from differentiating into autoantibody-producing cells by an active controlling T cell mechanism. It was assumed that the suppressor T-cell population was mediating its functions by acting directly on the B cell and not by regulating other T cells. The active role of T cells in preventing the development of autoimmunity in this model was confirmed by reconstituting, shortly after the final dose of irradiation, the Tx-irradiated mice with lymphoid cells from normal donors. Penhale and colleagues[19] also demonstrated that autoimmune diabetes would develop following the Txirradiation protocol in a strain of rats that was normally not susceptible to this disease. Taken together, the d3Tx model in the mouse and the Tx-irradiation model in the rat demonstrated that normally autoreactive helper and suppressor cells may coexist and that certain autoimmune responses are held in check by the equilibrium favoring suppressor activity.

IDENTIFICATION OF CD4+ CD25+ FOXP3+ REGULATORY T CELLS

An important extension of this hypothesis was that inhibition of autoreactive T cells by suppressor T cells was not a phenomenon unique to the neonate, but that in the normal adult animal, autoreactive T cells are also under the constant control of the suppressor T cells. If the suppressor lineage was deleted, damaged, or compromised in the adult animal, autoimmune disease might develop. Although a number of studies suggested that the Treg cells in the normal adult animal might be identified by the expression of certain membrane antigens (eg, high levels of CD5[20]), a major advance in our understanding of

the role of Treg cells was the demonstration by Sakaguchi et al.,[21,22] that a minor population of CD4+ T cells (10%) that coexpressed the CD25 antigen (the interleukin [IL]-2R α-chain) appeared to function as Treg cells in the normal adult. When CD25+ T cells were depleted from a population of normal adult CD4+ T cells and the remaining CD4+CD25- T

cells transferred to an immunocompromised recipient such as a *nu/nu* mouse, the recipients developed a spectrum of autoimmune diseases that closely resembled those seen following d3Tx (see Fig. 33.2). Cotransfer of the CD25+ cells prevented the development of autoimmunity. Similarly, the induction of disease post-d3Tx could also be prevented by reconstitution of the animals with CD4+CD25+, but not CD4+CD25-, normal adult T cells before day 14 of life.[23] CD8+CD25-T cells alone were not capable of inducing autoimmunity and enhanced the induction of disease induced by CD4+CD25- T cells. These studies solidified the role of the CD4+CD25+ T cells as a major subset of cells that plays a unique role in the regulation of the immune response. The autoimmune diseases induced by depletion of CD4+CD25+ T cells are uniformly accompanied by the development of organ-specific autoantibodies, suggesting that this mode of loss of T-cell tolerance also results in the breakdown of B-cell tolerance as well. It is likely that the activated self-reactive T helper cells provide signals to self-reactive B cells, rescue them from apoptosis, and stimulate autoantibody production.

Powrie and Mason[24] were the first to identify cell surface markers that distinguished between regulatory and effector T-cell populations in the rat. When athymic rats were reconstituted with small numbers of CD4+CD45RC^{high} T cells, they developed a severe wasting disease characterized by extensive mononuclear cell infiltration in the lungs, liver, thyroid, stomach, and pancreas 6 to 10 weeks later. No pathology developed in rats that received unseparated CD4+ T cells or CD45RC^{low} cells. It seemed likely from these studies that the CD45RC^{low} subset controlled the capacity of the RC^{high} subset to mediate the wasting disease. Fowell and Mason[25] directly demonstrated the suppressive effect of the RC^{low} subset in the Tx-irradiation model develped by Penhale. Transfer of RC^{low} CD4+ T cells completely inhibited the development of diabetes and insulitis. RC^{low} T cells from long-term Tx donors could protect as efficiently as cells from normal donors, demonstrating that the Treg cell is long-lived in the periphery. Subsequently, CD4+CD45RB^{low} subset in the mouse was shown to have regulatory properties similar to the CD4+CD45RC^{low} subset of the rat.[26] Taken together, these studies in mouse and rat model systems demonstrated for the first time that two well characterized cell surface antigens (CD25 and CD45RC^{low}/CD45RB^{low}) could be used to identify suppressor CD4+ T-cell subpopulations present in normal animals. In later studies,[27] it was shown that the CD25+ T within the CD4+CD45RB^{low} population mediated their suppressor activity.

CD4+CD25+ T cells typically represent 5% to 8% of the total population of T cells in the normal mouse lymph node (LN), or 10% to 15% of mouse CD4+ T cells (Fig. 33.4). CD4+CD25+ T cells can also be found in the thymus where they also represent about 5% to 10% of the mature CD4+CD8- population, or 0.5% of mouse thymocytes.[21,28] A population with an identical phenotype has been identified in the rat, in human peripheral blood, and in human thymus.[29,30,31,32,33,34,35,36] When compared directly to CD4+CD25- T cells, CD4+CD25+ T cells express slightly higher levels of CD5, have a slightly higher proportion of CD62L^{low} cells, and have a higher proportion of CD69+ cells. They express both intermediate and low levels of CD45RB, and are completely absent from the CD45RB^{high} population.[37] All of the CD4+CD25+ T cells express the TCR αβreceptor and are NK 1.1

negative. CD25+ and CD25- T cells have a similar distribution of TCR Vα or Vβ specificities.[28] One other unique property of CD25+ T cells in both mouse and man is that they are the only nonactivated T-cell population that expresses high levels of the cytotoxic T-lymphocyte antigen (CTLA)-4 antigen intracellularly.[27,38,39] The glucocorticoidinduced tumor necrosis factor (TNF)-like receptor (GITR, TNFRSF18) has also been shown to be expressed on the majority of resting CD4+CD25+ T cells and to be expressed at very low levels on CD4+CD25- T cells.[40,41] The GITR is upregulated on CD4+CD25- T cells following TCRmediated activation.

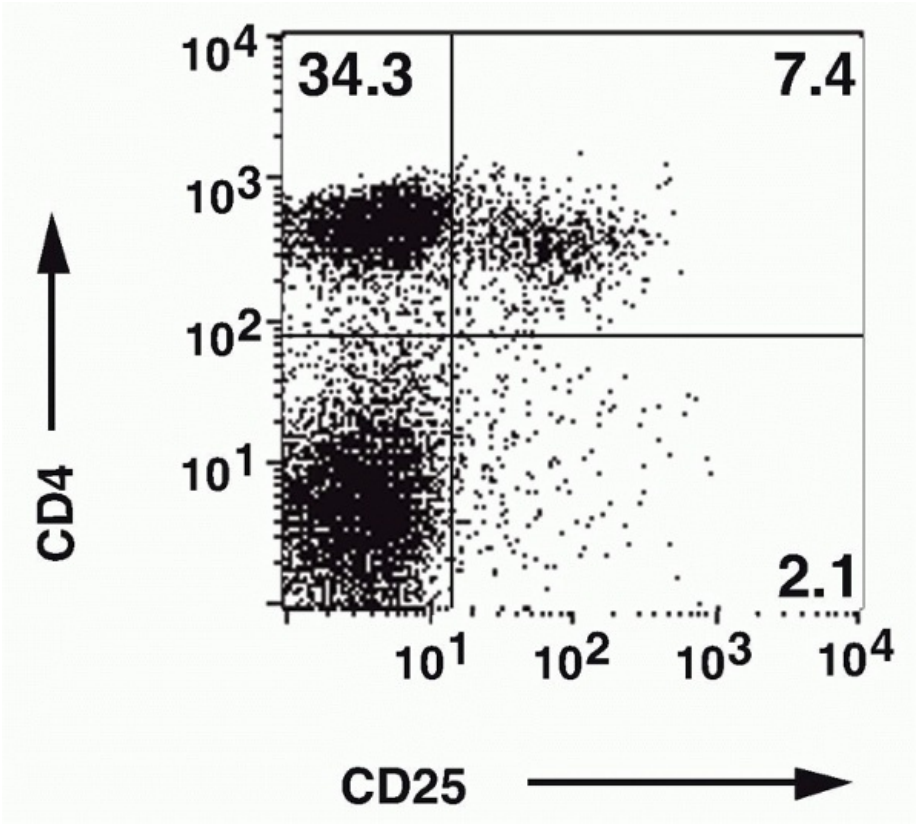

FIG. 33.4. Identification of CD4+ CD25+ T Cells in Normal Mouse Lymph Node. Adapted from Thornton and Shevach.[37]

A major advance in the study of T_{reg}s was derived from two related experiments of nature. Although CD4+CD25+ T cells were shown to display suppressive properties in multiple disease models, the value of CD25 has a marker is limited as CD25 is highly expressed on both activated CD4 and CD8 T cells, compromising its usefulness in studying Treg cells in settings of immune activation. The X-chromosome encoded forkhead transcription factor,

Foxp3, was identified as the key player in the biology of CD4+CD25+ T_{reg}s.[42,43,44,45] Young males with the immune dysregulation polyendocrinopathy enteropathy X-(IPEX) linked syndrome or a mutant mouse strain, scurfy, succumb to similar autoimmune and inflammatory diseases as a result of uncontrolled activation and expansion of CD4+ T cells. Both IPEX and

scurfy mice have mutations in a common gene, *Foxp3*, which encodes a forkheadwinged-helix transcription factor. There is an excellent correlation between expression of Foxp3 and CD25, but a minor population (˜10%) of Foxp3+ cells is CD25- and about 10% of CD25+ cells are Foxp3- (Fig. 33.5); the latter represent activated effector cells. Expression of Foxp3 only in the thymus using a proximal lck-driven transgene does not prevent disease in scurfy mice. Foxp3 expression in peripheral T cells is thus required for maintenance of Treg function. Retroviral-mediated transduction of Foxp3 expression in naïve T cells can convert these cells to a regulatory phenotype functioning in vitro in a manner similar to CD4+CD25+ Tregs. Furthermore, Foxp3-transduced naïve CD25- T cells also manifest suppressor activity in vivo and can inhibit the weight loss, diarrhea, and histologic development of colitis induced by transfer of CD25-CD45RB^{high} cells as effectively as Tregs.

Fontenot et al.[46] generated Foxp3 deficient (-/-) mice and demonstrated that Foxp3 is specifically required for the thymic development of Tregs. Mixed bone marrow chimeras using wild-type (WT) and Foxp3-/- bone marrow demonstrated that Foxp3-/- T cells behaved normally in the presence of WT Foxp3+ Tregs. Thus, the lethal autoimmune syndrome in Foxp3-/- mice results from a deficiency of Tregs and not from a cell intrinsic defect of Foxp3- T cells. Further study of the role of Foxp3 in Treg function has been greatly facilitated by the development of strains of mice in which a fluorescent protein such as green fluorescent protein (GFP) has been “knocked in” to the Foxp3 locus, permitting ready identification and isolation of Foxp3+ Tregs by cell sorting.[47] Studies of Treg development in the thymus of the Foxp3^{gfp} mice demonstrated that less than 0.1% of the CD4+CD8- thymocytes expressed Foxp3 within 12 hours after birth, and that the percentage of Foxp3+ CD4 single positive (SP) thymocytes increased slowly over the following days and reached a plateau of ˜4% at ˜21 days after birth. The largest single day change in the percentage of Foxp3 expressing SP occurred between days 3 and 4. Eighty percent of the Foxp3+ T cells on day 1 were CD4+CD8- SP cells. This result correlates with the early studies on the d3Tx mice that suggested that the generation of Treg cells is delayed relative to generation of nonregulatory CD4+ T cells. Foxp3 was not expressed in nonhematopoietic tissues. Foxp3 expression in peripheral TCR αβ+ T cells irrespective of CD25 expression correlates with suppressor activity.

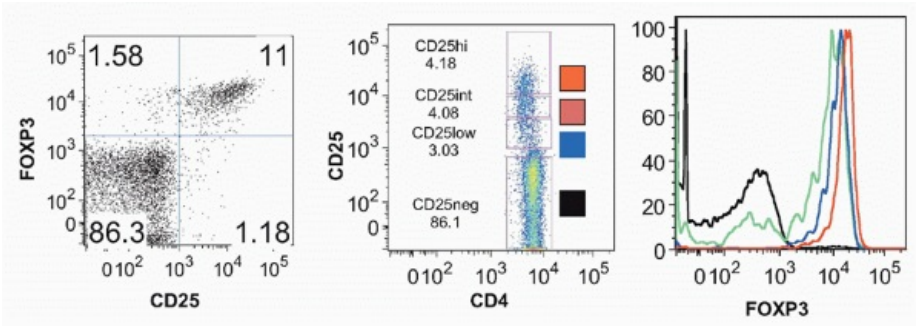

FIG. 33.5. Correlation between CD25 Expression and Foxp3 Expression in Mouse CD4+ Cells.

Direct proof that Foxp3+ T cells maintain control of autoreactive T cells in the periphery has been shown by using a targeting construct encoding the human diptheria toxin receptor fused to sequences encoding GFP and equipped with an internal ribosome entry site into the 3′ untranslated region of Foxp3.[48] Complete elimination of Foxp3+ cells was achieved after 7 days of treatment with diptheria toxin. Foxp3 elimination at birth led to a syndrome very similar to that seen in Foxp3-/- mice. Treg cell elimination in adult nonlymphopenic mice resulted in an even more rapid development of terminal autoimmune disease than in neonates. These studies demonstrate that T cells, probably expressing self-reactive TCRs, are targets of continuous Treg-mediated suppression. After Treg-cell ablation, those T cells become activated, produce secreted and membrane bound cytokines, and facilitate dendritic cell (DC) maturation. At day 7 after ablation, there are increased numbers of B cells, macrophages, Gr-1+ granulocytes, natural killer (NK) cells, and a 10-fold increase in the absolute numbers of DCs. Thus, DC dysregulation is a general phenomenon resulting from the absence of Treg cells. Furthermore, Foxp3-independent recessive and dominant tolerance mechanisms established in adult mice are not sufficient to protect mice from fatal autoimmunity after elimination of Treg. Even a partial

decreased level of Foxp3 protein in Treg cells as a result of induced dysregulation of Foxp3 gene transcription results in marked attenuation of Treg suppressor function.[49]

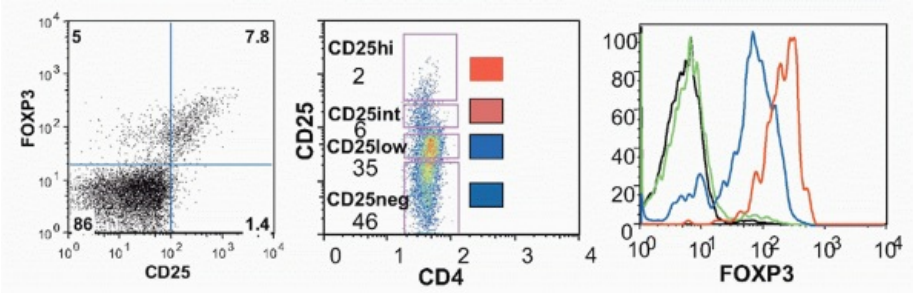

FIG. 33.6. Correlation between CD25 Expression and Foxp3 Expression in Human CD4+ Cells.

Isolation of human Tregs continues to be problematic as one must rely on expression of cell surface antigens. It was reported that among T cells, only the highest expressors of CD25 (˜2% of CD4+ T cells) exerted significant suppressive effects in vitro.[29] This observation was substantiated by a comparison of Foxp3 expression with CD25 expression on human CD4+ T cells. Almost all human CD4+ $CD25^{high}$ cells are Foxp3+, but a variable percentage of $CD25^{int}$ cells express lower, but substantial amounts of Foxp3 (Fig. 33.6). Flow cytometric isolation of the $CD25^{high}$ cells does allow one to obtain a population that is almost uniformly Foxp3+, but a substantial subset of Foxp3+ cells present in the $CD25^{int}$ population will be lost. It has been proposed that almost all of human Foxp3+ T cells can be identified as expressing low levels of the IL-7 receptor (CD127) and that $CD127^{low}$ expression can be

used to isolate human Treg.[50] However, CD127 is downregulated early in the course of T-cell activation, so the $CD127^{low}$ phenotype is also unlikely to be Treg-specific during an ongoing immune or inflammatory response. In addition, only about 40% of the $CD127^{low}$ population is Foxp3+ and even purified $CD4+CD127^{low}CD25+$ cells were only 85% to 90% Foxp3+. Nevertheless, the differential expression of CD127 has proven useful for the isolation of human Treg.

Because the number of Foxp3+ T cells is remarkably constant in normal animals in the absence of perturbation of the immune system, they have been frequently referred to as thymic-derived, "naturally occurring" Tregs,[51] whereas Foxp3+ T cells that are generated extrathymically are termed "adaptive or induced" Tregs. As both populations of Tregs can exert potent biologic functions in vivo and both are generated during the course of normal T-cell development and differentiation, this nomenclature is not accurate. This chapter will primarily describe the biologic functions of Foxp3+ T cells that will be referred to as Tregs irrespective of their site of generation. In the discussion of some of the papers published prior to the availability of reagents specific for the detection of Foxp3, they are referred to a CD4+CD25+ T cells. More precise definitions of the site of origin will be used where appropriate. The potential regulatory functions of Foxp3- T-cell populations will be summarized in section on Foxp3- Regulatory T cells.

BIOLOGIC PROPERTIES OF FOXP3+ REGULATORY T CELLS

Development of Regulatory T Cells in the Thymus

The potential role of the thymus in the generation of Treg cells was first described several years ago.[52] Most studies strongly support the view that the Foxp3+ Treg population is produced in the thymus as a functionally mature distinct T-cell subpopulation. Thymic Foxp3+ Tregs are not derived from peripheral cells that have recirculated from the periphery to the thymus because Tregs are developed in vitro in organ cultures of fetal thymus. Foxp3+ thymocytes are nonresponsive and suppress T-cell activation in vitro in a manner similar to Tregs derived from the periphery.[28] The capacity of Foxp3+ T cells to migrate from the thymus to the periphery was documented by injection of fluorescein isothiocyanate intrathymically. The percentage of Foxp3+ T cells within migrants and resident T cells was identical, suggesting that Foxp3+ T cells in the periphery can originate in the thymus.[53] Thymectomy at 4 to 5 weeks of age did not modify the number of Foxp3+ T cells in the periphery even when tested 19 months later.

It is widely accepted that conventional CD4+ and CD8+ T cells develop in the thymus by a process of positive and negative selection. Positive selection is mediated by interaction of developing T cells with MHC antigens on thymic cortical epithelium. Negative selection is mediated both by DCs and thymic medullary epithelium. As Treg cells have an antigen-experienced phenotype in the absence of exposure to foreign antigens, it seems logical that their TCRs would be biased toward recognition of self-antigens. A number of studies have suggested that Tregs undergo a unique developmental process during their generation in the thymus. When TCR-transgenic mice bearing a TCR specific for a determinant (S1) derived from influenza hemagglutinin (HA) in association with $I\text{-}E^{d}$ were crossed to mice expressing the HA transgene, the transgenic T cells were not deleted and a

large proportion expressed CD25 and functioned as Tregs.[54] Radioresistant elements of the thymus were shown to be both necessary and sufficient for the selection of Foxp3+ T cells in these doubly transgenic mice. Similar results were obtained when TCR transgenic mice on a RAG-/- background were mated to the HA transgenic mice, clearly indicating that thymocytes that can only express a single transgenic TCR can undergo selection to become Tregs. A second TCR transgenic mouse was generated that expressed a variant determinant of HA, but that recognized the S1 determinant with 100-fold less affinity. When these mice were bred to the HA transgenic mouse (S1), they did not have an increased frequency of Foxp3+ T cells. Thus, thymocytes with a low intrinsic affinity for the S1 peptide did not develop into Foxp3+ thymocytes in response to HA. These data are consistent with a model in which selection of Tregs that express a transgenic TCR depends on a high-affinity interaction of the TCR with its ligand. Treg differentiation results from interactions that lie in between the signaling strength required for conventional positive selection on one side and clonal deletion on the other side. It could not be determined from these studies whether this selection process occurs on cortical or medullary epithelial cells.

A number of other models have been proposed[55] for Treg differentiation in the thymus. Recent studies favor TCR specificity as playing a dominant role in thymic Treg cell development.[56,57] Transgenic mice expressing TCRs derived from Treg cells bore very few thymic Foxp3+ T cells in contrast to TCR-transgenic mice using foreign antigen-specific TCRs. The failure of these mice to develop significant numbers of Foxp3+ T cells suggested that developing T cells with the same antigenic specificity compete for a limited niche for Treg-cell development. In mixed bone marrow chimeras with varying proportions of polyclonal progenitors and Treg cell-derived TCRs, a striking inverse correlation was observed between the percentage of TCR-transgenic cells and the propensity of these cells to give rise to Foxp3+ T cells. When TCR-transgenic cells accounted for 10% of total cells, 1% expressed Foxp3, but when TCR-transgenic cells were only 0.1% of the total cells, 30% expressed Foxp3. This result suggests the existence of a niche that limits Treg cell development. Other studies have demonstrated efficient clonal deletion of CD4+Foxp3- T cells and the complete absence of Foxp3+ T cells in a transgenic mouse expressing a different Treg-derived TCR transgene consistent with the view that Treg-derived TCRs are self-reactive.[58]

Some studies have raised the possibility that Tregs are generated in the thymic cortex,[59] whereas others favor the view that the thymic medulla is the site where Treg precursors mature after contacts with tissue-specific peptides presented by thymic medullary epithelial cells or DCs.[60] It is likely that both both DCs and thymic medullary epithelial cells can facilitate Treg development.[61] It is still possible that different TCR specificities are selected by each APC subset. AIRE expression in thymic medullary epithelial cells might favor tissue specific antigens in the thymus, but Treg maturation is normal in AIRE-/- mice that have impaired presentation of tissue-specific antigens and in CCR7-/- mice that have defects in thymocyte trafficking. Some peripheral DCs can migrate into the thymus and present peripheral antigens to developing thymocytes. The ability of the different types of APCs to mediate negative selection versus Treg development may also differ.

Events in addition to TCR signaling are also required for the induction of Foxp3+ T cells. CD28 signaling also plays an important cell intrinsic role in the development of Foxp3+ T

cells in the thymus.[62] CD28 primarily improves the efficiency of Treg cell development rather than enhancing the number of TCRs that can facilitate Treg cell development. CD28 signaling is important for the generation of cytokine responsive Treg cell precursors, as the TCR repertoires of WT and CD28-/- mice were identical.[63] The ability of CD28 to support Treg generation does not require an intact phosphoinositide 3-kinase (PI3K)-binding motif as PI3K signaling through Akt and mammalian target of rapamycin (mTOR) will antagonize Treg differentiation.[64,65]

Cytokines also play a critical role in Treg development. The thymic population of Tregs is only mildly reduced in IL-2-/- or IL-2Rα-/- mice.[66] A more dramatic decrease is seen in mice with targeted mutations of IL-2Rγ, JAK3, or signal transducer and activator of transcription (STAT)5, signaling molecules shared by IL-7 and IL-15. Because neither IL-7 or IL-15 deficiency by itself affects the thymic production of Treg cells, it is likely that IL-2 is the principal common γ-chain cytokine required for intrathymic Treg cell development, but that in its absence IL-7 and IL-15 can compensate to a certain extent.[67] The development of Foxp3+ thymocytes occurs in two stages. A relatively small CD25+Foxp3- subset of CD4+ SP thymocytes is enriched in precursors of Foxp3+ Treg cells. These Foxp3- Treg precursors require common γ-chain cytokines, but no further TCR stimulation for acquisition of the mature Foxp3+ Treg phenotype. In this “two step model,” the first step is a TCR- and CD28-driven instructive phase, while the second step is the cytokine-driven consolidation phase.[68,69] Although multiple cytokines can induce Foxp3+ Treg cell differentiation, they all do so via STAT5 activation. Activated STAT5 is likely to directly bind and regulate the Foxp3 gene at the promoter and at an intronic enhancer region.[69] Transgenic mice expressing a constitutively active form of STAT5 have a marked increase in the percentage and total numbers of Foxp3+ Tregs.

While other cytokines that use the γ common chain can substitute for IL-2 for the development of Tregs in the thymus, IL-2 is required for the maintenance and survival of Foxp3+ T cells in the periphery. The numbers of Foxp3+ Treg cells in the periphery of IL-2-/-, IL-2Rα, and IL-2Rβ-/-[70] mice are substantially decreased or almost absent.[71] Partial or more profound defects both in the number and function of Foxp3+ T cells have been reported in mice deficient for CD80/CD86, CD40,[72] CD40L,[73] and Stat5a.[74] The one common factor that characterizes these mice is that the products of all the deficient genes have important roles in the production or responsiveness to IL-2. Treatment of mice with anti-IL-2 or with CTLA-4Ig to inhibit costimulatory signals also leads to a rapid decline in the number of Foxp3+ T cells.[38] As Foxp3+ T cells do not produce IL-2, this deficiency may

be secondary to the capacity of Foxp3- T cells to produce IL-2,[75] or to some intrinsic defect in the Foxp3+ T cells in their capacity to respond to IL-2. IL-2Rα-/- T cells in mixed bone marrow chimeras had a substantially decreased competitive fitness compared to WT Foxp3+ Tregs. The conclusion drawn from these studies was that IL-2 is an essential Treg cell growth factor in vivo and that in the absence of IL-2, Treg cells exhibit an impaired metabolic fitness. It appears that Foxp3 expression in Tregs establishes a gene expression program that renders Tregs critically dependent on paracrine IL-2 signalling resulting in repression of IL-2 production and the induction of IL-2Rα. IL-2 is not only required for the survival of Foxp3+

Tregs in the periphery, but also appears to be critical for maintenance of their suppressive functions.[76,77,78] Deletion of the proapoptotic factor, Bim, results in the restoration of normal numbers of Foxp3+ T cells in IL-2-/- mice, but Bim-deleted mice still exhibited lethal autoimmunity.[78]

The potential role of transforming growth factor (TGF)-β in the induction of Foxp3+ T cells during thymic development remains controversial. Liu et al.[79] demonstrated that very few Foxp3+ cells could be detected in the thymus of TGF-βRI-/- mice between 3 and 5 days of age. Later in life, the number of Foxp3+ T cells in the thymus increased and this expansion was driven by the production of IL-2. Very similar results were observed in TGF-βRII-/- mice, with a reduced number of Foxp3+ thymocytes at 3 to 5 days of age and increased numbers at 2 to 3 weeks of age.[80] The few Foxp3+ T cells in the TGF-βRII-/- mice expressed high levels of caspase and enhanced apoptosis associated with high amounts of the proapoptotic Bcl-2 family members, Bim, Bak, and Bax. Bim deficiency enhanced the number of peripheral Tregs. Thus, TGF-β is probably not essential for the induction of Foxp3 expression during Treg cell development, but the antiapoptotic effects of TGF-β are required for Treg survival.

Transcriptional Regulation of Regulatory T Cell Development

Recent studies of regulatory elements within the Foxp3 locus offer insights into the molecular mechanisms of Foxp3+ T-cell differentiation and maintenance.[81] Conserved noncoding deoxyribonucleic acid (DNA) sequence (CNS) elements at the Foxp3 locus encode information defining the size, composition, and stability of the Treg population (Fig. 33.7). CNS3 contains a DNase I hypersensitive site, and the NF-κB family member c-Rel binds to this element and likely facilitates the activity of the Foxp3 promoter. Gene targeting studies reveal an essential role for CNS3 in the induction of Foxp3 expression in the thymus and in the periphery. CNS3-/- mice remain healthy despite an approximately fivefold decrease in Treg cells compared to WT mice. Consistent with the documented binding of c-Rel to CNS3, c-Rel deficiency in thymic precursor cells results in a profound impairment in Treg differentiation.[82] In contrast to other CNS regions, CNS3 contains permissive chromatin in double positive (DP) and CD4SP cells that can facilitate binding of c-Rel as a homodimer. This result suggests that c-Rel may be a pioneer transcription factor that opens the Foxp3 locus to other transcription factors. It is likely that that c-Rel binding to CNS3 in cooperation with other transcription factors, including NFAT, CREB, p65, and Smad, facilitates formation of a c-Rel containing enhanceosome at the Foxp3 promoter. Other members of the NF-κB pathway are important for Treg differentiation, as mutations of PKCθ, CARMA1, Bcl-10, TAK1, and IKKβ greatly reduce thymic Treg numbers.[83]

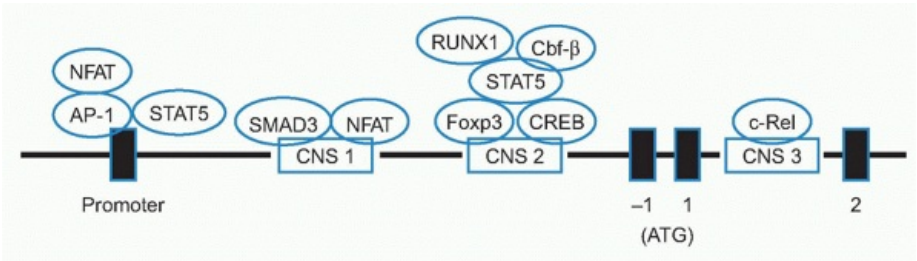

FIG. 33.7. Transcription Factors Controlling Foxp3 Expression. Adapted from Zheng et al.[81] and Ruan et al.[82]

CNS2 also known as the Treg-specific demethylated region contains a cytosin-phosphatidyl-guanosin (CpG) island whose methylation status is correlated with the stability of Foxp3 expression.[84] CNS2 CpGs are demethylated in Foxp3+ T cells, but fully methylated in Foxp3- T cells. While Foxp3 induction in the thymus and periphery was unimpaired in CNS2-/- mice, Treg cells lacking CNS2 progressively lost Foxp3 expression upon division. Thus, CNS2 has a nonredundant function for the maintenance of Foxp3 in the progeny of dividing Treg cells. Foxp3 is also recruited to CNS2 with the assistance of Runx-1 and its co-factor Cbf-β. The binding of the Foxp3-Runx-1-Cbf-β complex confers stability to Foxp3 expression and is also involved in facilitating Foxp3 promoter activity. The recruitment of Foxp3 to CNS2 and the resulting maintenance of Foxp3 expression represent the first description of a feed-forward mechanism enforcing heritable cell lineage destiny. Foxp3 binding to CNS2 occurs after and is dependent on demthylation of CNS2.

CNS1 contains NFAT, Smad3, and STAT5 binding sites. Analysis of mice deficient in CNS1 revealed that thymic differentiation was unaffected, whereas peripheral Foxp3 induction was severely impaired by CNS1 deficiency.[81] Deficiency in peripherally generated Treg cells did not result

in detectable tissue specific autoimmunity in CNS1-/- mice until 1 year of age. These results suggest that mechanistic requirements for thymic and peripherally induced Tregs are distinct from Tregs differentiated in the thymus.

T-Cell Receptor Repertoire Analysis of Foxp3+ Regulatory T Cells

As noted previously, several lines of evidence suggest that Treg development hinges upon a particular TCR specificity. Foxp3+ Tregs in general do not develop in TCR-transgenic mice lacking RAG genes, suggesting that only cells with certain TCR specificities can develop into Tregs. Several studies have addressed in detail the TCR repertoire of Foxp3+ Tregs and their antigen specificity.[85,86] Hsieh et al.[85] directly compared the sequences of the CDR3 region on Treg and conventional T cells and found that they are only partially overlapping. When immunodeficient mice were reconstituted with T cells expressing diverse Vα2 TCR α-chains from Treg or conventional T cells paired with a single Vβ chain, some of the Treg TCR reconstituted T cells were selfreactive, as they induced wasting disease in lymphopenic hosts, but not in conventional recipients. Although 40% of the TCR were strongly self-reactive in vivo, others were only intermittently and moderately self-reactive or nonreactive as measured by T-cell expansion in lymphopenic hosts. Other studies[86] have demonstrated a large degree of overlap in TCR usage between Foxp3+ and Foxp3- T cells. The recent experiments[56,57,58] demonstrating that TCR self-specificity is required for the intrathymic induction of Foxp3 expression strongly support the view that the TCRs of the Foxp3+ population are predominantly self-specific.

TCR repertoire analysis has also been used to determine the relationship between thymic Foxp3+ Treg cells and Foxp3+ Tregs in the periphery. A comparison of the TCR repertoire of thymic and peripheral Foxp3- and Foxp3+ T cells revealed that the TCRs from Foxp3+CD4+ peripheral T cells resembled those of thymic precursors and differed from TCRs expressed by Foxp3-CD4+ T cells; in addition, the diversity of Foxp3+ TCRs was greater than TCRs on Foxp3-CD4+ naïve T cells.[87] These studies suggested that the great majority of peripheral Foxp3+ Tregs derive from thymic precursors and that peripheral conversion from Foxp3- to Foxp3+ is rare. TCR repertoire analysis has also been applied to autoreactive T cells in mice deficient in Foxp3.[88] These mice did not exhibit a defect in negative selection. Activated, but not naïve, T cells in Foxp3-/- mice often used TCRs found in the Foxp3+ Treg TCR repertoire of normal mice, suggesting that T cells expressing these selfreactive TCR are not eliminated and might contribute to the pathology associated with Foxp3 deficiency.

Development of Foxp3+ Regulatory T Cells Extrathymically

One important question that must be addressed is whether the thymus is the only site for the generation of Foxp3+ Tregs. A number of studies performed both in vivo and in vitro have demonstrated that under certain conditions Foxp3+ Tregs can be generated extrathymically and that TGF-β is a key component in this process. Administration of peptide antigen to TCR transgenic mice bred onto the RAG-/- background, that lack Tregs, resulted in prolonged expression of CD25 only when the antigen was administered under tolerogenic conditions.[89,90] These CD25+ cells had some Treg properties. The mechanism of suppression used by these induced Tregs was not explored. One highly effective method for the induction of Tregs was to expose TCR transgenic T cells on a RAG-/- background in vivo to a continuous supply of subimmunogenic doses of agonist peptides delivered via a mini-osmotic pump. Many of the T cells became Foxp3+ and resembled thymic-derived Tregs in all their phenotypic and functional properties.[91] It was postulated from these studies that low doses of peptide presented over relatively long periods of time on nonactivated DCs represented a important mechanism by which Tregs could be generated in the periphery particularly to self-components that do not lead to tolerance in the thymus. Foxp3+ T cells were also induced when mice were treated with peptide agonist ligands targeted to DCs in minute doses by coupling them to antibodies directed to DCs under conditions of suboptimal DC activation.[92] Tregs induced with subimmunogenic conditions could subsequently be expanded by delivery of antigen in immunogenic conditions. DC-targeted de novo generation in vivo results in efficient demethylation of conserved CpG motifs within the Treg-specific demethylated region (CNS2) region of the Foxp3 locus, a predictive parameter for long-term stability of induced Foxp3 expression.[93]

One interpretation of the studies described previously is that weak TCR stimulation is favorable for the peripheral induction of Foxp3 and that robust TCR signaling during Treg cell generation stimulated the Akt-PI3K-mTOR pathway that antagonizes the induction of Foxp3[64] and results in cellcycle dependent maintenance of a silenced state of the Foxp3 locus.[94] More recent studies have examined the role of the strength of the antigenic signal required for the induction of Foxp3+ T cells in the periphery.[95] Foxp3+ cells induced by weak agonist peptides did not persist compared to cells generated by a higher affinity ligand. There appear to be qualitative differences between weak and strong signals whereby a few strong

signals may be different from many weaker signals. The few strong signals may specifically induce survival signals, while the many weaker signals may induce proapoptotic signals. There also appears to be a unique subpopulation of recent thymic emigrants that are $CD25^{hi}CD62L^{int}$ CD69+ that are capable of becoming Foxp3+ upon exposure to IL-2 alone in the absence of TGF-β.[96]

A number of groups[97,98,99,100] have presented studies that demonstrate a pivotal role for TGF-β in the generation of Foxp3+ Tregs in vitro. TCR activation in the presence of TGF-β converted naïve T cells into Foxp3+ (Fig. 33.8) cells with an anergic/suppressor phenotype. IL-2 plays a nonredundant role in TGF-β-mediated induction of Foxp3 expression in mouse CD4+ T cells. Once induced, Foxp3 expression was maintained both in vitro and in vivo in the absence of IL-2. Other cytokines utilizing the common γ-chain as part of their receptors were unable to induce Foxp3 expression in IL-2-/- cells. When T cells are activated through the TCR

in the presence of TGF-β, both RORγT and Foxp3 are transcribed and interact with each other. In the presence of IL-2, Foxp3 expression dominates leading to suppression of RORγT transcription, promoting Treg development. In contrast, in the presence of IL-6, and low levels of IL-2 the transcription of RORγT is favored which in turn represses Foxp3 transcription with resultant Th17 devlopment.[101]

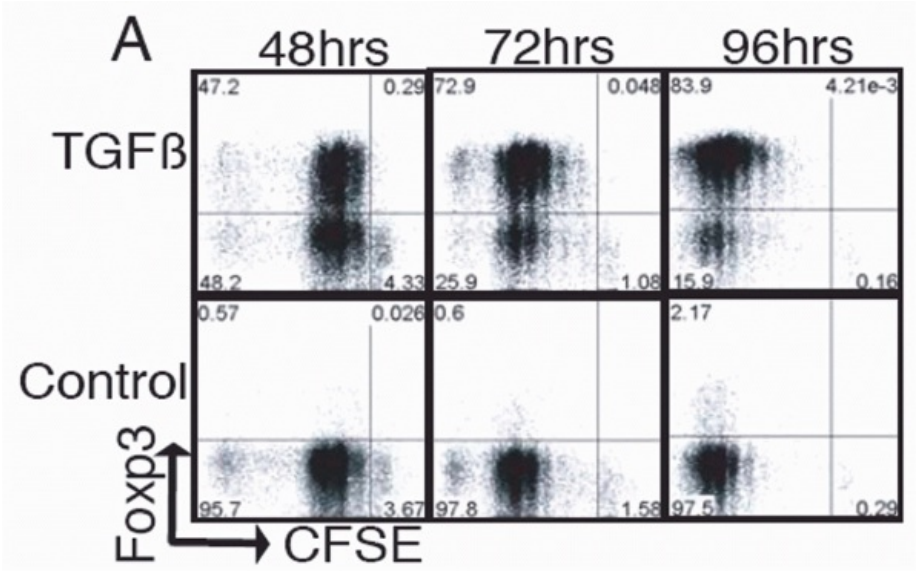

FIG. 33.8. Naïve Foxp3- T Cells were Cultured and Stimulated in the Presence of Transforming Growth Factor-χ. Foxp3 expression was determined by intracellular staining at the indicated times. Adapted from Davidson et al.[100]

TGF-β-induced Foxp3+ T cells not only exhibit unresponsiveness to TCR stimulation, but also suppress normal CD4+ T-cell activation and Th1 and Th2 cytokine production in vitro. The induction of Foxp3 results in downregulation of Smad7 and renders T cells highly susceptible to the regulatory effects of TGF-β signaling via Smad3/4.[98] Foxp3+ T cells

induced in vitro can suppress antigen-specific proliferation of CD4+ T cells in vivo and prevent house dust mite-induced mouse asthma.[97] One of the major factors preventing induction of Foxp3 expression in vitro is the presence of interferon (IFN)γ with subsequent STAT1 signaling.[102] Some studies suggest that TGF-β may also be capable of inducing Foxp3 expression in vivo. Peng et al.[103] used an inducible system for the transient induction of TGF-β in the pancreatic islets during the priming phase of diabetes. Approximately 40% to 50% of intraislet CD4+ T cells expressed CD25 and other characteristics of Tregs. However, it is not clear if high levels of TGF-β resulted in the in situ expansion of the small numbers of Tregs already present in the islets or if TGF-β induced the conversion of CD25- T cells to CD25+ suppressors.

The gut appears to be one of the major sites for the generation of Tregs in the periphery, and the gut contains a large number of Foxp3+ Tregs. Mucida et al.[104] first demonstrated that repeated antigen feeding induced antigenspecific Foxp3+ Treg cells in the absence of thymic-derived Tregs. Converted cells were rapidly found in the mesenteric LN, Peyer patches, and primarily in the small intestine lamina propria. Gut-associated lymphoid tissue has a number of unique properties that facilitate the generation of Foxp3+ T cells. A vitamin A metabolite, retinoic acid (RA), produced by gut DCs, can selectively induce molecules such as CCR9 and the integrin, α4β7, on both conventional T cells and Treg cells, and these cell surface antigens are involved in directing homing of cells to the gut. DCs from the lamina propria of the small intestine have the unique ability to generate Treg cells in vitro via a mechanism that involves the synergistic action of TGF-β and RA. A subpopulaton (25%) of lamina propria DCs express CD103, and this CD103+ subpopulation was responsible for the induction of Foxp3 in the absence of exogenously added TGF-β. Endogenous TGF-β was responsible for Treg conversion, as anti-TGF-β largely abrogated Treg induction. Addition of RA to splenic DC cultures enhanced Treg conversion, and blockade of nuclear RA signaling decreased converted Tregs, but RA alone is not sufficient for Foxp3 induction. Thus, the capacity of the intestinal immune system to produce TGF-β and RA explains the unique capacity of the gut to induce

tolerance.[105,106] In addition to the TGF-β induction pathway, Foxp3+ Tregs can also be induced via PD-L1-PD-1 ligand receptor pathway[107] and by environmental factors such as some aryl hydrocarbon receptor agonists.[108]

One major issue that remains to be addressed is the relative contribution of thymic-derived versus peripherally induced Tregs to the establishment of immune tolerance. Although Tregs are induced in the colitis model from Foxp3- T cells, the induced Tregs are not sufficient to prevent disease.[109] Some studies suggest that only the combination of thymic-derived Tregs and in vitro generated Treg cells could fully protect mice from developing inflammatory bowel disease (IBD) induced by naïve T cells from Foxp3-/- donors. When scurfy mice were reconstituted with thymic-derived Tregs alone, a marked inhibition of lethality was observed, but the treated mice still displayed signs of inflammation.[110] Surprisingly, the combined treatment with thymic-derived Tregs and conventional Foxp3- T cells, that could differentiate into Foxp3+ T cells, decreased inflammation. In vitro generated Treg cells could substitute for Tregs generated in vivo from Foxp3- conventional cells. One explanation for this result was that the TCR repertoires of the thymic-Tregs and the Tregs induced in the periphery were

largely nonoverlapping and that each Treg cell subset is responsible for recognizing different antigens. The major conclusions drawn from this study is that peripherally induced Treg cells are an essential, nonredundant regulatory subset that acts synergistically with thymic-Treg cells to enforce peripheral tolerance.

If a significant percentage of Foxp3+ T cells are generated at peripheral sites, one should expect that the TCR repertoires of peripheral- and thymus-derived Tregs to be different as peripheral conversion would allow for the generation of Treg cells specific for antigens not presented in the thymus such as those derived from commensal bacteria. Lathrop et al.[111] found a significant rate of conversion when CD4+Foxp3- T cells were transferred into lymphopenic hosts. There was considerable disparity in TCR usage between converted Foxp3+ and expanded Foxp3- T-cell subsets within the same host. The converted TCRs were found in the normal non-Treg cell subsets because the donor cells for these studies were normal Foxp3- T cells. However, some of these TCRs were also found in the normal Treg subset and made up 5% of the sequences in the normal Treg pool. It appears that some TCRs are able to facilitate both thymic and peripheral Treg cell development. It is likely that tissue-specific antigens influence the local Treg TCR repertoires as several studies suggest that the presence of an organ facilitates Treg-mediated tolerance to that organ.[112,113,114,115,116,117,118]

Peripherally induced Tregs may differ markedly from thymic-Tregs in terms of TCR repertoire expression, stability, suppressor mechanisms, and potential suitability for in vitro expansion and cellular therapy. Thus far, no cell surface antigen has been identified that allows one to reliably distinguish thymic-derived Tregs from Tregs induced in peripheral sites. Some studies have suggested that expression of Helios, a member of the Ikaros transcription factor family, distinguishes thymic Tregs from peripheral Tregs.[119] Helios was expressed intracellulary in 100% of Foxp3+ mouse thymocytes, but is only expressed by ~70% of Foxp3+ T cells in peripheral lymphoid tissues in both mouse and man (Fig. 33.9). Foxp3+ T cells induced in vivo by oral tolerance, following transfer of Foxp3- T cells to RAG-/- mice, or following induction by reconstitution of germ-free mice with bacteria,[120,121] were primarily Helios-. These studies suggest that a significant proportion of Foxp3+ Tregs are generared extrathymically. Further studies are needed to validate the use of Helios expression as a marker for thymic-derived Tregs. Major differences in the composition of the Treg pool may also exist between man and mouse. A subpopulation of human Tregs was highly proliferative in vivo with a doubling time of 8 days.[122] However, these cells were also susceptible to apoptosis and had critically short telomeres and low telomerase activity raising the possibility that they must be produced from another population source. Heteroduplex analysis of TCR from memory T cells and Tregs suggested that they are closely clonally related raising the possibility that a significant proportion of human Tregs are not thymus derived, but are generated from rapidly dividing highly differentiated memory CD4+ T cells.

Analysis of Gene Expression by Foxp3+ Regulatory T Cells

Both DNA microarray technology and serial analysis of gene expression technology have been used to compare patterns of gene expression between different cell types.[40,123,124] These technologies have also been applied to compare the patterns of gene expression in Tregs with Foxp3- T cells and other cell types with regulatory functions. One major goal of this approach is to determine whether Tregs simply represent a population of previously activated T cells or whether they display a unique pattern of gene expression that is correlated

with their functional properties. Most of the results are consistent with the latter possibility. Some genes are differentially expressed between the resting Foxp3- T cells and Tregs, while others are differentially expressed following activation.

TABLE 33.2 Genes Selectively Activated in CD4+CD25+ T Cells

- Signaling: COS, SOCS-1, SOCS-2, SLAP-130

- Secreted molecules: IL-10, IL-17, Enkephalin, ETA-1, ECM-1, MIP-1a, MIP-1b
- Cell surface molecules: CD2, OX40, CD25, CD122, GPCR83, GITR, Ly-6, Galectin-1, Thy-1

(Adapted from Hill et al.125)

A comparison of a number of these studies has permitted the identification of groups of genes that are relatively Treg specific and allow one to begin to define a distinct Treg molecular signature (Table 33.2). The “signature” includes both genes encoding certain cell-surface receptors, and genes encoding a wider array of transcription factors and other intracellular proteins.[125] Using a Treg to T conventional fold ratio of 1.5/1 or 1/1.5, 603 genes were differentially expressed, with 407 overexpressed and 196 underexpressed in Tregs. The vast majority of the signature's differential elements were already present in the thymus. Thus, most of the Treg cell signature is already specified at an early stage of lineage commitment, independent of peripheral influences. Many of the Treg signature genes also identify activation antigens expressed on activated conventional T cells including CTLA-4, GITR, and other members of the TNF-receptor superfamily that are expressed by activated effector cells. Some, including neuropilin, GITR, CD38, and CD5, appear to be shared with Foxp3-anergic T cells that do not exert suppressive functions.[126] On balance, the studies on global gene expression indicate that Tregs express a unique pattern of gene expression that may contribute to their survival and anergic state.

A Foxp3 chromatin immunoprecipitation method has been used to analyze the direct targets of Foxp3.[127,128] About 700 to 1000 genes contain Foxp3 binding regions, and many of these genes are up- or downregulated in Foxp3+ T cells, confirming that Foxp3 can function as both a transcriptional activator and repressor. However, Foxp3 target genes comprise only a small portion of Foxp3-dependent gene expression, suggesting that Foxp3 regulates a large part of its transcriptional program by acting on other transcription factors (Table 33.3). It is likely that some of genes encoding molecules that could potentially mediate suppressor function (eg, IL-10, granzyme B) are secondary Foxp3 targets, as they are not found in the group of genes that are direct Foxp3 targets.

One novel approach to understand the role of Foxp3 in directing Treg function is to engineer a mouse expressing the coding sequence of GFP knocked into the *Foxp3* locus together with disruption of Foxp3 protein expression.[129,130] Surprisingly, the GFP+Foxp3- T cells in these mice shared many phenotypic features with their GFP+Foxp3+ counterparts. The former are what might be termed Treg "wannabees," as they develop in normal mice and respond to signals required to induce Foxp3 expression. The GFP+Foxp3- cells were unable to produce IL-2 and effector cytokines, expressed elevated levels of CD25, were relatively nonresponsive to TCR stimulation, but lacked suppressor activity. Treg "wannabees" expressed some (including transcriptional activity at the Foxp3 locus), but not all, of the genes of the Treg signature. Thus, several of the characteristics of the Treg cell lineage can be selected and persist in the absence of Foxp3. Foxp3 does not function as the "master regulator" of the Treg lineage, but stabilizes or enhances certain Treg characteristics, particularly its immunoregulatory activities including suppression. Foxp3 is also not sufficient to elicit the full Treg signature after transfection or induction by TGF-β. Treg "wannabees" do not become conventional effector cells and transfer of these cells into RAG-/- recipients did not induce the scurfy phenotype.[88,131] It appears that WT mice have a population of self-reactive non-Tregs that express the Treg self-reactive TCR repertoire, which are not subject to negative selection but can potently induce autoimmune disease in the scurfy mouse.

Studies of the Treg "wannabee" mice indicate that certain Treg cell phenotypic properties including transcription of the Foxp3 locus and expression of some the Treg signature genes can be independent of Foxp3. One candidate family of genes that can regulate these Foxp3-independent Treg properties are the Foxo (Forkhead-box-O) family of transcription factors that play critical functions in the control of diverse cellular responses. Mice with a T cell-specific deletion of Foxo1 have defects in T-cell survival as well as defects in expression of the IL-7 receptor α-chain and CD62L.[132] Foxo1 is required for the inhibition of T-cell activation and Foxo1-/- mice develop a mild autoimmune disease. Foxo3 plays a role in DC function.[132] Mice with a deletion of both Foxo1 and Foxo3 develop a lethal inflammatory disease associated with a compromised Treg-cell differentiation. Foxo1 and Foxo3 function in a cell intrinsic manner to suppress IFNγ and IL-17 production. Foxo1/Foxo3-/- Treg cells fail to protect lymphopenic mice from autoimmunity induced by scurfy T cells or from colitis induced by Foxp3- T cells.[131] Mixed bone marrow chimeras containing bone marrow from Scurfy mice and Foxo1/Foxo3-/- developed a disease as severe as that observed with scurfy bone marrow alone; this was associated with fewer thymic and splenic Treg cells. Thus, it appears that Foxo proteins control the expression of Foxp3 and a subset of Treg cell-associated genes needed for suppressing inflammatory cytokine production in Treg cells. In chromatin-immunoprecipitation assays using antibody

to Foxo1 and Foxo3, Treg cells were selectively enriched in genomic fragments containing the CNS1 and CNS3 regions, but not the CNS2 region of the Foxp3 promoter. Foxo transcription factors constitute one element of higher order control[132,133] of Treg development and function.

SUPPRESSOR MECHANISMS UTILIZED BY FOXP3+ REGULATORY T CELLS

In Vitro Studies

An in vitro model system has been established for the analysis of Treg-cell function that allows rapid assays and that may offer some insights to the mechanism of action of Treg function in vivo.[37,134,135,136] This approach also allows a comparison of the requirements for activation (costimulation, antigen concentration) of Foxp3+ T cells compared to Foxp3- T cells. Purified Foxp3+ T cells were completely unresponsive to high concentrations of IL-2 alone, to stimulation with plate-bound or soluble anti-CD3, or to the combination of anti-CD3 and anti-CD28. They could be induced to proliferate when stimulated with the combination of anti-CD3 and IL-2. The most striking property of the Foxp3+ T cells is their ability to suppress proliferative responses of both CD4+Foxp3- and CD8+ Foxp3- T cells (Fig. 33.10). The Foxp3+ T cells must be activated via their TCR to suppress. No suppression was seen when Foxp3+ T cells were separated by semipermeable membrane from the CD25- T cells. This demonstrates that cell contact between CD25+ and CD25- T cells is required. Neutralization of the suppressor cytokines IL-4, IL-10, and TGF-β individually or in combination also had no effect on the Treg-mediated suppression. Similarly, Foxp3+ T cells from mice deficient in IL-4, IL-10, or TGF-β were fully competent suppressors. Indo-1-loaded Foxp3+ T cells did not flux calcium in response to TCR stimulation,[123] suggesting that they have a block in proximal signaling similar to that seen in T cells rendered anergic in vitro.

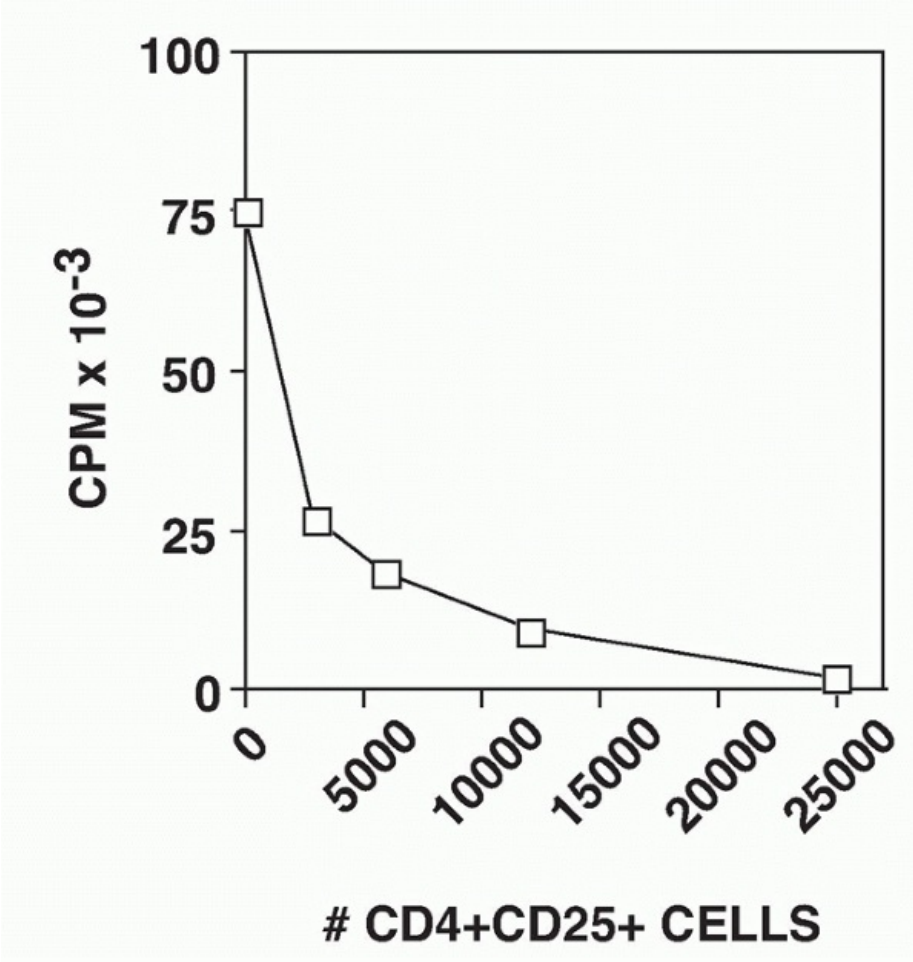

FIG. 33.10. CD4+ CD25+ T Cells Suppress the Proliferative Response of CD4+CD25-T cells. Graded numbers of CD4+CD25+ T cells were mixed with 5×10^4 CD4+CD25- T cells, T-depleted spleen cells, and soluble anti-CD3. Proliferation was measured after 72 hours. Adapted from Thornton and Shevach EM.[37]

Most studies have demonstrated that Foxp3+ T cells mediate suppression by inhibiting the induction of IL-2 messenger ribonucleic acid (mRNA) and mRNA for other effector cytokines in the responder Foxp3- T cells. Suppression can be abrogated by the addition of IL-2, thereby circumventing the block. Although IL-2 gene transcription was inhibited in the presence or absence of exogenous IL-2, the addition of anti-CD28 overcomes suppression by potently stimulating the production of endogenous IL-2 and overriding the suppressive effects of the Foxp3+ cells. Surprisingly, transcription of IL-2 mRNA was also restored in the cocultures in the presence of anti-IL-2. These results suggest that Tregs do not suppress the initial activation of Foxp3- T cells, but mediate their suppressive effects following production of IL-2 by the responder cells resulting in both the expansion of the Treg and induction/enhancement of their suppressor functions.[77] Foxp3+ T cells do not directly mediate the death of the responders, but induce a cell-cycle arrest at the G_1-S phase of the cell cycle. Such a cell-cycle arrest is often followed by cell death; it is difficult to recover significant numbers of viable cells when the suppressors and responders are cocultured for periods longer than 48 hours. Suppression of T-cell proliferation is the exclusive property of Foxp3+ T cells isolated from normal animals. The induction of CD25 expression by stimulating CD25- T cells via the TCR, in the absence of TGF-β, does not render the stimulated cells suppressive.

The role of IL-2 consumption in the suppressive function of Foxp3+ T cells is controversial. Treg cells express all three components of the high affinity IL-2R complex (CD25, CD122, and CD132), and one study[137] has suggested that Tregs may compete with Foxp3- T cells for IL-2 and thereby inhibit the proliferation of Foxp3- T cells secondary to the induction of a form of apoptosis dependent on the proapoptotic factor Bim. In a hybrid system in which human Treg cells were shown to efficiently suppress mouse Foxp3- T cells, the addition of an antihuman CD25 that blocks IL-2 binding had no effect on the function of the human Treg.[138] Taken together with the data that Foxp3+ Tregs inhibit the production of IL-2, it is highly unlikely that Tregs function as IL-2 “sinks,”[139] at least in vitro. IL-2 consumption might play a role in Treg suppression in vivo. However, WT Tregs suppress autoimmunity in IL-2Rβ-/- mice where all other cells in the recipient are nonresponsive to IL-2 directly demonstrating that effective suppression is not simply due to depriving IL-2 growth promoting signals to autoreactive T cells by Treg consumption of this cytokine.[140]

Foxp3+ T cells can be easily propagated in vitro for 3 to 14 days by stimulation initially with anti-CD3 and IL-2 and then expansion in IL-2 alone.[136] It has also been possible to clone murine Foxp3+ T cells by repeated stimulation with anti-CD3 and IL-2.[41] Following 7 to 14 days of activation and

culture in IL-2, activated Foxp3+ T cells remain nonresponsive and cannot be induced to proliferate when restimulated via their TCR in the absence of IL-2. The activated Foxp3+ T

cells have more potent suppressor activity on a per cell basis (three- to fourfold) than freshly explanted Foxp3+ T cells. Foxp3+ T cells that appear to be antigen-specific can be identified in mice that express a transgenic TCR. In general, the percentage of Foxp3+ cells is reduced in TCR transgenic mice (3% to 5% compared to 10% in normal animals). The expression of the transgenic TCR α-chain is a convenient tool that allows activation of the Foxp3+ T cells with peptide/MHC rather than with anti-CD3.[136] When Foxp3+ T cells from TCR-transgenic mice are activated with their peptide/MHC ligand and then expanded in vitro in IL-2, the activated suppressors are subsequently capable of suppressing the proliferative responses of fresh Foxp3- T cells from mice that express a different transgenic TCR. There is no MHC restriction in the interaction of the activated suppressors and the Foxp3- responders. Therefore, the suppressor effector function of activated Foxp3+ T cells in vitro is completely nonspecific (Table 33.4).

Treg-mediated suppression is highly sensitive to antigenic stimulation. For example, when Foxp3+ and Foxp3- T cells are prepared from the same TCR-transgenic mouse and stimulated with a specific peptide, the antigen concentration required to stimulate the Foxp3+ T cells to suppress is 10- to 100-fold lower than that required for triggering the proliferation of the Foxp3- T-cell population.[134] The partially activated phenotype of Foxp3+ T cells combined with their enhanced sensitivity to antigen stimulation suggests that they are highly differentiated in their function and are ready to mediate their suppressive functions immediately upon encounter with their target antigens. Their capacity to rapidly suppress responses in vitro suggests that they have been continuously stimulated by self-antigens in the normal physiologic state and continuously exert some degree of suppression in vivo.

Foxp3+ T cells suppress the proliferative responses of CD8+ T cells in a manner similar to that seen with CD4+ responders.[141] Marked suppression of the effector cytokine, IFNγ is also seen in the presence of Foxp3+ T cells. While suppression of the proliferation of CD4+ responders by Foxp3+ T cells can be completely reversed by the addition of IL-2 or anti-CD28, the suppression of CD8+ T-cell responses is not reversed by the addition of IL-2 or anti-CD28. The failure of IL-2 to abrogate suppression is secondary to a failure of full upregulation of the expression of CD25 on the responder CD8+ T cells. Foxp3+ T cells thereby prevent responses mediated by CD8+ T cells both by inhibiting their ability to produce IL-2 and by inhibiting their ability to respond to IL-2, thus disrupting CD4+ T cell help for CD8+ T cells.

TABLE 33.4 The Suppressor Effector Function of Activated CD4+ CD25+ T Cells is Completely Nonspecific

First Culture	Second Culture (TCR Tg CD4+CD25- T cells Specific For)	% Suppression
CD4+CD35+ from HA TCR Tg stimulated with $HA_{126\text{-}138}$ + IL-2 3 to 7 days	$I\text{-}A^d$ + $HA_{126\text{-}138}$	99

CD4+CD25+ T cells from mice expressing a TCR transgene specific for $HA_{126\text{-}138}$ were cultured with peptide, T-depleted spleen cells, and IL-2. They were then washed and mixed with CD4+CD25-T cells from mice expressing the same or different TCR transgenes and then stimulated with the appropriate peptide. (Adapted from Thornton and Shevach.136)

In general, murine Tregs failed to inhibit responses induced by plate-bound anti-CD3, but readily inhibited responses induced by soluble anti-CD3.[37] This finding raised the possibility that the cellular target of the Treg was the APC rather than the responder T cell, as responses to platebound anti-CD3 are relatively APC-independent, but other studies demonstrated that Foxp3+ T cells can mediate suppression in vitro via a T-T cell interaction and that the APC is not directly required for delivery of the suppressive signal.[141] Similar conclusions were drawn in other studies in which Foxp3+ T cells were shown to suppress responses of either mouse[142] or human.[33] Foxp3- T cells induced by anti-CD3 coupled to beads in the absence of APCs and can efficiently directly target responder T cells. It remains unclear whether the mechanisms utilized by Tregs to suppress the proliferation of Foxp3- T cells in the presence or absence of APCs are the same or whether assays of Treg function under these distinct conditions measure distinct components of Treg-mediated suppressor function.

Molecular Analysis of Regulatory T Cell Suppression and Anergy

Recent studies have attempted to define the biochemical and molecular pathways that mediate the anergic or nonresponsive state of Foxp3+ Tregs.[143,144] A number of studies have shown that Tregs exhibit diminished responses of both proximal and distal signalling pathways both in absolute amplitude and in duration when compared to the responses of CD25- T cells. Tregs have reduced phosphorylation of the TCR ζ-chain, reduced recruitment of ZAP-70, and reduced phosphorylation of SLP-76. Defects were seen in the activity of PLC-γ1 and in signals downstream of this enzyme including calcium mobilization, NFAT, NF-κB, and Ras-ERK-AP-1

activation. The diminished activity of PLC-γ1 in Tregs is likely to contribute, not only to the delay and reduced appearance of NFAT in the nucleus, but also to the attenuated activation of the PKC- and Ras-ERK-directed pathways as well. Other studies[145] have suggested that the proximal promoter of the IL-2 gene fails to undergo chromatin remodeling and remains in

a closed chromatin configuration.

Despite the widely recognized importance of IL-2 in Treg homeostasis, very little is known about the intracellular mechanisms that regulate IL-2R signaling in Tregs. Indeed, a defining characteristic of Tregs is their inability to expand in vitro upon stimulation with IL-2 alone despite expression of all three chains of the IL-2 receptor. It has been shown that JAK/STAT-dependent signaling is intact in Tregs stimulated with IL-2, but that downstream mediators of PI3K are not activated.[146] The nonresponsiveness of Tregs is associated with elevated levels of PTEN, a phosphoinositol 3,4,5-triphosphatase that catalyzes the reverse reaction of PI3K, negatively regulating the activation of downstream signaling pathways. In conventional T cells, the level of PTEN is downregulated after T-cell activation, but PTEN remains highly expressed in Tregs. A critical role of PTEN, in the nonresponsiveness of Tregs to IL-2, was established by studying PTEN-/- mice.[147] PTEN-/- Tregs readily proliferated after stimulation with IL-2 alone in vitro and exhibited enhanced peripheral turnover in vivo. They retained their ability to suppress effector T-cell responses both in vitro and in vivo. Forced expression of PTEN in recently activated non-Tregs inhibited their ability to expand in response to IL-2 confirming the ability of this lipid phosphatase to negatively regulate IL-2-dependent proliferation.

As anticipated from their heightened expression of PTEN, Tregs have a defect in the activation of the PI3K-AKT pathway indicated by a reduction in AKT phosphorylation.[64] Thymic-derived Tregs with established and stable Foxp3 levels were resistant to the effects of constitutively activated AKT, while activated AKT inhibits the induction of Foxp3 expression in Foxp3- T cells both in vitro and in vivo. IL-6 may block the differentiation of Tregs by activating an AKTdependent pathway. The repression of Foxp3 expression by active AKT required its kinase activity and was partly counteracted by rapamycin treatment placing mTOR as a downstream target of AKT. mTORC1 is more sensitive to rapamycin treatment, so it is likely that AKT is exerting part of its effect via mTORC1. Conversely, inhibition of the PI3K-AKT-mTOR pathway results in de novo expression of Foxp3 in a TGF-β-independent manner.[148]

The role of Foxp3 in directly controlling the activation of Tregs has been extensively studied. Many of the genes regulated by Foxp3 are also target genes for NFAT. The IL-2 and IL-4 genes are activated by NFAT and repressed by Foxp3, while the CD25 and CTLA-4 genes are upregulated by both NFAT and Foxp3. It is likely that Foxp3 represses IL-2 expression by competing with NFAT for binding to DNA. Foxp3 may also repress NFAT-driven cytokine transcription by sequestering NFAT away from DNA. Examination of the crystal structure of an NFAT:FOXP2:DNA complex revealed an extensive protein-protein interaction interface between NFAT and Foxp2.[149] Structure guided mutations of Foxp3, predicted to disrupt its interaction with NFAT, interfere in a graded manner with the ability of Foxp3 to repress expression of IL-2 and upregulate Treg markers CTLA-4 and CD25. Thus, NFAT can switch its transcription partner from AP-1 that drives T-cell activation to Foxp3 that programs Treg function. Foxp3 also has been shown to interact with the transcription factor AML1/Runx1 that is required for normal hematopoiesis, as well as activation of IL-2 and IFNγ gene expression.[150] The physical interaction of Foxp3 with RUNX1 suppresses IL-2 and IFNγ production and induces Treg cell-associated molecules such as CD25, CTLA-4, and GITR. Treg-cell deficiency of Cbf-β, a cofactor for all RUNX proteins, attenuated expression of

Foxp3 and resulted in high expression of IL-4. The RUNX1-Cbf-β heterodimer is indispensable for optimal expression of Foxp3, maintenance of suppressive function, and suppression of T effector responses.[151] Foxp3 can also directly interact with c-JUN/AP-1 in Treg cells, sequestering activated AP-1 in the nucleus, altering the subnuclear distribution of activated AP-1, and disrupting chromatin binding of activated AP-1.[152] Foxp3 can form a transcriptional repressor complex with several posttranslational modification enzymes such as the histone deacetylases HDAC1, HDAC7, and HDAC9, and histone acetyltransferase TIP60.[153]

Other transcription factors including Eos, a member of the Ikaros family, have been shown to play critical roles in Foxp3 dependent gene silencing in Tregs.[154] Silencing of Eos in Tregs abrogates their ability to suppress in vitro immune reponses and endows them with partial effector function, as they are capable of inducing IBD in vivo. Knockdown of Eos reversed Foxp3-mediated suppression of IL-2 production. Ninety percent of the genes suppressed by Foxp3 were no longer downregulated when Eos was knocked down in Tregs, while ninety-five percent of the Foxp3 upregulated genes were unaltered by Eos knockdown. One other gene that appears to be important in the regulation of Foxp3 suppressor function is the genome organizer SATB1, which is one of the genes most repressed in human and mouse Treg cells.[155] Foxp3 binds directly to the SATB1 locus in Treg cells and prevents SATB1 transcription. Foxp3+ T cells overexpressing SATB1, despite expressing normal levels of Foxp3, lost their suppressive activity and produced T effector cytokines, suggesting that downregulation of SATB1 in Treg cells was necessary for a stable suppressive phenotype. Thus, Treg-cell function not only depends on the induction of Foxp3-dependent genes that mediate suppressor function, but also on the specific repression of molecules such as SATB1 that prevent T effector function

Microribonucleic acids (miRNAs) also act as posttranslational regulators of Treg-cell phenotype, as mice with a deletion of either DICER or DROSHA, RNAaseIII enzymes necessary for miRNA maturation, convert Treg cells to Th1 or Th2 cells.[156] Conditional deletion of DICER in Treg cells confirmed that miRNA are critical for the homeostatic potential of Treg cells, as well as Treg-cell function in inflammation.[157] miRNA-155 is essential for the competitive fitness of Treg cells by modulating SOCS-1 expression thus regulating the response of STAT5 to limiting amounts of IL-2.[158] In contrast, miRNA-146a is important in the suppression

pathogenic Th1 responses by downregulating STAT-1 expression in Treg cells.[159]

Much less is known about the molecular/biochemical signals generated in the responder cell following interaction with Foxp3+ Tregs. Detailed time course studies in vitro have shown that suppression is established after 6 to 12 hours of contact with Tregs, and that responders are refractory to suppression after 12 hours of activation. As suggested by the requirements for IL-2 to activate suppressor function,[77] the IL-2 response of the responders is normal for the first 6 hours of the coculture and then abruptly terminates. Costimulation with anti-CD28 generated resistance to suppression by stabilizing IL-2 transcripts enabling the responder T cells to counterbalance transcriptional down regulation by Tregs.[160] Tregs do not inhibit the early induction of CD69 or CD25 and viability of responder cells was excellent at 36 hours.

Gene expression analysis in responder T cells using a microarray approach has shown that a set of genes expressed after culture with Tregs was distinct from genes induced in anergized T cells, T cells deprived of IL-2, or T cells treated with TGF-β.[161] Hopefully, further detailed studies of these genes will elucidate the specific pathways involved in Treg-mediated inhibition.

Production of Suppressor Cytokines by Regulatory T Cells

Most of the studies with either human or mouse Tregs that have studied suppression of T-cell activation in vitro have failed to identify a soluble suppressor cytokine. It is difficult to rule out the involvement of a cytokine that acts over short distances or a cell-bound cytokine. Nakamura et al.[162] raised the possibility that TGF-β produced by Tregs and then bound to their cell surface by an as yet uncharacterized receptor might mediate suppression in a cell contact-dependent fashion. In their studies, TGF-β was detected on the surface of resting and activated CD25+ T cells, and suppression could be reversed by high concentrations of anti-TGF-β monocloncal antibodies (mAbs). They postulated that latent (inactive) TGF-β bound to the cell surface of activated Tregs is delivered directly to responder CD25- T cells and is then locally converted to its active form. In contrast to these studies, Piccirillo et al.[163] were unable to show a requirement for either the production of TGF-β or responsiveness to TGF-β in Treg-mediated suppression. CD25- T cells from *Smad3*-/- and from mice expressing a dominant negative form of the TGF-β receptor II (TGFβRII), that are completely resistant to the immunosuppressive effects of TGF-β were readily suppressed by Treg cells from WT mice (Table 33.5). Tregs from TGF-β-/- mice were as efficient as Tregs from WT mice in mediating suppression of WT CD25- T cells. High concentrations of anti-TGF-β did not reverse suppression, nor did anti-TGF-β or a soluble form of the TGF-βRII inhibit suppression mediated by activated CD25+ T cells.

An alternative possibility is that TGF-β plays a role in the enhancement or maintenance of Foxp3+ Treg suppressor activity. Indeed, Marie et al.[164] have demonstrated that peripheral TGFβ1-/- Tregs expressed diminished levels of Foxp3. These studies suggested that TGF-β is required for maintenance of Foxp3 expression in peripheral Tregs, that the source of the TGF-β is not the Treg, and that paracrine production of TGF-β by APCs is needed for optimal Treg survival and suppressor function. Further evidence for the role of TGF-β in the maintenance of Tregs was derived from studies of mice with T cell-specific deletion of TGF-βRII.[165] In these mice, TGF-β was not required for induction of Foxp3 expression in the thymus and for the thymic development of Treg cells. In fact, TGF-βRII-/- mice have an increase in the percentage and number of Foxp3+ T cells in the thymus and increased BrdU uptake, suggesting that TGF-β normally inhibits the proliferation of thymic Tregs. Increased Treg proliferation was also seen in the periphery of TGF-βRII-/- mice, but these mice have a decrease in the percentage of Foxp3+ Tregs in the periphery, consistent with the possibility that TGF-β is essential for their survival in the periphery. When mixed bone marrow chimeras between TGF-βRII-/- and WT mice were generated, the knock out Foxp3- T cells demonstrated complete resistance to suppression by WT Tregs. This result suggests that there is a defect in a cell intrinsic mechanism of TGF-β-mediated control of T-cell reactivity in the TGF-βRII-/- T cells.

TABLE 33.5 CD4+ CD25+ Suppressor Function Occurs Independently of Transforming Growth Factor-β

CD4+CD25+	CD4+CD25-	% Suppression
Wild-type	Wild-type	Yes
Wild-type	Wild-type + anti-TGF-β	Yes
Wild-type	SMAD3-/-	Yes
SMAD3-/-	Wild-type	Yes
Wild-type	DNTGF$_{\beta}$RII	Yes

TGF, transforming growth factor.

CD4+CD25+ T cells were mixed with CD4+CD25- T cells in the presence of T-depleted spleen cells and soluble anti-CD3. Proliferation was measured at 72 hours. (Adapted from Piccirillo et al.163)

The TGF-β gene has been deleted in activated T cells and Treg cells or in Treg cells alone to determine the exact source of TGF-β for regulating T-cell tolerance and differentiation. Abrogation of TGF-β1 in activated T cells and Treg cells, but not in Treg cells alone, protected mice from experimental autoimmune encephalomyelitis (EAE) and was associated with compromised Th17 differentiation.[166] Th17 cells were the main producers of TGF-β1 in vitro and in vivo. TGF-β1 produced by Treg cells is not essential for Th17 differentiation in the EAE model.[167] Mice with a specific deletion of TGF-β1 in Tregs showed no signs of inflammation even at the age of 9 months. These mice had increased frequencies of Foxp3+ T cells in peripheral and mesenteric nodes, but not in the spleen, with no increase in conventional CD4+ or CD8+ T cells. These results demonstrate that TGF-β produced by Treg cells alone is specifically required for inhibiting Treg-cell proliferation.

The potential role of TGF-β as a mediator of Treg suppression must be reevaluated, as recent studies[168,169,170] have

identified GARP (LRRC32) as the cell surface receptor for latent TGF-β. Although the GARP/Latent TGF-β complex is also expressed by platelets, within the immune system, GARP expression is most often observed on activated Foxp3+ Tregs (Fig. 33.11). However, the function of the GARP/latent TGF-β complex on Tregs has remained elusive. Tregs that lacked the surface expression of LAP following treatment with TGF-β siRNA or the expression of GARP and LAP following treatment with GARP siRNA were somewhat less suppressive than Tregs treated with the control siRNA in the in vitro suppression assay. The roles for secreted or cell surface associated TGF-β as major mediators of the in vitro or in

vivo suppressive functions or other functions of Tregs remains to be further explored.

TGF-β does appear to play a major role in the in Treg-NK cell interactions.[171] Tregs were shown to inhibit NKG2D-mediated cytolysis in vitro largely by a TGF-β-dependent, IL-10-independent mechanism. Similarly, Tregs directly inhibited NKG2D-mediated NK cell cytotoxicity in vivo, resulting in suppression of NK cell-mediated tumor rejection.[172] Other studies have shown that human Tregs could also directly inhibit NK cell effector functions by a TGF-β-dependent mechanism with a concomitant downregulation of NKG2D receptors on the NK cell surface.[173] NK cell cytotoxicity was restored in the presence of Tregs when the cocultures were performed in the presence of cytokines known to activate NK cells such as IL-2, IL-4, IL-7, and IL-12. Curiously, in both of these studies, Treg cells did not induce a global inhibition of NK-activating receptors, but only an inhibition of NKG2D. In other experiments, depletion of Tregs resulted in enhanced proliferation of NK cells as well as their cytotoxic potential. The role of Tregs in the regulation of NKcell function has also been studied in a bone marrow graft rejection model.[174] One explanation for the susceptibility of NK cells to Treg control is that uninhibited NK cells might be a danger to the host in autoimmune diseases.

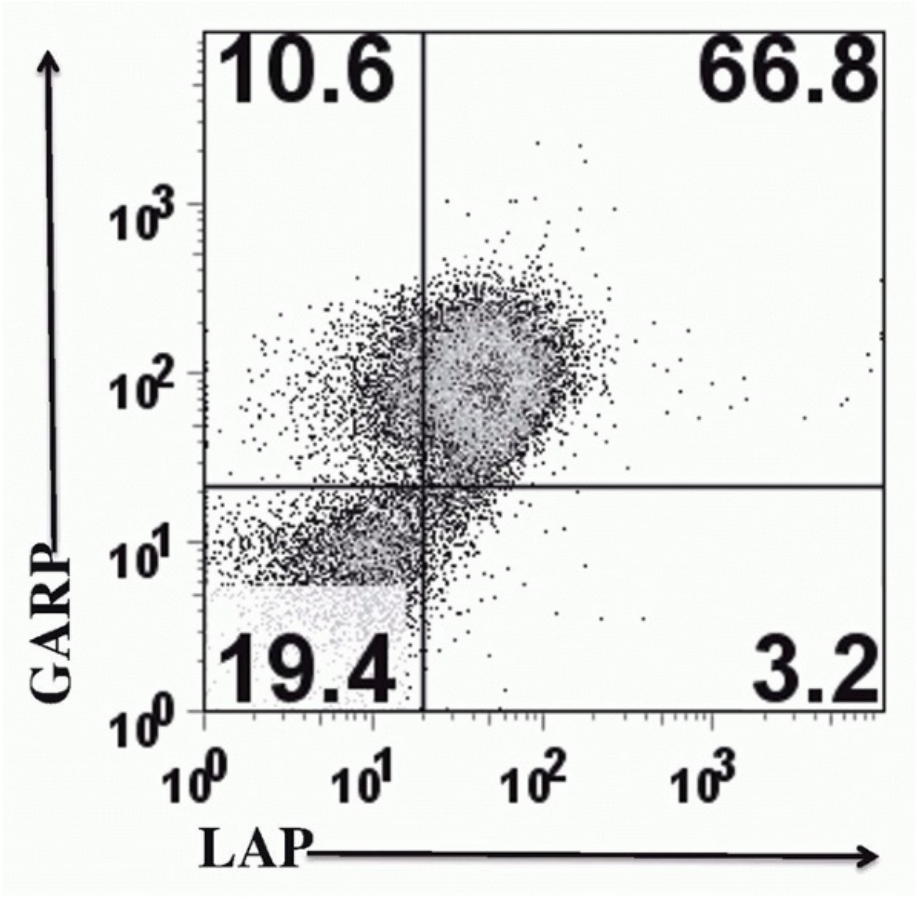

FIG. 33.11. A High Percentage of Activated Human Foxp3+ T Cells Express GARP and LAP. Adapted from Tran et al.[168]

The failure to observe suppression when Tregs are separated from responders does not rule

out the possibility that Tregs secrete an as yet uncharacterized factor that functions in gradient fashion and requires proximity between suppressor and responder. The newly described cytokine, IL-35, a heterodimeric member of the IL-12 family, composed of Epstein-Barr virus-induced gene 3 (Ebi3 which normally pairs with p28 to form IL-27) and p35 (which normally pairs with p40 to form IL-12) may subserve this function.[175] IL-35 is produced by activated Tregs and has been shown to act directly on responder T cells and suppress their proliferative responses. In addition, treatment of naïve mouse or human T cells with IL-35 induced a Foxp3- regulatory population (termed iTr35) that mediated suppression by secreting IL-35, but not IL-10 or TGF-β.[176] iTr35 were as effective as Foxp3+ T cells in preventing lethal autoimmunity in scurfy mice and completely protected mice from induction of EAE. Studies on the role of IL-35 have been hampered by the lack of a recombinant form of the cytokine, neutralizing antibodies, and characterization of its receptor.

Other secreted molecules may also play a role in Treg-mediated suppression including galectin-1 a member of a highly conserved family of β-galactoside binding proteins.[177] Galectin-1 is secreted as a homodimer and binds to many glycoproteins including CD45, CD43, and CD7 resulting in cell cycle arrest, apoptosis, and the inhibition of proinflammatory cytokine production on target cells. Galectin-1 is preferentially expressed in Treg cells and is upregulated upon TCR activation. Blocking galectin-1 markedly reduced Treg suppressor function in vitro and Treg cells from galectin-1-/- mice had reduced suppressor function. Galectin-10, another member of the Galectin family, is selectively expressed by Tregs.[178] However, Galectin-10 is primarily expressed intracellularly and is unlikely to be involved in suppression by Tregs.

Cell Contact-Dependent Mechanisms of Suppression

Cytolysis of target cells must also be considered as another potential mechanism for Treg-mediated suppression. Human Foxp3+ T cells that are activated with a combination of antibodies to CD3 and CD46 express granzyme A and kill activated CD4+ and CD8+ T cells and other cell types in a perforin-dependent, Fas/Fas-L-independent manner.[179] Activation of mouse Tregs also results in upregulation of granzyme B expression, and one report[180] has claimed that activated Treg kill responder cells by a granzyme B-dependent, perforin-independent mechanism. Other studies[181] demonstrated that activated mouse Treg cells inhibited the proliferative responses of B cells to polyclonal B-cell activators. Suppression of proliferation was due to increased cell death caused by the Treg cells in a cell contact-dependent manner. The induction of B-cell death was not mediated by Fas/Fas-L pathway, but depended on the upregulation of perforin and granzymes in the Treg.

It was originally proposed that Tregs target APCs by inhibiting the induction of the expression of costimulatory

molecules, or perhaps by competition for costimulatory signals.[182] In short-term cultures, Treg cells downregulated the expression of markers on immature bone marrow-derived DCs and inhibited their ability to elicit antigen-specific CD8+ T-cell responses in vitro. Activation of immature DCs with CpG DNA or lipopolysaccharide (LPS) abrogated the ability of the Treg to downregulate DC activation markers or to inhibit T-cell activation. Similarly, systemic activation of DC with CpG DNA or an agonistic anti-CD40 antibody completely inhibited the

antidiabetogenic activity of Treg cells in nonobese diabetic (NOD) mice.[183] Although these results suggest that Tregs exert their suppressive effects by keeping DCs in an immature state and that mature DCs are resistant to the effects of Tregs, other studies have shown that Tregs are capable of inactivating CD40L-prestimulated human DCs[184] and that Tregs can dampen immune responses induced by fully mature DCs in vivo.[185] Some of the differences in these studies may be secondary to Treg modulation of cytokine production by the DCs. For example, although Tregs were unable to prevent DC maturation or induction of IL-6 transcription in the presence of strong inflammatory stimuli, they were still able to modulate mature DC responses by enhancing transcription of the anti-inflammatory cytokine IL-10.[186] Treg-mediated enhancement of IL-10 production by fully mature DCs may result in inhibition of T-cell activation and is one mechanism by which Tregs can modulate the function of mature DCs.

Considerable controversy exists regarding the significance of the expression of CTLA-4 on Tregs and its potential involvement in their suppressor function. Takahashi et al.[39] have shown that the addition of the Fab fragment of anti-CTLA reverses suppression in cocultures of Treg and CD4+CD25- T cells. Read et al.[27] demonstrated that treatment of mice with anti-CTLA-4 abrogates suppression of IBD mediated by Treg cells. Reversal of suppression by anti-CTLA-4 or its Fab fragment in vitro has not been seen in all studies.[31,32,33,34,35,36,37] In studies[142] where Tregs suppress the activation of CD25- T cells in the absence of APCs, the addition of anti-CTLA-4 or anti-CD80/CD86 did not reverse suppression, suggesting engagement of CTLA-4 is not required for suppressor function. Treg from CTLA-4-/- mice are as efficient as WT Tregs in mediating suppressor function in vitro, but in contrast to WT Tregs, their suppressive effects were more dependent on TGF-β.[187] One possible functional role for CTLA-4 on Tregs would be to ligate CD80/CD86 on DCs or other cells. Some,[188] but not all,[189] studies have claimed that CD80/CD86-/- CD25- T cells are refractory to Treg suppression in vivo and in vitro, and that interaction of CD80/CD86 on CD25- T cells with a molecule on Tregs, most likely CTLA-4, is needed for suppression to be manifest.

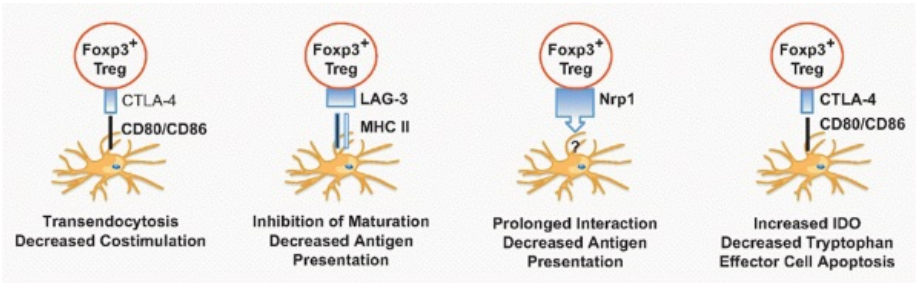

FIG. 33.12. Potential Mechanisms for Regulatory T Cell-Mediated Downregulation of Dendritic Cell Function.

The potential unique role of CTLA-4 as a mediator of Treg suppression has been

strengthened by the demonstration that animals with a selective deletion of the expression of CTLA-4 on Treg develop systemic autoimmunity by 7 weeks of age.[190] Thus, CTLA-4 deficiency in Treg cells alone is sufficient to cause fatal disease and maintenance of its expression in activated effector T cells is insufficient to prevent this outcome. Selective CTLA-4 deficiency does not alter the development or homeostasis of Treg cells or render them pathogenic. Foxp3+ T cells with a selective loss of CTLA-4 expression remain anergic, but are less suppressive in vitro. It has been proposed that the interaction of CTLA-4 on Tregs with its ligands, CD80 and CD86 on DCs blocks the subsequent increase of CD80 and CD86 expression or even downregulates CD80 and CD86 expression induced by CD40/CD40L interactions between T effector cells and DCs. Treg cells from CTLA-4-/- mice are defective when compared with Treg cells from WT mice in preventing the upregulation of CD80/CD86 expression. The major conclusions from these studies are that inhibition of CD80/CD86 expression limits the delivery of costimulatory signals to naïve T cells via CD28 resulting in defective T effector cell activation.

A molecular basis for this cell extrinsic function of CTLA-4 is needed (Fig. 33.12). Quershi et al.[191] postulated that because of its highly endocytic behavior, CTLA-4 can mediate the intercellular transfer of a ligand from one cell to its receptor on a different cell by a process termed transendocytosis. Studies by this group have demonstrated that following Treg activation, CTLA-4 interacts with CD80/CD86 and removes the costimulatory molecules from the cell surface, with subsequent degradation of these ligands inside the CTLA-4-expressing cells, thereby limiting CD28-driven costimulation. In contrast to CTLA-4, CD28 was not capable

of transendocytosis. Although this model can potentially account for Treg-mediated suppression and the phenotype of the Treg conditional CTLA-4-/- mouse, it should also be emphazsized that CTLA-4 expressed by activated T effector cells can also mediate transendocytosis of CD80/CD86.

An additional pathway (see Fig. 33.12) by which the interaction of CTLA-4 on Tregs with CD80/CD86 on DCs can result in suppression is the activation of indoleamine 2, 3-dioxygenase (IDO). IDO is responsible for the metabolism of the essential amino acid tryptophan. Reduced amounts of tryptophan after induction of IDO are associated with decreased activation of T cells.[192] Other studies have demonstrated that in addition to IDO, Tregs may induce multiple other enzymes that consume essential amino acids.[193] The reduction in essential amino acid levels resulted in reduced mTOR signaling that can potentially lead to the de novo induction of Foxp3+ T cells in a manner that is synergistic with TGF-β. This process may be primarily operative at sites of Treg-mediated suppression (eg, protection against skin graft rejection).

A number of other mechanisms have been proposed by which Treg cells abrogate the antigen-presenting activity of DCs or promote the secretion of suppressive factors by the target DC population. One cell surface antigen that may play in Treg-cell suppression of DC function is LAG-3 (CD223), a CD4 homolog that binds MHC class II molecules with very high affinity. Binding of LAG-3 to MHC class II molecules expressed by immature DCs induces an immunoreceptor tyrosine-based activation motif-mediated inhibitory signal that suppresses DC maturation and immunostimulatory capacity.[194] Because activated human, but not

mouse, T cells can express MHC class II, Treg cell-mediated ligation of LAG-3 on activated human T effector cells might also induce suppression of T-cell function. A second molecule that has been proposed to play a role in the interaction of Treg cells with DC is neuropilin-1 (Nrp-1). Nrp-1 is a receptor for class II semaphorins and a coreceptor for vascular endothelial growth factor. Nrp-1 is preferentially expressed on Tregs and can be induced by ectopic expression of Foxp3 in Foxp3- T cells.[195] Nrp-1 promotes long interactions between Treg cells and immature DCs. Anti-Nrp-1 abrogates suppression of proliferation mediated by Treg cells when the responder T cells are stimulated with low concentrations of antigen. These data suggest that the role of Nrp-1 is to give Treg cells a headstart over naïve responder T cells under conditions in which antigen is limiting.

Extracellular adenosine triphosphate (ATP) functions as an indicator of tissue destruction and may exert its effects on DCs. Intracellular ATP concentration is so high that substantial amounts of the nucleotide are released upon cell damage. CD39 is the dominant ectoenzyme in the immune system that hydrolyzes ATP or ADP to AMP and is expressed by a number of different cell types including Tregs. ATP can activate DCs and lead to the upregulation of CD86. The catalytic inactivation of extracellular ATP by CD39 is a potential anti-inflammatory mechanism used by Tregs.[196] The immodulatory effects of removal of ATP by CD39 can be amplified by the generation of adenosine. Adenosine can be generated by CD39 in concert with the 5′-ectonucleoside CD73, which dephosphorylates the CD39 product, AMP.[197] Adenosine signaling via the A2A receptor can inhibit the function of DCs and activated T cells. The documented ability of Tregs to convert ATP to adenosine provides direct evidence of the functional capacity of these enzymes and supports the notion that adenosine is a mediator of Treg function. Adenosine regulates T-cell function indirectly by reducing the secretion of proinflammatory cytokines including IL-12 and TNF-α from stimulated APC by 80% to 90%. The immunosuppressive function of adenosine may be mediated by increasing intracellular cyclic AMP.

Tregs can transfer cAMP to Teff via gap junctions, and elevating cAMP in Tregs renders them more suppressive.[198] Upon entrance to the target cell, cAMP inhibits IL-2 production and proliferation. Tregs also indirectly boost cAMP levels in target cells by augmenting adenosine-mediated signaling from extracellular nucleotides. One other metabolic pathway that can modulate Treg function targets the P2X7 receptor that is expressed at high levels on Foxp3+ T cells.[199] Nicotinomide adenine dinucleotide (NAD+) released by cell lysis or nonlytic mechanisms can activate the P2X7 receptor and induce Treg-cell death. The systemic administration of NAD+ has resulted in selective depletion of Treg cells and enhancement of an antitumor response.

Mechanisms of Suppression in Vivo

There are a number of major differences between the properties of Treg cells in vivo compared to in vitro. Although Treg cells are anergic or nonresponsive in vitro due to their failure to produce IL-2, Treg cells expand in vivo after engagement of their TCR by its cognate antigen in a manner indistinguishable from conventional T cells.[200,201] While most in vitro studies of Treg suppressor function do not implicate suppressor cytokines such as IL-10 as a mediator of suppression, studies in several in vivo models have shown that suppressor cytokines can be major contributors to the suppressive effects of Tregs.[202,203]

While the major effect of Tregs in vitro is to suppress the production of IL-2 by T effector cells, the role of IL-2 in the antigen drive expansion of CD4+ T cells has not been elucidated and antigen-specific cells from IL-2-/- mice expand normally in vivo when triggered via their TCR.[204] Taken together, it is difficult to translate from in vitro studies of Treg function to the in vivo situation. As a major goal of research in this area is the manipulation of Treg function in vivo in disease, a clear understanding of Treg biology in vivo is required. Specifically, which mechanisms from the long list of mechanisms proposed for Treg suppressor function in vitro are used in vivo?

The production of IL-10 by Foxp3+ Tregs plays an important role in many disease models including EAE, IBD, and the immune response to parasites. However, none of the mechanisms proposed for suppression have been proven to operate in unmanipulated animals. Surprisingly, selective disruption of IL-10 in Treg cells led to spontaneous colitis[205] and augmented immune response-associated pathology in skin and lungs. Thus, in unmanipulated mice, IL-10 produced by Tregs plays an important role in suppressing immune inflammation at environmental interfaces. While

the production of TGF-β by Foxp3+ Tregs has been implicated in the suppressive function of Tregs in vivo, a number of experiments have also demonstrated that autocrine TGF-β1 expression is not essential for Treg suppression in vivo. Transfer of TGF-β1-/- splenocytes to RAG-2-/- mice induced disease with features similar to those of the TGF-β1-/- mice and disease transfer was accelerated by the depletion of TGF-β-/- CD25+ T cells. Importantly, cotransfer of TGF-β1-/- Tregs clearly attenuated disease in RAG2-/- recipients of CD25-depleted spleen and lymph nodes, but suppression was incomplete when compared to WT Tregs.[206] Although TGF-β appears to play a nonredundant role in control of intestinal inflammation, Tregs from TGF-β1-/- mice were capable of inhibiting IBD induced by $CD45RB^{high}$[207] or CD4+CD25- T cells[208] in vivo. Furthermore, Tregs from mice expressing a dominant negative form of the TGF-βRII are also capable of inhibiting colitis, suggesting that TGF-β is not required for the function of Tregs. Importantly, the suppressive function of TGF-β-/- Treg cells was abrogated by anti-TGF-β indicating that TGF-β is absolutely required for protection from IBD in this model, but can be provided by a non-Treg cell source.

The in vitro studies demonstrating the cytotoxic activity of Tregs suggested that one should reevaluate the concept of “cytotoxic/suppressor cell” because it appears at least in vitro that Tregs can mediate both of these functions. It remains to be determined whether Tregs can develop into cytotoxic cells in vivo. It has been difficult to demonstrate granzyme B expression by Treg cells in vivo, but Cao et al.[209] have demonstrated that 5% to 30% of Treg cells in the tumor microenvironment express granzyme B and are lytic for NK cells and cytotoxic T-lymphocytes in a granzyme B- and perforin-dependent manner. Foxp3+ T cells also reduce granule exocytosis in cytotoxic T-lymphocytes. This inhibitory effect did not require long-lasting contacts between Foxp3+ T cells and cytotoxic T-lymphocytes, but was dependent on the secretion of TGF-β. It has also been shown that polyclonal Foxp3+ T cells limit DC survival in tumor draining LN through an antigen- and perforin-dependent mechanism involving direct contacts between Foxp3+ Tregs and tumor antigen presenting DCs.[210] Depletion of Foxp3+ Tregs resulted in an increase in the the number of DCs in tumor draining LN, a marked arrest in antitumor CD8+ T cell migration, increased T-cell priming, and

subsequent tumor rejection. This study concluded that the Foxp3+ T cells kill the DC directly, but did not rule out indirect effects of Tregs on the survival of the DC.

Mice that lack Foxp3+ T cells develop spontaneous germinal centers and have high titers of autoantibodies. In many models of organ-specific autoimmune disease, Treg cells suppressed the activation of autoantigen-specific T cells and inhibited the production of autoantibodies to the target organ. As B cells and autoantibody production are prominent mediators of pathology in many autoimmune diseases, it is critical to understand the potential for Tregs to control autoantibody production. While it is clear that Tregs can suppress antibody production by blocking T helper functions, a number of other studies have suggested that Tregs can exert a direct effect on certain B-cell functions. Bystry et al.[211] were the first to suggest that Treg cells could inhibit LPS-mediated B-cell activation. Lim et al.[212] demonstrated that human Tregs can suppress B cell-dependent Ig production and class switch recombination by a cell contact-dependent mechanism in the absence of T helper cells. Foxp3+ Treg cells were identified in T-B area borders and within germinal centers of human lymphoid tissues.[213] Treg cells were also able to suppress the expression of AID, a key enzyme involved in class switch recombination and affinity maturation. The biochemical mechanisms for the suppression of B-cell function in these studies remain unclear.

Treg cells can also control the magnitude and the quality of the germinal center response.[214,215] To complete maturation and exit the germinal center, a B cell must receive help in the form of prosurvival signals from a specialized subset of CD4+ T cells termed T follicular helper (Tfh) cells. Tfh cells mediate selection of only those B cells that express highaffinity variants of their original B-cell receptor. However, cross-reactive affinity-matured B cells that also recognize self-antigens could still be positively selected and allowed to exit the germinal center contributing to the development of autoimmunity. Together with results demonstrating that Treg cells can directly inhibit B-cell activation in vitro, these data suggest that Treg cells may have important function in regulating germinal center responses. Antigen-induced germinal centers contain a substantial population of Foxp3+ Treg cells that have been termed TfTreg. They phenotypically mirror Tfh cells in their expressison of CXCR5, a chemokine receptor that promotes T-cell migration into germinal centers and shares a common developmental pathway that requires contact with B cells and expression of both the signaling adapter SAP and the transcription factor Bcl-6. TfTreg cells likely play an important role in preventing autoantibody production and enforcing self-tolerance after somatic hypermutation. The molecular pathways by which they mediate these complex effects remain to be elucidated.

The potential pathways of Treg suppression in vivo are more complex than those used in vitro. The Treg must able to localize to various parts of the body such that close contact with most effector T cells with a given antigen specificity either directly or through an APC intermediate becomes possible. Unlike the culture situation, there is ample space for T cells to evade suppression in vivo unless Tregs can localize with them in response to antigenic stimulation that begins in antigen-draining lymph nodes. A number of possible mechanisms for the suppressive function of Tregs in vivo have been proposed including whether they inhibit the priming and expansion of T effector cells, block the migration of T effector cells from the site of immunization (eg, the draining LN) to the target organ, or inhibit the differentiation of naïve precursors into pathogenic T effector (Th1, Th2, or Th17) cells.

The first studies to directly examine the effects of Tregs on priming immune responses in vivo used two-photon laserscanning microscopy.[216,217] After entering the LN through high endothelial venules, T cells travel through a region near the paracortical T cell zone and B cell follicles where tissue emigrant DCs are found. In the absence of antigen, T cells move freely within the T cell zones of the LN. In contrast,

in the presence of antigen, T cells interact with the antigenloaded DCs first by a process termed swarming that ultimately results in arrest of their locomotion for a period of hours before they again become motile. Taken together, these studies demonstrated that both Treg cells and T effector cells formed similar clusters with DCs. In the absence of Tregs, cluster formation by T effector cells was more sustained. Cluster formation by Tregs preceded the inhibition of T effector activation. Treg cells appeared to block T effector cell priming by decreasing the contact time between DCs and the naïve CD4+ T cells. Surprisingly, no direct interactions between Treg and T effector cells were observed in these studies, indicating that the major suppressive effects of Tregs were directed to the DCs. The results of these studies are consistent with models that propose that Treg cells can preferentially interact with DCs and either prevent the subsequent interaction of DCs with T effector cells or ultimately lead to inactivation of the DCs. It remains unclear why Tregs that express the same TCR as the T effector cells would preferentially interact with DCs. One explanation is the expression of higher levels of molecules mediating cell adhesion such as LFA-1[218] or Nrp-1.[195]

Another approach to analyze the effects of Tregs on T effector expansion and differentiation involved the transfer of congenically marked carboxyfluorescein diacetate succinimidyl ester-labeled TCR-transgenic naïve T cells to normal recipients with or without congenically distinct pre-activated polyclonal Tregs.[219] Following immunization with antigen in complete Freund's adjuvant (CFA), the numbers and activation status of the transferred transgenic T cells were analyzed at various time points. Surprisingly, cotransfer of Tregs did not inhibit T effector proliferation and resulted in a twofold increase in the absolute number of T effector cells present in the draining LN. There was no difference in the expression of activation markers on the T effectors immunized in the presence or absence of Tregs, and most importantly, there was no difference in the percentages of T effector cells producing IFNγ and IL-17. The total number of T cells in the LN is determined not only by in situ proliferation and expansion, but also by the contribution of entry and exit from the LN. In mice that received T effector cells only, the ratio of T effector cells in the LN to T effector cells in the blood was approximately 2:1. In contrast, in the mice that received T effector cells and polyclonal Tregs, the ratio was 10:1. Mice that received Tregs had fewer antigenspecific T cells when challenged at a peripheral site 1 week after priming. Thus, in the presence of polyclonal Tregs, fewer cells leave the lymph node to enter the circulation, and few cells are therefore available to respond to antigen at a distant site. The retention of antigen-specific cells at the site of immunization was associated with a decreased level of expression of the sphingosine 1-phosphate receptor 1 (S1P1). S1P1 mediates the response of primed T cells to high levels of S1P in the circulation and promotes their exit from the LN. It is unclear if this is the only mechanism operative in this model or if the Tregs target the T effector cells directly or mediate their effects indirectly by acting on DCs.

Klein et al.[200] were the first to initiate a detailed in vivo analysis of the properties of antigen-

specific Tregs. They obtained Tregs from TCR/antigen doubly transgenic mice and transferred them alone or in combination with naïve T cells of the same antigen specificity to normal immunocompetent mice. They observed that both Tregs and naïve antigen-specific T cells expanded in similar fashion 8 days after immunization. In cotransfer studies, Tregs did not inhibit the proliferation of naïve T cells in vivo in the draining LN when analyzed 90 hours after immunization.[200] After this time point, in the absence of the Tregs, the T effectors continued to expand, while in the presence of the Tregs their numbers remained stable. The percent of cytokine producing cells 8 days after priming was identical in the groups that did or did not receive Tregs. The conclusions drawn from this study were that Tregs had a late effect in vivo on the expansion of T effector, but had no effect into their differentiation into cytokine producing T effector cells. Other studies used an identical cotransfer model but observed marked suppression of the expansion of the antigen-specific T effector cells, as well as marked inhibition of cytokine production (IL-2 and IFNγ) 96 hours after cell transfer.[220,221,222] A correlation between Treg-mediated suppression and Treg division was observed in these studies; this is consistent with the view that Treg activation is a key requirement for effective immunosuppression in vivo. The differences between these studies and the study of Klein et al.[200] are not clear but may reflect the type of immunization and the ratio of Tregs to naïve T cells in the transfer inoculum.

The failure of T effector cell expansion in the presence of Tregs suggests that the major target of the suppressive functions of the Tregs is APCs. Hanig and Lutz[221] cotransferred peptide-pulsed bone marrow DCs, that had been matured with LPS, with antigen-specific T effector cells with or without antigen-specific Tregs to normal recipients. Clustering of DCs with both T effector and Tregs was observed in the spleen at 24 hours after cell transfer. Similarly, when all populations were injected simultaneously, no effects of Tregs on total spleen cell size and T effector numbers were observed for the first 48 hours. Maximum expansion of spleen size and numbers of T effector cells were detected at 72 hours after injection and modest (25%) suppression was seen at this time point when Tregs were cotransferred. Lower numbers of T effector cells in the memory phase of the response were seen when Tregs were coinjected. In contrast, when Tregs were transferred 10 to 24 hours before the T effector cells, cluster formation was completely inhibited and marked suppression of T effector cell expansion was seen. Thus, in this model using antigen-pulsed bone marrow DCs that had been prematured in vitro by treatment with LPS, Treg-mediated suppression required that the Tregs be preactivated in vivo. When Tregs and DCs were injected 24 hours before the T effector cells, marked downregulation of the expression of CD80/CD86, PDL-1, and PD-L2 was observed 48 hours later on DCs matured with TNF or LPS. No changes of ICOS-L, CD70, CD40, or MHC class II expression were observed. The conclusions drawn were that the Treg-mediated block in T effector cell expansion was mediated by downregulation of specific costimulatory molecules on the DC surface that in turn indirectly control the T effector cell expansion. However, Tregs could not inhibit T effector cell expansion and modulation of DC cell surface antigen expression, when

the DCs were matured with the combination of LPS and anti-CD40. Thus, certain modes of DC activation may result in a stimulatory DC that is completely resistant to Treg-mediated suppression.

Similar results were obtained in cotransfer studies using preactivated antigen-specific Tregs

that had been induced in vitro by exposure to TGF-β and IL-2. Cotransfer of antigenspecific Tregs resulted in a > 90% inhibition of the expansion of the naïve T effector cells (Fig. 33.13) and complete inhibition of the induction of effector cytokine production.[222] While the expansion of the T effector cells was inhibited, the Tregs in these mice readily proliferated, consistent with the earlier studies.[200] Again, it is likely that the Tregs in this model were inhibiting antigen presentation by acting on DCs. No evidence for Treg killing of DCs was observed, and the Tregs did not produce IL-10 that could potentially suppress the capacity of DCs to present antigen or deliver costimulatory signals. An alternative possibility is that the Tregs may inhibit chemokine production by the DCs resulting in inhibition of further recruitment of the transferred DCs to the site of immunization and less T effector cell activation.[223] It is still difficult to rule out direct effects of the Tregs on the responder T cells in vivo. It is possible that Tregs and T effector cells could interact with the same antigen-presenting DCs and complex interactions between all three cells would occur in this milieu. T effector production of IL-2 is required for the maintenance of Foxp3 expression in the transferred TGF-β-induced Tregs.[224] The molecular pathways that might play a role in Treg-mediated inhibition of APC function in vivo remain to be elucidated. The interacton of CTLA-4 on the Treg with its ligands CD80/CD86 represents the leading candidate.[225,226]

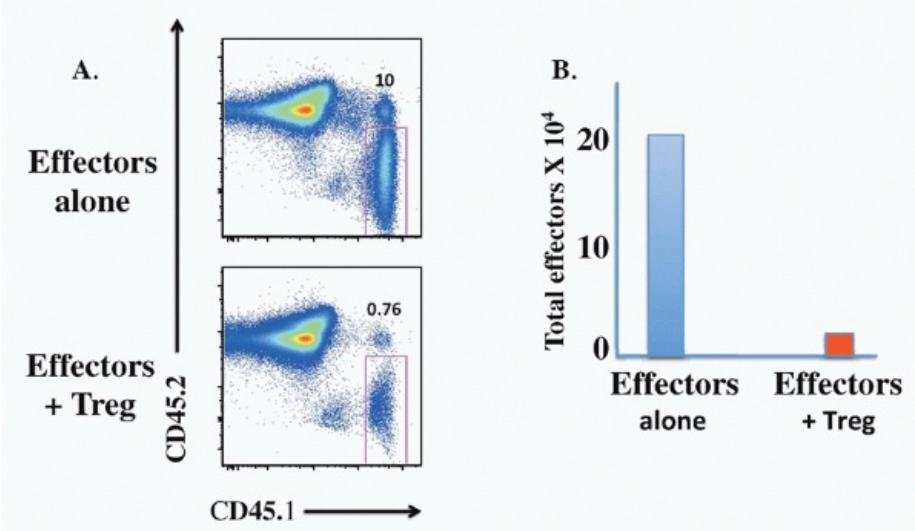

FIG. 33.13. Antigen-Specific Regulatory T (Treg) Cells Inhibit the Expansion of Antigen-Specific T Effector Cells in Response to Immunization. CD45.1 antigen-specific T cells were cotransferred to CD45.2 mice with Tregs specific for the same antigen. Following immunizations the **(A)** percentage and **(B)** absolute number of the T effectors were quarantined.

Reversal of and Resistance to Suppression

One approach to determining potential cell surface antigens involved in the process of Treg-mediated suppression has been to reverse suppression with antibodies to candidate antigens. One member of the TNFRSF, the GITR (TNFRSF18), has been shown to play an important role in regulation of T-cell suppressor activity. Both a polyclonal antiserum and an

mAb to the GITR appeared to be able to reverse suppression mediated by freshly isolated CD25+ T cells.[40,41] However, the GITR is expressed on two populations of cells (resting Tregs and activated CD4+CD25- cells) that do not manifest suppressor activity. It is therefore very unlikely that the GITR is the molecule responsible for mediating suppressor effector function. Surprisingly, culturing CD25+ T cells with the anti-GITR in the presence of IL-2, but in the absence of anti-CD3, resulted in a vigorous proliferative response and breaking the non-responsive state of the Tregs to stimulation with IL-2.

These studies were originally interpreted as indicating that anti-GITR functioned as an agonist for the GITR resulting in a signal that instructs the Tregs not to mediate their suppressive functions. As both CD25- and Tregs can

express the GITR, it was impossible to conclude that the anti-GITR mediated its effects by acting solely on the Tregs. When combinations of WT and GITR-/- CD4+CD25- and Tregs were used in coculture experiments, ligation of the GITR on the CD25- responders, not the Tregs, was required to abrogate suppression.[227] These results suggest that interactions of the GITR with its ligand, the GITR-L, provided a signal that renders effector T cells resistant to the inhibitory effects of Tregs. Similar conclusions were drawn from studies in which the costimulatory effects of anti-GITR in vivo were maintained following depletion of Tregs.[228] The GITR-L was shown to be expressed on a number of different resting APC populations including DCs, macrophages, and B cells, and to be downregulated on activation. Thus, engagement of the GITR on T effector cells by its ligand on APCs early during the course of an immune response may render the responder cells resistant to suppression by Tregs.

Other studies have implicated additional members of the TNFRSF as potential targets for reversal of Treg-mediated suppression. The capacity of Tregs to inhibit graft-versushost disease (GVHD) was reversed when Tregs were treated with an anti-OX40 mAb.[229] Injection of tumor-bearing mice with an agonistic anti-OX40 also appeared to inactivate intratumor Tregs and resulted in tumor rejection.[230] Stimulation of human Tregs in vitro in the presence of TNF or in the presence of an agonistic mAb to TNFRII reversed their in vitro suppressive activity and appeared to downregulate their expression of Foxp3.[231] One problem with the interpretation of these studies is that activated conventional T cells also express high levels of the GITR, OX40, and TNFRII, and it is difficult to determine the precise site of action of the agonistic mAbs. As shown with the anti-GITR, the majority of the “reversal” of suppression may actually be the result of enhanced resistance of the activated T effector cells to the suppressive effects of the Tregs. This explanation is also compatible with the observations of Pasare and Medzhitov[232] that soluble factors released by activated DCs can act directly on T effector cells, but not Tregs, to render them resistant to suppression. Other members of the TNFRSF appear to actually enhance Treg function. Stimulation of Tregs with an agonistic mAb to TNFRSF25 (also known as DR3) resulted in marked expansion of Tregs in vivo, and these expanded Tregs protected mice against the induction of allergic lung inflammation.[233]

In addition to the role of APC-derived signals in rendering responder cells resistant to suppression, a number of mutations in TCR signaling and costimulatory pathways also appear to render responder cells completely resistant to the inhibitory signals delivered by Tregs. One of the best examples of a defect in resistance to regulation is the cblb-/- mouse.

Cbl-b is an E3 ubiquitin ligase that negatively regulates the CD28 costimulatory pathway and downregulates the PI3K/Akt pathway. In the absence of cbl-b, mice develop CD28-independent hyperactive responses and autoimmunity. Treg from cbl-b-/- mice function normally in vitro, but CD25- T cells from cbl-b-/- mice are resistant to suppression in vitro and in vivo by WT Tregs.[234] Effector T cells from a number of other mutant mouse strains exhibit a resistance to suppression similar to that seen with cbl-b-/- effectors (Table 33.6). Many of these strains have in common a hyperactivated PI3K/Akt pathway that may be a direct or indirect target for Treg-mediated suppression.

REGULATORY T CELL SPECIALIZATION

The functional specialization of T effector cells is due to the expression of master transcription factors, namely T-bet, GATA-3, and RORγt, which control the differentiation of Th1, Th2, and Th17 subsets, respectively. In general, these subsets mediate proinflammatory and potentially responses that are harmful. Treg cells also use the Th cell-associated transcription factors to maintain or restore immune homeostasis (Fig. 33.14). Treg cells expression of IFN regulatory factor 4 (IRF4), a transcription factor involved in the control of IL-4 production and and Th2 cell differentiation, is required for Treg-mediated control of Th2-type inflammatory responses. Mice in which IRF4 is specifically deleted in Foxp3+ Tregs develop a lymphoproliferative disease that is associated with a selective expansion of IL-4 and IL-5 producing Th2 cells and have elevated serum levels of of IgG1 and IgE, and develop splenic germinal centers.[235] IRF4 is also crucial for the differentiation of Tfh cells. The increase in germinal centers in mice with a Treg cell-specific deletion of IRF4 in the absence of an increase in IL-13-producing cells or eosinophil numbers suggested that Treg cell-specific expression of IRF4 may be needed to control a specific component of Th2 cell-associated inflammation, Tfh-cell activation, and high-affinity antibody production.

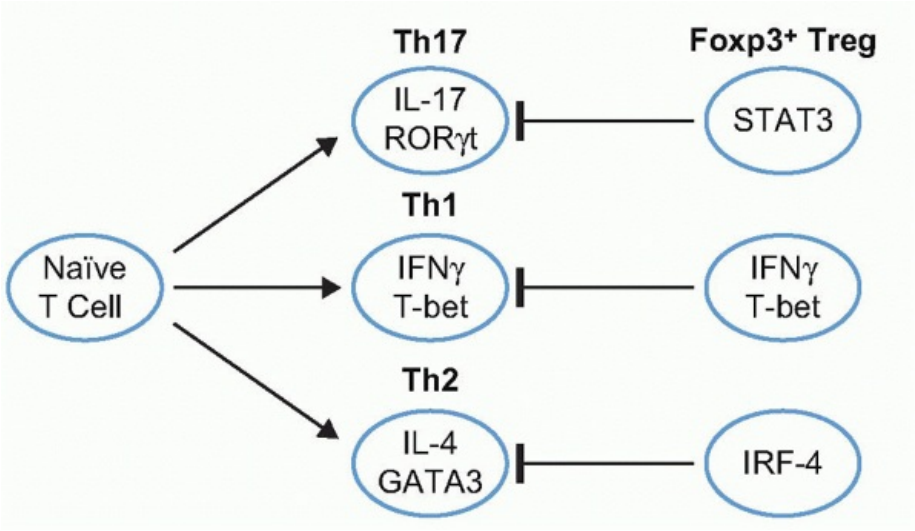

FIG. 33.14. Specialization of Regulatory T Cell Function. Adapted from Zheng et al.,[236] Koch et al.,[235] and Chaudry et al.[237]

While T-bet is the master transcription factor controlling Th1 responses, it is also expressed by a subset of Treg cells and is required for Treg cell homeostasis and function during polarized Th1 responses. While IFNγ can inhibits the peripheral generation of Foxp3+ Treg cells from naïve CD4+ T cells,[102] IFNγ signaling through STAT1 activation drives T-bet expression in Treg cells resulting in control of Th1-type immune responses. IFNγ may thus limit the magnitude and duration of Th1-type inflammatory responses. T-bet+ Treg accumulate at sites of Th1 inflammation and T-bet-/- Treg cells display impaired proliferation during Th1-type inflammation and do not control the expansion of IFNγ-producing Th1 cells when transferred into scurfy mice.[236] The failure of T-bet-/- Treg cells to control Th1-driven inflammatory responses may result from their inability to survive and proliferate in a highly polarized Th1-type environment.

Lastly, conditional deletion of STAT3 in Treg cells results in the selective dysregulation of Th17 responses accompanied by development of a spontaneous fatal intestinal inflammation with elevated levels of IL-17 production.[237] The mechanisms by which T-bet, IRF4, and STAT3 control Treg cell activity during Th1, 2, and 17 responses are still unclear but likely involve control of Treg-cell migration, function, and homeostasis. Selective expression of transcription factors associated with a given Th responses may induce molecular changes needed to restain a particular response. This hypothesis has important implications for the therapeutic uses of Treg cells as it implies that specific subsets of Treg cells may be needed in treating Th1-, Th2-, and Th17- mediated inflammatory diseases.

REGULATORY T CELL PLASTICITY

The studies on Treg specialization have demonstrated the potential benefical effects of T helper cell produced inflammatory cytokines on the ability of Tregs to control pathologic immune responses mediated by those cytokines. Other studies have challenged the notion of a committed Foxp3+ Treg cell lineage and raised the possibility that Treg cells can lose

Foxp3 expression when present in an inflammatory milieu or following transfer to an immunodeficient environment and be “reprogrammed” to become pathogenic T effector cells. For example, during infection with *Toxoplasma gondii*, Treg cells lose Foxp3 expression and become IL-12 responsive. They can then express high levels of T-bet, acquire Th1 effector characteristics, and produce IFNγ contributing to lethality.[238] Furthermore, when Treg cells were cultured under Th17 or Th1 polarizing conditions, a substantial fraction of IL-17+Foxp3+ and INFγ+Foxp3+ T cells were observed.[239] Thus, IL-6 may potentially convert Treg cells into proinflammatory Th17 cells in a proinflammatory environment.[240,241] No evidence of reciprocal conversion of Th17 cells to Treg was observed.

The Treg and Th17 programs of differentiation are clearly linked,[101] and Foxp3 and RORγt transcription factors can interact with one another.[101] Whereas transduction of naïve CD4+ T cells with RORγt induced IL-17 expression, cotransduction with Foxp3 abrogated IL-17-producing capacity when Foxp3 contains its exon 2-encoded domain, which is required for binding to to RORγt. After in vitro induction of RORγt and Foxp3 by TGF-β, cells do not express IL-17 and have the potential to differentiate into either Th17 or Treg depending on the cytokine environment. In the presence of proinflammatory cytokines (IL-6, IL-21, or IL-23) and low concentrations of TGF-β, RORγt expression is further elevated and Foxp3 expression is reduced resulting in Th17 differentiation. Conversely, in the absence of proinflammatory cytokines and high concentrations of TGF-β, Treg induction is promoted. IL-2 suppresses RORγt expression and promotes the induction of Tregs.[242] Runx1 can also form a complex with RORγt to promote Th17 differentiation, but can also interact with Foxp3 to suppress IL-2 and IFNγ production, resulting in enhancement of Treg suppressor function. Functional plasticity in cells that coexpress Runx1 and RORγt may be governed by the ability of Runx1 to cooperate with either transcription factor.[243] Foxp3+ Treg cells in Peyer patches differentiate into Tfh cells that can then participate in germinal center formation and IgA synthesis in the gut.[244]

The potential plasticity of Tregs is supported by epigenetic studies of cytokime gene expression. Wei et al.[245] have performed genome-wide examination of histone modifications and DNA methylation that accompany changes in gene expression in CD4+ T cell subsets. Trimethylation of histone H3 lysine 4 (H3K4me3) is a permissive mark found in the promoters and enhancers of active genes, whereas trimethylation of histone H3 lysine 27 (H3K27me3) is present in broad domains that encompass inactive genes. The epigenetic marks found at the IFNγ, IL-4, and IL-17 genes correlate precisely with Th1, Th2, and Th17 lineages. However, these genes in Tregs were bivalently modified, and this result is consistent with their potential plasticity. These bivalent modifications may allow specific lineage regulator gene loci to be activated under different polarizing conditions thus allowing reprogramming of Tregs into other lineages.

In addition to having permissive epigenetic modification of T effector cytokine genes, Tregs may express GATA3, the canonical Th2 transcription factor. GATA3 is highly expressed in Tregs at barrier sites such as the skin and the gut and is readily expressed in Tregs following TCR activation. Treg intrinsic expression of GATA3 is required for maintenance of high level of Foxp3 expression and promotes Treg accumulation at inflamed sites.[246] Expression of GATA3 was not seen in Tregs expressing T-bet or RORγt. In one study, GATA3 expression by

Tregs was required for Treg accumulation in inflammatory conditions such as GI infection or EAE and GATA3-/-. Tregs failed to control colitis due to impaired accumulation. Another study demonstrated a more profound defect in Treg function in Treg conditional GATA-/- mice, including the development of a generalized inflammatory disorder, decreased expression of Foxp3 and Foxp3 signature genes, and decreased suppressor function in vitro.[247]

Two groups recently generated mice that were engineered to track the fate of Foxp3+ cells in vivo. In these systems, mice expressing the Cre recombinase in Treg cells under control of regulatory elements from the Foxp3 gene, were crossed with mice in which the Cre-mediated recombination removes a stop codon from within a fluorescent protein

encoding a reporter gene that was knocked into the ubiquitously expressed Rosa 26 locus. Thus, in these animals, cells even transiently expressing Foxp3 are permanently marked, and their phenotypic properties can be spatially and temporarily examined. Using this system, Zhou et al.[248] reported that a portion of CD4+Foxp3+ T cells downregulate Foxp3 and acquire the ability to produce effector cytokines such as IFNγ even in the absence of any experimental manipulation. The frequency of these ex-Treg cells was increased in the pancreatic islets of NOD mice, indicating that they may contribute to immune pathology. These studies suggest that highly polarized inflammatory environments can subvert Treg-cell function by converting them to Foxp3- effector T cells. The other study demonstrated that Foxp3 expression by Treg cells is remarkably stable, even in highly inflammatory settings.[249] The discrepancies in these studies may be due to differences in the inflammatory sytems used to examine Treg stability in vivo, or to differences in the way the reporter mice were constructed. Alternatively, Tregs that have lost Foxp3 may not be the product of reprogramming of committed Treg cells, but may represent the products of a minor population of uncommitted cells that transiently express Foxp3.[250] These cells can accumulate by selective expansion and under the appropriate environmental conditons differentiate into Th1, Th2, or Th17 T effector cells.[251]

FOXP3- REGULATORY T CELLS

Thymic-derived Foxp3+ Tregs or Foxp3+ Tregs induced in peripheral sites represent the major populations of Tregs that have been characterized in both normal physiologic studies and in disease models. A number of other Treg populations have been described in both mouse and man, and many of these also appear to exert potent Treg functions in certain defined situations. One important distinction between these induced populations of Tregs and the thymicderived Foxp3+ Tregs is that the TCR of the former are very frequently specific for known antigens, while the antigenspecificity of the Foxp3+ T cells are likely preferentially specific for self-peptide MHC class II.

Th3 Cells

One of the first approaches used for the induction of Tregs was the administration of antigen via the oral route. Oral tolerance takes advantage of the normal physiologic process that is needed to prevent systemic immune responses to ingested proteins. Oral administration of antigen at low doses induces populations of Tregs that secrete suppressor cytokines, while higher antigen doses result in deletion or clonal anergy of autoreactive precursors. Pretreatment with orally administered antigen-induced suppressor populations that inhibited

pathology in a number of different animal models of autoimmunity including EAE, collagen-induced arthritis, and uveitis.[252] Bulk T cells from orally tolerized animals can suppress active immune responses to other antigens in the microenvironment, a phenomenon called antigen-driven bystander suppression. The suppressor cells from orally tolerant mice have been termed Th3 cells and mediate their suppressive effects primarily by secreting TGF-β. A major advance in our understanding of the function of regulatory cells following oral tolerance was the study by Chen et al.,[253] which successfully isolated T-cell clones from the mesenteric lymph nodes of SJL strain mice that had been orally tolerized to myelin basic protein. These clones produced large amounts of TGF-β and varying amounts of IL-4 and IL-10. Most importantly, upon adoptive transfer to normal recipients, they suppressed EAE induced with either myelin basic protein or proteolipid protein. Their in vivo suppressive activity could be neutralized with anti-TGF-β. The selective induction of Tregs via the oral route is thought to be secondary to certain poorly characterized properties of the gut mucosal microenvironment, most likely the type of resident APCs.[254,255]

Although the oral administration of antigen represents a potentially easy way to induce Tregs, progress in this area has been slow because it has been difficult to determine the antigen concentration that is capable of inducing Tregs, but which does not induce deletion. It has also been very difficult to isolate the types of clones described previously in the EAE model in other systems or to identify Treg cells that exclusively produce TGF-β in other models. The therapeutic utility of orally administered antigens in autoimmunity has primarily been demonstrated in pretreatment protocols, and oral administration of antigen was ineffective in treating animals once disease has been initiated. Nevertheless, in animal models, the oral administration of antigen can result in the induction of Foxp3+ antigen-specific Tregs that can modulate immune responses. These Foxp3+ Treg populations can produce TGF-β, but the relationship of the Foxp3+ Tregs to what was formally described as Th3 cells remains unclear.

T Regulatory 1 (Tr1) Cells

One important lesson that can be derived from the experiments on oral tolerance is that the milieu in which T cells are primed is critically important in determining whether regulatory rather than effector T cells will be generated. Decreased expression of costimulatory molecules on APCs or the presence of suppressor cytokines such as IL-10 and TGF-β may generate suppressor T cells rather than effector T cells. The production of these suppressor cytokines by Tregs may lead to the generation or expansion of additional regulatory cells via a positive feedback loop.

One of the first studies demonstrating the potential importance of IL-10 in the generation of Tregs was derived from an analysis[256] of patients with severe combined immunodeficiency (SCID) who received transplants of human leukocyte antigen (HLA)-mismatched hematopoietic stem cells. Complete immunologic reconstitution was achieved in the absence of graft versus host disease. CD4+ T-cell clones reactive with host MHC antigens from these patients produced IL-10, but not IL-2, after antigen-specific stimulation in vitro. It therefore seemed likely that endogenous IL-10 production in the transplanted patients was responsible for maintaining tolerance in vivo. The IL-10 may prevent the activation of host reactive T cells or suppress APC function and cytokine production by host APCs. The high IL-10

production in vivo may reflect a chronic activation of donor T cells and host monocytes.

IL-10 is a cytokine produced by numerous cell types including activated T cells, B cells, mast cells, and macrophages, and primarily acts by inhibiting the maturation and function of APCs. The activation of CD4+ human T cells in the presence of IL-10 renders them nonresponsive or anergic.[257] Activation of human CD8+ T cells with allogeneic APC and IL-10 also results in reduced proliferation and cytotoxicity. T cells rendered anergic by the addition of exogenous IL-10 in an mixed leukocyte reaction (MLR) become unable to respond to a rechallenge with the same antigen. IL-10-iinduced anergy is strictly antigen-specific as treated T cells retain normal proliferative and cytotoxic responses toward other protein antigens and third-party alloantigens.

Collectively, these studies suggest that IL-10 itself is a major factor for the induction of suppressive IL-10-producing T cells. Culture of mouse or human CD4+ T cells with antigen or alloantigen in the presence of IL-10 results in the generation of IL-10-producing T-cell clones. Most of these T-cell clones produce high levels of IL-10 and TGF-β, moderate amounts of IFNγ and IL-5, but no IL-2 or IL-4. CD4+ T cells generated in this manner have been termed T regulatory 1 (Tr1) cells.[258] Tr1 cells proliferate poorly following polyclonal TCR-mediated or antigen-specific activation and do not expand significantly under standard T-cell culture conditions. This low proliferative capacity is due in part to autocrine production of IL-10, as anti-IL-10 mAbs partially restore proliferative responses. The intrinsic low proliferative capacity of Tr1 cells has been a major limitation and has hindered their detailed characterization. The ability to generate human Tr1 cells is enhanced by the addition of IFNα .[259] Tr1 cells can be generated from human cord blood with IFNα alone, as cord blood T cells have the intrinsic ability to produce IL-10. IFNα and IL-10 do not act as general antiproliferative agents, but rather as factors that induce the differentiation of Tr1 cells and inhibit the growth of non-Tr1 cells in the culture.

Tr1 cells do not express Foxp3 and can be generated in the absence of Foxp3+ Tregs. Both human and mouse Tr1 clones suppress immune responses in vitro. Antigeninduced proliferation of naïve CD4+ T cells was dramatically reduced following coculture with activated Tr1 clones that were separated from the responding cells by a trans-well insert. The capacity of either human or mouse Tr1 clones to suppress CD4+ T cell proliferation was reversed by the addition of anti-TGF-β and IL-10 mAbs.[258] Some IL-10-producing Tr1 cells suppress the proliferation of naïve CD4+ T cells by an IL-10-independent, cell contact-dependent mechanism.[260,261] Human Tr1 cell clones also suppress the production of Ig by B cells, as well as the antigen-presenting capacity of monocytes and DCs. Most importantly, it could be shown[258] that mouse Tr1 clones have regulatory effects in vivo and suppress Th1-mediated colitis induced by transfer of $CD45RB^{hi}$ cells into SCID mice. Suppression was only seen if the Tr1 clones were activated by antigen-specific stimulation via their TCR. Because the function of Tr1 cells is mediated by IL-10 and TGF-β, these studies imply that Tr1 clones can suppress active immune responses to unknown antigens in the microenvironment by an antigen-driven bystander suppression mechanism similar to the mechanism proposed for Th3 cells in oral tolerance. Although IL-10 was originally described as a product of mouse Th2 cells, Tr1 clones are also capable of regulating Th2 responses including antigenspecific IgE production.[261] Anti-IL-10R antibodies reversed this inhibitory effect.

An alternate approach to the generation of Tr1 cells in vitro has involved pharmacologic manipulation of the microenvironment during T-cell priming.[262] The immunosuppressive drug 1, 25(OH)2-vitamin D3 (VitD3) acts on APCs and activated T cells. VitD3 inhibits antigen-induced T-cell proliferation, cytokine production, and the maturation of human DCs, leading to inhibition of the expression of CD40/CD80/CD86 expression. Similarly, the glucocorticoid dexamethasone inhibits key transcription factors involved in the regulation of a number of inflammatory cytokine genes. When naïve CD4+ T cells were stimulated through their TCR in the presence of the combination of VitD3 and dexamethasone, the primed T cells produced IL-10, but not IFNγ, IL-4, or IL-5. The IL-10-producing cells developed independently of Th1 (IL-12, IFNγ) and Th2 (IL-4) polarizing cytokines, and addition of these cytokines inhibited the development of the IL-10-producing cells. Although the induction of these Tregs could not be induced by IL-10, endogenous IL-10 production was required because addition of anti-IL-10R antibodies substantially reduced the number of IL-10-producing T cells. The development of the IL-10-producing T cells occurred under conditions where the expression and/or activation of key transcription factors involved in Th1 (T-bet) and Th2 (GATA3) differentiation was minimal, suggesting that the IL-10 producers were completely unrelated to conventional Th1 or Th2 cells. VitD3/dexamethasone-induced Tr1 cells are also capable of inhibiting the induction of Th1-mediated autoimmune disease in vivo. One common theme to emerge from the studies on the in vitro induction of Tr1 cells, either by the addition of IL-10 or of pharmacologic agents, is that both of these modalities are likely to inhibit the maturation and activation of DCs and to generate what has been termed “tolerogenic DCs.”[263] Clinical trials are ongoing to evaluate the potential therapeutic effects of Tr1 cells in the prevention and treatment of GVHD after bone marrow transplantation. The clinical protocol involves the transfer of ex vivo generated Tr1 cells to patients with hematologic cancers treated with hematopoietic stem cell transplantation. Treatment of patients with IL-10-anergized donor T cells has potential to reconstitute immunity, prevent GVHD, while guarding against infection and recurrence of cancer.

The inability to expand Tr1 cells in large quantity has hampered progress in understanding the biology of these cells. The relationships between Tr1 cells that produce IL-10 and Foxp3+ Tregs that also produce IL-10 remain unclear. IL-10 reporter mice have been generated[264] in which expression of IL-10 was replaced with expression of a Thy-1.1 reporter, facilitating identification of cells producing IL-10 spontaneously in vivo. This mouse stably identifies all cells in which IL-10 alleles have been previously activated as well as those

cells actively transcribing IL-10. Foxp3+IL-10- Treg cells were more frequenct in LN and spleen, while Foxp3+IL-10+ Treg cells were more frequent in the lymphoid tissues of the large intestine. In the small intestine and Peyer patches, Foxp3-IL-10+ Treg cells were the most predominant population and had a cytokine profile, proliferative response, and suppressive function typical of Tr1 cells. The Foxp3-IL-10+ population developed from Foxp3- precursors in all tissues and its development was dependent on TGF-β but not IL-10. The presence of these cells in the gut may explain why IL-10-/- mice and mice treated with an anti-IL-10R succumb to intestinal inflammation despite having normal numbers of Foxp3+ cells in the intestines. Thus, IL-10 has a nonredundant function in maintaining immune homeostasis to the diverse intestinal microbiota. The relative contributions of the Foxp3+IL-10+ and Foxp3-IL-10+ producing subsets is still unclear. As the two populations are located in different parts of the intestinal tract, it remains possible that a distinct class of commensal

organisms would preferentially induce both of the subsets.

Recent studies have demonstrated that IL-27, a member of the IL-12 cytokine family consisting of two subunits, p28 and EBI3, is a differentiation factor for the generation of IL-10-producing Tr1 cells.[265,266] IL-27 is secreted by tolerogenic DCs that were conditioned in vitro or in vivo by Foxp3+ Treg cells. These Treg-modified DCs express plasmacytoid-like markers. The addition of IL-27 to naïve T cells induced expansion and differentiation of CD4+ T cells that secreted high levels of IL-10.[267] IL-27-driven Tr1 cells proliferate poorly following TCR-mediated activation and suppress T effector responses through IL-10 production. Granzyme B is also induced by IL-27 during Tr1 differentiation and may mediate suppression of T effector responses by cytolysis. IL-27 also can induce IL-10-producing human Tr1 cells.[268] Signaling via the arylhydrocarbon receptor may modulate Tr1 differentiation. Naïve T cells differentiated in vitro with IL-27 in the presence of the arylhydrocarbon receptor ligand, TCDD, had enhanced secretion of both IL-10 and IL-21.

CD8+ Regulatory T Cells

Most of the early studies on T suppressor cells in the mouse demonstrated that they were confined to the CD8+ subset. Almost all of the recent studies on suppressor/regulatory T cells in mouse or man have focused on CD4+ T cells. Several studies have suggested that potent CD8+ suppressor cells may also exist. Repeated stimulation of human T cells in the MLR resulted in a progressive decrease of the capacity of CD4+ T cells to proliferate when rechallenged with the APCs used for priming. The relative nonresponsiveness of the stimulated CD4+ T cells could be restored by depletion of CD8+CD28-, but not CD8+CD28+, T cells from these cultures. The stimulated CD8+CD28- T-cell population was devoid of cytotoxic activity for either CD4+ T cells or the APCs used for priming. When the CD8+CD28- T cells were added to mixtures of CD4 cells and APCs, they inhibited proliferation,[269] but suppression was only observed when the stimulatory APCs shared at least one HLA class I allele with the original stimulator population. The regulatory effect of the CD8+ suppressors was not restricted either by class I or class II MHC antigens expressed by the responder CD4+ T cells. Suppression mediated by CD8+CD28- T cells required cell-cell contact and was not reversed by antisuppressor cytokine antibodies. Coincubation of the CD8+ suppressors with CD4+ responders had no effect, while coincubation of the CD8+ T cells with the APCs rendered the APCs unable to stimulate CD4+ proliferation. Phenotypic analysis indicated that the CD8+ suppressors blocked the upregulation of costimulatory molecules such as CD80/CD86, CD54, and CD58 on the APCs.[270] The mechanism by which the CD8+ suppressors deactivate APC functions has been shown to involve upregulation of the genes encoding Ig-like transcript 3 (ILT3) and ILT4.[271] These inhibitory receptors are structurally and functionally related to killer cell inhibitory receptors. Thus far, the biologic activity of these CD8+CD28- suppressor populations has only been studied in vitro. Their potential roles in mediating immunosuppression in vivo as well as their relationship to CD4+ suppressor cells remain to be explored. It has been proposed that antigen-specific MHC class I restricted CD8+CD28- Tregs first induce ILT-expressing tolerogenic DC, which in turn generate CD4+ Tregs.[272]

Regulatory CD8+ T cells have also been generated in vitro by stimulation with unique

subpopulations of DCs.[273] When naïve CD8+ T cells were stimulated in vitro with CD40L-activated monocyte-derived DCs (DC1), the primed CD8+ T cells proliferated when restimulated with allogeneic target cells, secreted large amounts of IFNγ, and had potent cytotoxic activity. In contrast, when naïve CD8+ T cells were stimulated with CD40L-activated plasmacytoid DCs (DC2), the primed CD8+ T cells proliferated poorly, displayed weak cytotoxic activity, and secreted primarily IL-10. DC2-primed CD8+ T cells inhibited the ability of naïve CD8+ T cells to proliferate to allogeneic monocytes, immature DCs, or mature DCs. Both the generation of CD8+ suppressor cells and their suppressor function could be markedly inhibited by anti-IL-10, but not by anti-TGF-β. Dhodapkar et al.[274] have measured the ability of immature DC cells to modulate the immune response in vivo in humans. Injection of immature DC pulsed with influenza matrix peptide resulted in an expansion of antigen-specific tetramer binding CD8+ T cells. These CD8+ cells were capable of proliferating when stimulated with antigen in vitro, but were defective in IFNγ secretion and lacked cytotoxic function. These findings indicate that immature DC can dampen preexisting antigen-specific effector function in man. The potential suppressive function of the CD8+ T cells that responded to the iDCs was not studied. The relationship of these CD8+ T cells to those induced in vitro with DC2 cells is unknown. Wei et al.[275] have isolated plasmacytoid DCs from malignant ascites of patients with ovarian cancer. These DCs, upon CD40L activation, could induce antigen-specific CD8+ IL-10-producing Tregs that suppressed the responses of tumor antigen-specific CD4+ T cells. A unique subpopulation of mouse CD8+ T cells that express high levels of the IL-2R β-chain (CD122) has been shown to have immunoregulatory activity.[276] CD8+CD122- are Foxp3- and inhibit the activation of both CD8+ and CD4+ T cells in vitro by an IL-10-dependent mechanism as CD8+CD122+ T

cells from IL-10-/- could not suppress T-cell activation in vitro, but may exert some suppressive effects in vivo.[277]

Qa-1 Restricted CD8+ Regulatory T Cells

Mice genetically deficient or depleted of CD8+ T cells have demonstrated a clear role for CD8+ T cells in regulating EAE. CD8+ T cells from mice that had recovered from EAE downregulated or killed some CD4+ neuroantigen-specific T-cell clones. Inhibition was blocked by antibodies to the MHC class Ib molecule Qa-1, but not by anti-MHC class Ia molecules.[278] It has been proposed that Qa-1 self-peptide complexes expressed by activated CD4+ T cells trigger the TCR on CD8+ cells. These CD8+ T cells then differentiate into suppressor cells that in turn suppress the CD4+ T cells that express the same Qa-1 self-peptide complex. The CD8+ Treg population can target a peptide from the conserved region of the TCR.[279] The mechanism of suppression has not been fully defined, although it may involve cytotoxicity or the secretion of suppressor cytokines. Human CD8+ T cells restricted by HLA-E, the human homologue of mouse Qa-1, may have similar functions.[280]

Double Negative Regulatory T Cells

The majority of T cells in normal mice and humans that express the TCR-αβ chains also express either the CD4 or CD8 coreceptor molecules. However, 1% to 5% of the peripheral TCR-αβ population express CD3 but not CD4 or CD8. Double negative (DN) T cells can be

divided into NKT cells and NK-marker negative DN Tregs. DN Tregs do not develop from CD8+ precursors, nor is CD8 expression required for their development in vivo.[281] Functional DN Tregs develop outside of the thymus and may mature from chronically activated CD4+ T cells. DN T cells have been shown to have immunoregulatory activity both in vivo and in vitro in both mouse and man.[282,283] DN Tregs have the ability to acquire alloantigens from APCs and present them to alloreactive syngenic effector T cells in human in vitro studies. DN suppressors generated in this way kill alloreactive CD4+ and CD8+ T responders that express functional Fas by a mechanism involving Fas/Fas-L interactions. These activated DN cells were only able to kill syngeneic targets activated by the same alloantigenic stimulus. A significant difference was noted between the mean percentages of DN Tregs in patients who developed GVHD after stem cell transplantation when compared to those that did not. All patients in whom DN Tregs were expanded to > 1% did not develop GVHD, suggesting that the expansion of these cells may prevent the development of GVHD.[284]

Regulatory T Cell-Induced Regulatory T Cells—Infectious Tolerance

One possible mechanism to increase the efficiency of Foxp3+ Tregs is that Tregs induce anergy or suppressor activity in the Foxp3- responders as a form of infectious immunologic tolerance. It has been shown that human CD4+CD25+ T cells induce CD4+CD25- T cells to become Tregs that are capable suppressing by producing IL-10[285] or TGF-β,[286] thereby mediating suppression of naïve CD4+ T cells. Similar studies in the mouse demonstrated that coculture of Tregs with Foxp3- responder cells resulted in the induction of both TCR and IL-2 unresponsiveness in the responder population.[287] The responder cells remained Foxp3- and exerted suppressor activity in a cell contact-dependent manner that was partially abrogated by anti-TGF-β.

One problem with these early studies is that it was difficult to determine if the regulatory populations induced by coculture with presumably Foxp3+ T cells actually were induced to express Foxp3. Recent studies have demonstrated that activation of Foxp3- T cells in the presence of activated Foxp3+ T cells resulted in the induction of Foxp3 expression in the Foxp3- population.[288] The induction of Foxp3 expression was mediated by TGF-β produced by the Foxp3+ inducer population in a contact-dependent fashion. The newly induced Foxp3+ T cells mediated suppression both in vivo and in vitro. Foxp3+ T cells have also been shown to mediate infectious tolerance locally at the site of a transplanted skin allograft. The induced cells were suppressive and prevented potential efectors from rejecting grafts.[289]

REGULATORY T CELLS AND DISEASE

Animal Models of Autoimmune Disease

One of the most widely used experimental models for the study of Treg function is the animal model of IBD. Transfer of CD4+CD45RB^{high} cells to SCID mouse recipients resulted in the development of a wasting disease and colitis 6 to 8 weeks after T-cell transfer. This disease was characterized pathologically by epithelial cell hyperplasia, goblet cell depletion, and transmural inflammation.[290] There was a 20- to 30-fold accumulation of Th1 cells in the intestine compared to normal mice. Treatment of recipients with anti-IFNγ, anti-TNF-α, or anti-

IL-12 inhibited the induction of disease. Transfer of CD45RB^{low} cells did not induce colitis, and cotransfer of RB^{high} and RB^{low} cells prevented the development of colitis. A ratio of 1:8 RB^{low} to RB^{high} was able to prevent disease. When CD45RB^{low} cells were fractionated into CD25+ and CD25- fractions, control of intestinal inflammation was primarily mediated by the CD25+ (Foxp3+) fraction.[27] CD45RB^{low} CD25- cells did exert some suppressive function when transferred at high cell concentrations.

Treatment of recipients of RB^{high} cells with IL-10 inhibited the development of colitis (Table 33.7). This treatment inhibited the accumulation of Th1 cells in the intestine, but did not induce Tregs, as colitis developed when IL-10 administration ceased. Treg isolated from IL-10-/- mice are able to inhibit colitis induced by CD4+CD45RB^{hi} cells, indicating that IL-10 secretion by Tregs is not required. However, control of colitis by CD25-CD45RB^{low} cells was found to be highly dependent on IL-10.[291] In contrast, Treg-mediated suppression of autoimmune gastritis involves a cell contact-dependent mechanism of suppression, and IL-10 and TGF-β are not involved.[292] One reason for this difference is that the pathogenesis of autoimmune gastritis and IBD are quite distinct. Bacteria play a required role in IBD, whereas

autoimmune gastritis can be induced by d3Tx of germ-free mice. It remains possible that suppression of IBD involves both the cell contact-dependent and the cytokine-mediated pathways of suppression. IL-10 is required to first dampen the inflammatory response induced by intestinal bacteria. Once this response is reduced, cell contact-mediated suppression can become operative.

TABLE 33.7 Role of Cytokines in the Pathogenesis and Treatment of Irritable Bowel Disease

Treatment	Effect on Disease
Anti-IFNγ(days 1 + 4)	Substantial protection
Anti-IFNα(days 1 + 4)	No protection
Anti-TNF (weekly)	Protection during treatment only
IL-10	Protection during treatment only
IL-4	No protection
CD4+CD25+ T cells	Complete protection
CD4+CD25+ T cells + anti-IL-4	Complete protection

CD4+CD25+ T cells + anti-IL-10R	Protection with naïve CD45RB^{hi}
CD4+CD25+ T cells + anti-IL-10R	No protection with naïve CD45RB^{low}
CD4+CD25+ T cells + anti-TGF-β	No protection

IFN, interferon; IL, interleukin; TNF, tumor necrosis factor.

(Adapted from references 290 and 291)

One advantage of the IBD model is that CD4+CD25 + CD45RB^{low}(Foxp3+), but not CD4+CD25-CD45RB^{low}, T cells can cure ongoing colitis 4 weeks after transfer of CD4+CD45RB^{high} T cells.[293,294] Tregs proliferate and accumulate in the mesenteric LN and also in the colonic lamina propria. At both sites, the progeny of the Tregs are in direct contact with CD11c+ DCs as well as effector T cells. These findings suggest that regulation of an active immune response by Tregs occurs in the draining LN as well as at the site of inflammation. During the cure of intestinal inflammation, the majority of the Foxp3+ T cells are IL-10-secreting cells. Whereas Foxp3+ cells are present in similar frequencies in both the secondary lymphoid organs and lamina propria of colitic animals, the IL-10-producing cells are selectively enriched in the colonic lamina propria. The gut environment may condition the Tregs to differentiate into IL-10-producing Tregs in the colon. Alternatively, the accumulation of Tregs in the colon may be attributed to the preferential expansion of a minor subset of IL-10 producers contained in the transferred population.

The NOD mouse represents the best experimental model for autoimmune diabetes. It is widely accepted that Foxp3+ Tregs play a critical role in the regulation of disease in this animal model.[295] The islets of Langerhans become rapidly infiltrated with immune cells several weeks prior to the onset of diabetes. Diabetes progression may relate to a subsequent failure in the maintenance of Treg function. Chatenoud et al.[296] have examined whether CD4+CD25+ Tregs play a protective role in the NOD mouse. Young NOD/SCID recipients were injected intravenously with mixtures of splenocytes from NOD mice and Tregs. Tregs from young (6-week-old) prediabetic mice significantly protected against diabetes in this model. Protection could be reversed by treatment of the recipient mice with anti-TGF-β, but not anti-IL-4 or anti-IL-10. Interestingly, anti-TGF-β did not reverse protection mediated by Tregs derived from the thymus. Analysis of Treg function in the NOD mouse is difficult because not all animals will develop disease and it takes a long time for disease to develop. Green et al.[297] have developed a model of insulin-dependent diabetes mellitus (IDDM) in which a regulatable TNF gene is expressed in the pancreatic islets. When these mice were crossed to mice expressing CD80 in their islets and TNF is expressed for 25 days from birth, diabetes is delayed. In contrast, if TNF expression is allowed to continue for 28 days, the regulatory mechanisms are overcome and the animals rapidly develop diabetes. The autoreactive effector cells in this model are exclusively CD8+ T cells. Tregs could be isolated from the islets and draining pancreatic node, but not from other nodes or spleen; they could suppress the development of disease in animals in which TNF was expressed for

28 days. These regulatory cells were extremely potent; protection could be transferred with as few as 2 × 10^3 Tregs. This sitespecific accumulation of regulatory cells may be the result of localized production of chemokines that specifically recruit Tregs to the site of inflammation. Alternatively, the Tregs in the draining node may be antigen-specific and generated in situ by stimulation by islet-derived antigens.

Antigen-specific Tregs from the TCR-transgenic BDC2.5 mice that recognize an islet-derived antigen have been expanded with coimmobilized anti-CD3/anti-CD28 in the presence of IL-2.[298] These expanded Tregs prevented the development of diabetes in NOD mice, survived long-term in vivo, but required antigen exposure for functional activity. Islet autoantigen-specific BDC2.5 Tregs were significantly more effective than polyclonal Tregs in regulating autoimmune responses in vivo. Importantly, expanded BDC2.5 Tregs were able to reverse diabetes, in conjunction with 500 syngeneic NOD islets, when transferred into NOD mice that had been diabetic for 2 weeks. The expanded Tregs were also capable of inhibiting diabetes in newly diagnosed NOD mice.

These results raise the possibility that Tregs might be isolated from patients during remission or soon after disease onset, expanded, and used to treat patients at the time of maximal disease activity to moderate the inflammatory response. Indeed, Masteller et al.[299] were able to expand Tregs with the BDC2.5 specificity by stimulating NOD Tregs with beads coated with a mimitope peptide complexed to MHC class II (I-Ag^7) that is recognized by the BDC2.5 TCR. The expanded Tregs were more efficient than polyclonal Tregs in suppressing autoimmune diabetes. Thus, small numbers of autoantigenspecific Tregs may be clinically efficacious because they can suppress polyclonal pathogenic T-cell responses either by bystander cytokine production or by recruitment of endogenous Tregs while avoiding the pan-immune suppression that might be induced by polyclonal Tregs.

The site of action and mechanisms of action of Tregs have been explored in autoimmune diabetes models.[300] Tregs had

little or no effect on the expansion of effector cells, but suppressed IFNγ production by the effectors in the pancreatic LN and seemed to slow the migration of effector cells into the islets perhaps through a reduction in their expression of CXCR3 in the pancreatic LN. One problem with studies of Treg-mediated protection from autoimmune disease is that they frequently involve transfer into lymphopenic hosts where interpretation of the results may be difficult secondary to stimulation of the effector population that is seen in response to lymphopenia. Foxp3-/- NOD mice have been used to analyze where and how Treg cells exert their control on diabetes under experimental conditions not influenced by homeostatic expansion of effector populations.[301] Tregs did not delay or hinder the activation and expansion of anti-islet T cells in the pancreatic LN nor the timing of their infiltration into the islets, but primarily prevented locally damaging consequences of autoimmune infiltration in the islets. It appears the Tregs primarily impinge on autoimmune diabetes by suppressing destructive T cells inside the islets, more than during the initial activation in the draining LN. Further studies are clearly needed to resolve these conflicting findings as a detailed understanding of the site and mechanism of suppression of experimental autoimmune disease will facilitate translation of the therapeutic use of Tregs for treatment of autoimmune disease in man.

In studies of the relationships between Treg cells and T effector cells in the pancreatic lymph nodes of NOD mice, it was noted that progression to diabetes was associated with an increase in Treg cells in the pancreatic LN at the time of diabetes onset.[302] However, disease progression was associated with a decrease in the percentage of Treg cells in the pancreatic islets with a concomitant loss of CD25 expression and of expression of the antiapoptotic factor, Bcl-2 in the intraislet Tregs. CD4+ T cells from islets produced less IL-2 following stimulation in vitro than did CD4+ T cells from spleen, suggesting that a deficiency in IL-2 production is responsible for the loss of Tregs in the islets. Administration of IL-2 promoted Treg survival and and protected the mice from diabetes. In the NOD mouse model of type I diabetes, the idd3 region on mouse chromosome 3 is associated with a lower production of IL-2, a decreased proportion of Treg cells, and increased susceptibility to disease. The agonistic activity of an IL-2/anti-IL-2 complex was exploited as a therapeutic agent for type 1 diabetes in NOD mice. This complex extends the half-life of IL-2 from 30 months for free IL-2 to 48 to 72 hours for complex IL-2. A low dose of complex increased expression of IL-2Rα and prosurvival factor, Bcl-2, by Treg cells and prevented the onset of diabetes. A high dose of the complex accelerated the progression to type 1 diabetes secondary to the enhancing autoreactive effector T cells that express the high affinity IL-2Rα .[303] Similar results were observed in the animal model of multiple sclerosis and EAE. Pretreatment of mice with the complex modulated disease induction, whereas administration of the complex after disease initiation resulted in a more severe disease course.[304]

EAE is the major animal model for the study of multiple sclerosis; Tregs have been shown to play a role in this model. When the Treg population of naïve C57BL/6 mice was supplemented with CD4+CD25+ Tregs from a normal donor before the active induction of EAE by immunization with an encephalitogenic peptide from myelin oligodendrocyte glycoprotein (MOG), the Tregs conferred significant protection. Protection was associated with the presence of Th2 cytokines and a markedly decreased CD4+ T cell and APC infiltrates in the CNS.[305] These studies suggested that Tregs might inhibit the homing of pathogenic T cells to the CNS. McGeachy et al.[306] demonstrated that that the accumulation of CD25+Foxp3+ cells in the CNS correlated with the recovery phase of EAE. As few as 104 CNS-derived CD25+ cells significantly reduced disease severity in recipients, whereas the same number of naïve CD25+ T cells had no effect. Although the mechanism of action of the Tregs in protection from EAE was not completely elucidated, CD25+ T cells were the major source of IL-10 in the CNS and IL-10 production was crucial for full recovery from EAE. Using tetramers, it was shown that MOG-specific Tregs expanded alongside MOG-reactive T effector cells in the draining LN before migration to the spleen and accumulation in the CNS. MOG-reactive Tregs in peripheral sites showed suppressive activity against naïve MOG-reactive T cells, whereas Tregs derived from the CNS failed to suppress the in vitro proliferation of CNS-derived T effector cells due to the high levels of inflammatory cytokinies coming from the T effector population. During recovery, there was a dramatic change in the Treg:T effector ratio in the CNS in favor of Tregs.[307]

Tregs suppress the differentiation and function of Th1 and Th2 cells in vitro and in vivo.[308,309] Other studies[310] have shown that freshly isolated Tregs inhibit the IL-4-induced development of Th2 cells, but had no influence on established Th2 cells. In contrast, preactivated Tregs inhibited cytokine production and proliferation of established Th2 cells.

CD4+Foxp3+ Tregs modulate the development of experimentally induced asthma in mice genetically predisposed or comparatively resistant to the development of airway resistance. In vivo depletion of Tregs in resistant animals before initial antigen contact increased airway hypersensitivity reaction, airway eosinophilia, and IgE synthesis, and was associated with Th2 cytokine production, while Treg-cell depletion had no effect on allergen-driven airway hypersensitivity reaction in susceptible mice.[311] Enhancement of the allergic phenotype in resistant mice was associated with stimulation of DC function, suggesting that the Tregs do not act on effector T cells, but act indirectly via the DC. Th2 polarized CD4+ T cells depleted of CD25+ cells induce increased airway eosinophilia after adoptive transfer.[312] Allergen-specific CD4+CD25+ T cells from TCR transgenic mice inhibited the classical pathology associated with allergic asthma including airway hypersensitivity reaction, lung eosinophilia, and Th2 cytokine production in immunocompetent mice. Their effects were dependent on IL-10, but Treg cells exerted their suppressive effects in vivo independently of their capacity to produce IL-10, by inducing IL-10 production from recipient CD4+ T cells.

Mice with an established helminth infection are less prone to allergic airway inflammation as measured by the inflammatory infiltrate in bronchial lavage fluid or peribronchial and perivascular inflammation. Helminth infection with *Heligmosomoides polygyrus* protects from allergic airway

responses by acting downstream from allergen sensitization and can be transferred from infected mice to uninfected presensitized animals by CD25+ T cells. Th2 effector cytokines (IL-5 and IL-13) were diminished, but allergen-specific IgE was not changed. Thus, chronic parasite infection may maintain a high level of activation in Tregs so that they primarily target the effector mechanisms resulting in decreased inflammation in a previously sensitized allergy-prone host.[313]

Immune Homeostasis

Lymphocyte numbers in a normal adult animal remain stable throughout life. A homeostatic equilibrium exists between the numbers of newly produced cells, self-renewal of peripheral T cells, and the numbers of dying cells. The mechanism that controls the number of peripheral lymphocytes is unknown. The regulation of the numbers of naïve and memory CD4+ and CD8+ T cells is independently controlled. Most studies of the effects of Tregs in vivo in the suppression of autoimmune disease involve the transfer of the effector populations to a T cell-deficient mouse. T-lymphocytes undergo a rapid, vigorous proliferative response when transferred to an immunodeficient recipient. We assume that some of the inhibitory effects of Tregs in autoimmunity are related to their ability to be specifically activated by autoantigens. An alternative possibility is that a major component of Treg function is to nonspecifically inhibit lymphopenia-induced proliferation[314] and thereby prevent the development of autoimmune disease. CD4+Foxp3+ T cells might be potent inhibitors of lymphopenia-induced proliferation, but any T-cell population with an activated effector/memory phenotype might also be capable of mediating inhibition.[315]

Surprisingly, both CD4+CD25- (including RBhigh cells) T cells and CD4+CD25+ T cells were capable of proliferating in a lymphopenic host with proliferation beginning on days 3 to 4 posttransfer and reaching as many as eight divisions by days 21 to 28 after transfer.

CD4+CD25+ T cells did not inhibit this early phase of “homeostatic proliferation” of CD4+CD25- T cells.[316] Although CD4+CD25+ T cells have been shown to inhibit the accumulation of CD25- T cells 2 to 6 months after transfer to a RAG-/- recipient by an IL-10-dependent mechanism, this result must be interpreted with caution.[317,318] The fact that CD25- T cells almost always induce some form of organ-specific autoimmune disease demonstrates that CD25- T cells have undergone some form of autoantigen-specific proliferation in addition to the lymphopenia-induced proliferation. As described previously, CD4+Foxp3+ T cells are highly efficient inhibitors of the induction of these autoimmune diseases. It should be noted that transfer of CD25+Foxp3+ T cells to immunodeficient mice results in loss of expression of CD25 by a majority of the transferred cells.[123] The significance of this finding is unknown as the recovered CD25- T cells retain the ability to suppress T-cell activation in vitro.

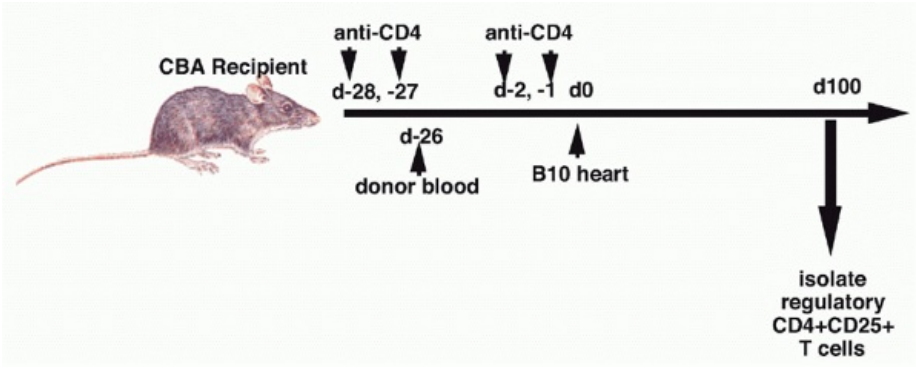

FIG. 33.15. Induction of Regulatory T Cells for Tolerance to Alloantigens. Adapted from Hara et al.[320]

Allograft Rejection and Graft-versus-Host Disease

A considerable body of data exists that regulatory/suppressor T cells exist in patients and animals with long-term surviving allografts.[319] Analysis of the properties of these cells in vitro has been hampered because bulk populations of T cells from tolerant recipients proliferate normally when cultured in vitro with donor alloantigens and frequently secrete a proinflammatory Th1 pattern of cytokines. It appears that the Tregs are masked by the presence of naïve T cells responding to alloantigens. In animal models, a number of protocols have been used to induce tolerance to allografts (Fig. 33.15). Tolerance to cardiac allografts in mice can be induced by pretreatment with a donor-specific blood transfusion combined with depleting or nondepleting anti-CD4 antibody.320 It is likely that the protective effects of this protocol were mediated by the induction of CD4+ Tregs, as complete depletion of CD4+ T cells fails to induce tolerance. Pretreated mice accepted cardiac grafts, and cells from these mice could transfer tolerance to naïve recipients. CD4+ T cells were responsible for both the induction and maintenance of tolerance.

In studies of allograft rejection across a full H-2 difference, the differential expression of CD45RB has facilitated separation of nontolerant naïve T cells from the induced Treg

cells.[319] RB^{high} cells from tolerant mice responded normally to challenge with alloantigen in vitro and were able to reject allogeneic skin grafts when transferred alone to T cell-deficient mice. In contrast, $CD45RB^{low}$ cells failed to mount a proliferative response, to secrete cytokines in response to alloantigen in vitro, and to induce allograft rejection in vivo. The addition of $CD45RB^{low}$ cells to an MLR with $CD45RB^{high}$ cells as responders resulted in inhibition of proliferation. $CD45RB^{low}$ T cells from long-term tolerant mice were able to suppress responses to alloantigen in vitro only when the donor alloantigens were presented by the indirect pathway of allorecognition by the APCs present in the culture. One explanation for this result is that it is potentially advantageous for the Tregs to respond to alloantigens via the indirect pathway because Tregs may require constant stimulation to maintain their function. Passenger leukocytes rapidly migrate out of the graft and the graft tissues lack costimulatory molecules. Donor-derived allopeptides must be presented by recipient APCs for stimulation of the Tregs in vivo and for the detection of functional activity of these cells in vitro. All of the suppressive activity of the $CD45RB^{low}$ cells was mediated by the CD4+CD25+ T-cell subset contained in that pool. The suppressive capacity of the Treg cells in this model in vitro and in vivo was reversed by anti-IL-10R but not by anti-IL-4. Tregs can also be isolated from mice pretreated with donor alloantigen in combination with depleting anti-CD4 but not transplanted with an allograft.[320]

In studies examining induction of tolerance to minor histocompatibility antigens on allografts following protocols similar to those used previously, both CD4+CD25+ and CD4+CD25- T cells from tolerant mice could mediate suppression but suppression required 10 times more CD4+CD25- T cells.[321] Both populations may have a significant role in maintaining transplantation tolerance as the number of CD25- T cells is 10 times higher than CD25+ T cells in the tolerant mouse. It is possible that some of the CD25- T cells have lost expression of CD25 during the tolerance induction protocol, that effector cell death in the CD25- T cell pool unmasked the presence of Tregs, or that some of the CD25- T cells express Foxp3. In contrast to the results with a major MHC difference, CD4+CD25+ T cells from naïve mice could also prevent naïve T cells from rejecting skin grafts from donors differing at minor loci, although five times more cells were required than from tolerant donors. The enhanced potency of CD25+ T cells from tolerant mice may be secondary to expansion of an alloantigen-specific population. The capacity of T cells from tolerant donors or CD25+ T cells from normal mice to mediate their suppressive function could not be neutralized by anti-CTLA-4, anti-IL-10, or anti-IL-4.

A short treatment of mice with saturating amounts of nondepleting anti-CD4 can induce tolerance to foreign protein antigens and enables long-term survival of minor antigen mismatched skin or MHC mismatched cardiac grafts. The addition of anti-CD40L can extend this effect to full donor-specific tolerance such that second donor grafts are accepted at any later time whereas third-party grafts are rapidly rejected. The maintenance of tolerance is dependent on CD4+ Tregs that can suppress both CD4+ and CD8+ naïve T cells after transfer into secondary recipients. Treg cells are found not only in recipient lymphoid tissue after transplantation but also at the graft site. The localization of Treg cells at more than one site in vivo is important if Tregs are to effectively control aggressive immune reactivity to the graft. In lymphoid tissues, Treg cells might be effective at blocking the initiation of an aggressive response against the graft whereas, at the graft site, they can inhibit the effector

activity of aggressive cells that have escaped regulation and migrated to the graft. Depletion of Tregs resulted in reversal of the tolerant state induced by anti-CD40L and allograft rejection.[322] Mast cells appear to play an important role in this mode of tolerance induction as tolerance induction by the combination of anti-CD40L and infusion of allogeneic cells could not be induced in mast cell-deficient animals.[323]

Regulation observed in therapeutic tolerance probably is maintained both by preexisting Tregs together with induced Tregs. In one model, antigen stimulation in the presence of a nondepleting anti-CD4 has been shown to convert CD4+Foxp3- T cells into Foxp3+ Tregs in a TGF-β dependent manner in vivo; this correlates with lifelong acceptance of the graft.[324] Treg cells that recognize donor MHC I molecules through the indirect pathway of allorecognition have been shown to be responsible for the phenomenon of linked unresponsiveness.[324] Linked suppression in vivo seems to correlate with the in vitro finding that once Tregs are activated, they can suppress the activation of other T cells responding to antigen presented by the same APCs in an antigen-nonspecific manner.

The inability of T-cell populations containing large numbers of CD25+ T cells to mediate GVHD strongly raised the possibility that CD25+ T cells might actually be capable of inhibiting CD25- effectors in cotransfer studies. Freshly isolated CD25+ T cells only modestly inhibited GVHD when mixed with CD25- T cells in equal numbers, while alloantigen-stimulated, cultured CD25+ T cells profoundly inhibited the capacity of CD25- T cells to inhibit rapidly lethal GVHD.[325] In murine models, transplantation of bone marrow into a lethally irradiated host does not cause GVHD; cotransfer of naïve donor T cells (CD4+, CD8+, or both) is required to induce GVHD. Depletion of Tregs from the donor graft accelerated the course of GVHD and increased lethality. Transfer of Tregs with naïve T cells from the donor protected lethally irradiated recipients from GVHD morbidity and decreased GVHD-related mortality[326] across minor and major MHC class I and/or class II barriers in various mouse strain combinations. The effect of Tregs on GVHD is likely to be early and to affect the maturation and expansion of effector cells. $CD62L^{hi}$ Tregs are more potent suppressors of GVHD presumably due to their ability to migrate to secondary LNs where they are primed and activated.[327] As host APCs are necessary to trigger acute GVHD, it is possible that the activated Treg function by downregulating costimulatory molecules and thereby prevent the activation of effector

T cells. Hoffman et al. showed decreased protection from GVHD with Tregs derived from IL-10-/- animals.[328]

The most analogous model to the murine models of GVHD induction is the administration of donor lymphocyte infusions to humans with relapsed leukemia after allogeneic hematopoietic cell transplantation so as to obtain a graftversus-tumor effect. The development of GVHD after donor lymphocyte infusion is associated with tumor clearance. However, Tregs controlling GVHD may also cause suppression of tumor immunity. Edinger and colleagues[329] found that adoptive transfer of donor Tregs effectively decreased the incidence and severity of GVHD without abrogating the graft-versus-tumor response. In this model, cotransfer of Tregs markedly decreased the proliferation of alloreactive effector cells in secondary lymphoid organs by > 90% at day 7 but did not inhibit the activation of the effectors as judged

by activation marker expression and cytokine production. One possibility is that the decrease in the proliferation and expansion of the alloreactive T effector cells was sufficient to control acute GVHD, but this decrease was not complete, and the remaining donor T effector cells were sufficient to effectively mount a graft-versus-tumor effect.

A model has been developed to demonstrate that human Treg cells can inhibit GVHD and graft rejection in vivo in the mouse. When human peripheral blood mononuclear cells are transferred to NOD/*scid*/IL2Rγc^{null} mice, the recipients develop a xeno-GVHD. When autologous expanded human Tregs are cotransferred with the peripheral blood mononuclear cells, marked amelioration of the GVHD is observed.[330] One marker of chronic allograft dysfunction is transplant arteriosclerosis with neointimal thickening of arteries in the allograft. A chimeric human mouse model that resembles transplant arteriosclerosis has been developed in which allogeneic human peripheral blood mononuclear cells elicit rejection of human arterial segments that have been transplanted into a mouse.[331] When human Treg cells that had been expanded in vitro were cotransferred with the peripheral blood mononuclear cells, abrogation of transplant arteriosclerosis was observed.

Tregs also play a facilitating role in bone marrow engraftment. Joffre et al.[332] found that Tregs provided allospecific protection of transplanted bone marrow from host rejection. Enhanced engraftment with Tregs also increased long-term donor chimerism in animals that received Tregs compared to those that received bone marrow transplants only. Recipients of Tregs demonstrated tolerance to host and donor antigens but mounted responses to third-party antigens.[333] Treg therapy has been evaluated for the prevention of GVHD following hematopoietic stem cell transplantation in man.[334,335] One trial was primarily a safety trial of human in vitro expanded Tregs isolated from umbilical cord blood. No serious side effects were observed and some reduction of GVHD was observed. The most comprehensive trial to date was performed by Di Ianni et al.[335] This study involved 28 patients with high-risk hematologic malignancies who underwent HLA-haploidentical stem cell transplantation. No posttransplantation immunosuppression was given, and freshly isolated Tregs were administered without in vitro expansion. The incidence of GVHD was markedly decreased, and the Treg treatment was not associated with an increased risk of leukemia relapse or with a increased incidence of infection with opportunistic pathogens. It is likely that multiple trials of of Treg therapy for the prevention of GVHD in man will be conducted in the future.

Tumor Immunity

Many tumor-associated antigens recognized by autologous tumor-reactive lymphocytes are antigenically normal selfconstituents. Tumor immunity is therefore autoimmunity, and the mechanisms for maintaining immunologic self-tolerance may hinder effective tumor immunity. Studies by North and Bursuker in the early 1980s[336] demonstrated the role of suppressor T cells in the prevention of tumor immunity. The suppressor T cells in these experiments of North and Awwad were shown to be CD4+CD8-, but were not characterized further.[337]. Onizuki et al.[338] were the first to suggest that Foxp3+ T cells played an important role in inhibiting tumor immunity. They first depleted CD4+CD25+ T cells by injecting a depleting anti-CD25 mAb and noted that this led to regression of a number of tumors that grew progressively in nondepleted mice. The depletion had to be performed not later than day 2

after injection of the tumor. Coadministration of anti-CD8 inhibited the tumor regression induced by anti-CD25 depletion, suggesting that CD8 T cells were responsible for tumor regression. Shimizu et al.[171] drew similar conclusions when they transferred CD25-depleted or CD25-containing spleen cells to *nu/nu* recipients and then challenged them with normally nonimmunogenic tumors. In the recipients of CD25-depleted cells, tumors grew but then regressed; in contrast, all recipients of spleen cells containing CD25+ T cells died from rapidly growing tumors. Long-lasting tumor immunity to rechallenge could also be demonstrated in the recipients of the CD25-depleted spleen cells.

Taken together, the studies on depletion of CD4+CD25+ T cells and the transfer of CD4+CD25- T cells strongly suggest that the effectiveness of a tumor vaccine would be greatly enhanced by removal of CD4+CD25+ T-cell suppressor activity. Indeed, Sutmuller et al.[339] were able to demonstrate that antibody-mediated depletion of CD25+ T cells followed by vaccination with a granulocyte macrophage-colony stimulating factor-transfected melanoma cell line resulted in enhanced tumor rejection. Tumor rejection was accompanied by skin depigmentation, suggesting that autoreactive immune responses are involved in this process. Depletion of CD25+ T cells followed by anti-CTLA-4 treatment and vaccination resulted in the most potent antitumor response (Table 33.8). Thus, CD25 depletion and anti-CTLA-4 treatment increase the immunogenicity of a tumor vaccine by distinct mechanisms involving nonredundant pathways. CTLA-4 blockade enhances the induction of antitumor effector cells by removing the normal inhibitory signals generated by CD80/CD86 interactions with CTLA-4.

Experiments with adoptively transferred mouse Treg cells provided a direct link between Treg cells and reduced tumor immunity. Tumor-specific CD8+ T cells were transferred with either Treg cells or conventional T cells into mice bearing B16 melanoma. In mice that received Treg cells, but not

in mice that received CD25- T cells, CD8+ T cell-mediated immunity was abolished. Treg cells may mediate their suppressive effect by inhibiting T-cell priming in lymphoid organs or by reducing the effector function of tumor antigen-specific cells. Antony et al.[340] have shown that transfer of Treg cells reduced the therapeutic efficiency of adoptively transferred tumor antigen-specific effector T cells in a mouse melanoma model. Depletion of intratumoral Treg cells induced potent T-cell tumor immunity and resulted in regression of large established tumors. Administration of anti-GITR antibody protected mice from B16 tumor challenge and induced tumor regression in mice bearing carcinogeninduced sarcomas and colon carcinomas.[341] The anti-GITR likely costimulated T effector functions to make the effector cells resistant to Treg-mediated suppression.

TABLE 33.8 Depletion of CD4+ CD25+ T Cells Augments the Immune Response to a Tumor Vaccine

Treatment	% Surviving d90

None	0
Anti-CD25 (day -4)	20
GM-CSF vaccine (day 0, 3, 6) + anti-CD25 (day -4)	50
GM-CSF vaccine (day 0, 3, 6) + anti-CTLA-4 (day 0, 3, 6)	50
GM-CSF vaccine (day 0, 3, 6) + anti-CD25 (day -4) + anti-CTLA-4 (day 0, 3, 6)	100

CTLA, cytotoxic T-lymphocyte antigen; GM-CSF, granulocyte macrophage-dolony stimulatinf factor.

(Adapted from Sutmuller et al.339)

Although these studies in well-characterized animals models demonstrate the role of CD4+CD25+ T cells in inhibiting tumor rejection, it is often difficult to extrapolate from tumor immunity studies in rodents to humans. Woo et al.[342] have shown that Foxp3+ T cells exist in high proportions (˜33%) in the tumor-infiltrating lymphocytes of patients with nonsmall-cell lung cancer. It is not known if these tumor-infiltrating Foxp3+ T cells are thymic-derived or are generated in the tumor microenvironment from Foxp3- T cells. Foxp3+ Tregs may also be induced at the site of the tumor because of the high concentrations of TGF-β secreted by tumor cells. Nevertheless, these findings suggest that one component of the immune response to tumors in humans is the generation of tumor-specific suppressor T cells. A high frequency of Treg cells has been noted in many other human cancers. Treg cells have been extensively studied in human ovarian cancer.[343] Treg cells within the ovarian tumor microenvironment expressed Foxp3, inhibited tumor antigen-specific CD8+ T-cell cytotoxicity, and contributed to tumor growth in vivo in a human-SCID mouse chimeric model. An accumulation of Treg cells in the tumor predicted a striking reduction in survival.

A number of mechanisms have been proposed for Treg-mediated suppression of tumor immunity. As Tregs express CTLA-4, one possible model is that engagement of CD80/CD86 on tumor APCs may induce production of the immunosuppressive molecule, IDO (see Fig. 33.12). IDO-expressing APCs are found in human tumors and within draining LNs. Alternatively, ovarian tumor-associated macrophages, but not normal macrophages, express B7-H4, a negative regulator of T-cell responses.[344] Treg, but not normal T, cells induced B7-H4 on monocytes, macrophages, and myeloid DCs, and rendered them immunosuppressive.

The spectrum of tumor-specific antigens recognized by Tregs has not yet been defined. In one case, cloned Tregs from a melanoma recognized LAGE-1, a cancer and testis-specific antigen, and suppressed LAGE-1-specific T-cell activation.[345] It is important to identify the ligands for Treg cells to compare them to the ligands for tumor-specific effector cells and to determine whether there are ligands that are exclusively recognized by Treg cells and whether Treg cells recognize mutated tumor antigens. Tregs are able to recognize some

tumor antigens identified serologically by recombinant expression cloning (SEREX). Adoptive transfer of Tregs from mice immunized with SEREX antigens enhanced pulmonary metastasis and accelerated tumor development indicating that acceleration of tumorigenesis and enhancement of metastasis may be secondary to the immunosuppressive effects of Tregs in the immunized hosts.[346] A major concern that remains to be addressed is whether vaccination with certain tumor antigens might promote Treg cell clonal expansion.

The concept of reversing immunosuppression in cancer has merit as a therapeutic approach. CTLA-4 blockade improves tumor immunity but also resulted in severe but treatable autoimmune responses in patients.[347] The mechanistic link between the effects of treatment with anti-CTLA and Treg function remain to be determined. Depletion of Tregs should be beneficial for cancer patients. Denileukin diftitox (Ontak [Eisai, Inc. Woodcliff Lek, NJ]), a ligandtoxin fusion protein, consists of full-length IL-2 fused to the enzymatically active and translocating domains of diptheria toxin. It has been hypothesized that this agent will lead to depletion of Tregs in vivo but it also might deplete CD25+ effector cells. In one trial, patients received a single does of Ontak followed by vaccination with DCs transfected with total tumor ribonucleic acid.[348] Treg cells were eliminated in a dose-dependent manner and Ontak-treated vaccinated patients had an improved tumor-specific effector T-cell response. In other studies, Ontak had variable effects on Foxp3 messenger ribonucleic acid expression in CD4+ T cells in patients with melanoma, and no significant clinical efficacy was observed.[349] Depletion of Tregs to improve tumor immunity should be a major goal in tumor immunotherapy. Thus far, attempts to deplete Tregs in patients with cancer using cyclophosphamide, the anti-CD25 mAb daclizimab, or Ontak have not been successful.[350]

Other models raise the possibility that Tregs may have a beneficial effect in preventing tumorigenesis. A widely used model for human colorectal carcinogenesis is the “multiple intestinal neoplasia” mouse, which has a germline mutation in the *Apc* tumor-suppressor gene.[351] Transfer of Treg cells reduced the multiplicity of epithelial adenomas in these mice by an IL-10-dependent mechanism. Recipients of Tregs showed increased apoptosis and downregulation of cyclooxygenase-2 within

tumors coinciding with tumor regression. In this model, aspirin and cyclooxygenase inhibitors also decreased the risk for colon cancer by inhibiting cyclooxygenase-2. As Tregs can suppress bacterially triggered inflammatory responses in the bowel of mice, the ability of Tregs to traffic and suppress inflammation likely explains their therapeutic efficacy in this model. As inflammatory mediators drive tumor development, Tregs and anti-inflammatory drugs exert their effect by modulating the levels of these molecules.

Immunity to Infectious Agents

Treg cells dampen immune responses in a wide variety of infections caused by bacteria, fungi, parasites, and viruses, especially those that persist in the host. One of the most important roles of Tregs may, in fact, involve modulation of the immune response to infectious agents to prevent the lethal consequences of an overwhelming inflammatory response during the course of a productive immune response to an invading microorganism. Treg and effector cells must maintain equilibrium between no immunity at all and immunopathology. This critical role of Tregs is well illustrated by the immune response of mice to infection with

Pneumocystis carinii (PC). When SCID mice chronically infected with PC are reconstituted with CD4+CD25- T cells, they develop a severe inflammatory response in their lungs that is ultimately fatal. Animals injected with CD25+ T cells alone did not become moribund and only manifested transient weight loss. Cotransfer of CD25+ T cells prevented the development of the PC-driven fatal pulmonary inflammation induced by CD25-T cells but also suppressed the elimination of PC mediated by the CD25- T cells. Protective CD25+ T cells are needed to inhibit the lethal immunopathologic response mediated by the PC-specific CD4+CD25- T cells but they also inhibited complete clearing of the organism.[352] Although Tregs may target CD4+ and CD8+ T cells responding to an infectious challenge, Tregs have also been shown to act on the innate immune system in the response to *Helicobacter hepaticus*.[353]

The role of Foxp3+ T cells in the immune response to infection includes more than suppression of inflammation.[354,355] Foxp3+ T cells also maintain persistence of infection and promote chronicity. The persistence of pathogens following clinical cure is a hallmark of certain viral, bacterial, and parasitic infections. In clinical and experimental forms of leishmaniasis, small numbers of viable organisms persist within lymphoid tissue and within the site of former skin lesions following self-cure or successful chemotherapy. As low numbers of parasites persisting in the dermis can be efficiently transmitted back to their vector sandflies, the expansion and/or recruitment of regulatory T cells to the site of *Leishmania major* infection might reflect a parasite adaptive strategy to maintain its transmission cycle in nature. Despite the absence of sterilizing immunity, these individuals maintain strong lifelong immunity to reinfection, a status similar to the concomitant immunity described in tumor models.[356]

In healed C57BL/6 mice, CD4+CD25+ Treg cells accumulate in sites of *L. major* infection in the skin.[357] These cells are exclusively derived from CD25+ T cells and not from activated CD25- T cells. They suppress the expansion of and killing mediated by *L. major*-specific effector cells. Although IL-10 produced by CD25+ T cells is essential to the establishment of persistent infection, early in the infectious process CD25+ T cells can promote parasite survival and growth in an IL-10-independent manner. Later in the course of infection, IL-10 is absolutely required for development of the chronic lesion as recipients of CD25+ T cells from IL-10-/- mice ultimately healed and completely cleared the parasite from the site. IL-10 produced by Tregs contributes directly to parasite persistence by either modulating APC function, inhibiting cytokine production by Th1 cells, or by rendering macrophages refractory to IFNγ that is needed for intracellular killing.

When rechallenge studies were performed in IL-10-/- mice or in WT mice that were treated during the chronic stage of their primary infection with anti-IL-10R, conditions that result in complete clearance of parasites from the skin and draining LN, reinfection at a site distant from the initial infection resulted in parasite loads that were comparable to those following primary infection in naïve mice. Because healed mice treated with control antibody maintained strong immunity to reinfection, the maintenance of a residual source of infection, secondary to IL-10 production by CD25+ T cells at the lesion site, is required for preservation of acquired immunity to *L. major*. Treg cell lines isolated from chronic *L. major* are able to respond to parasiteinfected DCs by proliferating and producing IL-10.[358] The cells that have undergone proliferation express and maintain Foxp3 expression. It appears that the parasite has specifically evolved to manipulate DCs in a manner that favors and sustains Treg

proliferation. Most importantly, the *L. major*-specific cell lines maintain their suppressive functions in vivo, as transfer of the lines to chronically infected mice results in massive disease reactivation and dissemination.

Th1 effector cells are induced during the course of infection with *Bordetella pertussis* and ultimately play a critical role in the clearance of bacteria from the respiratory tract.[359] Antigen-specific Th1 responses in the lung and local LNs are severely suppressed during the acute phase of infection. *B. pertussis* has evolved a number of strategies to circumvent protective immune responses. One bacterial component, filamentous HA, is capable of inhibiting LPS-driven IL-12 production by macrophages and DCs, and stimulating IL-10 production. Filamentous HA may contribute to the suppressed Th1 responses during acute infection with *B. pertussis* by the induction of T cells with regulatory activity as a result of its interactions with cells of the innate immune system. Repeated stimulation of T cells from the lungs of mice acutely infected with *B. pertussis* resulted in the generation of Tr1 clones specific for filamentous HA. Tr1 cells could only be generated from the lungs of infected animals and not from spleen. These Tr1 cells secreted high levels of IL-10 and inhibited protective immune responses against *B. pertussis* in vivo and in vitro. Suppression was substantially reversed by anti-IL-10 in vivo. The capacity to induce Tr1 cells is thereby exploited by a respiratory pathogen to evade protective immunity and suppress protective Th1 responses at local sites of infection.

Analysis of cytokine production by T cells from patients with chronic hepatitis C virus infection identified antigenspecific regulatory T cells that secreted IL-10 in addition to IFNγ-producing circulating Th1 cells[360]; no IL-4-producing T cells were identified. IL-10-producing cells were detected in a higher proportion of patients with chronic infection than in those who had cleared the virus. Taken together with the studies on *L. major* and *B. pertussis*, these studies on hepatitis C virus strongly support the general concept that many infectious agents have evolved mechanisms for selective activation of either naturally occurring CD25+ T cells or the generation of IL-10-producing Tr1 cells from CD25- T cells. The ultimate result is perpetuation of the chronic infectious state with incomplete clearing of the infection. Depending on the extent of suppression of effector T cells in the host, the consequences of the chronic state may be protective immunity (*L. major*) or continued pathogenmediated organ destruction (hepatitis C virus).

Many viruses such as herpesviruses, hepatitis viruses, and retroviruses evade immunologic destruction during acute infection and establish chronic, persistent infections that may culminate in life-threatening diseases. Friend virus (FV) infection in mice has been used as an experimental model to study retrovirus-induced immunosuppression and may offer insights into our understanding of immunosuppression associated with human immunodeficiency virus (HIV). Mice chronically infected with FV are unable to reject both FV-induced and unrelated immunogenic tumors. CD8+ T cells from acutely infected mice produced perforin, granzyme A, and granzyme B, and display recent evidence of degranulation and in vivo cytotoxicity. Activated T cells from chronically infected mice were deficient in cytolytic molecules and showed little evidence of recent degranulation and in vivo cytotoxicity. CD4+, but not CD8+, T cells from infected mice can transfer suppression to normal mice and can inhibit the generation of CTL in culture.[361] Suppression could be substantially reversed by the addition of anti-CTLA-4, but not anti-IL-10R, to the cultures. FV-induced Tregs suppress CD8+ T cells

in vitro regardless of the TCR specificity of the CD8+ T cells.[362] It is unknown whether the Tregs in chronically infected mice are specific for any viral proteins. Depletion of Foxp3+ T cells early after infection resulted in an increase in virus-specific CD8+ T cells on day 10 postinfection, enhanced production of IFNγ and TNFα, and a 10-fold reduction in viral load.[363]

As HIV infection in man in many respects mimics the animal models of chronic retroviral infections, several studies have begun to examine Treg function as different stages of HIV infection. Kinter et al.[364] found that in the majority of HIV-infected but still healthy individuals, $CD25^{hi}$ Treg cells significantly suppressed cellular proliferation and cytokine production by CD4+ and CD8+ T cells in response to HIV antigens in vitro. Suppression was cell contact-dependent and IL-10- and TGF-β-independent. Patients with strong HIVspecific suppression in vitro had lower levels of viremia and higher CD4/CD8 T-cell ratios than patients who did not have Treg activity. These data suggest that the suppression of CD4+ T-cell activation by Tregs may make HIV replication less favorable as the virus must replicate within the CD4+ T cell itself. Thus, in this chronic infection model, the suppressive functions of Tregs may actually be beneficial to the patient.

The contribution of Tregs has been most clearly shown in responses to chronic infections. Much less is known about the role of Tregs in modulating acute viral infections. In the murine model of herpetic stromal keratitis, depletion of Tregs before infection resulted in lesions of greater severity and permitted the induction of disease with lower infecting doses of virus.[365] Cotransfer of Tregs with CD25- T cells reduced lesion severity and diminished the Ag-specific cytokine response of splenic CD4+ T cells. The mechanism of action of Tregs in this model is not fully elucidated. Tregs inhibit the induction of virus specific CD4+ T cells, but may also modify the expression of homing molecules involved in T-cell migration to the ocular inflammatory site or of pathogenic T cells to extralymphoid inflammatory sites. Tregs can also control the intensity of secondary responses to herpes simplex virus and may also influence the magnitude of immunologic memory.

Pathogen-specific Treg cells have been detected in a few studies using whole pathogen preparations as targets without the identication of specific target epitopes. The role of Treg cells in facilitating the persistence of infections with *Mycobacterium tuberculosis* is unclear. Rigorous depletion of Treg cells during early infection results in enhanced bacterial clearance.[366] Early arrival in the lung of *M. tuberculosis*-specific T cells is associated with enhanced immune control and lower bacterial burdens; Treg cells slow this recruitment process. This result differs from studies of infection with herpesvirus concluded that Treg cells facilitate effector T-cell recruitment to tissue sites of infection.[367] Studies using TCR-transgenic cells specific for an epitope derived from *M. tuberculosis* attempted to identify Tregs specific for the same epitope recognized. Treg cells specific for this epitope were not found.[366] Virus-specific Treg cells have been detected in mice infected with a strain of mouse hepatitis virus. Polyclonal Treg cells from normal mice will decrease weight loss, clinical scores, and demyelination when adoptively transferred into mice infected with this viral strain. Treg cells for two viral epitopes were detected using peptide-MHC class II tetramers 6 to 7 days after infection, at the same time as CD4+ effector T cells. The virus-specific Foxp3+ cells expressed both IFNγ and IL-10 in the CNS after infection and

suppressed T-cell proliferation of cognate epitope-specific CD4+ T cells.[368] IFNγ expression by these cells was maintained during both acute and chronic phases of infection. The identification of Tregs specific for a pathogen-derived epitope is consistent with the view that exposure and immunization may expand not only protective T-cell subsets, but also T-cell subsets that impede protection. Overall protection likely depends on the relative ratio of protective versus suppressive T-cell subsets.

Autoimmune Disease in Man

A large body of data supports the existence of Foxp3+ T cells in humans,[29,30,31,32,33,34,35,36] and the in vitro characterization of human Foxp3+ cells suggests that they are identical to their murine counterparts. Tr1 cells have been readily induced in cultures of human T cells, and a number of studies have

supported the existence of cell populations with Tr1-like properties in humans. Danke et al.[369] have shown that deletion of Tregs in vitro allows marked clonal expansion of autoreactive T cells in vitro. In mice, Foxp3 seems to be a robust marker for thymic-derived and induced Treg cells. However, many human CD4+ T cells transiently express Foxp3 during activation.[370,371,372] It also remains controversial if human T cells that are induced to express Foxp3 by activation in the presence of TGF-β acquire regulatory function.[372] It has recently been shown that culture of naïve human T cells (CD4+CD25-CD45RA+) in the presence of TGF-β and rapamycin[373] or in the presence of TGF-β and RA[374] results in the generation of functional Foxp3+ human Tregs. Nevertheless, it is clear that Foxp3 alone is not a reliable marker for human Treg cells. The combined expression of Foxp3 and low levels of CD127 may be more reliable.

There is currently no clear evidence that a global deficiency in the number of Treg cells is the source of failed regulation in the more common forms of autoimmunity.[375] There may be differences in Treg phenotypes in disease including the numbers of CD4+CD45RA+Foxp3+ and CD4+CD45RA-Foxp3+ Tregs.[376] The peripheral induction of Treg might also be defective in IBD. In fact, increased numbers of Treg cells are frequently observed in the affected tissues of patients with rheumatoid arthritis, IBD, and psoriasis, suggesting that Treg function may be compromised by cell extrinsic factors such as the cytokine milieu or overactive APC function, resulting in resistance to suppression. Several studies in patients with different autoimmune diseases have demonstrated a defect in the function of Tregs, raising the issue as to whether this may be a common denominator in the cause of human autoimmune disease (Table 33.9). In many of these studies, it was definitively shown that the decrease in Treg function was due to defect in the Treg subset rather than secondary to responder T cells that were refractory to suppression. One possibility is that Tregs may have migrated into the target tissue so that blood Treg function is depressed, but Treg function from the target tissue may actually be enhanced. For example, the frequency of $CD25^{hi}$ T cells was much greater in the synovial fluid as compared to the peripheral blood in adult patients with rheumatoid arthritis and such synovial fluid-Treg demonstrated normal suppressive activity in vitro.[384] Functional defects in in the ability of Tregs from rheumatoid arthritis to suppress proliferation were not present but the Treg from rheumatoid arthritis patients appeared to have a selective defect in suppression of IFNγ secretion. This selective

suppression was associated with overexpression of TNFα in the synovial tissues of rheumatoid arthritis subjects, decreased Foxp3 expression, and impaired CTLA-4 expression.[385,386,387] Treatment of patients with rheumatoid arthritis with anti-TNFα restored the capacity of the Tregs to suppress cytokine production. It remains unclear whether the treatment acted directly on Tregs or whether it acted on the pathogenic T effector cells or modified the inflammatory milieu. Appropriate caution should be exercised in interpretation of these studies. As discussed previously, identification of human Foxp3+ Tregs is difficult; many of the studies published thus far have only utilized high levels of CD25 expression to identify human Tregs and did not validate the isolated populations for Foxp3 expression by intracellular staining.

TABLE 33.9 Human Diseases with Abnormal Regulatory T Cell Function

Disease	Reference
Multiple sclerosis	377
Myasthenia gravis	378
Rheumatoid arthritis	385
Autoimmune polyglandular II	379
Lupus erythematosis	380
Psoriasis	381
Type I diabetes	382
Human immunodeficiency virus/acquire immunodeficiency syndrome	383

Enhancement of either the numbers, function, or survival of Tregs represents a goal for the treatment of autoimmune and allergic diseases as well as for inhibition of allograft rejection.[334,335] One might expand either CD4+CD25+ T cells or Tr1 T cells to generate sufficient numbers of cells for infusion back into patients.[388,389] If Foxp3+ Tregs recognize organ-specific antigens and if these antigens can be identified, it may be possible to generate lines or clones of antigen-specific suppressor T cells in vitro that could be used therapeutically. Organ-specific Tregs would home to their target, be activated by their target autoantigen, but mediate bystander suppression, as their effector function would be nonspecific. Alternatively, as a number of factors (eg, IL-6 or the GITR-L) can render effector cells resistant to the suppressor function of Tregs, blocking or neutralizing these factors may enhance Treg function. Ultimately, further studies of the molecular basis of Treg-mediated

suppression should allow the development of mAbs or small molecules[390] that could enhance their suppressor effector function.

CONCLUSION

The hypothesis proposed[3] more than 40 years ago, that a distinct lineage of T cells mediated immune suppression, has been confirmed by major advances only in the last 15 years. The identification of the transcription factor, Foxp3, in 2003 solidified a large body of experimental data.[43,44,45] Yet, numerous critical issues remain to be studied. While Foxp3 is the major factor controlling Treg function, other, as yet uncharacterized, factors upstream of Foxp3 likely play a role in Treg development. Translation of a large body of experimental data on Tregs in animal models to the clinic represents a daunting task. Major questions remain as to the mechanisms used by Tregs to suppress distinct immune responses in different environmental conditions. Until we have a complete understanding of these mechanisms, manipulation of Treg function with small molecules or biologics will present a major challenge.

Chapter 34

The Mucosal Immune System

Yasmine Belkaid

INTRODUCTION

Most antigens encountered by the immune system enter the body through the mucosal surfaces of the respiratory, gastrointestinal (GI), and urogenital tracts, and the vast majority of infectious microorganisms use the mucosae as portals of entry. These sites are, therefore, charged with the formidable task of protecting the host from environmental and pathogenic challenges while preserving vital physiologic tissue functions. The GI tract in particular represents the most reactive and complex immune environment of the host. Along with its constant exposure to food antigen and primary role in acquisition of metabolites, gut mucosal surfaces host complex microbial communities whose combined membership outnumbers host somatic cells. This enormous and highly variable antigenic load presents a significant challenge for the host immune system. When uncontrolled, reactivity against innocuous antigens such as those derived from food and intestinal flora poses a substantial risk that can lead to tissue damage and severe inflammatory disorders. Therefore, multiple highly specialized innate and adaptive immune cell types, as well as structural features, have been put in place to prevent overt reactivity and favor the induction of tolerogenic responses. However, tolerance is not the only fate of the immune response at mucosal sites as a certain degree of constitutive activation and inflammation is beneficial for the host, not only to reinforce the barrier, but also to allow for the development of protective responses when required. Indeed, the majority of infectious diseases worldwide either target or are acquired through mucosal surfaces of the GI, respiratory, and genital tracts. The complex and highly dynamic maintenance of immune tolerance to mucosal antigens concomitantly with the induction of protective responses to pathogens requires an arsenal of unique cells specifically conditioned by the mucosal environment. Some of the main actors in this control are unique antigen-presenting cells (APCs), various regulatory T (T_{reg}) cell populations, intraepithelial lymphocytes (IELs), as well as recently identified innate lymphoid cells (ILCs). Further, the mucosal environment is under dominant control by the microbiota and dietary metabolites that direct the development and function of both innate and adaptive mucosal responses.

MUCOSAL COMPARTMENTALIZATION

The Gut-Associated Lymphoid Tissue

The mucosal immune system of the GI tract contains unique cell subsets that are structured in such a way as to favor the coexistence of the host with its flora, support food absorption,

as well as induction of effector responses to pathogens.[1] The primary barrier preventing transit of microorganisms and large molecules from the environment into the body is a simple epithelium made up of a single layer of cells overlaid with mucus and connected by junctional complexes. The gutassociated lymphoid tissue (GALT) can be divided into effector sites consisting of lymphocytes scattered throughout the epithelium and lamina propria (LP) of the mucosa and organized inductive sites. These inductive sites include the largest lymph node of the body, the mesenteric lymph node (MLN), Peyer patches, as well as cryptopatches and isolated lymphoid follicles (ILFs) that are distributed along the wall of the small and large intestine.[1] ILFs are inducible structures recently described in both mice and humans that develop after birth in response to environmental signals, such as those derived form the microbiota.[2,3,4] Peyer patches are macroscopic lymphoid aggregates consisting of large B-cell follicles with interspersed T-cell areas found in the submucosa along the length of the small intestine. In these structures, the lymphoid areas are separated from the intestinal lumen by a single layer of epithelial cells known as the follicle-associated epithelium and a more diffuse area below the epithelium known as the subepithelial dome. Notably, the follicle-associated epithelium contains unique cells referred to as microfold cells that have the capacity to transport organisms and particles from the gut lumen across the epithelial barrier.[5] These cells also represent a major point of pathogen entry.[5]

Antimicrobial Peptides

A central strategy utilized by the mucosal immune system to maintain its homeostatic relationship with the microbiota and limit pathogen exposure is to minimize contact between luminal microorganisms and the epithelial cell surface. This is accomplished by promoting a physical barrier through the production of mucus, immunoglobulin (Ig)A, and antimicrobial proteins. All intestinal cell lineages, including enterocytes, goblet cells, and Paneth cells, can produce antimicrobial peptides. These molecules play a significant role in the control of pathogenic infections as well as in limiting exposure to the commensal microbiota. Epithelial cell-derived antimicrobial proteins are members of a diverse family including defensins, cathelicidins, and C-type lectins.[6] Some of these molecules, such as α-defensins, are constitutively expressed. In other cases, engagement of pattern recognition receptors (PRRs) by commensally derived products induce the expression of a variety of antimicrobial peptides, which are critical to prevent translocation of gut bacteria across mucosal barriers.[6] These proteins can exert antimicrobial functions by direct killing resulting from enzymatic attack of the bacterial cell wall or by

disrupting the bacterial inner membrane.[6] Additionally, some antimicrobial proteins can function by depriving bacteria of essential heavy metals, such as iron.[7] One of the best characterized mucosal antimicrobial peptides is RegIIIγ. This lectin is expressed soon after birth or following colonization of germfree mice.[8] Production of RegIIIγ is tightly controlled by the flora in an MyD88-dependent manner and has a direct microbicidal effect on gram-positive bacteria.[8,9,10] Similarly, the PRR nucleotide-binding oligomerization domain-containing protein (NOD) 2 controls expression of a subset of α-defensins and cryptdins by Paneth cells.[11] Critically, antimicrobial proteins are retained in the mucus layer and are virtually absent from the luminal content.[12] Such a feature allows antimicrobial activity to be

concentrated within a region bordering the epithelial cell layer. Recent findings demonstrate that the accumulation of RegIIIγ in the mucus contributes to the maintenance of the segregation between the microbiota and the host intestine.[13]

Mucus

The stratified mucus layer plays a crucial role in the maintenance of the physical segregation between the microbiota and host tissue, as well as preventing pathogen invasion and supporting their clearance. In particular, the mucus layer limits commensal and pathogenic bacterial contact with the epithelium preventing transport of bacteria to distal sites.[14] To date,[17] mucus (MUC) genes have been described,[7] of them coding for secreted mucins (MUC2, MUC5A, MUC5B, MUC6, MUCC19, MUC7, and MUC8) that are differentially expressed in various mucosal compartments.[14] The secreted, gel-forming, mucin glycoproteins that constitute the major macromolecular component of mucus are produced by goblet cells found throughout the GI tract and airways. In the airways, both mucus cells and serous cells produce defined mucins.[15] Paneth cells represent another major secretory cell type within the GI tract.[14] Mucus is found in the entire GI tract but varies in thickness ranging from 700 μm in the stomach and large intestine to 150 to 300 μm in the small intestine.[16] The inner layer of the colonic mucus is attached to the epithelium and has a stratified appearance, ranging in thickness from 50 to 100 μm. Based on its structural capacity, this layer acts as a filter and is impermeable to commensal bacteria.[17,18,19] The inner mucus layer is renewed by goblet cell secretion and at its luminal border is converted into an outer mucus layer. This outer layer expands in volume allowing commensal bacteria access to this zone.[18] Contrasting the large intestine, the small intestine is only covered by a single layer of mucus that is not attached to the epithelium and more permeable to bacteria.[16,20] Of note, commensal bacteria have a high proportion of their genome devoted to production of enzymes involved in glycan degradation and are able to utilize the released mucin monosaccharides as energy sources.[21,22]

MUCOSAL ANTIBODIES

About three-quarters of total antibody production is composed of IgA, in the order of 3 to 5 g produced per day in humans, with the vast majority secreted across barrier surfaces.[23,24,25] In contrast, IgG is dominant in urine, bile, genital, and bronchoalveolar secretions; IgD is detected in nasal lacrimal as well as bronchoalveolar secretions,[26,27,28]; and IgE in nasal bronchoalveolar and intestinal secretions in the context of allergy.[29] Human B cells produce two IgA subclasses, IgA1 and IgA2, whereas mice only produce one kind of IgA.[30,31] IgA1 can be detected at systemic and mucosal sites, whereas IgA2 is essentially only present at mucosal sites.[32] IgA can exist in a dimeric form called secretory IgA that is the main Ig found in mucus secretions, including tears, saliva, colostrum, and secretions from the genitourinary tract, GI tract, prostate, and respiratory epithelium.[23,24,25] IgA is a major factor involved in the host-microbe dialogue at mucosal sites. It is critically important for shaping the microbiota, mediating pathogen clearance, neutralizing toxins and inflammatory microbial molecules such as lipopolysaccharides, as well as preventing adhesion of commensal bacteria to the

epithelial surfaces by generating steric hindrance.[30,31] Moreover, it can also induce bacterial agglutination and interact with the mucus layer through secretory component.[33,34,35,36,37,38] One remarkable feature of IgA is its capacity to disseminate between mucosa-associated lymphoid structures. Such a feature allows specificities of IgA present in breast milk to be matched to the dominant microbes resident in the maternal microbiota.[39,40] IgA induction is exquisitely sensitive to the presence of commensal bacteria in the intestine, and germ-free mice have very low levels of IgA that can be restored by commensal colonization.[41,42,43,44]

Immunoglobulin A Generation and Secretion

More than 40 years ago, Peyer patches were identified as the major source of IgA-producing B cells.[16] IgA can also be generated in regional lymph nodes as well as in ILFs.[45] The diffuse tissue of the LP can also support IgA production in the absence of follicular structures.[46,47,48] In order to express IgA, B cells must undergo class switch recombination in which deoxyribonucleic acid (DNA) is spliced out of the heavy chain constant region loci to replace the μ/δ genes with the α gene segment downstream of the recombined VDJ segment. The GC-rich splice sites upstream of the gene segment for each Ig constant region are the targets for enzymes such as activation-induced (cytidine) deaminase (AID), which catalyze the reaction sequence. In humans, there are two Cα regions generating the two IgA isotypes, IgA1 and IgA2.[30,31,32] Following induction in the intestinal lymphoid structures, B cells recirculate through the mesentery, lymphatic systems, and the bloodstream to home back to the intestinal mucosa where they develop into IgA-secreting plasma cells. Secretory IgA is produced as a result of cooperation between plasma cells in the LP that secrete dimeric IgA and epithelial cells that transport IgA into the lumen. This mechanism of transport involves covalent binding of dimeric IgA to the polymeric Ig receptor, which then carries it within vesicles through intestinal epithelial cells to the luminal surface. At this point, IgA is released by proteolytic cleavage of the polymeric Ig receptor leaving a fragment of the transport protein (termed secretory component) that remains associated with the joining chain of the IgA dimer forming a secretory IgA complex with noninflammatory protective functions.[49,50,51] Indeed, secretory IgA can bind to bacteria without activating complement or stimulating the release of inflammatory mediators by innate cells.[52,53]

T-Dependent and -Independent Immunoglobulin A Generation

Mucosal IgA can recognize antigen with high- and lowaffinity binding modes.[54] Generally, high-affinity IgA neutralizes microbial toxins and invasive pathogens whereas low-affinity IgA confines commensals to the lumen.[32] Highaffinity IgA is believed to emerge from follicular B cells stimulated in a T cell-dependent manner, whereas low-affinity IgA can develop from extrafollicular B cells stimulated in a T cell-independent fashion.[55] However, such distinction of origin and function is not absolute.[56] Antigen at mucosal sites can stimulate IgA responses through T cell-dependent pathways that are initiated in mucosal lymphoid structures such as Peyer patches and MLN.[54]

Various mechanisms can promote the induction of IgA in a T cell-independent manner. In particular, transforming growth factor (TGF)-β that is highly enriched at mucosal surfaces controls B-cell responsiveness and promotes class switch recombination to IgA, in combination with interleukin (IL)-2 and IL-10 that act synergistically.[57] Mechanistically, TGF-β1 binds to the TGF-β receptor complex that has a sterile transcript for the Iα locus upstream of the Sα recombination segment. Such a phenomenon is associated with signaling via mothers against decapentaplegic-2, -3, and -4 that bind to the Iα promoter in combination with the runt DNA binding factor RUNX3.[58,59,60,61,62,63,64] A cytokine of the tumor necrosis factor (TNF) ligand family referred to as B cell-activating factor (BAFF) and a proliferation-inducing ligand (APRIL) can also induce NF-κB activation and IgA induction.[65,66] Further, as will be described in more detail later in this chapter, synthesis of the vitamin A metabolite retinoic acid (RA) by GALT dendritic cells (DCs) is crucial for the generation of mucosal IgA.[67,68]

Immunoglobulin A in Host Microbe Interaction

IgA plays a major homeostatic role by controlling host interactions with the microbiota as well as a protective role against pathogens.[6,69] Although nonspecific IgA can limit epithelial invasion, pathogen-specific IgA plays an important role in the control of mucosal infections. For example, IgA production has been shown to control *Shigella flexneri* during infection by binding the bacteria at the mucosal layer,[37] whereas IgA against the O-antigen component of lipopolysaccharides can protect against *Salmonella* infection.[70] IgA can also shape the microbiota composition, as demonstrated in mice lacking IgA that have expansion of segmented filamentous bacteria (SFB) and other *Clostridium*-related species in the intestinal tract.[71] In the context of IgA-microbiota dialogue, IgA responses lack typical memory characteristics and respond rapidly to changes in gut flora composition. This point was demonstrated using reversible colonization of mice with a strain of auxotrophic *Escherichia coli* that required nutrients unavailable from mammalian host metabolites.[72] IgA responses persisted in the absence of bacteria; however, introduction of additional species of bacteria caused a rapid decline in IgA specific for the auxotrophic *E. coli*.[72] As the microbiota composition can fluctuate in the context of infection or due to dietary changes, such a strategy would promote a dynamic IgA repertoire, allowing IgA to swiftly adapt to the commensals present at a given time.[72]

TABLE 34.1 Subsets of Intraepithelial Lymphocytes in Mice and Humans

Subsets		Frequency	T-Cell Receptor Repertoire
Mouse	TCRαβ+CD4+	< 15%	MHC-class II restricted Oligoclonal
	TCRαβCD8αβ	20%-30%	MHC-class II restricted

	TCRαβCD8αβCD8αα		Oligoclonal
	TCRαβCD8αα	20%-50%	Nonclassical MHC class I restricted
	TCRαβCD8-CD4-		Oligoclonal
	TCRγδCD4-CD8-	40%-70%	Nonclassical MHC class I ?
	TCRγδCD8αα		
Human	TCRαβCD8αβ	70%-80%	MHC-class I restricted Oligoclonal
	TCRαβ+CD4+	10%-15%	MHC-class II restricted Oligoclonal
	TCRγδCD4-CD8-	5%-20%	Nonclassical MHC class I ?
	TCRγδCD8+		
	CD3-CD103+	< 10%	

CD, cluster of differentiation; MHC, major histocompatibility complex; TCR, T-cell receptor

INTRAEPITHELIAL LYMPHOCYTES

IELs reside within the epithelial layer and represent a highly heterogeneous group of cells distributed along the GI tract[73] (Table 34.1). IELs represent one of the most abundant T-cell populations, and it has been estimated that 1 IEL is present for every 4 to 10 epithelial cells in the small intestine and 30 to 50 in the large intestine.[74] These cells are important in the induction of both protective and regulatory responses at mucosal sites. They express features of adaptive and innate immune cells that allow them to survey tissue based not only on antigen recognition but also stress signals.[73] IELs can be divided based on their expression of αβ and γδ T-cell receptors (TCRs) and further subdivided on the basis of

their cluster of differentiation (CD)8 expression with a large fraction expressing CD8αα (see Table 34.1).[75]

Homeostasis of Intraepithelial Lymphocytes

In the small intestine, IELs are highly abundant and are essentially composed of TCRαβ+ or TCRγδ+ CD8+ T cells. In contrast, in the large intestine the frequency of IELs is reduced and mostly represented by TCRαβ CD4+ T cells.[74,76,77,78] Although the development and origin of the various IELs is the subject of long debate, all IEL subsets are progeny of bone marrow precursors that initially develop in the thymus.[79] Some IEL precursors go through alternative self-antigen-based thymic maturation processes that lead to the functional maturation of CD4 and CD8αβ double negative, TCRαβ-expressing or TCRγδ-expressing T cells that directly migrate to the intestinal epithelium.[80,81,82] The capacity of IELs to home to the intestinal epithelium is controlled by the expression of CCR9 on the surface of IEL precursors and its ligand CCL25.[83,84] IELs also express the integrin αEβ7 (CD103) that can interact with E-cadherin on epithelial cells.[85] Additionally, the mucosal environment leads to the induction of IELs from conventional TCRαβ+ cells that have matured as antigen-experienced cells in response to cognate antigen.[75] In particular TGF-β, highly enriched in the gut, leads to the development of TCRαβ+CD8αα+ IELs and the coexpression of CD8α in conventional CD4+ T cells.[86] IEL repetoire is polyclonal at birth and in response to exogenous stimuli, including luminal antigens and microbial composition, these cells expand to become oligoclonal in the adult.[87] The development and expansion of IELs is also highly controlled by the cytokine IL-15 and by dietary metabolites. In particular, vitamin D and the arylhydrocarbon receptor, whose ligands are metabolized from the vegetable-derived phytochemical indile-3-carbinol, are required for the proper homeostasis of these cells.[75,88,89] Although mice and human IELs share a number of features, some notable differences exist in terms of their composition and phenotype[90] (see Table 34.1).

Intraepithelial Lymphocyte Functions

IELs have complex functions that include the promotion of local immunity concomitant with the maintenance of barrier integrity. Moreover, a role for IELs in promoting host defense has been revealed in various models of mucosal infection. For instance, TCRαβ+ CD8αβ+ IELs can promote effector responses to a variety of pathogens such as *Eimeria vermiformis*, *Encephalitozoon cuniculi*, and *Toxoplasma gondii*.[91,92,93,94] In the context of bacterial or parasitic infections, IELs can mediate pathogen clearance via their capacity to produce various inflammatory mediators such as interferon (IFN)γ and TNF-α.[95] IELs can also promote immunity to nematodes by releasing cytokines such as IL-13 that can promote mucus formation.[96] Moreover, IELs express various natural killer (NK) receptors, endowing them with a strong cytolytic activity leading to the direct elimination of damaged or infected cells.[75] Additionally, their protective role can result from the capacity of these cells to maintain the integrity of tight junctions between epithelial cells, therefore preventing epithelial transmigration of pathogens.[97] In this regard, IELs have been associated with the maintenance of barrier function in the context of simian immunodeficiency virus (SIV) or human immunodeficiency virus (HIV).[98,99] IELs can also exert regulatory function at mucosal sites. In particular, TCRγδ IELs play a major anti-inflammatory role via their capacity to promote tissue repair upon injury and to release an array of factors with regulatory properties. In particular, γδ T cells produce large amounts of keratinocyte growth factor,

which plays an important role in supporting epithelial integrity.[100,101] Further, these cells can abundantly produce the immunoregulatory cytokines IL-10 and TGF-β that can both limit inflammatory responses at mucosal sites.[102,103,104] In mice, TCRγδ IELs express predominantly Vγ5 and Vγ1, whereas in humans TCRγδ IELs express essentially the Vγ1 gene segment.[38] To date, little is known about the specificity of these cells.

Although the role of IELs is to maintain mucosal homeostasis, various lines of evidence suggest that in defined settings, IELs can also contribute to tissue damage and inflammation. For instance, the number of TCRγδ+ cells correlates with disease severity in inflammatory bowel disease (IBD) patients and, experimentally, these cells have been shown to promote mucosal inflammation.[105,106,107,108] Further, CD8αβ+ IELs can also contribute to the initiation of experimental colitis. More particularly, IELs have been associated with the exacerbation of celiac disease, an inflammatory disorder in genetically susceptible individuals associated with the induction of inflammatory T-cell responses against dietary gluten.[90] Celiac disease is characterized by a dramatic increase of the IEL compartment.[90] TCR-activated CD8αβ+ TCRαβ+ IELs cause severe villous atrophy by targeting intestinal epithelial cells that express stress-induced major histocompatibility complex class I polypeptiderelated sequence antigen in an NKG2D-dependent manner.[109,110] Additionally, IL-15, a factor that is overexpressed in various mucosal disorders including celiac and Crohn diseases,[90] can trigger potent cytotoxic responses by CD8 αβ+ IELs via a NKG2D-DAP10-dependent signaling pathway.[109] Supporting a role for IELs in celiac disease pathogenesis, genome-wide association studies have identified a number of genes involved in the development, migration, and cytotoxic/NK function of IELs.[111]

Mucosal Mononuclear Phagocytes

Immune reactivity against nonpathogenic gut elements is not only wasteful but is also known to lead to severe tissue damage. However, the development of active immunity is required to protect the host against invasive pathogens. This tight equilibrium is under the control of a complex network of mucosal mononuclear phagocytes (MPs) with unique properties (Fig. 34.1). Mucosal MPs form an organized cellular network in the LP and are distributed throughout the GALT.[112] In the LP, major histocompatibility complex II^{hi} $CD11c^{hi}$ MPs can be subdivided into two main populations defined as CD103+CD11b+CX3CR1- and CD103-CD11b+CX3CR1+. Although some debate exists in the

literature, the current consensus is that CD103+ cells are mucosal DCs with capacity to rapidly migrate into lymphoid structures, whereas the CX3CR1+ populations are considered to be tissue resident macrophages.[113] The gut also contains a minor population of CD103+CD11b-CD8α+CX3CR1-DCs believed to be associated with ILFs.[114] Additionally, the gut is home to plasmacytoid DCs.[115] APC subset distribution varies anatomically with CD103+CD11b+ DCs mostly represented in the duodenum and CD103-CD11b+ DCs enriched in the large intestine.[116]

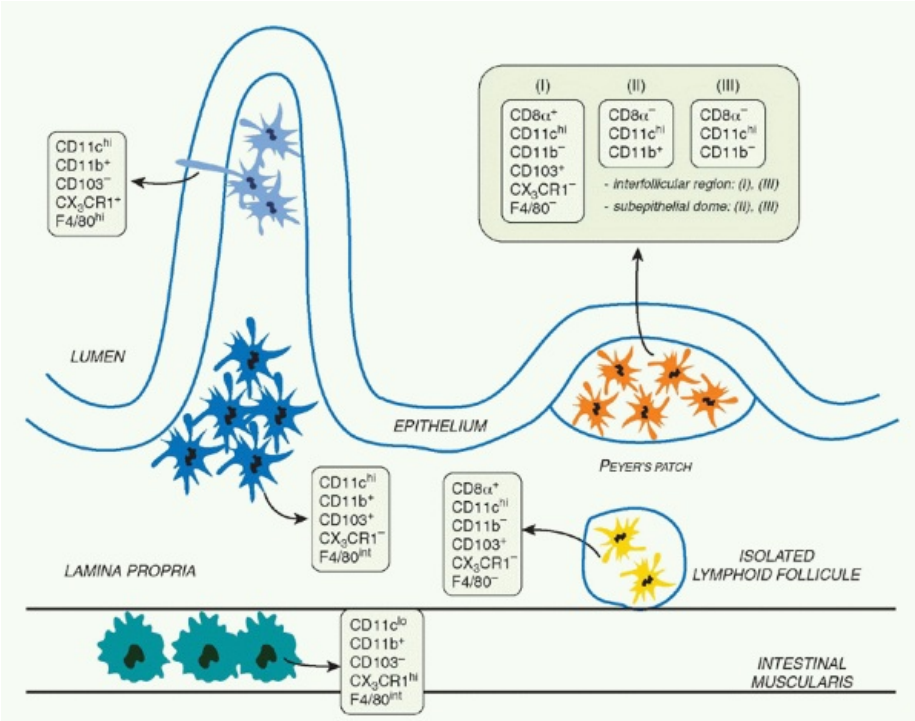

FIG. 34.1. Composition of the Gastrointestinal Mucosal Mononuclear Phagocyte Network.

Origin of Mucosal Mononuclear Phagocytes

In the intestine, DC-restricted progenitors (termed common DC precursors) and pre-DCs give rise to CD103+CD11b+ and CD103+CD11b- populations.[113,117] In contrast, CD103-CD11b+ cells are monocyte derived.[113,117] Various cytokines, including FMS-like tyrosine kinase 3 ligand, granulocyte macrophage-colony stimulating factor, and macrophagecolony stimulating factor, control MP development and homeostasis.[118] In the gut, these cytokines have a differential effect on the various MP subsets. Flt3L controls the differentiation of CD103+ DC (CD11b+ and CD11b-), granulocyte macrophage-colony stimulating factor the differentiation of CD103+CD11b+ DCs, and macrophage colony-stimulating factor receptor (M-CSFR) controls the homeostasis of CD103-CD11b+ cells.[113,117,119] The fractalkine receptor CX3CR1 also controls the development of CD103-CD11b+ CX3CR1+ cells, likely via its capacity to control the recruitment of progenitors to the tissue.[120] A number of transcription factors have been associated with DC lineage specification.[121] In the gut, CD103+CD11b- DCs are highly dependent upon the transcription factors Id2, Irf8, and Batf3, whereas CD103+CD11b+ DCs are Notch2 dependent.[113,122,123,124]

Antigen Uptake and Cell Trafficking

Luminal antigens, including macromolecules, bacteria, and viruses, gain access to the cells of Peyer patches and ILFs through microfold cells, present in the follicle-associated epithelium.[125,126,127] Microfold-cell transport is promiscuous and mediated by binding to surface-expressed carbohydrates in regions free of overlying mucus, but can be enhanced by

the presence of antigen-specific IgA by immune targeting with anti-M-cell antibodies[128,129] or by oral administration of toll-like receptor (TLR)2 or TLR4 ligands.[130] A second site for antigen entry into the intestine is the nonfollicular absorptive epithelium, where both soluble

antigens and bacteria can gain access to DCs in the LP. This can occur by trans- or paracellular transport or by receptormediated trafficking, such as occurs through the neonatal FcR expressed on absorptive epithelial cells in humans.[131] Luminal antigens can also be directly sampled by mucosal DCs. Indeed, subepithelial DCs can penetrate the epithelium monolayer by extending dendrites into the lumen, allowing them to sample particles and bacteria.[132,133,134] In the terminal ileum, this process is tightly dependent on the fractalkine receptor CX3CR1 and controlled by the microbiota in an MyD88-independent manner.[132,133,135] In addition to CX3CR1, CCL20 can also contribute to transepithelial dendrite formation.[133] Luminal antigen can gain access to mucosal sites by direct damage to the epithelium, as can occur during IBD or in response to infection with HIV[136] or *Shigella flexneri*.[137] Antigen sampling may also occur by uptake of exosomes from epithelial cells or across villous microfold cells.[138] Even in the absence of infection or inflammation, LP DCs constitutively traffic to MLN,[139] which appears to be a relatively active process. These migratory DCs can carry self- or cell-associated antigens from apoptotic epithelial cells[140] or soluble proteins given orally.[141] Soluble antigens given orally can be processed by LP DCs, which then migrate to the MLN in a CCR7-dependent manner.[142] Various lines of evidence support the idea that CD103+ DCs have enhanced migratory capacity to lymphoid structures compared to other mucosal MP subsets. Indeed, CD103+ DCs are highly represented in the gut afferent lymphatics,[119] constitutively migrating to the MLN at steady state, and are the first to reach the MLN under inflammatory conditions.[113,119] In response to inflammation, various signals including lipopolysaccharides and flagellin can influence the capacity of mucosal DCs to transport intestinal commensals and pathogenic bacteria to the MLN.[143,144] A remarkable feature of this process is that commensal loaded LP DC migration is restricted to the mucosal immune compartment by the MLN.[143] Such a process is believed to contribute to the compartmentalization of mucosal immune responses. Although as further discussed, mucosal MP can promote the induction of tolerance under steady-state conditions, the function of these cells is highly contextual, and under inflammatory settings mucosal MP can rapidly adopt a highly inflammatory phenotype and induce effector responses.[145]

VITAMIN A AND MUCOSAL IMMUNITY

In the early 20th century, various studies identified dietary constituents that were essential for mammalian health. A single factor present in lipids was essential for growth and survival, which they termed “fat soluble factor A.”[146] Subsequently designated vitamin A, studies over the years have demonstrated the pleiotropic influence of this nutrient, ranging from promoting eyesight and organogenesis to metabolism and immunologic fitness.[147,148,149,150] In particular, the vitamin A metabolite RA plays a central role in the control of various aspects of

innate and adaptive immune responses at mucosal sites.[151,152] The effects of RA in mucosal immunity range from promoting effector cell migration to mucosal tissue and IgA generation, to the control of oral tolerance.[153]

Acquisition, Storage, and Metabolism of Vitamin A

Vitamin A is a fat-soluble essential nutrient obtained from foods containing vitamin A precursors (ie, carotenoids) or vitamin A itself in the form of retinyl esters.[154,155] Following absorption and arrival into circulation, retinyl esters enter the liver, where most of the vitamin A in the body is stored (Fig. 34.2).[156] Liver retinyl esters are continually hydrolyzed into retinol and deployed into circulation.[157] Once inside a cell, widely expressed alcohol dehydrogenases oxidize retinol into retinal, which can then bind to more selectively expressed retinaldehyde dehydrogenases (RALDHs) for oxidation into RA. Prior to its action, RA binds to nuclear receptors, including retinoic acid receptors (RARs) and retinoid X receptors.[158,159] Notably, all-trans RA exclusively binds retinoid X receptors via heterodimers with the RAR family, which consists of three receptors: RAR alpha (RARα), beta (RARβ), and gamma (RARγ).[158] Although RA is constitutively present in serum at low levels,[160] RALDH expression is tightly controlled.[147] GALT DCs express messenger ribonucleic acid for Aldh1a2, the gene encoding RALDH2.[119,161,162] In particular, basal Aldh1a2 expression in GALT DCs is enriched in CD103+ DC subsets.[162,163,164] Vitamin A itself is absolutely required for DC production of Aldh1a2 during homeostasis.[162,165,166] Although dispensable at steady state, microbial stimuli may affect RALDH expression during an inflammatory or infectious response.[167,168,169] In addition to DCs, several nonhematopoietic lineages within the GI tract and GALT, such as epithelia and stromal cells, share the capacity to synthesize RA (see Fig. 34.2).[161,166,170,171,172]

Role of Vitamin A in Migration to Mucosal Sites

Appropriate immune responses depend on the ability of effector and regulatory lymphocytes to home to the site of infection or injury. In this regard, DCs have been shown to foster lymphocyte migration into tissues where antigen was initially encountered.[173] One of the dominant actions of vitamin A on the mucosal immune system is associated with the capacity of its metabolite RA to promote the migration of effector cells to mucosal tissues. In particular, CD103+ DCs from the GI tract and GALT can induce the mucosal homing markers—integrin heterodimer α4β7 and chemokine receptor CCR9—on stimulated effector T and B cells.[163,174,175] The insight that mucosal DCs triggered α4β7 and CCR9 through their capacity to synthesize RA was based on the seminal observation that adding RA to T cells during activation selectively induced these gut homing markers.[161] In a reciprocal fashion, blockade of RAR-mediated signaling and transcription in cultures containing GALT DCs reversed induction of α4β7 and CCR9.[161,176] Recently, RA was revealed to predominantly affect the α4 subunit of α4β7 via binding of RARα to a retinoic acid receptor response element within the regulatory region of the α4 gene.[177,178] An RA response element half-site was also recently discovered in the promoter region of CCR9, which RARα/retinoid X receptor heterodimers were able to bind to.[179] These data together with the prominent

expression of Rarα, the gene encoding RARα, in CD4+ T cells pinpoint RARα as a dominant mediator of CD4+ T-cell trafficking into mucosal sites.

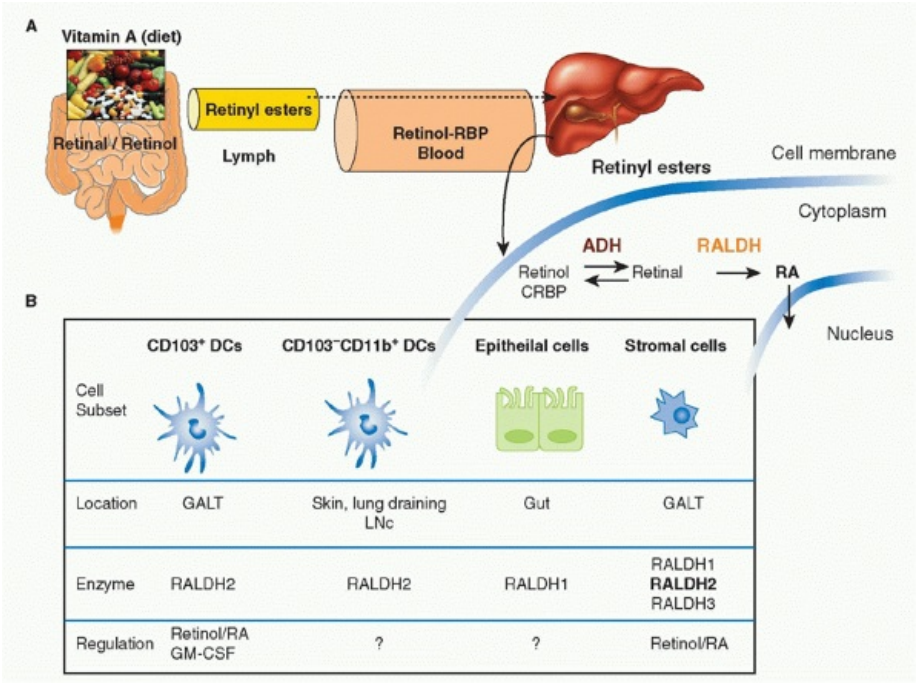

FIG. 34.2. Metabolism and Major Cellular Sources of Retinoic Acid (RA). Dietary vitamin A is absorbed in the intestine and transported through the lymphatics into the circulation where it enters the liver for storage. Retinol chaperoned by retinol binding protein is constitutively deployed from the liver into circulation. It is also secreted in bile that drains into the small intestine. Upon entry into cells, retinol is reversibly oxidized into retinal via the alcohol dehydrogenase enzyme family. Depending on the cell type (see Table 34.1), retinal can undergo irreversible metabolism into RA via retinal dehydrogenases (RALDH). Table 34.1 provides an overview of major cellular sources of RA at steady state including cellular location, the isoform(s) of RALDH that are expressed, and the factors known to induce RALDH expression in each cell type.

Retinoic Acid in Infection and Immunity

Recent human data highlight the correlation between vitamin A status and T-cell function.[180] Impaired and/or dysregulated T-cell responses have been observed in various models of infection and vaccination strategies in the context of vitamin A and retinoid receptor deficiency.[181,182,183,184,185] Experimentally, these results support a role for RA in the development of both Th1- and Th17-cell responses (Fig. 34.3).[181,182,183,184,185] RA signaling appears to control the fate of T-cell immunity largely through RARα and RARγ.[184] In particular RA controls the capacity of CD4+ T cells to respond to antigen by regulating TCR signaling.[184] Further, RARα regulates the maturation of DCs in the GALT[165] and their ability to drive inflammatory responses in certain pathologic settings.[186] These data illustrate

the ability of RA to regulate a network of innate and adaptive immune cell functions that, through nonredundant receptor signaling pathways, support functional immune responses. The discovery that RA served as a critical factor in the generation of IgA-secreting B cells offered further evidence of a multifactorial role for RA in mucosal immunity.[67] A number of studies have demonstrated the potent capacity of DCs from the intestinal LP, MLN, and Peyer patches to drive naïve B-cell differentiation into IgA+ B cells,[68,187,188] and the ability of stromal derived cells to support IgA+ class switching in activated B cells.[189,190] Synthesis of RA by GALT DCs was crucial for the generation of IgA by B cells, as antagonism of RA signaling significantly reduced IgA production.[68,188] Complementing this finding, addition of RA to DC cocultures in which DCs lacked the capacity to synthesize RA restored IgA+ production. Notably, microbial induced cytokines, such as IL-6, were also integral cofactors in this process.[68,188] This was also the case when stromal LP cells or stromal-derived follicular DCs from Peyer patches and MLN were assayed for their ability to foster the generation of IgA+ B cells.[189,190] In a manner analogous to peripheral DCs, peripheral follicular DCs were able to efficiently support IgA+ production only when treated with RA and in the context of Myd88-dependent microbial stimulus. 190 Intriguingly, this gain of function was dependent on the ability of RA signaling to induce secretion of TGF-β in peripheral follicular DCs.[191] RA signaling was shown to promote a similar effect (ie, induction of TGF-β production) in

bone marrow-derived DCs via inhibition of suppressor of cytokine signaling 3 activity.[192] These findings suggest interdependency between TGF-β- and RA-propagated signals in several cell lineages.

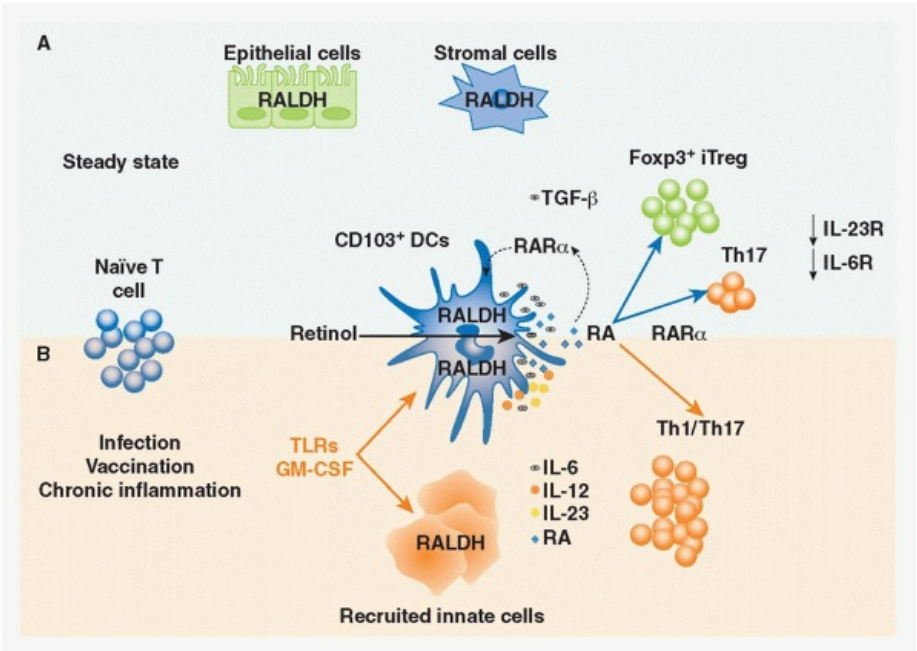

FIG. 34.3. Contextual Role of Retinoic Acid (RA) in Mucosal Immunity. Gut-associated lymphoid tissue is an RA-rich environment containing a large number of RA-synthesizing cells, including resident epithelia (intestinal epithelial cells) and stromal

cells, as well as migratory cluster of differentiation (CD)103+ dendritic cells (DCs). Under steady-state conditions (*top*), RA sustains oral tolerance and helps maintain barrier integrity. These processes are mediated in large part by the ability of RA to support the induction of Foxp3+ inducible regulatory T and Th17 cells. Lamina propria CD103+ DCs induce and recruit heterogeneous CD4+ T-cell populations at steady state as a result of their ability to respond to commensal derived signals and produce both RA and transforming growth factor-β. During inflammation or infection (*bottom*), the inflammatory milieu triggers altered cytokine production by CD103+ DCs, leading to retinoic acid receptor α-dependent effector CD4+ T-cell activation and differentiation. Innate cell populations, including antigen-presenting cells, are recruited during inflammation and also contribute to RA production. Factors in the inflammatory milieu, including toll-like receptor ligands and the cytokine granulocyte macrophage-colony stimulating factor, promote retinaldehyde dehydrogenase activity in CD103+ DCs and potentially in recruited innate cells.

Another significant source of IgA production is B1 B cells, which contribute to homeostatic mucosal integrity and early responses to pathogens. RA was recently shown to be required for the steady-state maintenance of this compartment through direct regulation of NFATc1.[86] Combined with the capacity of RA to generate IgA+ B cells and facilitate their mucosal localization, vitamin A deficiency leads to severe decreases both in intestinal and serum IgA levels.[86,188] Altogether, these findings underscore the importance of RA in IgA responses and humoral immunity.

Resulting from its pleiotropic effects on the mucosal immune system, RA can also, in a context-dependent manner, contribute to mucosal inflammation (see Fig. 34.3). Almost 30 years ago, mice fed a diet high in vitamin A were observed to exhibit more vigorous responses against grafts and tumors.[193,194] These findings suggested that elevated retinoid levels could potentially predispose an individual to exuberant immune responses. In this regard, exposure to RA during inflammation contributed to loss of oral tolerance and reactivity to dietary glutens in a mouse model of celiac disease.[186,195] More specifically, RA was demonstrated to synergize with IL-15 to promote mucosal DC production of IL-12p70, which exacerbated responses to the glutenderived antigen, gliadin.[186] These data resonate with several reports, describing a possible association between pharmacologic retinoid treatment and spontaneous development of IBD, and point to vitamin A metabolic pathways as potential instigators of chronic inflammation.[196,197]

IMMUNE REGULATION

The mucosal environment requires a complex network of immunoregulatory mediators to maintain its integrity at steady state and in the face of infection or inflammation. Because of the extraordinary antigenic pressure at these sites, many mucosal cell types can in a context-dependent manner exert

regulatory activities. Under homeostatic conditions, the coordinated action of these cells results in the induction of regulatory responses toward dietary or commensal derived antigens.

Oral Tolerance

The acquisition of oral tolerance—the active suppression of inflammatory responses against the myriad of antigens derived from food and the microbiota—is a fundamental aspect of the mucosal immune system. Multiple mechanisms are involved in the induction of oral tolerance.[198] Experimentally, oral administration of soluble proteins results in systemic tolerance that prevents the initiation of potentially damaging inflammatory responses upon rechallenge with the antigen in the periphery.[199,200,201] A complex regulatory network, including specialized populations of APCs, lymphocytes, and innate cytokines, controls GI tract homeostasis and converges to favor the induction of regulatory responses toward antigens present at mucosal sites. Early reports suggested that commensals played a role in this process as oral tolerance could not be induced in the absence of gut flora or gut flora-derived signals.[198,202,203,204,205] Over the last few years, various populations of T_{reg} cells have been ascribed a central role in the induction of oral tolerance. CD4+ T_{reg} cells, in particular, play an essential role in maintaining peripheral immune tolerance as well as preventing autoimmunity and chronic inflammation with several subsets described on the basis of their origin, generation, and mechanism of action. In a simplistic manner, these cells can be divided into endogenous T_{reg} cells, represented by thymically derived Foxp3+ T_{reg} cells and inducible T_{reg} cells, such as IL-10-producing T_{reg} cells[206] or inducible Foxp3+ T_{reg} (iT_{reg}) cells.[207,208] Although the precise mechanisms by which these cells coordinate their functions to maintain the delicate balance between immunity and tolerance remain incompletely understood, it can be conceived that collaboration and cross-talk among the aforementioned T_{reg} cell populations is required for the integrated control of mucosal immune responses (Fig. 34.4).

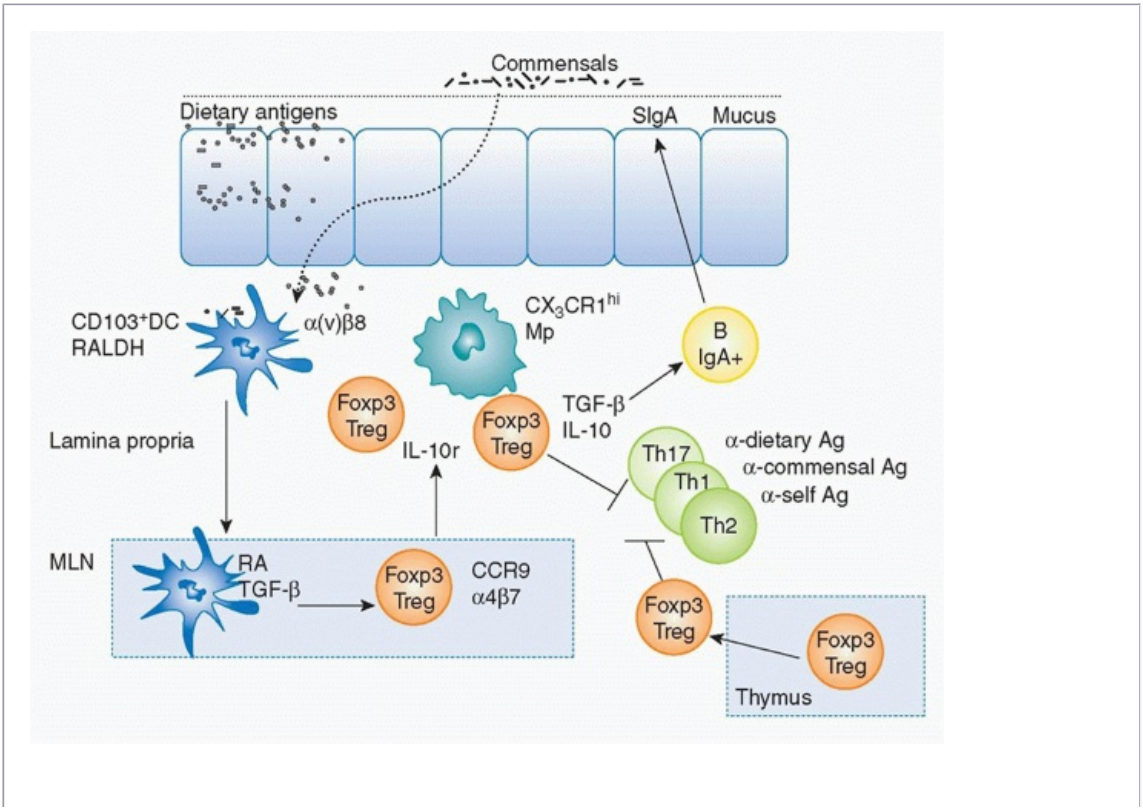

FIG. 34.4. Induction of Foxp3+ Regulatory T (T_{reg}) Cells at Mucosal Sites. Under steady-state conditions, cluster of differentiation (CD)103+ dendritic cells (DCs) uptake directly or indirectly commensals and dietary antigens, and constitutively migrate to the mesenteric lymph node (MLN). In the MLN, based on their capacity to metabolize vitamin A (retinaldehyde dehydrogenase) and produce retinoic acid (RA) and to activate transforming growth factor (TGF)-β (α(v)β8+); CD103+ DCs induce Foxp3+ T_{reg} cells from naïve T cells. Exposure to RA induces gut homing receptor CCR9 and α4β7 that allows the migration of these cells to the gut mucosa. In the gut, Foxp3+ T_{reg}s can be expanded by CX3CR1 macrophages in an interleukin-10-dependent manner. At mucosal sites, inducible T_{reg}s and thymically derived T_{reg}s can limit a range of effector responses directed against dietary or commensal-derived antigens. Further, T_{reg} cells in a TGF-β-dependent manner can also promote immunoglobulin A responses that in turn limit contact with the microbiota.

Thymically Derived Foxp3 Regulatory T Cells

Foxp3-expressing T_{reg} cells were initially described as a unique population of CD4+ T cells that prevent the expansion of self-reactive lymphocytes and subsequent autoimmune disease.[209] Foxp3+ T_{reg} cells maintain both peripheral and mucosal homeostasis throughout the lifespan of the host.[210] These cells are classically defined by their constitutive expression of the IL-2 receptor α-chain (CD25), cytotoxic T-lymphocyte antigen 4, the TNF receptor family member glucocorticoid-induced TNF-receptor-related protein), OX40,[211] CD39, CD73,[212] and high levels of folate receptor.[213] Sustained expression of Foxp3 in T_{reg} cells is critical for maintaining their regulatory function.[214] Several elements and in particular factors downstream of TCR signaling, such as calcium signaling, as well as the NF-κB and Ras-ERK pathways, have been shown to be important for both the induction and sustained expression of Foxp3 expression.[215] For instance, signaling through cooperation of NFAT/Foxp3 complexes and the NF-κb pathway through c-Rel and binding of Runx1-Cbf-β complex to the CNS2 loci in the Foxp3 gene are critical for T_{reg} cell function and sustained Foxp3 expression.[216,217,218,219,220] In addition to these factors, T_{reg} cells are exquisitely dependent on survival factors and in particular IL-2.[221,222,223] Deletion or loss of function mutation in the gene encoding FOXP3 results in fatal inflammatory disease in mice and humans, which is often associated with intestinal inflammation.[224] Indeed, Foxp3 T_{reg}s are highly enriched in the small and large intestine and play a central role in the control of mucosal homeostasis.[224] At these sites, Foxp3+ T_{reg} cells primarily act by controlling harmful

responses against dietary and microbial antigens via their capacity to directly or indirectly control a variety of immune cells including B cells, NK cells, NKT cells, CD4 and CD8+ T cells, as well as monocytes and DCs.[225,226] T_{reg} cells can exert their regulatory function using numerous and highly redundant mechanisms.[226] For example, Foxp3+ T_{reg} cells can

control DC function in a cytotoxic T-lymphocyte antigen 4-dependent manner.[227,228,229] These cells can also produce a variety of immunoregulatory mediators such as adenosine and IL-35.[212,230,231] In some instances, the capacity of Foxp3+ T_{reg}s to control effector responses has been ascribed to their capacity to compete for survival factors such as IL-2.[232] Notably, the cytokine TGF-β also contributes to the suppressive role of T_{reg} cells at mucosal sites. Mice deficient in molecules associated with TGF-β signaling such as Smad3 or Smad4, or in factors required for the cleavage of latent TGF-β, develop mucosal inflammation and colitis.[233,234,235,236] Mucosal T_{reg} cells express large amounts of TGF-β, and this production is required to mediate their regulatory function during experimental colitis.[237] The regulatory role of TGF-β derived from T_{reg}s can be direct, resulting from the capacity of this cytokine to target innate and adaptive cells,[238] as well as indirect. Indeed, TGF-β-dependent stimulation of intestinal IgA responses represents another mechanism by which T_{reg} cells can reinforce intestinal homeostasis.[239]

The cytokine IL-10, and in particular T cell-derived IL-10, plays a nonredundant role in limiting inflammatory responses in the intestine.[240] Mutations in the IL-10 receptor are associated with IBD in humans, and mice deficient in IL-10 or IL-10 receptor develop spontaneous intestinal inflammation.[240,241,242] In particular, the function and maintenance of Foxp3+ T_{reg}s is highly dependent on the presence of this cytokine.[243] The capacity of T_{reg}s to limit mucosal inflammation requires their sustained production of IL-10 at mucosal sites.[244,245,246,247] Further, IL-10 can act directly on Foxp3+ T_{reg} cells to maintain Foxp3 expression and the suppressive capacity of these cells.[243] T_{reg}-derived IL-10 can act on a large array of immune cells, including APCs, by limiting their activation status and capacity to present antigen.[248,249] Further, IL-10-derived T_{reg}s can directly target effector T cells including Th1 and Th17 cells.[250,251]

Regulatory T Cell Plasticity at Mucosal Sites

The capacity of T_{reg} cells to control defined polarized settings can be associated with the acquisition of specific transcription factors. For instance, interferon regulatory factor 4, T-bet, and signal transducer and activator of transcription 3 impact their capacity to control Th2, Th1, and Th17 responses, respectively.[252,253,254] These data support the idea that T_{reg} cells can partially mimic the phenotype of the effector T cells they have to regulate, a property that could endow them with finely tuned homing, survival, or functional properties. However, in some extreme settings, such plasticity can also be associated with the expression of effector cytokines.[255,256,257,258,259] Furthermore, both in humans and mice, T_{reg} cells that reside in the intestine can express RAR-related orphan receptor (ROR)γT, which can be associated with their production of IL-17.[260,261] Importantly, fate-mapping strategies revealed that a significant proportion of IL-17 effector T cells in the gut had expressed Foxp3.[262] To preserve tissue integrity at mucosal sites, mechanisms are in place to sustain T_{reg} cell survival, stability, and plasticity. For instance, in the gut, T_{reg} cells express high levels of the canonical Th2 transcription factor GATA-3 that promotes their

fitness during inflammation and limits their acquisition of effector cytokine production.[263,264]

Induction of Regulatory T Cells at Mucosal Sites

Although immunologic tolerance is likely to be achieved via multiple and redundant mechanisms,[198] over the past few years a role for induced Foxp3 T_{reg} cells has taken center stage in our understanding of this process. Aside from evidence that natural Foxp3+ T_{reg}s arise and mature in the thymus, Foxp3+ T_{reg}s can develop extrathymically under certain conditions. Both naïve murine[207,265] and human T cells express Foxp3 and acquire suppressive activity in vitro following TCR stimulation in the presence of TGF-β.[207,265,266] In vivo, delivery of subimmunogenic doses of antigen as well as endogenous expression of foreign antigens in a lymphopenic environment can also induce peripheral Foxp3+ T_{reg} development.[267,268,269] Notably, the GALT is a preferential site for the peripheral induction of Foxp3+ T_{reg} cells (see Fig. 34.4).[164,208,270,271,272] Mice in which Foxp3+ T_{reg} cells could not be induced failed to establish oral tolerance and develop aberrant Th2 responses at mucosal sites.[269,273,274] Development of iT_{reg} cells requires transcription factor binding to the intronic enhancer element (enhancer-1) of the foxp3 locus, also known as conserved noncoding sequence 1, and is dependent on several soluble mediators, including TGF-β, IL-2, and the vitamin A metabolite RA.[164,184,208,270,275,276,277] In particular, this process is tightly controlled at steady state by the capacity of a specialized population of gut tropic DCs expressing CD103 that activate latent TGF-β and produce RA.[164,208,278] Indeed, CD103+ DCs lacking the TGF-β-activating integrin alpha(v)beta8 fail to induce Foxp3+ T_{reg}s and develop colitis.[279,280,281] Further, because of their high level of RALDH2 expression, CD103+ DCs constitutively produce large amounts of RA.[119,161,162,163,164] RA derived from mucosal DCs serves as a potent cofactor in the generation of iT_{reg} cells in the presence of TGF-β.[164,208,270] In addition to supporting iT_{reg} differentiation, RA-initiated trafficking signals are required for a sustained accumulation of iT_{reg} cells in the gut.[282] Upon arrival at the mucosal site, Foxp3+ T_{reg} cell expansion and therefore proper acquisition of tolerance is propagated through IL-10-mediated interactions with LP resident CX3CR1+ macrophages.[243,278,282]

Foxp3+ T_{reg} conversion may be of particular importance during chronic mucosal infections. It is apparent from mouse models that augmentation of the Foxp3+ T_{reg} compartment is a feature common to a number of chronic infections including helminth infections.[283,284,285,286,287] Foxp3+ T_{reg} can both favor parasite persistence[287] and limit infection-induced immunopathology.[286] A key mechanism by which helminths are thought to regulate the host immune response is through the release of a complex mixture of excreted/secreted products.[288,289,290] Notably, helminth excreted/secreted products contain TGF-β homologues that have the potential to target DC and T cells to support Foxp3+ T_{reg} conversion.[291,292,293]

Immune regulation at mucosal sites is a complex task that requires the coordinated actions of numerous regulatory cells. Indeed, in addition to Foxp3+ T_{reg} cells, the mucosal environment promotes the differentiation of diverse population of T_{reg} cells. For instance, the gut contains a substantial population of CD4+ T cells producing IL-10, referred to as Tr1 cells,[206] that also contribute to the regulation of mucosal responses. Notably, several subsets of DCs with regulatory properties have been described with the capacity to induce IL-10 secretion from T cells or induce oral tolerance under steady-state conditions.[1,294,295,296] Although the precise mechanisms controlling the generation of these cells is not completely understood, various factors have been associated with their induction. For instance, IL-10, IFN-α, and IL-27 as well as inhibitory or costimulatory molecules such as inducible costimulator-L and CD46 can promote Tr1 differentiation.[297,298,299,300] Further, DCs modified by T_{reg} cells can produce IL-27 that in turn can induce the generation of Tr1 cells in a c-MAf-dependent manner.[301,302] Other cytokines produced by CD4+ T cells such as IL-35 have also been associated with mucosal T-cell regulation.[230] The cytokine IL-35 is a recently described heterodimeric cytokine consisting of Epstein-Barr virus-induced gene 3 and the p35 subunit of IL-12.[303] T_{reg}-mediated suppression induces, via the concerted action of IL-10 and IL-35, a population of T_{reg} cells characterized by their production of IL-35, referred to as iTR35. Although human natural T_{reg}s do not express IL-35,[304] human naïve CD4+T cells can be induced to become IL-35-producing T_{reg} cells in the presence of this cytokine or in the presence of virus-exposed DCs.[305]

CONTROL OF BARRIER FUNCTIONS AND MUCOSAL IMMUNITY BY TH17 CELLS

Cytokines of the IL-17 family play a central role in mucosal homeostasis and immunity. In humans and mice, the IL-17 cytokine family consists of six members: IL-17A (also referred to as IL-17), IL-17B, IL-17C, IL-17D, and IL-17E (also referred as IL-25). IL-17A and IL-17F share close sequence homology and can both signal through IL-17 receptor A and IL-17 receptor C expressed on both hematopoietic and nonhematopoietic cells.[306] The cytokine IL-17A is secreted by a subset of CD4+ T cells termed Th17 cells, that can also express the cytokines IL-22, IL-17F, and IL-21.[306] Differentiation of naïve CD4+ T cells into Th17 cells requires TCR recognition of its cognate antigen presented on major histocompatibility complex class II by professional APCs, such as DCs or monocytes. Moreover, Th17-cell differentiation in vivo is driven by the cytokines IL-6 and TGF-β, whereas IL-23 and IL-1β are required for the rapid and sustained activation of these cells.[306,307] Notably, the requirement for IL-6 is specific to mucosal sites and not required for Th17 cell priming in the spleen, whereas IL-1 plays a nonredundant role for priming of Th17 lineage cells in all tissues.[308]

Both Foxp3+ T_{reg}s and Th17 cells are enriched in the gut, and the balance between the two populations is tightly controlled by factors involving the cytokine milieu, the microbiota, and dietary elements.[309] The cytokine TGF-β plays a central role in this balance and in the maintenance of mucosal homeostasis.[309] In addition to the aforementioned role of TGF-β in

promoting T_{reg} cells and oral tolerance, TGF-β is also involved in the generation Th17 cells.[310] The induction of both cell types is highly sensitive to the concentration of TGF-β, with high doses favoring T_{reg} fate and low doses favoring Th17 differentiation.[311] TGF-β can promote this indirectly by suppressing naïve T-cell differentiation into Th1 or Th2 cells. The current understanding is that in the gut, IL-6 in combination with TGF-β leads to the generation of Th17 cells.[265] The transcription factors RORγt and RORα coordinate the differentiation of Th17 cells, whereas signal transducer and activator of transcription 3 (a transcription factor downstream of IL-6 receptor and IL-23 receptor) and the arylhydrocarbon receptor control RORγt expression levels and enhance cytokine secretion.[307,312]

Given the central role of IL-17A and in particular IL-22 in controlling innate barrier responses, these cytokines play a major role in mucosal immunity to microbial challenge and commensal containment[313,314] (see Fig. 34.4). IL-17, in concert with IL-22, which signals through the IL-22 receptor located on nonhematopoietic cells, can induce signal transducer and activator of transcription 3-dependent innate epithelial defense mechanisms.[315] These epithelial responses include a large array of inflammatory cytokines, chemokines, inducible nitric oxide synthase (iNOS), as well as antimicrobial peptides such as RegIIIγ and RegIIIβ, lipocalin-2, and defensins.[310,314,315,316,317] Further, stimulation via IL-17 or IL-22 reinforces tight junctions between enterocytes and enhances epithelial cell proliferation.[315] Indeed, lack of RORγT, IL-17, or IL-22 has been associated with poor containment of commensal bacteria and increased microbial translocation.[314,318] Additionally, via their capacity to act on epithelial cells and modulate inflammatory responses, IL-17 and IL-22 confer protection against a large range of GI pathogens including Helicobacter *pylori*, *Citrobacter rodentium*, and *Salmonella enterica*.[99,316,319,320,321,322,323] Further, *C. rodentium*-induced colitis triggers a robust colonic Th17 response by the second week after infection, which is required for full protection against this pathogen.[317,324] Defects in mucosal integrity have been linked to the pathogenesis of HIV and SIV. During chronic progressive HIV/SIV infection, there is a significant and progressive insult to the intestinal mucosa associated with massive depletion of CD4+ T cells, impaired epithelial structural integrity, and translocation of commensal products.[325,326] Notably, these changes are associated with preferential loss of IL-17- and IL-22-producing CD4+ and CD8+ T cells from mucosal sites, supporting a role for these cytokines in promoting mucosal barrier function during HIV/SIV infections.[327,328,329,330,331] The protective role of IL-17A during infection is also associated with the capacity of this cytokine to induce neutrophil granulopoiesis by stimulating epithelial cells to secrete granulocyte-colony stimulating factor and stimulate the recruitment of neutrophils by local stromal cells.[332] Furthermore, IL-17A and IL-17F can directly activate neutrophil cellular responses at sites of inflammation.[306]

Innate Lymphoid Cells

ILCs represent a novel family of hematopoietic effectors that serve protective or inflammatory roles in innate immune responses. The prototypic members of the ILC family

are NK cells and lymphoid tissue-inducer (LTi) cells that induce the development of lymph

nodes and Peyer patches during fetal life.[333] More recently, the ILC family expanded with the identification of ILC2s also referred as “natural helper” cells, or “nuocytes,” which have been shown to produce IL-5 and IL-13 that are associated with T helper type 2 responses. Additional ILC populations with characteristics of both NK cells and LTi cells have been referred to as NK22 cells, natural cytotoxicity receptor 22 cells, or NK receptorpositive LTi cells. These cells, which are essentially only present in tissue, are characterized by their rapid and abundant production of cytokines. At steady state, the intestinal LP harbors a large number of ILCs and in particular LTi cells, NK22 cells, and ILC2s.[334] Recent evidence demonstrates that these innate cells play a major role in the control of mucosal homeostasis as well as during immune responses.

Origin of Innate Lymphoid Cells

LTi cells arise from common lymphoid progenitors in an IL-7-dependent manner.[335] The inhibitor of DNA binding (Id2), which inhibits E-box proteins and the development of common lymphoid progenitors in B cells, also contributes to the development of LTi cells from common lymphoid progenitors. 336 NK22 cells arise from an α4β7 negative RORγT$_{low}$ precursor, and their final differentiation also depends upon Id2.[337,338] The development of RORγT ILCs depends on the expression of RORγT, whereas the development of ILC2s depends on the expression of RORα.[339,340,341,342] The transcription factors Tox and Runx1 are also required for the generation of LTi cells.[343,344] The arylhydrocarbon receptor is another factor involved in the generation of RORγT ILCs and their production of IL-22.[345,346,347] Notch signaling is additionally required for LTi, NK22 cells, and ILC2 generation.[337,342,345,348]

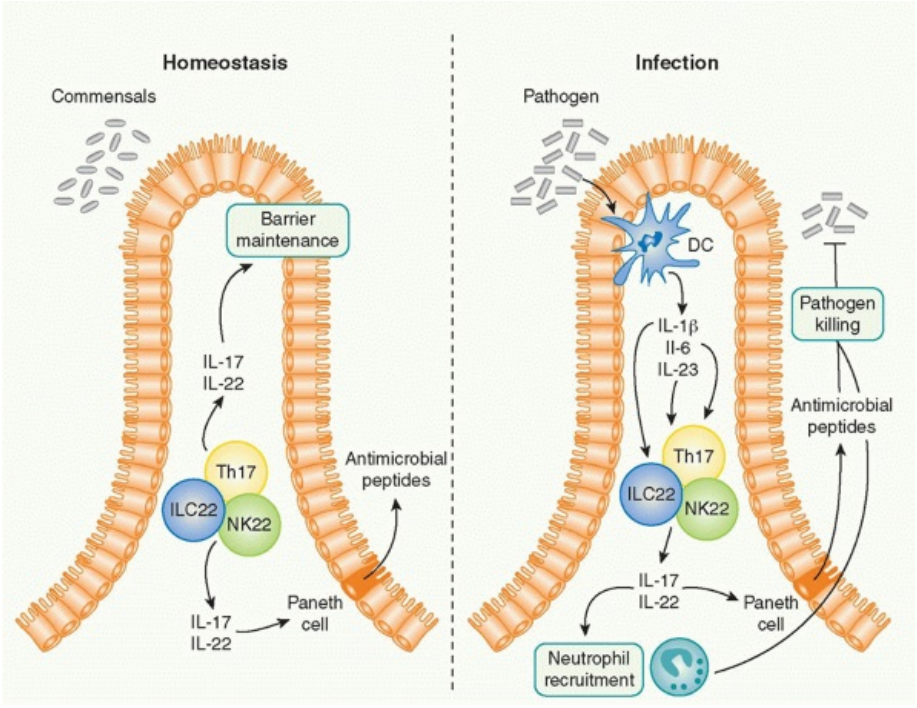

FIG. 34.5. Roles of Innate Lymphoid Cells (ILCs) and Interleukin (IL)-17 Family Members in Mucosal Immunity. Under steady-state conditions, IL-22 and IL-17 from

ILCs and Th17 cells promote commensal containment by promoting barrier integrity and the production of antibacterial peptides. In the context of infections with extracellular or intracellular pathogens, mucosal dendritic cells and recruited cells can release various mediators (transforming growth factor-β, IL-6, IL-23, and IL-1 β) that drive IL-17 and IL-22 production by innate lymphocytes. IL-22 primarily acts on epithelial cells (such as Paneth cells) to promote barrier functions such as enhancing production of antimicrobial peptides that control bacterial growth, whereas IL-17 acts to promote recruitment and activation of neutrophils that prevent bacterial spread.

Roles of Innate Lymphoid Cells in Mucosal Immunity and Homeostasis

RORγt expressing ILCs produce high levels of cytokines such as IL-17 and IL-22 that are known to trigger antimicrobial peptides by epithelial cells.[349,350] For instance, at steady state, RORγT ILCs are the major producers of IL-22 in the intestinal LP (Fig. 34.5).[350] As previously discussed, both IL-17 and IL-22 play a major role in mucosal homeostasis and immunity. 351 In the complete absence of RORγt+ cells, mice are less capable of controlling inflammation and display increased

bacterial translocation.[318] In particular, ILCs expressing RORγt are believed to play a major role in the containment of commensals.[314] ILCs (NK22 and LTi) can contribute to host protection against bacterial invasion via their capacity to produce large amounts of IL-22.[339,352] The expression of IL-22 by these cells is locally controlled by arylhydrocarbon receptor and IL-23.[345,347] As a result of their production of inflammatory cytokines, ILCs can also contribute to mucosal inflammation and pathology. For example, in mice lacking conventional lymphocytes, colitis induced by infection with *Helicobacter hepaticus* is triggered by a subset of Sca-1+ RORγt+ ILCs that express IFNγ and IL-17.[353] Notably, increases in ILCs expressing IL-17 and IL-22 has been reported in patients with IBD.[354] ILC2s, on the other hand, play a major role in responses to helminths.[336,355,356] Notably, helminths can trigger large amounts of IL-33 and IL-25 production by epithelial cells that in turn expand ILC2s and trigger their production of IL-4, IL-6, IL-5, and IL-13.[336,355,356] The production of these cytokines, and IL-13 in particular as a result of its capacity to trigger mucin production by goblet cells, contribute to worm expulsion.[336,355,356] A population similar to ILC2s has been described in the human gut and in the context of chronic respiratory inflammation.[357]

ROLE OF THE MICROBIOTA IN MUCOSAL IMMUNITY

All mucosal surfaces are covered by a diverse and abundant microbiota. The human intestine in particular harbors and is in constant contact with 1,000 trillion microbes, composed of an estimated 4,000 strains.[358,359] Recent studies have changed our perspective of commensal microbes from benign passengers to active participants in both the postnatal development of mucosal and systemic immunity, and in its long-term steady-state function (Fig. 34.6).

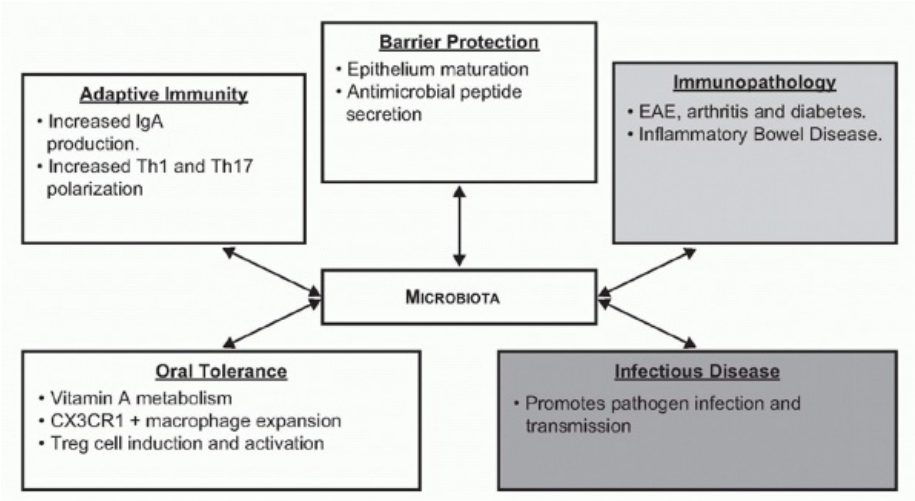

FIG. 34.6. The Microbiota Controls Various Aspects of Mucosal and Systemic Responses. The microbiota controls the intestinal barrier and antimicrobial peptide production. The microbota also controls effector responses by inducing immunoglobulin A and effector T-cell responses and induces oral tolerance through a multitude of mechanisms including toll-like receptor signaling, innate cell population recruitment, vitamin A metabolism, and the activation of regulatory T cells. On the negative side, the microbiota can contribute to inflammatory disorders such as inflammatory bowel disease, arthritis, or diabetes. Further, the microbiota is also required for transmission of a number of viruses and parasites. In a reciprocal manner, each of these response can influence the microbiota composition.

Role of the Microbiota in Mucosal Immune System Development

Various features of host protective structures and innate immunity develop extensively after birth, due in large part to the interaction with the recently acquired microbiota.[360] Studies performed in germ-free animals revealed that the microbiota plays a critical role in secondary lymphoid structure development.[361,362] This also includes fortification of the intestinal barrier through epithelial cell maturation and angiogenesis of a capillary network that facilitates transport of white blood cells.[363,364] The molecular mechanisms responsible for this development remain incompletely understood, but at least in part involves a variety of PRRs, which are capable of detecting microbe-associated molecular patterns including TLRs, NOD-like receptors, and RA inducible gene-like receptors.[365] Several lines of evidence indicate that microbial signals are also responsible for the induction and development of ILFs from cryptopatches in the intestinal tract. Notably, ILFs appear within the first weeks after birth of mice and can eventually number in the hundreds.[3] The current model hypothesizes that gram-negative bacterial-derived peptidoglycans are sensed by NOD1 expressed on intestinal epithelial cells.[366] The intestinal epithelial cells subsequently express CCL20 and β-defensin 3, which

activate LTi cells leading to the formation of ILFs.[367,368,369] An alternative but not exclusive model proposes that the activated LTi cells would engage lymphoid tissue organizer cells,

which are mesenchymal in origin, to express CCL20 for the recruitment for B cells. Other critical components of host defense are represented by the mucus layer and antimicrobial peptides both under the tight control of the flora, as discussed previously.[17,370,371] Engagement of PRRs by commensally derived products induces expression of a variety of antimicrobial peptides including RegIIIγ, which are critical to prevent translocation of bacteria through the rest of the host tissue.[6,8] Similarly, as previously discussed, the PRR NOD2 controls expression of a subset of α-defensins and cryptidins by Paneth cells.[11]

Control of Effector and Regulatory Responses by Commensals

Although mucosal surfaces have to constitutively integrate a multitude of microbial-derived signals, experimental evidence suggests that defined bacteria or microbial products can play a dominant role in the induction of a distinct class of immune responses (see Fig. 34.6). At steady state, the gut is home to a large number of lymphocytes, many of them with the potential to produce cytokines such as IL-17, IL-22, IFNγ, and/or IL-10.[185,372] The flora tightly controls this constitutive production of cytokines, as germ-free mice show extensive deficiencies in basal cytokine production.[187,372] Further, in the absence of flora, the CD4+ T-cell population is diminished, disproportionately affecting Th1 and Th17 cells, although T_{reg} frequencies are maintained or increased in the small intestine.[185,372] Colonization of germ-free mice with complex microbiota orchestrates a broad spectrum of T helper (Th1, Th17) and T_{reg} cell responses.[373] Recent advances revealed that the microbiota can directly promote the induction and/or activation of T_{reg} cells at mucosal sites. The first demonstration that a single symbiont molecule could promote regulatory responses was provided by the identification of polysaccharide A (PSA), which is produced by a prominent human symbiont *Bacteroides fragilis*.[362] Colonization of germ-free mice with *B. fragilis* or treatment with purified PSA directs immune system development.[362] Furthermore, via PSA expression, *B. fragilis* can protect mice from experimental colitis induced by *Helicobacter hepaticus*, a commensal bacterium with pathogenic potential.[374] This protective activity was associated with the capacity of PSA to induce or expand IL-10-producing CD4+ T cells.[374,375,376] Additionally, *B. fragilis* was able to promote T_{reg} cell function via a TLR2-dependent mechanism, a phenomenon associated with its capacity to limit IL-17 responses.[377] Induction of T_{reg} cells is not restricted to *B. fragilis* as the presence of *Clostridium* species also promotes T_{reg} cell accumulation via, at least in part, its capacity to create a TGF-β-rich environment. 378 This induction of T_{reg} function requires TCR-mediated signals, MyD88, and Ticam-1, as well as signaling via IL-10 receptor.[378] Based on the fundamental role of T_{reg} cells in maintaining mucosal homeostasis, it is likely that rather than being restricted to defined bacteria, most indigenous flora have evolved to favor this aspect of the regulatory network. Notably, colonic T_{reg} cells have a TCR usage distinct from those at other locations and a fraction of them can react preferentially to antigens derived from the commensal population.[379] These results suggest a major role for the microbiota in shaping the repertoire of tissue resident T_{reg} cells and in the maintenance of host-microbe mutualism at barrier sites.

Defined groups of bacteria have been associated with specific immunologic signatures. For example, mice lacking a key group of microbes (SFB) have severely decreased numbers of mucosal Th17 cells in the small intestine, although the T_{reg} compartment is expanded in this environment.[372,373,380] Remarkably, SFB in association with a specific-pathogen-free flora, can trigger intestinal inflammation in the lymphopenic host.[381] Indeed, SFB colonization of germ-free mice leads to increased T_{reg} cells as well as IFNγ- and IL-17-producing CD4 T cells in the small intestine and colon.[372,373,380] However, absolute numbers of these cells are not restored to the level of those mice with a complete microbiota, suggesting that as expected, SFB may be sufficient for such changes but needs to synergize with other microorganisms to coordinate the full maturation of the intestinal immune system. Scanning electron microscopy has revealed that SFB adhere tightly to Peyer patches and epithelial cells of the small intestine, a property that likely explains its dominant role on the mucosal immune system.

Specific commensal-derived ligands can also control effector T-cell balance at mucosal sites. Many of these ligands signal through the toll-like family of receptors.[382] TLRs are widely expressed by cells of hematopoietic origin, as well as nonhematopoietic cells, including the epithelial cells lining the intestinal tract.[383] Bacteria flagellin is a structural protein that forms the main portion of flagella and promotes bacterial chemotaxis, adhesion, and invasion of host tissue in the context of pathogenic bacteria. Many commensal bacteria also have flagella, and several lines of evidence indicate that interaction of commensal flagellin with TLR5 plays an important role in the GI tract. TLR5 is highly expressed by LP DCs from the small intestine and in particular on $CD11c^{hi}CD11b^{hi}$ DCs.[68,144] Flagellin-stimulated LP DCs express IL-6, IL-12, chemokines, prostaglandin, and antimicrobial peptides.[144] Further, LP DCs induce RORγT+ Th17 cells as well as Th1 cells from naïve CD4+ T cells in response to flagellin in vitro.[68] Of note, flagellin also represents an immunodominant antigen in patients with Crohn disease.[384] Several lines of evidence also support the idea that commensal derived flagellin plays a regulatory role in the GI tract as mice lacking TLR5 spontaneously develop colitis. 385 Furthermore, mice lacking TLR5 overexpress genes associated with innate and adaptive immunity, contributing not only to colitis development but also to their enhanced protection against infection to enteric pathogens such as *Salmonella*.[386]

TLR9 recognizes unmethylated cytosine phosphate guanosine dinucleotides, which are abundant in prokaryotic DNA found in intestinal flora. Using synthesized sequences containing cytosine phosphate guanosine, previous studies have shown that engagement of TLR9 expressed on DCs, T_{reg}s, and conventional T cells can limit T_{reg} cell suppressive

function.[387,388] In mice, gut flora DNA plays a major role in intestinal homeostasis through TLR9 engagement,[145] and constitutive interactions between gut flora DNA and TLR9 in the GI tract can act as an immunologic adjuvant and critically controls the balance between T_{reg} and effector T cells.[145] Notably, commensal bacteria also contain suppressive motifs that account for the differential effect of DNA from defined bacteria species.[389] It has also been noted that bacterially infected apoptotic cells trigger DC production of IL-6 and TGF-β, which are critical for Th17 induction in mice, through recognition of phosphatidylserine exposed on

the apoptotic cells.[390]

Adenosine 5′-triphosphate (ATP) can modulate immune cell function by means of activation of the ATP receptors, P2X and P2Y, and commensal bacteria have been shown to generate large amounts of ATP.[391] Consistent with this observation, germ-free animals have reduced ATP in their feces compared to conventional mice. ATP derived from commensal bacteria can activate LP DCs, leading to the differentiation of Th17 cells.[391] The critical role of commensalderived ATP is further underscored by the observation that administration of ATP exacerbates a T-cell-mediated colitis model with enhanced Th17 differentiation.[391] These data provide evidence that commensal-derived metabolites could directly affect T-cell polarization.

By virtue of their capacity to control immune responses, promising results have been obtained with probiotics— bacteria known to confer a health benefit to the host—in the treatment of human inflammatory diseases of the intestine and in the prevention and treatment of atopic eczema in neonates and infants. Some of the effect of probiotics is believed to be associated with the induction or expansion of T_{reg} cells. For instance, in mice, treatment with the probiotic *Lactobacillus* and/or *Bifidobacterium* suppressed trinitrobenzene sulfonic acid (TNBS)-induced colitis,[392,393] as well as allergic responses possibly resulting from the induction of TGF-β production[394] and stimulation of T_{reg} cells that are able to suppress allergic responses.[395] There is also good evidence of probiotic modulation of DCs toward a proregulatory phenotype.[396,397] Multiple reports indicate that bacteria with known anti-inflammatory properties such as *Bifidiobacteria*, *Lactobacilli*, and *Streptococcus salivarius* are capable of promoting both T_{reg}- and IL-10-producing FoxP3- Tr1 cells.[375,397,398,399,400,401]

Role of Commensals in Mucosal Inflammation

A role for the gut microbiota is now well established in the pathophysiology of mucosal inflammatory diseases and in particular IBD.[402] Despite differences in the target site and inflammatory processes associated with the two forms of IBD, compelling evidence generated from studies of human patients and experimental models indicate that both disorders depend upon the presence of the microbiota.[403] Early studies demonstrated that the critical effector cell in most models of experimental colitis that involve the adaptive immune system is the CD4 T cell.[403,404,405] One striking experimental example of the influence of the flora on mucosal disorders is that of mice that develop a spontaneous and transferrable form of ulcerative colitis.[406] Deficiency of T-bet in the innate immune system (T-bet-/- RAG2-/- ulcerative colitis [TRUC] mice) leads to exaggerated TNF production by DCs, which together with the absence of T_{reg} cells creates a chronic inflammatory state that modulates the composition of the microflora and eventually leads to the development of colorectal cancer.[406,407] Colitis in TRUC mice is caused by increased production of TNF-α by colonic DCs as restoration of T-bet expression specifically in the CD11c+ populations allowed for reduced TNF-α production and prevented neoplasia and excessive inflammation.[407] Interestingly, transfer of the microbiota from TRUC mice into wild-type recipients also

transfers the colitis, indicating that microbiota shifts are likely the cause of disease. Two species, *Proteus mirabilis* and *Klebsiella pneumoniae*, are found at increased frequency in TRUC mice and can induce colitis in specific-pathogen-free wild-type mice.[408]

Inflammasomes, complexes that function as sensors of endogenous or exogenous damage-associated molecular patterns, can also play a role in controlling the delicate homeostatic relationship with the flora.[409] Deficiency of NLRP6 inflammasome from colonic cells results in reduced IL-18 levels and shifts in microbiota composition characterized by expansion of the bacterial phyla *Bacteroidetes* (*Prevotellaceae*) and TM7. Further, these mice spontaneously develop colitis and are more susceptible to chemically induced colitis.[409] As observed in TRUC mice, colitogenic potential of this microbiota is transferable to neonatal or adult wild-type mice.

The gut also represents one of the primary sites of exposure to pathogenic microbes. In this environment, the proinflammatory properties of commensals can directly contribute to the pathogenesis of mucosal infection. One of the first examples of this scenario was demonstrated in an oral model of *Toxoplasma gondii* infection in which pathology is associated with exuberant sensing of commensals via TLRs.[410,411] This infection is also characterized by a reduction of the flora complexity and increase in gram-negative bacteria that in turn exacerbates the pathologic process.[410] Disruption of the microbiota composition has also been documented in the context of other enteric infections such as *Citrobacter rodentium* or *Salmonella typhimurium*.[412,413] In addition to microbial changes induced by infection, as previously discussed, accumulating evidence indicates that host genotypes reciprocally affect microbiota composition, which in turn alters host responses.

Bystander Effects of Gut Commensals on Peripheral Responses

One consequence of the immune system's reliance on microflora for optimal development and immunoregulation is that antibiotic therapies may result in unintended activation of immune effector mechanisms. In experimental models, antibiotic treatment renders mice more susceptible to induction of food allergy[414] as well as allergic airway inflammation.[415] For the human population, antibiotics are seen as major modifiers of beneficial human-microbe interactions[416] superimposed on alterations caused by other exogenous factors including urbanization, global travel, and dietary changes.[417] The acute effects of antibiotic treatment on the

native gut microbiota range from self-limiting diarrhea to life-threatening pseudomembranous colitis induced by bacteria filling the niches created by the reduction in bacterial diversity.[418] The long-term consequences of such perturbations for human-microbial symbiosis are more difficult to discern, but chronic conditions such as asthma and atopic disease have been associated with childhood antibiotic use and an altered intestinal microbiota.[419,420,421] More direct evidence of the systemic influence of the microbiota on peripheral immune responses were recently provided. Indeed, despite being confined to mucosal surfaces, gut microbiota can impact immune responses at distal sites. For instance, peptidoglycan from radio-labeled *E. coli* could be found in the serum and improved killing of *Streptococcus pneumoniae* and *Staphylococcus aureus* by bone-marrow derived neutrophils in a NOD1-

dependent manner.[422] Importantly, microbe-associated molecular patterns can be detected in the bone marrow where their signaling can alter hematopoiesis.[422] Further, bacterial products can induce monocyte emigration in response to very low levels of TLR ligands.[423] Whether the diffusion of commensal products into the bloodstream contributes to steady-state monocyte egress from the bone marrow remains to be determined. The microbiota also has the ability to regulate immune responses against various infections as mice given broad-spectrum antibiotics mounted a severely blunted T- and B-cell response against an intranasal infection with the A/PR8 strain of influenza, resulting in elevated viral titers.[424]

In addition to protective immunity, gut commensals can also alter autoimmune conditions. Mice lacking intestinal microbiota develop less severe disease in models of arthritis and experimental autoimmune encephalomyelitis.[376,425] Moreover, colonization with SFB promotes autoimmune arthritis through the induction of antigen-specific Th17 cells, which promote autoantibody production via B-cell expansion in germinal centers. A recent study further showed that recruitment and activation of autoantibody-producing B cells from the endogenous immune repertoire depends on availability of the target autoantigen and commensal microbiota.[426] The commensal microbiota can also help to reduce inflammation as colonization of mice with *B. fragilis* results in the expansion of IL-10-producing T_{reg} cells, which limit the proinflammatory mechanisms of experimental autoimmune encephalomyelitis in a TLR2-dependent manner.[376] Indeed, diabetes in the nonobese diabetic mouse model has been related to their housing conditions and presumably their commensal flora. When nonobese diabetic mice were genetically deficient for MyD88, induction of disease was delayed and associated with distinct floral changes to MyD88 intact controls.[427] Further, a recent study indicates that nonobese diabetic mice naturally colonized with SFB have a correlative protection from diabetes.[428] Finally, single chain fatty acids, such as acetate, are one of the most important metabolites provided by commensal organisms.[429] It has been shown that the recognition of these single chain fatty acids by innate immune cells is critical for the regulation of inflammation in response to not only intestinal injury but also in models of arthritis and allergy.[430]

MUCOSAL INFLAMMATION

Inflammatory Bowel Diseases

Chronic inflammatory syndromes arise as a consequence of genetic polymorphisms in concert with accumulating environmental exposure to toxins, pathogens, and diet.[431,432,433] IBDs refer to chronic inflammatory disorders affecting the GI tract.[434] There are two main clinical forms of IBD: Crohn disease, which can affect any part of the GI tract, and ulcerative colitis, the pathology of which is restricted to the colonic mucosa.[434] The etiology of these disorders is complex and believed to be the consequence of genetic factors, the host immune system, and environmental triggers such as the microbiota.[435] Individual genome-wide association study scans have identified more than 70 susceptibility loci in Crohn disease and 47 susceptibility loci for ulcerative colitis.[436,437,438,439,440] Some of these risk factors are associated with innate defenses. For instance, patients with Crohn

disease and those with NOD susceptibility have reduced α-defensin expression. Further, genetic variants in the transcription factor TCF4 that is involved in Paneth cell maturation and function have been associated with ileal Crohn diseases.[441] Paneth cell defects have also been associated with IBD. Patients who are homozygous for the T300A disease-risk allele of the autophagy gene ATG16L1 as well as in mice hypomorphic for ATG16L1 are more prone to inflammatory disorders.[442]

Effectors of Mucosal Inflammation: Tumor Necrosis Factor-α, Interleukin-23, TH1, Th17, and Nucleotide-Binding Oligomerization Domain-Containing Protein-Like Receptors

Multiple inflammatory mediators required to sustain mucosal homeostasis and immunity have also been associated with the etiology of IBD (Fig. 34.7). TNF-α, for instance, can contribute to mucosal tissue damage, and anti-TNF-α antibody treatment is highly effective in a large proportion of patients with IBD.[443] The cytokine IL-23 has been associated with a variety of autoimmune disorders and in particular intestinal inflammation.[444] Genome-wide association studies reported a strong association of polymorphisms in IL-23R and IL-12B gene loci with Crohn disease and ulcerative colitis.[436,437,438,439,440] The cytokine IL-23 can promote mucosal inflammation via its capacity to enhance proliferation of effector T cells, reduce Foxp3 T_{reg} cell induction, and induce pathogenic IL-17/IFNγ CD4+ T cells.[445] Notably, IL-17/IFNγ CD4+ T cells responding to IL-23 have been isolated from the guts of patients with Crohn disease,[446] and in phase II clinical trials anti-IL-12p40 monoclonal antibodies that target both IL-12 and IL-23 have shown clinical efficacy in a subset of patients.[443]

Studies in T-cell transfer colitis suggest that IL-17A and IL-17F can have redundant proinflammatory effects in the gut.[447] Th17 cells are highly enriched in the inflamed mucosa of mice and patients with IBD. Notably, chronic inflammation in the context of high levels of IL-17 has also been associated with the emergence of colitis-associated cancer.[448] A role for IL-22 in mucosal inflammation has been

recently proposed in the etiology of IBD. In patients with Crohn disease, high serum levels of this cytokine correlates with increased disease activity and susceptibility associated with IL-23R polymorphism.[449] Association of IBD with polymorphisms in NLRP3 and IL-18 receptor accessory protein strongly suggest role for IL-1β and IL-18 in mucosal inflammation.[449] Indeed, both IL-1β and IL-18 are increased in patients with IBD, and mice deficient in IL-18 are resistant to colitis.[450,451] In summary, although it is clear that various factors contribute to mucosal inflammation, much remains to be learned in order to understand the relative contributions and contextual role of these cytokines in mucosal inflammatory disorders (see Fig. 34.7).

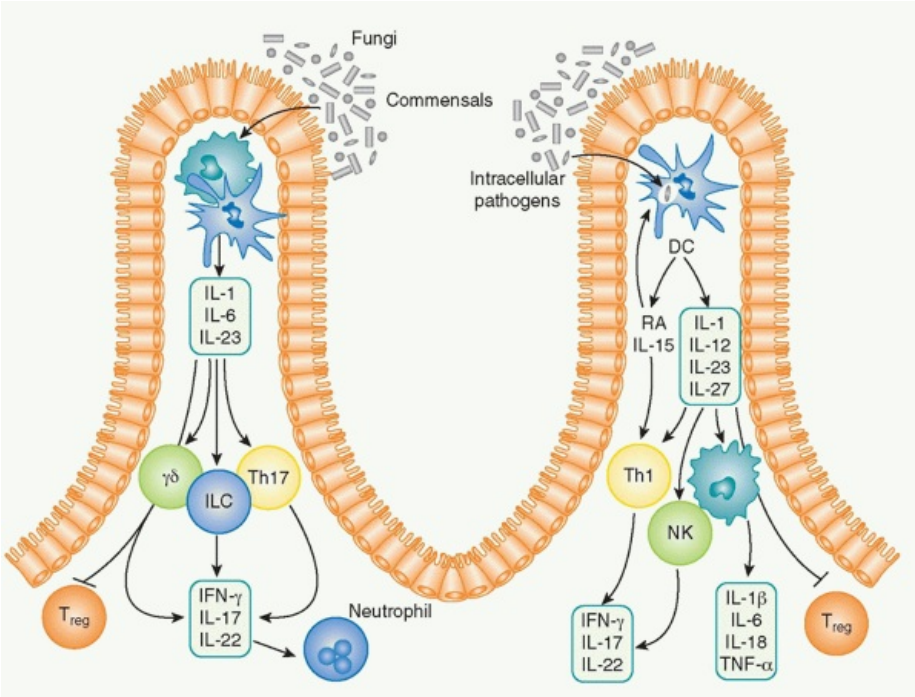

FIG. 34.7. Induction of Mucosal Effector Responses during Infection. Under inflammatory conditions, resident and recruited mononuclear phagocytes (MPs) produce inflammatory cytokines in a contextual-dependent manner. In responses to fungi and commensal bacteria, interleukin (IL)-1, IL-6, and IL-23 released by these cells can promote IL-17 and IL-22 responses by γδ T cells, innate lymphoid cells, and Th17 cells. These cytokines can act to promote intestinal barrier function as well as to promote the recruitment and activation of neutrophils. In the context of intracellular infections, mucosal and recruited MPs can produce various cytokines including IL-12 that can directly activate NK cells and promote the induction of Th1 responses. Effector T cells can in turn promote the effector function of resident macrophages. Commensal bacteria can promote both types of immune responses and in both settings, inflammatory cytokines limit regulatory T-cell induction. Overexpression of these effector responses combined with impairment of regulatory responses can lead to tissue damage and mucosal inflammation.

ACKNOWLEDGMENTS

Thanks to all the members of the Belkaid Laboratory for helpful discussions and in particular to Drs. Nicolas Bouladoux for assistance with figure preparation and John Grainger for critical reading of the chapter.

Chapter 35

Neurophysiologic Reflex Mechanisms in Immunology

Sangeeta S. Chavan

Kevin J. Tracey

INTRODUCTION

A fundamental principle in biology is that organ function is maintained within a narrow physiologic range, one optimal for health. Heart rate, body temperature, and the output of all organ systems are controlled by homeostatic mechanisms. The nervous system occupies a crucial role in establishing this healthy range of organ function. There is continuous communication between the nervous system and the other organ systems, linked by two major information highways (Fig. 35.1). One route is neural, which transmits action potentials via nerves that travel directly into the organs back and forth to the nervous system. The other is humoral, which utilizes the circulatory system to deliver hormones, inflammatory mediators, and other soluble factors that shuttle information from the immune system to the nervous system, and back again from the neuroendocrine organs to the immune system.

The immune system, the principle organ system of host defense, exerts significant influences on the function of the other organ systems, and the magnitude of these responses is crucial to physiologic homeostasis. For example, cytokines modulate the metabolism of hepatocytes, adipocytes, and skeletal muscle cells to mobilize fatty acids, glucose, and other energy stores required for new protein synthesis in lymphocytes and other immune cells to support antibody production, and other essential molecules. Inflammatory mediators also modify the activity of cells in the nervous system, disrupting homeostasis and producing fever, anorexia, and avoidance behavior. These protective responses, which together improve the odds of the organism surviving infection and injury, are frequently the major signs and symptoms of disease. Decades of prior work revealed how the immune system communicates with the nervous system by utilizing both communication routes, the humoral and neural, to change the behavior of the organisms. Quite recently, however, advances in neurophysiology and immunology elucidated mechanisms by which these incoming signals from the immune system stimulate regulatory signals that return from the nervous system to the immune system through neural networks that maintain immunologic homeostasis.

These neural reflexes are essential for maintaining a healthy immune response for optimal function during infection and injury, termed “immunologic homeostasis.” Impairment of these fundamental reflex mechanisms leads to unregulated immune responses, uncontrolled cytokine production, and deviations of organ system function outside of the homeostatic range. This chapter focuses on the basic principles underlying the neurophysiologic mechanisms that regulate immunologic homeostasis.

ORGANIZATION OF THE NERVOUS SYSTEM

To understand the role of neural reflexes and the neuroendocrine system in maintaining immunologic homeostasis, it may be illustrative to review the basic organization of the nervous system. It is comprised of the central nervous system (the brain and spinal cord) and the peripheral nervous system (Fig. 35.2). The peripheral nervous system is comprised of two parts: the voluntary or skeletal nervous system, which enables purposeful, conscious actions, like piano playing; and the involuntary or autonomic nervous system, which innervates organs to provide a major information conduit that regulates homeostasis. The autonomic nervous system normally functions without conscious involvement. There are two divisions of the autonomic nervous system: the sympathetic and parasympathetic. Most organs receive input from both of these autonomic divisions, which deliver information that adjusts organ output according to setpoints established in the brainstem and hypothalamus.

The neuron, the principle information-transmitting cell of the nervous system, communicates with other cells by action potentials that propagate unidirectionally along axons away from the neuronal cell body. Arrival of action potentials at the axon terminus causes the release of neurotransmitters into the synaptic cleft, the narrow space adjacent (< 20 nM) to the innervated neuron or somatic cell. This converts the electrical information carried in the axon into molecular (or pharmacologic) information, because secreted neurotransmitters bind to specific receptors expressed on the innervated cell. Ligand-receptor interaction leads to signal transduction that modulates the behavior of that cell in response to the arrival of a train of action potentials. Henry Dale, the Nobel Laureate discoverer of acetylcholine, recommended that autonomic nerves be described by the neurotransmitters they produce, not their function (ie, not as “sympathetic” or “parasympathetic”). This is an important point that will be emphasized again in this chapter. Autonomic neurons may be adrenergic (using catecholamines), cholinergic (using acetylcholine), or peptidergic (using neuropeptides) as their principle neurotransmitter.

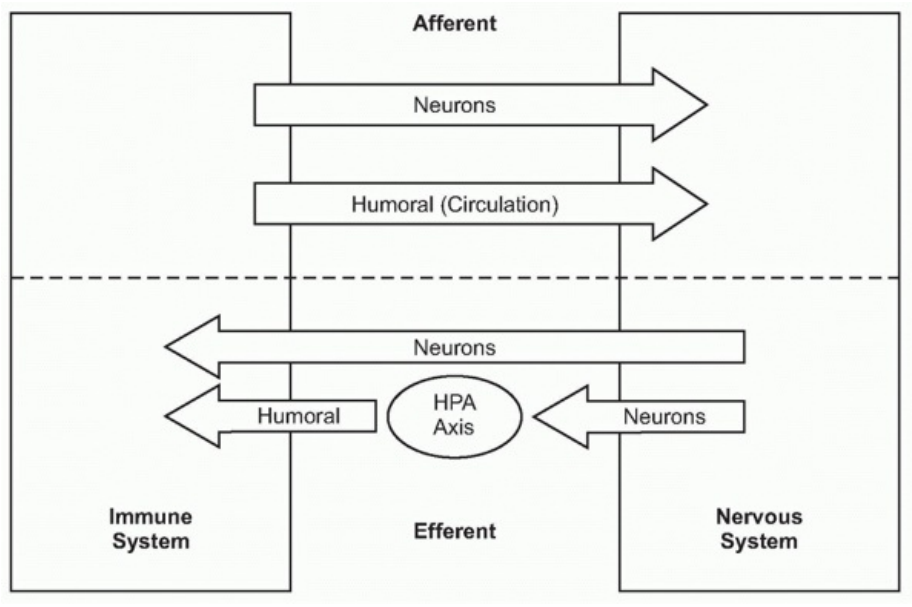

FIG. 35.1. Neural versus Humoral Communication Pathways between Nervous

System and Immune System. Neural pathways communicate to distant organ systems via action potentials transmitted through efferent nerves travelling to various organs. Alternatively, peripheral nerve endings get activated by systemic cytokines and transmit signals to the central nervous system. In humoral pathways, the central nervous system activates the hypothalamic-pituitary-adrenal axis to secrete glucocorticoid hormones in circulation that in turn modulates immune functions. The immune system utilizes the circulatory system to deliver inflammatory mediators to the central nervous system.

The autonomic nervous system provides the principle communication pathway by which the nervous system rapidly adjusts specific cellular functions to maintain homeostasis. The nervous system can also communicate to other organ systems via the neuroendocrine organs, a humoral pathway that relies on the bloodstream to deliver the final signal. As compared to the neural communication pathway, the additional steps of hormone release and transit through the circulatory system means that neuroendocrinederived homeostatic regulation signals are delivered much more slowly than neural action potentials. The primary signal in both systems, however, is neural, because neuroendocrine signaling is initiated by neurons in the brainstem and hypothalamus that relay action potentials to the autonomic nuclei, and the pituitary gland, to regulate the release of pituitary hormones into the bloodstream. This modulates the endocrine organ output of glucocorticoids (GCs), thyroid hormones, catecholamines, and other circulating hormones that influence cellular function and metabolism in other organ systems. Neural signaling mechanisms adjust cellular responses in an extremely rapid time frame, whereas the neuroendocrine system establishes longer-term, more chronic homeostatic setpoints.

THE NERVOUS SYSTEM MAINTAINS ORGAN SYSTEM HOMEOSTASIS

The basic physiologic unit that maintains organ homeostasis is the reflex. A neural reflex circuit is comprised of three components: a sensory arc, a relay or interneuron arc, and a motor arc (Fig. 35.3). The sensory (afferent) neural path relays information to the central nervous system. Sensory neurons respond to pressure, vibration, temperature, and other molecular signals (eg, taste) that trigger action potentials that travel to the spinal cord or brainstem. Molecular products of infection, injury, and inflammation including bacterial endotoxin, interleukin (IL)-1, and tumor necrosis factor (TNF) can also activate specific receptors on sensory neurons, which initiate afferent action potentials that transfer information to the central nervous system. Within the central nervous system, interneurons receive the incoming signals from sensory nerves and transfer the information to other brainstem nuclei,

which coordinate the efferent, or outgoing, signals back to the organs. In a neural reflex, which operates extremely quickly, the signals are projected back to the organs via neuronal action potentials. In a neuroendocrine reflex circuit, the efferent neurons project to the hypothalamic-pituitary-adrenal axis, which in turn regulates circulating hormone levels over more prolonged periods of time.

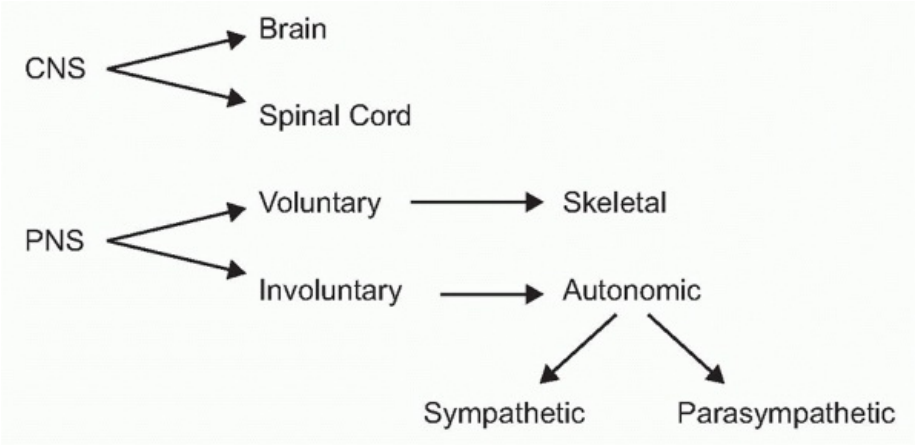

FIG. 35.2. Organization of the Nervous System. The nervous system is comprised of central nervous system (CNS) and peripheral nervous system (PNS). The CNS is comprised of two parts: the brain and the spinal cord. Most of the important processing of the information takes place in the CNS. The PNS is comprised of two divisions: the voluntary-somatic nervous system and the autonomic nervous system. The voluntary nervous system allows the brain to consciously (or voluntarily) monitor the environmental stimuli and respond to it. The autonomic nervous system maintains the physiologic balance of various visceral organs systems, such as respiratory, endocrine, cardiovascular, gastrointestinal, etc. The autonomic nervous system is further subdivided into sympathetic nervous system and the parasympathetic nervous system.

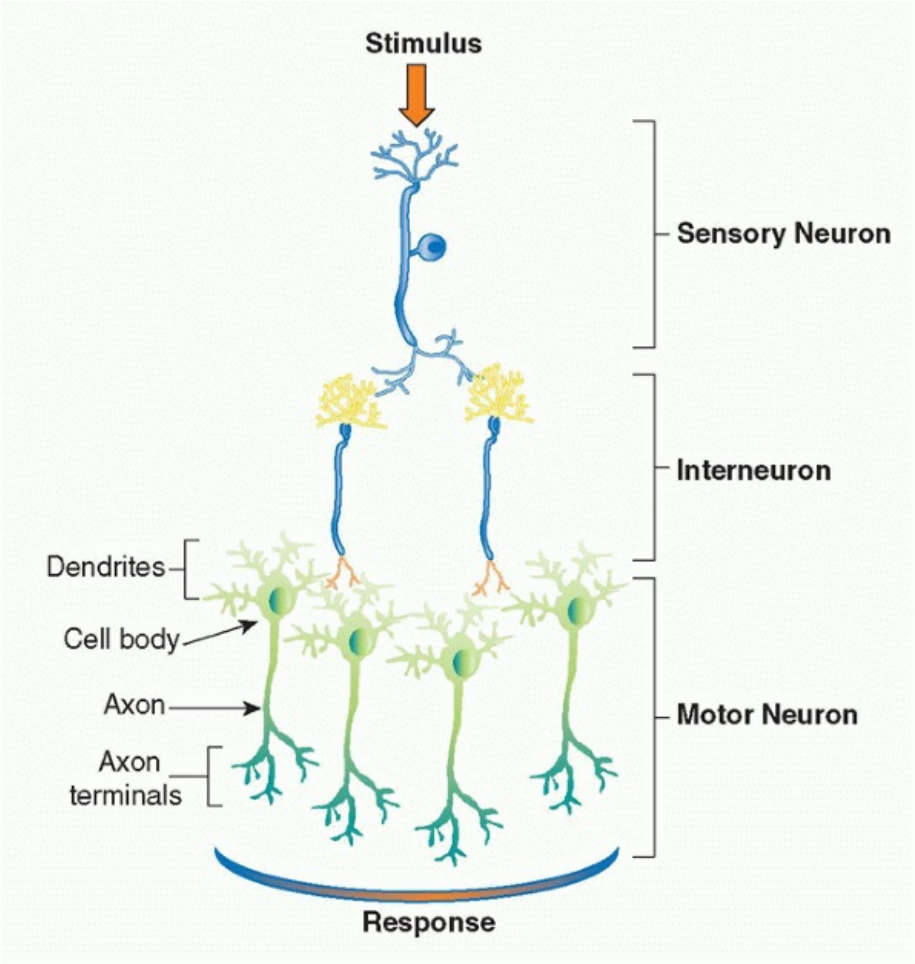

FIG. 35.3. The Neural Reflex Circuit. A neuron, the basic signaling unit of the nervous system, is comprised of a cell body containing the nucleus, dendrites that primarily receive chemical message from other neurons, an axon that can extend for significant length, and transmits electrochemical message to other cells. Three types of neurons comprise the neural reflex circuit: sensory neurons, interneurons, and motor neurons. The sensory neurons respond to stimulation from external or internal environment and transmit signals to the central nervous system. Motor neurons transmit information from the central nervous system to the periphery. Interneurons provide connections between sensory neurons and motor neurons, because they receive signals from the sensory nerves and project the outgoing signals via their axons to the dendrites of the motor neurons.

A useful example of reflex circuits that maintain homeostasis of organ function is the acute neural regulation of heart rate and the chronic neuroendocrine regulation of blood pressure. The heart rate control circuit begins with pressuresensitive neurons that transmit information about heart rate to interneurons in the brainstem. These relay information to efferent brainstem nuclei that activate either adrenergic or cholinergic nerves that project back to the heart. The descending neural signals either increase or decrease heart rate in response to deviations from the heart rate setpoint as established in the brainstem. Blood pressure also activates sensory neurons, which initiate signals that modulate the renin-angiotensin system, and the hypothalamic pituitary axis. These neuroendocrine responses establish hormone

levels that maintain chronic blood pressure levels. In both examples (heart rate and blood pressure), the reflex circuit is initiated by information traveling from the periphery to the nervous system; they differ in that neural signals elicit rapid changes in organ output, whereas the humoral pathway works to maintain long-term stability.

These reflex principles governing the cardiovascular and other relatively accessible organ system were established a long time ago. Only quite recently has it become possible to understand how these reflex principles operate in the more diffuse immune system. The remainder of this chapter reviews the neural and humoral mechanisms underlying the reflex control of immune homeostasis by the nervous system.

THE IMMUNE SYSTEM IS INNERVATED

As reviewed in Chapter 3 in this volume, the immune system is comprised of circulating cells and resident or tissue fixed cells residing primarily in the spleen, liver, lymph nodes, thymus, lungs, intestines, central nervous system, and bone marrow. These anatomic sites are richly innervated by the autonomic nervous system via neurons that are adrenergic, cholinergic, and peptidergic.[1,2,3] These neural circuits provide an anatomic and functional basis for direct neural communication between the nervous system and cells of the immune system. The majority of nerve fibers innervating the lymphoid tissues are adrenergic. They enter the lymphoid organs by traveling with the arterial vasculature; upon entering the tissue, they form networks that distribute to fields of lymphocytes and macrophages in the parenchyma. Innervation of lymphoid tissue is regional, primarily found in T-cell- and plasma-cell-rich zones, and lacking in nodular regions and zones of maturing B cells.[3]

Nerve terminals in the lymphoid tissues can undertake the appearance of a classic synapse on immune cells, which may be lymphocytes (Fig. 35.4),[4] eosinophils, mast cells, and

macrophages.[3,5] These innervated cells express receptors for cholinergic (acetylcholine), adrenergic (norepinephrine and epinephrine), and peptidergic (vasoactive intestinal peptide, pituitary adenylate cyclase activating peptide, calcitonin gene-related peptide), and other (substance P, histamine and serotonin) neurotransmitters.[6] Release of neurotransmitters in response to action potentials propagated along these neurons specifically alters the metabolism, biochemistry, and gene expression patterns in the immune cells. Thus, neurotransmitter release converts the electrical signals propagated along neurons to the immune system into molecular or pharmacologic signals that exert discrete action on the responding immunocompetent cells.

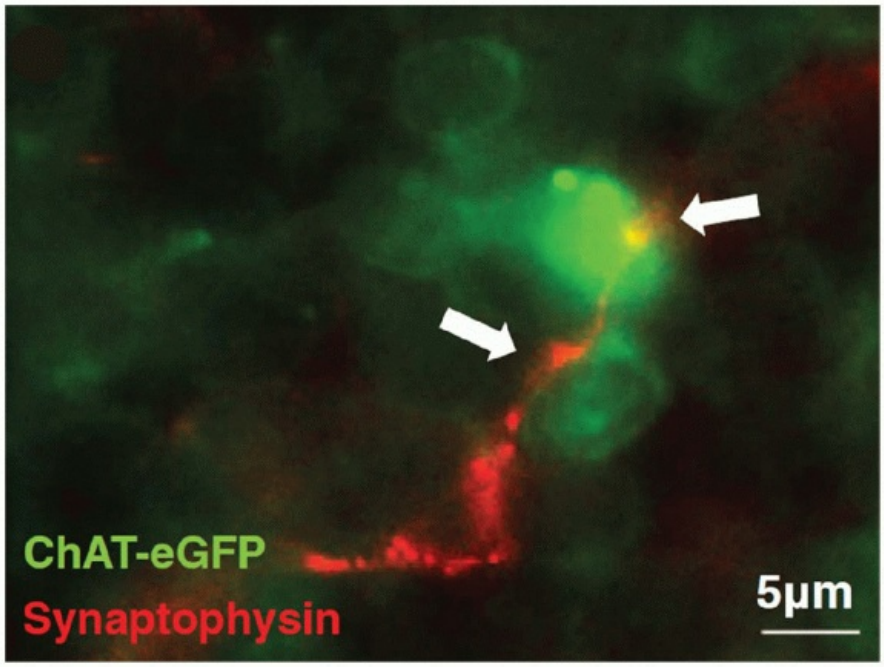

FIG. 35.4. Splenic Nerve Forms a Synapse with Lymphocyte. Immunohistochemical analysis of splenic nerve endings (synaptophysin, *red*) in direct contact with lymphocyte (choline acetyltransferase-enhanced green fluorescent protein+, *green*) in the white pulp of the spleen. Magnification × 630. Adapted from Rosas-Ballina et al.[4]

Innervation of the immune cells within lymphoid organs is not a static phenomenon, because the number, density, and distribution of nerve fibers can undergo dynamic changes during immune responses. The molecular products of an immune response significantly influence the remodeling of nerve fibers and the expression of neurotransmitter receptors in lymphoid organs. Nerve fiber density is increased in the spleen and thymus of SCID mice, which lack functional T and B cells, and in nude mice, which lack T cells.[7,8,9] Reconstitution of SCID or nude mice with T-lymphocytes restores the normal pattern of innervations, indicating that immune cells modulate neural network formation. Additionally, systemic or regional inflammatory challenges lead to increase in nerve fiber distribution in the lymphoid organs such as thymus, lymph nodes, and spleen.[10,11,12] A reduction in splenic nerve fibers is observed during adjuvant arthritis in rodents, a finding that is accompanied by significant changes in spleen cytokine release.[13,14] Co-culture studies have established that neurons can selectively establish and maintain contacts with immune cells, and that cytokines (IL3, IL6, granulocyte macrophage-colony-stimulating factor-1, and nerve growth factor) derived from immune cells promote neurite expansion.[15,16,17] Integrins and other cell adhesion molecules also participate in the dynamic nature of nerve and immune cell interaction. Thus, the changing milieu in the immune system organs provides important signals that prune or expand the neural network to these organs. As will be explained in more detail subsequently, these changing neural networks in turn modify the ongoing immune response.

Together with other data that are beyond the scope of this chapter, these findings indicate that the nervous system is hardwired to the major organs of the immune system and is

capable of conveying information that modulates immune cell function. These neural connections are plastic, operate rapidly, and are positioned to monitor and modify the immune response to products of infection, injury, or invasion.

THE NERVOUS SYSTEM MONITORS IMMUNE SYSTEM ACTIVITY

As the nervous system enjoys two routes to communicate with the immune system (neural and humoral), the immune system can also send information to the nervous system through both avenues (see Fig. 35.1). Indeed, peripheral inflammation profoundly affects the function of the brain and central nervous system (CNS) though both neural and humoral mechanisms. Molecular products of inflammation alter neurogenesis, neural plasticity, learning, and memory. They also produce fever, anorexia, and acutephase responses. Cytokines and other immune system-derived molecules traveling in the circulation can influence neurons in the central nervous system through five mechanisms that circumvent the blood-brain barrier (BBB), the tight endothelial junctions that normally partition large or hydrophilic molecules in blood from the extracellular fluid compartment in the CNS. First, cytokines can pass through circumventricular regions of the brain, anatomic areas where the BBB is absent or incompetent.[18,19,20] Cytokines carried in the circulation to these brain regions can directly interact with neurons residing in the hind brain and brainstem. Second, cytokines can be actively transported across the BBB via a saturable transporter system.[21,22,23,24] This depends upon endothelial cell expression of specific cytokine binding transporter receptors that mediate the active chaperoning of the cytokines across the BBB and into CNS extracellular fluid.[25,26,27] Third, endothelial cells and perivasculature macrophages can bind circulating cytokines or pathogenassociated stimulatory molecules on the intraluminal side, and respond by secreting cytokines and other inflammatory mediators into the brain parenchyma on the adluminal side.[28,29,30] Fourth, activated immune cells, including monocytes/macrophages, can traverse the microvasculature, crossing from the circulation and entering the CNS parenchyma, where they can produce cytokines.[31] Fifth, cytokines can act on peripheral sensory nerve endings at the site of infection or injury, and the ascending action potentials can activate neurons and glial cells in the CNS to secrete cytokines.[32,33,34,35] Together, the net influence of these pathways is to provide mechanisms by which cytokines and other soluble immune system mediators can directly influence the activity of neurons in the CNS, which modifies the activity of neural signaling networks.

For example, several cytokines have pyrogenic activity, meaning that they activate fever responses. Early work on these mechanisms focused on the roles of blood-borne IL-1 and TNF entering the hypothalamus and altering the function of hypothalamic thermoregulatory nuclei that regulate body temperature. More recent discoveries revealed that the vagus nerve also communicates direct neural signals to mediate IL-1-induced fever. The vagus nerve connects the major body organs to the brainstem, and as many as 80-90% of the neurons that travel in the vagus nerve are afferent (sensory). This provides an important, rapid, and efficient neural route for communicating information about the organ milieu to the brain.[36] These afferent vagus nerve fibers express receptors for IL-1 and other inflammatory mediators.[32,37,38,39,40,41,42] Activation of these receptors by binding to IL-1 is an important mechanism for initiating fever, because cutting the vagus nerve prevents the

development of fever in animals receiving of IL-1 by intra-abdominal injection.[38,43,44] Cytokine-activated afferent vagus nerve signals alter the function of thermoregulatory hypothalamic nuclei and the activity of other neurons in brainstem, hypothalamus, and limbic structures (Fig. 35.5). Other sensory nerve fibers including,

for example, the glossopharyngeal nerves, can be activated by cytokines to mediate fever.[35,45,46] Neurophysiologic studies have demonstrated that administration of IL-1 in visceral organs stimulates the generation of action potentials that travel in the vagus nerve sensory arc, ascend to the brainstem, and return to the spleen and other organs.[47,48,49] Signals ascending to the nucleus tractus solatarius can be relayed throughout the brain, to the parabrachial nucleus, the thalamus, the paraventricular nucleus, the central nucleus of the amygdala, the insula cortex, the infralimbic cortex, the anterior cingulate cortex, and the medial prefrontal cortex. Thus, cytokines do not have to enter the bloodstream to mediate the onset of fever and other behavioral responses, because they can also activate these responses by binding to sensory neurons in distant peripheral tissues.

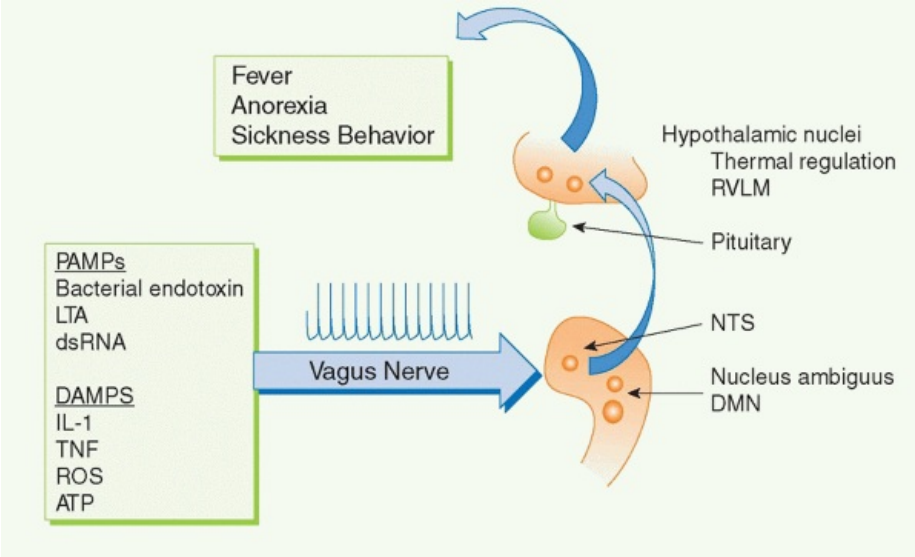

FIG. 35.5. Systemic Cytokines Modulate the Central Nervous System via Vagus Nerve. Products derived from infectious agents and sterile injury lead to cytokine release by the innate immune system. The systemic cytokines activate the afferent signals in the vagus nerve, which in turn transmits the information to the central nervous system, mediating the alteration of thermoregulatory hypothalamic nuclei resulting in fever, anorexia, and other symptoms related to sickness behavior. DMN, dorsal motor nucleus; NTS, nucleus tractus solatarius; RVLM, rostral ventrolateral medulla.

There are also immunocompetent cells residing within the CNS that can be activated to produce immunologically active molecules within the brain and spinal cord, where these mediators can exert their effects on neurons, locally. Numerous cell types in the CNS produce cytokines (and other inflammatory mediators) including astrocytes, microglia, lymphocytes, and dendritic cells. Immunocompetent cells are present in the choroid plexus, meninges, and brain parenchyma, and microglia form a regularly spaced network of resident cells throughout

the CNS. Microglia are morphologically, phenotypically, and functionally related to the monocyte/macrophage cell lineage.[50,51,52] They are quiescent in healthy conditions, but respond rapidly to pathological conditions associated with infection, injury, invasion, or neuronal degeneration.[53] Microglial activation leads to cell proliferation, enhanced expression of cytokines and other inflammatory mediators, and recruitment to inflammatory sites.[50,54] Activation of micoglia and neurons by molecular products of inflammation induces the release of cytokines (e.g., IL1, IL6, and TNF) and other inflammatory mediators (e.g., prostaglandins and nitric oxide) (Table 35.1). The local production of these mediators alters the activity of brainstem nuclei that mediate the onset of fever, anorexia, sickness behavior, acute-phase responses, and other neurologic responses.

Activated microglia upregulate the activity of phospholipase A2 and cyclooxygenases that catalyze the synthesis and release of prostaglandins and other eicosanoid mediators of inflammation. Other cells in the nervous system can be activated to release eicosanoid mediators during inflammation including astrocytes, neurons, and endothelial cells in the brain vasculature. Eicosanoid metabolites function in autocrine and paracrine signaling loops by binding to specific G-protein-coupled receptors expressed

on neurons. Receptor-ligand signal transduction culminates on pathways that increase intracellular cyclic adenosine monophosphate (cAMP) concentrations. Eicosanoid signaling in neurons has been implicated in the development of fever, acute-phase protein responses, and impaired memory and learning. Infection, trauma, neurodegenerative diseases, and acute and chronic inflammatory diseases are all associated with increased release of cytokines and eicosanoids in the brain. Importantly, low-level eicosanoid production is necessary for neuronal homeostasis and is essential in the mechanisms underlying memory formation and neural plasticity (Fig. 35.6). Eicosanoid levels that are either too high or too low impair memory development, thermoregulation, and feeding behavior. An inverted U-shaped doseresponse curve links IL-1 levels to memory function, which may be attributable to IL-1 signaling mechanisms that stimulate eicosanoid release in these mechanisms.[55,56] The neurophysiologic mechanisms underlying memory impairment in inflammatory conditions have been studied in brain slices, and addition of cyclooxygenase-2 inhibitors restores amyloid β-mediated impairment of long-term potentiation, the cellular neurophysiologic mechanism that links neuronal activity to memory formation.[57]

TABLE 35.1 Inflammatory Mediators Produced by Microglia and Other Immunocompetent Cells that Alter Neurologic Behavior

Inflammatory Mediator	Effects
IL1, IL2, IL6, IL8, TNF, MIP1, IFNα, IFNγ	Fever
IL1β, IL6, TNF, prostaglandins	Pain
IL1β, IL6, IFNγ, TNF	Anorexia

IL1β, IL6, TNF, IL2, IFNγ	Depression
IL1β, IL6, TNF, IL8, CRP	Anxiety
IL1, IL6, TNF, prostaglandins	Decreased neurogenesis
IL1, IL6, TNF, prostaglandins	Impaired memory and learning
IL1, IL6, TNF, prostaglandins	Impaired neural plasticity
IL1β, IL6, TNF, TGFβ, IL8, MCP1	Alzheimer disease pathogenesis
IL1β, TNF, HMGB1, IL6, IFNα	Epilepsy pathogenesis
IL1α, IL1β, IL6, TNF, IL18, ROS, TGFβ, IL10	Ischemia/stroke pathogenesis

CRP, C-reactive protein; HMGB, high mobility group box; IFN, interferon; IL, interleukin; MIP, macrophage inflammatory protein; ROS, reactive oxygen species; TNF, tumor necrosis factor.

Activated microglia are also stimulated to produce increased levels of reactive oxygen species (ROS), including hydrogen peroxide, superoxide anion, and hydroxyl radicals. Like other inflammatory mediators, ROS are homeostatically regulated because their activities can be both deleterious and beneficial.[58,59] At low concentrations, free radicals play an important role in several cellular signaling systems. ROS regulate redox sensitive transcription factors such as NF-κB, AP-1, and nuclear factor of activated T-cells, and the redox state of tyrosine phosphorylated proteins, thereby having an impact on many transcriptional networks and signaling cascades important for neurogenesis. Low concentrations of ROS play a significantly beneficial role in neurogenesis. However, elevated ROS levels are extremely neurotoxic because they oxidize essential macromolecules such as enzymes and cytoskeletal proteins, lipids, and nucleic acids leading to neuronal death by apoptosis. ROS-mediated neuronal toxicity and degeneration is implicated in the pathogenesis of Alzheimer disease, Parkinson disease, and other neurodegenerative disorders.[60,61] Physiological ROS levels facilitate synaptic plasticity and cognitive function, but elevated ROS levels impair these functions. Thus, even within the CNS itself, the regulation of immune responses establishes a critical level of immunologic homeostasis that is crucial for normal, healthy nervous system function.

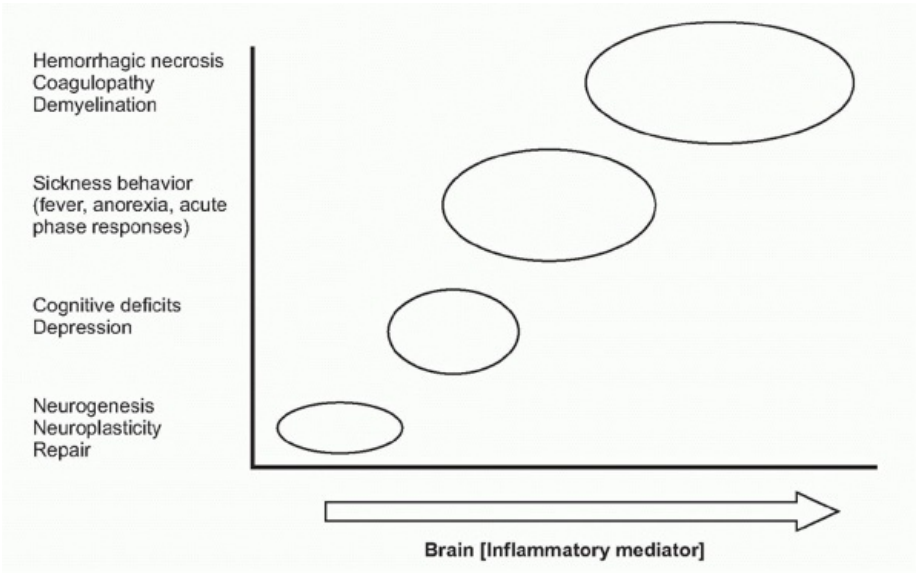

FIG. 35.6. Neural Responses to Inflammatory Mediators. Immune mediators can access the central nervous system and influence virtually every aspect of the brain function relevant to optimal brain functioning including neuronal development and function (neurogenesis and neural plasticity), behavior changes (cognitive deficits, sickness behavior), and hemorrhagic necrosis. The response of the nervous system is modulated by the nature of the immunologic mediators, as well as magnitude and duration of exposure.

NEURONS RESPOND SPECIFICALLY TO IMMUNE SYSTEM MOLECULES

Immune mediators that influence neuronal function in turn modify the behavior and physiology of the organism, because behavior and physiologic setpoints are primarily governed by the nervous system. The output of the nervous system is dependent upon the nature of the immunologic mediators, as well as magnitude and duration of exposure.

Immune system-derived signals can therefore produce a range of nervous system-mediated organism responses that cover a spectrum ranging from beneficial to deleterious (see Fig. 35.6). Some examples are presented in the following.

Neurogenesis produces thousands of new neurons every day in the mammalian brain, primarily within the subventricular zone and the subgranular zone. The activity and replication capacity of neural stem cells in these regions, which are multipotent and self-renewing, are regulated by immune system mediators including IL-1, IL-6, and TNF. Intracortical brain injury and systemic inflammation that activates microglial cells impairs neurogenesis. IL-1, IL-6, and TNF released by activated microglia play a pivotal role in this suppression of neurogenesis.[62,63] IL-1 induces impairment of hippocampal neurogenesis via two mechanisms. The first is by activation of hypothalamuspituitary-adrenal (HPA) axis and GC secretion that in turn lead to impaired hippocampal neurogenesis.[64,65,66] The second mechanism involves a direct inhibitory effect of IL-1 on neuronal progenitors via IL-1 receptor-mediated mechanism leading to NF-κB activation. This inhibitory effect of IL-1 can be attenuated by blockade of IL-1 signaling.[64,67,68] Elevated IL-1 levels have been implicated

in several syndromes associated with impaired neurogenesis, including depression, stroke, infection, and stress. TNF signaling through the TNF receptor type I inhibits neurogenesis and induces differentiation of neural stem cells toward astrocytic, rather than neuronal, phenotypes.[69,70,71] IL-6 inhibits neurogenesis by decreasing cell survival and reducing neuronal differentiation.[63,72]

Learning and memory are neuronal processes that produce persistent changes in brain neural networks. In the hippocampus, a brain region that occupies a critical role in these functions, neural networks are extremely plastic. The neurophysiologic basis of this plasticity requires long-term potentiation (LTP) and long-term depression, the activitydependent enhancement or attenuation synaptic efficacy. Under homestatic conditions, cytokines play a crucial role in the trophic support of neurons that enhances neuronal integrity. In inflammatory conditions, however, enhanced cytokine production is detrimental, because IL-1, IL-6, and TNF produced by activated microglia, or entering the hippocampus from the circulation, suppress LTP and impair synaptic plasticity.[73] This significantly impairs the organism's ability to learn and remember. Exposure of rat hippocampal slices to IL-1 or TNF leads to suppression of LTP and basal synaptic transmission.[73,74] Low IL-6 levels are involved in mediating transition between short- and longterm plasticity, but at increased levels, IL-6 interferes with LTP process.[75] LTP is accordingly suppressed in diverse inflammatory conditions including infection, trauma, neurological diseases, stress, and aging.[76,77,78,79,80]

Cytokines and prostaglandins are directly implicated in the impairment of learning and memory that accompanies infection, stress, and aging. Systemically and locally (brain) elevated levels of IL-1 specifically interferes with hippocampal dependent spatial learning.[81,82,83] Chronic transgenic expression of IL-1 in the hippocampus produces microglial activation and increased production of inflammatory mediators with impairment in spatial memory and long-term contextual fear memory, another hippocampal-dependent memory phenotype.[84,85] IL-1 has also been implicated in mediating the detrimental effects of stress and aging on memory in the hippocampus.[86,87,88] Age-related memory impairment is associated with significant increases of IL-6 in the circulation and brain, and administration of IL-6 inhibitors can prevent memory loss.[89,90] The acute administration of IL-6 failed to produce any significant memory impairment,[91] providing an example of the importance of exposure duration to determining the net response of the nervous system to immune system-derived mediators. The role of TNF in modifying memory is less clear, because knockout animals rendered deficient in TNF do not have memory impairment.[92] Elevated TNF levels do impair performance tasks that are hippocampus dependent, and these responses are dependent upon the age of the organism and the duration of TNF exposure, which may be attributable to TNF stimulating the release of IL-1 and IL-6.[93,94,95]

Higher levels of cytokines and other inflammatory mediators complicate infection and injury, resulting in subjective feelings of sickness in the form of malaise, lethargy, fatigue, coldness, numbness, reduced appetite, and muscle and joint pain. Together with fever, these responses are termed “sickness behavior.”[96,97,98] For many decades, sickness behavior was presumed to be directly mediated by the molecular products of pathogen invasion that

directly altered neuronal, and therefore, nervous system functions. Advances in understanding cytokine biology revised this view and demonstrated that sickness behavior is a highly organized immune and nervous system behavior that enhances the ability of the organism to recover.[96,97,98] The principle mediators of sickness behavior are produced by the immune system during infection or injury, including IL-1, IL-6, TNF, and dangerassociated molecular pattern molecules (DAMPs). These have a pivotal role in orchestrating the inflammatory response and in restoring homeostasis.

The effects of immune system-derived signaling molecules on nervous system function and behavior is not limited to acute and subacute infection or injury: they also contribute to the pathogenesis of autoimmune and autoinflammatory diseases. Depression and cognitive impairment are disabling complications of chronic autoimmune diseases, including systemic lupus erythematosis. Up to 30% of lupus patients have elevated levels of antideoxyribonucleic acid autoantibodies that cross-react with the N-methyl-D-aspartate receptor to mediate an agonistic signal in neurons. The BBB in these patients is porous to these antibodies, enabling high levels of these signaling antibodies to accumulate in the hippocampus, where the agonist N-methyl-D-aspartate activity is cytotoxic to neurons, impairs LTP, and adversely influences learning and memory.[99,100,101,102] This has significant implications for neural developmental disorders, because the pups of antibody-bearing pregnant dams have evidence of hippocampal cytotoxicity and developmental abnormalities associated with behavior and learning.

NEURAL SIGNALS MAINTAIN IMMUNE SYSTEM HOMEOSTASIS

At this point, we have reviewed how immune system-derived molecules deliver information to the nervous via humoral and neural routes, which reports the organism's immune status to the brain. Signaling is accomplished by activation of afferent neurons in the periphery, accomplished by the direct action of mediators that either cross the BBB, or are produced locally within the brain and spinal cord. Neurons respond to this information by generating action potentials and by altering their cellular physiology that modifies the behavior in neural networks and shapes physiological responses. The result is that the organism alters its behavior and physiological status. As discussed in the following, these incoming signals occupy a critical role in initiating reflex responses to the immune system. These outgoing signals from the nervous system to the immune system utilize both of the major communication routes, neural and humoral. These will be considered separately.

A NEURAL CIRCUIT THAT REGULATES IMMUNITY IS THE "INFLAMMATORY REFLEX"

In the 1990s, a surreptitious finding led to the discovery of the inflammatory reflex, a prototypical neural circuit that regulates the output of the innate immune system. The experiments that were being performed had originally set out to delineate the anti-inflammatory mechanisms of CNI-1493, a tetravalent guanylhydrazone that inhibits the release of TNF and other cytokines released during innate immune responses. The investigators observed that the intracerebral administration of extremely low quantities of CNI-1493 significantly inhibited serum TNF during endotoxemia. This was an extremely puzzling result because the quantities of CNI-1493 delivered were below the efficacy concentration threshold necessary to suppress cytokine release from macrophages in vitro.

Reasoning that the presence of CNI-1493 in the brain was activating neurons that in turn relayed these signals to the peripheral immune system, the investigators repeated the experiments, only this time the animals were first subjected to vagotomy, a procedure to surgically interrupt the vagus nerve. The vagus nerve (which is named for its wandering course) innervates all of the major organs of the reticuloendothelial system: liver, lung, spleen, kidneys, and gut. Selectively cutting the vagus nerve completely abolished the anti-inflammatory actions of CNI-1493 administered into the brain.[103,104] This first established that molecular signals originating in the brain could be transduced into neural signals that were transmitted by the vagus nerve to inhibit the innate immune system (Fig. 35.7).

The vagus nerve, the tenth cranial nerve, originates in the brainstem. It is named for its wandering path through the neck, thorax, and abdomen, where it terminates on ganglia in close proximity to target organs. Up to 90% of the neural fibers in the vagus nerve are sensory, which transmit sensory information to the brain. These afferent signals in response to IL-1 in peripheral tissues are both necessary and sufficient to initiate fever and other sickness behavioral responses to injury or infection.[32,38] In the inflammatory reflex, both the afferent and efferent nerve signals travel in the vagus nerve. It is a prototypical neural circuit that modulates inflammatory responses in regionally, tissue-specific manner. Inflammatory molecules of exogenous (ie, pathogen-associated molecular pattern molecules [PAMPs]) or endogenous (ie, DAMPs) origin activate afferent nerve fibers in the vagus nerve that travel to the brainstem. As the incoming signals arrive there, they are relayed to interneurons in the nucleus tractus solatarius, which relays signals to the motor nuclei of the vagus nerve, including the nucleus ambiguous and the dorsal motor nucleus of the vagus. This culminates in action potentials that return along the vagus nerve via efferent vagus nerve fibers to the reticuloendothelial organs. There is another relay station in the outgoing pathway, because the vagus neurons terminate in the celiac ganglion, a small collection of neurons that feed axons into the splenic nerve, the only efferent nerve to the spleen.[5] Electrical or pharmacologic stimulation of the efferent vagus nerve arc produces acetylcholine release in the spleen, the neurotransmitter that suppresses macrophage cytokine release.[105] This efferent circuit of the inflammatory reflex is termed the “cholinergic anti-inflammatory pathway.”

The inflammatory reflex controls immune cell function in the spleen by transmitting action potentials through two serially connected neurons. The first is preganglionic, originating in the dorsal motor nucleus and nucleus ambiguous in the brainstem, and the second is postganglionic, originating in the celiac ganglion, the location of neural cell bodies that project axons in the splenic nerve to innervate the spleen.[106,107] The secondary splenic nerve fibers are adrenergic, not cholinergic, and utilize norepinephrine as the primary neurotransmitter.[108] Ablation of splenic neurons impairs the regulation of spleen TNF by vagus nerve stimulation, indicating that splenic neurons are integral to the cholinergic anti-inflammatory pathway. This occurs because action potentials transmitted by the efferent vagus nerve fibers culminate in the release of acetylcholine from nonneuronal splenic cells. Recently, the cellular source of this splenic acetylcholine was identified as T-lymphocytes in the spleen.[105]

T- and B-lymphocytes possess the essential molecular components required to synthesize and release acetylcholine. These include choline acetyltransferase, the enzyme that

catalyzes the biosynthesis of acetylcholine, and the high-affinity choline transporter that exports acetycholine from the cells.[109,110,111] T-cell activation by phytohemagglutinin, phorbol ester, and dibutyryl cAMP can enhance the synthesis and release of acetylcholine.[112] Splenic nerve fibers terminate in close proximity with lymphocytes to form synapse-like structures, and these lymphocytes express beta-adrenergic receptors that can respond to the neurotransmitter released by splenic nerve action potentials.[1,3,113,114] The first proof that these acetylcholine producing T cells were essential to the inflammatory reflex came from studies in nude mice, which lack functional T cells but do have B cells. Reconstitution of T cells by adoptive

transfer restores the inflammatory reflex in nude mice.[105] The identity of these acetylcholine producing spleen T cells has recently been accomplished by studying transgenic mice that express enhanced green fluorescent protein under the control of transcriptional regulatory elements for choline acetyltransferase. Only 2% to 3% of total T cells express green fluorescent protein, indicating that only a relatively small subset of total spleen T cells synthesize acetylcholine. The majority of these acetylcholine producing T cells are cluster of differentiation (CD)4+, and predominantly express markers of the memory phenotype, $CD44^{high}$ $CD62L^{low}$. Although only 4% of CD4+ T cells express acetylcholine, a total of 10% to 11% of the $CD44^{high}$ $CD62L^{low}$ memory population express acetylcholine. These cells reside within close proximity to adrenergic nerve endings in splenic white pulp parenchyma. T-lymphocytes express β2 adrenergic receptors, and stimulation of these receptors enhances acetylcholine release from this T-cell subset.[105,115]

The molecular mechanism of acetylcholine inhibition of macrophage activation and cytokine release requires signaling through a specific cholinergic receptor, the " α7 nicotinic acetylcholine receptor" (α7 nAchR). It is expressed by macrophages and other cytokine-producing cells.[116,117] Animals deficient in vagus nerve signaling by cutting the vagus or splenic nerves, or lacking molecular signaling components of the cholinergic anti-inflammatory pathway by α7 nAchR gene knockout or administration of pharmacologic α7 nAchR antagonists, are rendered exquisitely sensitive to inflammatory challenges. Because the cholinergic anti-inflammatory pathway normally provides a braking mechanism to restrain excessive cytokine release, an incomplete inhibitory neural circuit (as occurs in α7 nAchR knockout mice or when the vagus nerve is surgically cut) produces exaggerated innate immune responses. Preclinical studies in animal models and humans have established that vagus nerve activity is impaired during inflammation, an observation that agrees with an important role played by this neural circuit in maintaining normal immunologic homeostasis.

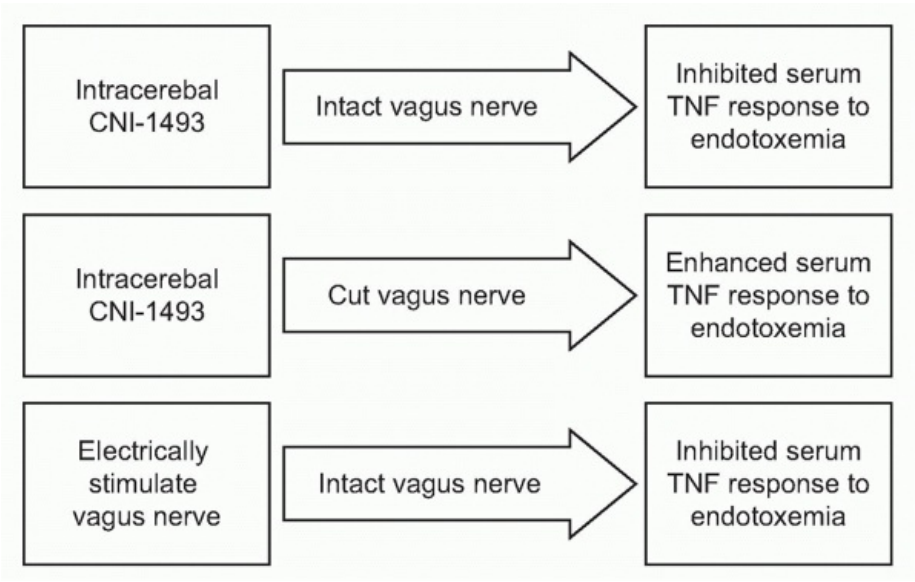

FIG. 35.7. Discovery of the "Inflammatory Reflex." Intracerebroventricular administration of CNI-1493, a tetravalent guanylhydrazone attenuates systemic inflammatory responses. This effect is abolished when animals are subjected to selective vagotomy, indicating that CNI-1493 relays signals to the periphery via the action potentials in the efferent vagus nerve. This was confirmed by activating the action potentials in the efferent vagus nerve by direct electrical stimulation. These observations provided the first experimental evidence for molecular signals generated in the brain and transmitted to the periphery by vagus nerve to inhibit the innate immune responses.

The identification of this neural circuit launched the development of selective α7 nAchR agonists as experimental therapeutics, and this has facilitated the first studies of signaling mechanisms. Selective α7 nAchR agonists significantly attenuate cytokine release by macrophages in response a range of PAMPs and DAMPs that interact with TLR2, TLR3, TLR4, TLR7, TLR9, and RAGE.[118] Signal transduction via α7 nAchR on macrophages leads to physical interaction between α7 nAchR and adenylate cyclase 6, which generates increased levels of intracellular cAMP. This leads to increase in of the transcription factor cAMP response element binding protein, and subsequent increase in expression of c-fos. Activation of c-fos attenuates NF-κB activity leading to inhibition of transcription of cytokines.

It is important to consider that the inflammatory reflex and the cholinergic anti-inflammatory pathway are neither "parasympathetic" nor "sympathetic" (Fig. 35.8). This point has created some confusion in the literature because there has been a tendency to ignore Henry Dale's original recommendation, as noted previously, that neural circuits should be described by their neurotransmitters, not their function. The inflammatory reflex has been incorrectly described as "parasympathetic," based on reasoning that the vagus nerve is classically considered to be the principal parasympathetic nerve. But as defined here and elsewhere, in the inflammatory reflex the neural signals are transmitted in the vagus nerve, then pass through the adrenergic splenic nerve before being converted back to a cholinergic signal by the T cells in the spleen.[5,105] The primary neuron (vagus) is cholinergic, the secondary neuron (splenic) is adrenergic, and terminal neurotransmitter (acetylcholine) is produced by T-lymphocytes. This circuit does not conform to either sympathetic or parasympathetic, a

point that cannot be overstressed. Perhaps the strongest argument for this point is that the cholinergic anti-inflammatory pathway can be activated

experimentally by electrically stimulating the adrenergic splenic nerve, which is often labeled (inappropriately) as a “sympathetic” nerve. Clearly, lucid understanding requires precise nomenclature, because the inflammatory reflex, while perhaps the most completely characterized neural regulatory circuit to the immune system, is not the only neural pathway that modulates immunological homeostasis.

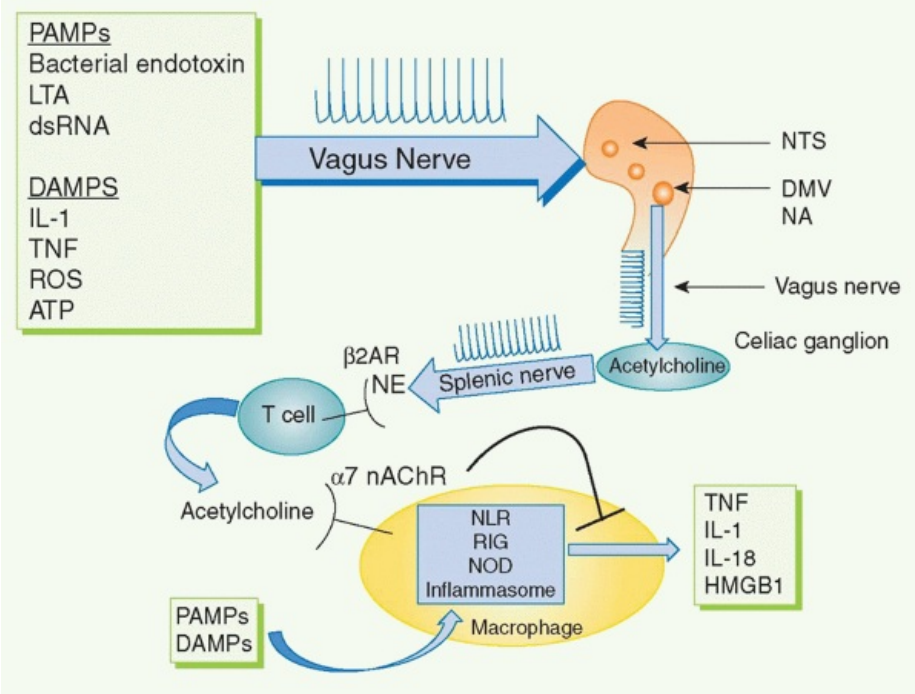

FIG. 35.8. The Inflammatory Reflex and the Cholinergic Anti-inflammatory Pathway are Neither “Parasympathetic” nor “Sympathetic.” In the inflammatory reflex, the cytokine mediators generated in response to infectious or sterile injury challenges are sensed by the afferent (sensory) vagus nerve, which transmits the information to the brain. The efferent arm of the inflammatory reflex is called the cholinergic anti-inflammatory pathway. The brain network generates the efferent (motor) vagus nerve signals that transmit via the cholinergic vagus nerve to secondary adrenergic splenic nerve, and terminate in acetylcholine production by T-lymphocytes. The terminal neurotransmitter, acetylcholine, inhibits cytokine production via pathways dependent on the α7 subunit of the nicotinic acetylcholine receptor on macrophages.

ADRENERGIC NEURONS MODULATE DIVERSE RESPONSES IN LYMPHOCYTES, MONOCYTES, AND OTHER IMMUNE CELLS

As described previously, many organs of the immune system receive innervation from adrenergic neurons that are postganglionic, residing in ganglia in the vicinity of the target organs. The preganglionic signals, which originate in neurons residing in the intermediolateral cell column of the lateral horn of the spinal cord adjacent to T1-L2, are

transmitted to the ganglia via myelinated axons that exit the spinal cord through ventral nerve roots. Within the brainstem, the major nuceli that control the activity of neurons in the sympathetic chain are located in the paraventricular nucleus of the hypothalamus, the rostral ventrolateral medulla, the ventromedial medulla, and the caudal raphe nucleus. Within the immune system organs, the major neurotransmitter of the adrenergic postganglionic neuron is norepinephrine, but other neurotransmitters (eg, vasoactive intestinal peptide) can also be released from these neurons. Within the spleen, these neurons can terminate as close as 6 nm from the resident lymphocyte (see Fig. 35.4).[1,113]

Norepinephrine biosynthesis from tyrosine is catalyzed by tyrosine hydroxylase, which is the rate-limiting enzyme in the process. Norepinephrine biosynthesis is completed by membrane-bound dopamine-hydroxylase residing in vesicles at the axon terminus. Once released by the arrival of action potentials in the postganglionic neuron, norepinephrine binds to three beta adrenergic receptors (β1-3), but the principle receptor implicated in modulating immune cell responses is β2, a member of the classic 7-transmembrane heterotrimeric guanine nucleotide-binding protein (G-protein) receptor family. β2 androgen receptor (AR) ligand-receptor interaction stimulates adenylyl cyclase activity and increases intracellular adenosine 3,5-cAMP and protein kinase A activity. This enhanced protein kinase A activity has been implicated as a critical step in signal transduction leading to downstream target responses and altered transcriptional activity. Norepinephrine signaling via βAR has been implicated as immunosuppressive on lymphocytes, monocytes, macrophages, natural killer cells, and neutrophils via β-adrenoceptors. In B cells, norepinephrine signaling via β2 has been implicated in enhancing proliferation and antibody responses.

On the other hand, norepinephrine can also interact with αARs, a receptor class that exerts proinflammatory and immunostimulatory effects. The expression of αAR and βAR within a given immune cell can be influenced by the activation status of the cell and by the presence of hormones and inflammatory factors in the extracellular milieu. The net effect of an immune cell response to norepinephrine is critically dependent upon the ratio of αAR and βAR expression. Therefore, because of absent information about AR expression and the specific contribution of αAR and βAR to signal transduction in a given cell, it is not generally possible to predict the net influence of norepinephrine on the immune response as inhibitory or stimulatory.

To this point, therefore, we have reviewed the principles governing the neural regulation of innate and adaptive immune responses. The first regulatory steps are initiated by incoming signals from PAMPs, DAMPs, hormones, and mediators derived from the immune system itself that signal to the nervous system via humoral and neural routes. This

incoming information is processed by brainstem nuclei, then relayed to neurons in the nuclei that regulate the output of the cholinergic and adrenergic input to the immune system. These neural circuits can be mapped and studied, one example being the prototypical inflammatory reflex that was defined by combining basic neurophysiology and immunobiology techniques to *in vivo* studies of immunologic homeostasis. It is likely that the future application of these techniques to other neural circuits will reveal the functional importance of other reflex mechanisms that operate through adrenergic and cholinergic neural signaling to modulate the cellular substrates of immunity.

A HUMORAL CIRCUIT THAT REGULATES INNATE IMMUNITY IS THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

Having reviewed the neural reflex regulation of the immune system, what follows is a review of a principle humoral pathway from the nervous system that maintains immunologic homeostasis. The neuroendocrine system provides a major regulatory influence on the immune system that operates chronically and transmits its terminal signals by modulating hormone levels in the circulation. This signaling network, comprised of the hypothalamus, the pituitary gland, and the adrenal glands, and termed the "HPA axis," is the major source of GCs. In the mid-20th century, Kendall, Reichstein, and Hench first demonstrated the anti-inflammatory and immunosuppressive effects of GCs, for which they later received the Nobel Prize, and since then effects of these hormones on immune function has been exhaustively studied. The HPA axis is activated by physical, psychological, and immunologic stress that cause release of corticotrophinreleasing hormone and arginine vasopressin by neurons arising in the paraventricular nucleus of the hypothalamus. Corticotrophin-releasing hormone and arginine vasopressin induce adrenocorticotropic hormone secretion from the anterior pituitary gland, which enters the circulation, travels to the adrenal gland, and stimulates GC release from the adrenal cortex. Thus, the HPA axis functions as another set of brakes on the immune system in order to prevent damage to the organism caused by an excessive immune system activation. It shares this role with the inflammatory reflex, except that it transmits anti-inflammatory signals via the humoral pathway, which can maintain long-term immunologic homeostasis, instead of through hardwired neural circuits that can operate much more rapidly to alter immune responses.

The predominant effector molecules of the HPA axis are GCs, and their major effect on the immune system is to produce immunosuppression. Chronic stress or infection is associated with chronically elevated GC levels that have been implicated in suppressed cytokine release, impaired antibody responses to vaccination, increased susceptibility to bacterial and viral infections, and a shift from Th1 to Th2 phenotype that can enhance delayed-type hypersensitivity responses. Deficiencies in HPA axis function are associated with increased susceptibility to autoimmune, autoinflammatory, infectious, and other injury syndromes associated with activation of innate immune responses. To extend the brake-failure analogy, impairment of the HPA axis by surgical lesions, genetic ablation, or pharmacologic intervention renders animals and humans exquisitely sensitive to exaggerated immune responses that damage host tissues and impair organ function. Deficient HPA axis restraint on immune responses has been implicated in the pathogenesis of systemic lupus erythematosis, rheumatoid arthritis, Sjogren syndrome, inflammatory bowel disease, psoriatic arthritis, severe sepsis, burn injury, septic shock, viral infection, and the response to a range of bacterial toxins. Thus, the neutrally regulated output of the HPA axis occupies an important role in maintaining immunologic homeostasis in the intact organism.

GC signal transduction is mediated by receptor ligand interaction with receptors that are widely expressed by immune system cells. There are two major isoforms of the GC receptor (GCR), termed α and β, formed by alternative splicing.[119] The αGCR form expressed in nearly cell types has a C-terminal ligand binding domain, and mainly mediates transcriptional modifying actions of GCs, whereas the βGCR isoform is a dominant negative inhibitor.[120,121] The diverse responses of different cell types to GC are partially dependent on the ratio of α and β GCRs expressed. GCs exert anti-inflammatory and

immunosuppressive effects by several mechanisms.[121,122] The GC-GCR complex is translocated to the nucleus where it binds to target deoxyribonucleic acid sequences that activate anti-inflammatory genes (transactivation) or attenuation of proinflammatory genes (transrepression). Nuclear GC-GCR complexes also mediate epigenetic modification by activating histone deacetylases, which remove acetyl groups from histone tails, leading to increased chromatin density resulting in inhibition of transcription factor binding and gene silencing. Moreover, GC-GCR complexes can activate human airway trypsin and induce activation of anti-inflammatory genes.[123] These nuclear actions and genomic effects of GC-GCR signaling occur within hours, but alternative GC-GCR signaling mechanisms have been implicated for more rapid responses to receptor-ligand interaction.[124,125]

GCs present in high concentrations can intercalate into plasma and mitochondrial membranes leading to altered physiochemical properties that produce changes in membrane associated protein function.[124,125,126] In immune cells, this produces reduced calcium and sodium cycling across the plasma membrane, and decreased mitochondrial adenosine triphosphate synthesis, which is essential for cytokine synthesis, chemotaxis, phagocytosis, and antigen processing and presentation.[127,128] These responses to GCR also alter cellular transmembrane potentials, which contribute to the immunosuppressive and anti-inflammatory phenotypes. Membrane-bound GCR (mGCR), a variant of cytosolic GCR formed by alternative splicing, a promoter of switching or posttranslational modification,[129] is found in peripheral blood mononuclear cells in patients with autoimmune diseases. The frequency of mGCR-positive monocytes is associated with increased disease activity, suggesting that mGCR may contribute to the pathogenesis of inflammatory and autoimmune diseases.[130,131] Targeting mGCR in T cells inhibits lymphocyte-specific protein kinase and Fyn, leading

to inhibition of T-cell receptor signaling and subsequent cytokine synthesis, cell migration, and proliferation.[132,133,134] GCs can mediate nongenomic effects by binding to cytosolic GCR (cGCR) without triggering either nuclear translocation of GC-cGCR complex or effect on transcription.[135] Proteins, such as heat shock proteins, chaperonins, and Src, released from a multiprotein GC-cGCR complex following binding with GCs are responsible for some of nongenomic effects of GCs. cGCR also attenuate arachidonic acid release, which is required for cell growth and several metabolic and inflammatory reactions.

Whereas chronically elevated GC, as occurs during stress or chronic illness, is primarily immunosuppressive, the acute release of GC occupies an important protective role in the early response to infection and injury. Increased GC levels mediate the redistribution, margination, and trafficking of lymphocytes, monocytes, and neutrophils. The resolution of the acute event is associated with a return to normal GC levels. Immunosuppressive complications occur when inflammation fails to resolve, the stimulus to GC release persists, and the side effects of excessive GC and dysregulated GCR responses become manifest.

TABLE 35.2. Therapeutic Strategies Targeting the Components of the Inflammatory Reflex

Disease Model	Activation Method	Result
Sepsis induced by lethal peritonitis	Transcutaneous stimulation of cervical vagus nerve	Inhibition of serum HMGB1 levels and improved survival
	Administration of the α7 nAChR agonist GTS21 and choline	Inhibition of serum HMGB1 levels and improved survival
Endotoxin-induced shock	Direct electrical stimulation of the cervical vagus nerve	Inhibition of serum TNF and attenuation of shock
Lethal endotoxemia	Administration of the α7nAChR agonist GTS21 and choline	Inhibition of serum TNF and improved survival
Pancreatitis	Administration of the α7 nAChR agonist GTS21	Decreased pancreatitis severity
	Vagotomy and administration of an α7 nAChR agonist	Increased pancreatitis severity
Peripheral inflammation in subcutaneous tissue	Direct electrical stimulation of the cervical vagus nerve	Inhibition of the neutrophil recruitment to the wound
Hemorrhagic shock	Direct electrical stimulation of the cervical vagus nerve	Decreased hypotension severity, inhibition of TNF secretion
Ischemia-repurfusion injury secondary to	Direct electrical stimulation of the	Inhibition of cytokine production in spleen, liver, and heart, and

suprarenal aortic clamping	cervical vagus nerve	attenuation of shock and tissue damage
Collagen-induced arthritis	Surgical stimulation of the cervical vagus nerve	Decreased arthritis severity
	Administration of the α7 nAChR agonist AR-R17779	Inhibition of TNF secretion and decreased arthritis severity
	Vagotomy	Increased arthritis severity
Ileus	Vagotomy	Increased ileus severity
	Administration of the α7 nAChR agonist AR-R17779	Attenuation of postoperative ileus and intestinal inflammation
Myocardial infarction	Direct electrical stimulation of the cervical vagus nerve	Inhibition of cardiac myoglobin release during reperfusion injury
Colitis	Administration of α7 nAChR agonists and vagotomy	Increased colitis severity
	Administration of α7 nAChR agonists	Decreased colitis severity
Ventilator-induced lung injury	Administration of α7 nAChR agonists	Inhibition of cytokine levels in lung and plasma, and amelioration of lung injury
Obesity	Administration of α7 nAChR agonists	Improves glucose homeostasis and insulin sensitivity Reduces weight gain

IMPAIRED NEUROPHYSIOLOGIC CONTROL OF IMMUNE HOMEOSTASIS CONTRIBUTES TO NONRESOLVING INFLAMMATION

Failure of the neural and humoral reflex mechanisms that operate to normally restrain the immune system can produce “nonresolving inflammation,” which contributes significantly to the pathogenesis of atherosclerosis, obesity, cancer, obstructive pulmonary disease, asthma, inflammatory bowel disease, neurodegenerative disease, multiple sclerosis, rheumatoid arthritis, and other important syndromes.[136] The treatment of inflammatory and autoimmune diseases, including rheumatoid arthritis and inflammatory bowel disease, has benefited significantly by clinical use of anti-inflammatory agents that prevent the

activity of ongoing inflammatory responses, but do not force it to resolve. Anti-TNF- and anti-IL-1-based therapeutics have been administered to millions of patients who have recognized improved qualities of life, diminished pain and tissue destruction, and disease remissions. These anti-inflammatory agents are distributed by the circulatory system and function systemically to modify the activity of specific cytokines or cellular targets. While these therapies have been successful in many, in some cases these agents are ineffective or even immunosuppressive, resulting in potentially serious secondary infections. There remains a strong mandate to develop new anti-inflammatory treatment approaches by continuing to focus on fundamental mechanisms that regulate inflammatory responses in order to restore processes that lead to the resolution of the immune response.

Understanding the neurophysiology of the inflammatory reflex may lead to an ability to exploit it for development of novel therapeutic strategies. Electrical and pharmacologic stimulation of the inflammatory reflex in experimental models have demonstrated the efficacy of this approach in preclinical models of inflammatory diseases. Electrical stimulation of the vagus nerve or pharmacological activation of α7 nAchR signaling reduces the magnitude of inflammatory response by 50% to 75%, but does not completely eliminate cytokine activity. These results suggest that while activation of inflammatory reflex attenuates the immune response significantly, it does not induce immunosuppression. This concept has been evaluated in a range of infectious and sterile injury experimental laboratory models including infection, hemorrhagic shock, and ischemia-reperfusion injury (Table 35.2).

There is also evidence that the inflammatory reflex is impaired in humans with nonresolving inflammation. Vagus nerve activity can be measured in humans by evaluating the instantaneous heart rate variability (the time duration between individual heart beats). Vagus nerve activity leads to slowing of heart rate under basal condition, which transiently increases heart rate variability. Clinical data reveals that vagus nerve activity is depressed or absent during inflammation, and inversely correlates with exaggerated immune responses and increased morbidity and mortality.[137,138,139,140] The association between impaired vagus nerve activity and increased inflammatory responses has been studied in numerous inflammatory diseases, including inflammatory bowel disease, systemic lupus erythematosus, rheumatoid arthritis, and sepsis.[141] In septic patients, mortality in subjects with decreased vagus nerve activity on admission was significantly higher than in septic patients with normal vagus nerve activity (63.6% vs. 0%, respectively).[142] In patients with rheumatoid arthritis, decreased vagus nerve activity has been associated with increased levels of circulating cytokines.[143] Decreased heart rate variability has been significantly associated with risk of

development of atherosclerosis, a disease where inflammatory responses play a pathogenic role in the onset and maintenance of disease.[144] Taken together, these clinical data indicate that the loss of the modulating effect of the inflammatory reflex may aggravate the immune responses, contributing to nonresolving inflammation and exacerbation of disease pathology.

It is plausible to activate the inflammatory reflex to therapeutic advantage by selectively stimulating the vagus nerve or pharmacologically activating the α7 nAchR pathway. Studies involving the use of direct vagus nerve stimulation, aimed at attenuating inflammatory responses but not leading to immunosuppression, are in progress.[145,146] Direct vagus nerve stimulation has been used widely to treat patients with medically refractory partial-onset seizures. So far, more than 50,000 individuals have received implantable vagus nerve stimulators for treatment of epilepsy. Vagus nerve stimulation, carried out by implanting a small pacemaker-like device in the chest, is safe, effective, and well tolerated. It is possible that a similar device, designed to periodically activate vagus nerve, can be used to treat chronic inflammatory diseases. In place of an implantable device, it may also be possible to develop pharmacologic approaches to activate α7 nAchR, a new anti-inflammatory drug target. Studies are in progress to evaluate the efficacy of vagus nerve stimulation and the use of α7 nAchR agonists in modulating the immunologic responses in human disease.

The first use of GCs to treat rheumatoid arthritis occurred prior to our current advanced understanding of the neuroendocrine regulation of the immune system. Today, it is possible to consider that in the future, patients may derive clinical benefit from medical neurostimulating devices that target the inflammatory reflex and other neural circuits that provide the basis for maintaining immunologic homeostasis. It is even possible that these devices will restore the resolution of inflammation for some patients and replace antiinflammatory drugs.

Chapter 36

Complement

B. Paul Morgan

DEFINITIONS AND HISTORY

Complement comprises a set of proteins present in plasma and other biological fluids, and on cell membranes, that together play key homeostatic roles in combating infection and disposal of waste. Complement is a central pillar of innate immunity, a ready-to-go, fast-response system that efficiently targets pathogens and toxic waste.

The discovery of complement dates back to the late 19th century when a number of pioneering biologists, including Josef Fodor, George Nuttal, and Hans Buchner, were exploring the bactericidal activities of plasma and serum.[1] They showed that fresh serum contained an activity that could efficiently kill some types of bacteria, and that this bactericidal activity decayed as the serum aged ex vivo and was rapidly lost when the serum was exposed to heat. To describe this heat-labile activity, Buchner coined the enigmatic term “alexin,” from the Greek and roughly translated as “without a name.” Jules Bordet extended these serum bactericidal studies using cholera bacilli and showed that sera from choleraimmune individuals efficiently killed the organism, whereas sera from nonimmune individuals did not; heating the immune serum caused loss of this bactericidal effect, suggesting it was related to Buchner's alexin.[2] Bordet then did a clever experiment: first incubating cholera bacilli with heat-treated immune serum (which alone did nothing), then adding fresh nonimmune serum; the bacilli were killed, demonstrating that killing of cholera bacilli required two serum components, a heat-stable component present only in immune serum which he termed “sensitiser,” and a heat-labile component present only in fresh serum, alexin. Around the same time, Paul Ehrlich was exploring how immune serum caused hemolysis of animal erythrocytes; he also found that these same two components were required. The heat-stable component present only in immune serum he termed “amboceptor” (and later immune body or antibody), while the heat labile alexin, he called “complement,” to indicate that it merely complemented the inherent hemolytic effect of amboceptor.[3]

Over the first few years of the 20th century, an intense debate continued regarding the nature of complement and its relationship to antibody, with Bordet and Ehrlich as the main protagonists. The “complement fixation test,” developed by Bordet and his coworkers around 1900 as a means of testing whether an individual possessed antibodies against a particular bacterium (ie, was immune), relied on the fact that complement was consumed when antibody bound its target and demonstrated conclusively that complement was a distinct activity in serum.[4] This test, the mainstay of immune diagnostics for a century, is still used for some

pathogens today. The famous Glasgow physician and pathologist Sir Robert Muir, writing in 1906, described complement as “that labile substance of normal serum that is taken up by the combination of an antigen and its antibody,”[5] a definition it would be hard to improve on today.

Over the next 20 or so years, a number of scientists used the serum fractionation techniques that were state of the art at the time to investigate the “substance” called complement. Euglobulin precipitation (by dialysing serum against water) revealed that neither the re-dissolved euglobulin precipitate nor the dialyzed serum supernatant alone possessed complement hemolytic activity; however, when re-combined, complement activity was restored, demonstrating the need for at least two components, termed C′1 and C′2. The precipitable euglobulin C′1 component was inactivated by heating to 56°C, while the soluble C′2 component was heat-stable. By the mid-1920s, other manipulations of serum, including adsorption on yeast particles, incubation with ammonia or treatment with cobra venom had shown that there were at least four separable components necessary for complement activity, termed C′1, C′2, C′3, and C′4.[6]

The physicochemical nature of complement also attracted much interest and debate until 1941, when a landmark paper from Louis Pillemer and his colleagues showed clearly that each of the components C′1 to C′4 was protein in nature.[7] Recognition of the protein nature of the complement components fueled a frenzy of protein chemistry activity that, by the mid-1960s, had further refined the components C′1 to C′4, in particular demonstrating that C′3 actually contained six separate proteins; the nine complement component proteins were therefore termed C′1, C′2, C′4, C′3a, C′3b, C′3c, C′3d, C′3e, and C′3f. The euglobulin, C′1, was also shown to be a complex of three different proteins. In 1968, a Committee on Complement Nomenclature met under the auspices of the World Health Organization to simplify and standardize, resulting in the modern terminology, in order of reaction, C1, C4, C2, C3, C5, C6, C7, C8, and C9.[8]

Up to the 1950s, complement research was focussed on the antibody-dependent activity recognised by Bordet and Ehrlich. Then, in 1954, Pillemer made a startling discovery: serum contained a protein that he called properdin (from the latin, *perdere*, which means to destroy) that could trigger complement attack on pathogens without the need for antibody.[9] This finding was hailed as a “magic bullet” against infection and was so newsworthy that it was featured in *Time* magazine under the banner “Medicine: Death to Germs.”[10]

Others strongly denied the existence of the extraordinary properdin system, accusing Pillemer of carelessness or worse; perhaps in part due to this criticism, Pillemer committed suicide in 1958, leaving others in the 1960s to confirm and extend his findings. In 1971, Hans Muller-Eberhard and Manfred Mayer independently provided definitive proof of the existence of the properdin system, which they called the alternate pathway (now alternative) to distinguish from the original antibody-dependent classical pathway of activation.[11,12] Identification of complement proteins unique to this pathway soon followed.

Up until the end of the 1950s, complement proteins were considered, with no good evidence, to be minor plasma components, present in trace amounts and hence difficult to work with. This misconception was laid bare in 1960 with the demonstration by Hans Muller-Eberhard

and colleagues that the β1c-globulin band visible on serum electrophoretograms, was in fact C3, a major component accounting for 1% to 2% of total plasma proteins.[13] Other complement proteins were soon shown to be relatively abundant in plasma, opening the door to their purification and functional characterization.

The next major leap forward was the recognition of the enzymatic nature of complement. Irwin Lepow and colleagues in the late 1950s had demonstrated that C′1 was associated with enzymatic (esterase) activity. By the mid-1960s, they had achieved a remarkable understanding of this first step of complement activation[14]; they showed that the enzyme comprised three distinct protein subunits (C′1q, C′1r, C′1s), that formation of the C′1 complex required calcium ions, that its substrates were C′4 and C′2 in that order, and that the enzyme was controlled by a plasma C′1 esterase inhibitor. It was soon recognized that a puzzling disease, hereditary angioedema, long associated with complement activation, was caused by a deficiency of this inhibitor,[15] launching the field of complement therapeutics.

Around the same time, Muller-Eberhard and colleagues showed that activation of C′3 was also enzymatic in nature. They showed that a cell-bound complex of C′1-activated C′4 and C′2 could cause activation of many molecules of C3 and their deposition on the cell surface in an active form.[16] It took another 15 years before the mechanism by which activated C′4 and C′3 attached to membranes was identified, when Brian Tack's group showed that both these molecules possess a labile, buried thioester group, exposed on activation, that covalently attached the proteins to surfaces.[17,18]

One problem with starting a history is knowing when to stop. The brief history above is incomplete and ends 40 years ago, and much that is noteworthy has occurred since then! However, that more recent history will form part of later descriptions, so I will draw a line here. Before moving on, I will remark that the use of “apostrophes” in complement nomenclature was quietly dropped in the late 1970s, so henceforth they will not be featured.

THE COMPONENTS AND PATHWAYS OF COMPLEMENT

In the 21st century, the term **complement** encompasses some 35 plasma and membrane proteins. The pathway components (Table 36.1) are outnumbered by regulatory proteins (Table 36.2) that limit activation in plasma and on self cells, and receptors (Table 36.3) that bind complement proteins to trigger a range of cellular responses. The complement proteins interact with one another to provide an effective and efficient antimicrobial defense system, along with a growing list of other roles, for example, in immune complex handling and priming for adaptive immune responses. Critical features include activation by diverse triggers, enzymatic amplification at multiple steps, and rigid control to prevent damage to self. Complement activation can be initiated in a variety of ways to target different pathogens and toxic agents. The literature describes three distinct activation pathways, although in reality, these pathways are closely interlinked. Antibodydependent activation, described by Ehrlich and others at the beginning of the 20th century, was for many years the only known pathway, now termed **the classical pathway (CP)**. The re-discovery by Pillemer in the 1950s of an antibodyindependent, pathogen-triggered pathway for complement activation laid the foundations for the **alternative pathway** (**AP**). A third activation pathway, antibody independent and triggered by pathogen-specific sugars, was described in the 1980s; at first given a variety of names to reflect the activating sugars, it is now universally known as the

lectin pathway (**LP**). These three activation systems share common components but also have pathway-specific ones.

The Classical Pathway

Antibody-dependent triggering of the CP begins with immunoglobulin (Ig)G or IgM antibody bound to its target antigen either on a pathogen or host cell membrane, or on an immune complex. IgM, a large, pentameric molecule, is the most efficient activator of complement; a single IgM molecule bound to antigen is, in theory, sufficient to generate a nidus for complement activation. Free IgM in plasma does not activate complement; however, binding to antigen through its five antigen binding domains generates major structural change affecting the whole molecule, causing it to transition from a planar to a staple conformation. These events expose complement binding sites in the constant (Fc) regions of each of the five subunits that initiate the process of complement activation. In contrast, multiple IgG molecules, bound close together on the target, termed an immune array, are needed to trigger complement activation. Again, conformational changes occur, exposing complement initiation sites in the Fc regions of the molecule. Not all IgG subclasses possess complement binding sites; IgG1 and IgG3 are strong complement activators, whereas IgG2 is a weak activator and IgG4 does not activate complement at all.

The first component of the CP is C1, a large multimeric protein comprising one copy of C1q and two copies each of C1r and C1s, held together noncovalently in a calcium-dependent complex. C1q, the recognition unit of the C1 complex, is itself multimeric, made up of six subunits, each comprising a collagenous stalk and a carboxy-terminal globular head; the six subunits are tightly associated along the collagenous stalks but separate in the head regions, giving the classical electron microscopy image of a “bunch

of tulips” (Fig. 36.1). To add further complexity to this, the most complex of complement proteins, each of the six C1q subunits is itself assembled from a trimer of homologous chains termed C1q-A, C1q-B, and C1q-C, intertwined in a triple helix in the stalk but distinct in the globular head. C1r and C1s, the proteolytic units of the C1 complex, are homologous serine proteases that associate with one-another in a calcium-dependent linear tetramer complex in the order C1s-C1r-C1r-C1s. When bound in the C1 complex, the tetramer folds upon itself in a figure-eight conformation and sits between the globular heads, held in place by ionic bonds between acidic residues in C1r/C1s and a single basic residue in each of the six C1q stalks (see Fig. 36.1).[19]

TABLE 36.1 Component Proteins of the Complement Pathway

Pathway/Component	Structure	Function	Plasma Level
Classical pathway			
C1q	460 kDa collectin, six subunits each of three	Binds immobilized	150 mg/L

	25 kDa chains	IgG/IgM to initiate the CP	
C1r	85 kDa single chain	In C1 complex, activates C1s	50 mg/L
C1s	85 kDa single chain	In C1 complex, cleaves C4/C2	50 mg/L
C4	S-S bonded heterotrimer, α, 97 kDa, β, 75 kDa, γ, 33 kDa	C4b fragment target-bound via thioester is the receptor for C2	500 mg/L
C2	100 kDa single chain	C2a fragment bound to C4b cleaves/activates C3	25 mg/L
Alternative pathway			
Factor B	110 kDa single chain, C2 homologue	Bb fragment bound to C3b cleaves and activates C3	200 mg/L
Factor D	25 kDa single chain protease	Cleaves factor B to activate	5 mg/L
Properdin	Oligomers of 53 kDa chain	Stabilizes the C3bBb complex	20 mg/L
Lectin pathway			
MBL	200-600 kDa collectin, two to six subunits each comprising three 32 kDa chains	Binds mannan sugars on pathogens to initiate the LP	0-5 mg/L (broad normal range)
Ficolin-1 (M-ficolin)	440 kDa lectin, 12 subunits each 36 kDa	Binds carbohydrate epitopes on pathogens to initiate the LP	0.05 mg/L

Ficolin-2 (L-ficolin)	420 kDa lectin, 12 subunits each 35 kDa	Binds carbohydrate epitopes on pathogens to initiate the LP	5 mg/L
Ficolin-3 (H-ficolin)	590 kDa lectin, 18 subunits each 3 kDa	Binds carbohydrate epitopes on pathogens to initiate the LP	5 mg/L
MASP-1	90 kDa single chain	Uncertain; in mouse, activates pro-fD to active fD	5 mg/L
MASP-2	74 kDa single chain	In complex with MBL or ficolin, cleaves C4/C2	0.4 mg/L
MASP-3	94 kDa single chain	Uncertain, perhaps as MASP-2	4 mg/L
MAp19(s-MAP)	19 kDa single chain	Suggested MASP-2 inhibitor	0.2 mg/L
MAp44(MAP-1)	44 kDa single chain	Suggested MASP-2 inhibitor	1.4 mg/L
Common			
C3	S-S bonded heterodimer, α, 110 kDa, β, 75 kDa	Central component in all pathways, C3b major opsonin	1200 mg/L
C5	S-S bonded heterodimer, α, 115 kDa, β, 75 kDa	Binds C6 to initiate TP, C5a major effector molecule	75 mg/L
Factor I	S-S linked heterodimer,	Serine proteasel	30 mg/L

	heavy (50 kDa) and light (38 kDa) chains	cleaves C3b/C4b in presence of cofactor	
Terminal pathway			
C6	110 kDa single chain	Binds C5b, C5b6 receives C7	50 mg/L
C7	100 kDa single chain	Binds C5b6, C5b-7 attaches to target cell	90 mg/L
C8	α (64 kDa) and γ(22 kDa) chains S-S linked, β chain (65 kDa) noncovalently associated	Binds C5b-7, C5b-8 receives C9	60 mg/L
C9	70 kDa single chain	Binds C5b-8 to form MAC	60 mg/L

CP, classical pathway; fD, factor D; Ig, immunoglobulin; LP, lectin pathway; MAC, membrane attack complex; MASP, mannan-binding lectin-associated serine protease; MBL, mannan-binding lectin; TP, terminal pathway.

For C1 activation to occur, at least two of the six head domains must be engaged simultaneously, explaining both the efficiency of activation by the multivalent IgM and the

P.866

P.867

need for a critical surface density of IgG, the immune array, for activation; this latter limitation reduces the risk of inappropriate activation of complement on host tissues. Binding of the C1q globular heads to antibody Fc is itself a complex series of events; an exposed calcium ion in the head mediates the initial binding and induces further binding events that cause rotation of the head domain. These conformational changes stress the C1s-C1r-C1r-C1s tetramer tightly gripped between the C1q stalks, thereby triggering the autoactivation of C1r via cleavage at a single site to yield a two-chain disulphide-bonded active protease. Activated C1r then cleaves its homologous substrate, C1s, at a single site to generate the active C1s protease.[*,19]

TABLE 36.2 Regulatory Proteins of the Complement Pathway

		Plasma

Regulator	Structure	Function	Level/Cell Expression
Fluid phase			
C1 inhibitor	Single chain, 100 KDa, heavily glycosylated	Serine protease inhibitor binds and inactivates C1r, C1s, MASP-2, others	150 mg/L
Factor H	Single chain, 150 kDa, 20 SCRs	AP convertase decay accelerator and fI cofactor	300 mg/L
Factor H-like 1	Single chain, 42 kDa, seven SCRs	As for fH	10 mg/L
C4b binding protein	550 kDa oligomer comprising seven α chains (eight SCRs) and one β chain (three SCRs)*	CP convertase decay accelerator and fI cofactor	200 mg/L
Carboxypeptidase N	280 kDa dimer of heterodimers of 83 kDa and 55 kDa	Inactivates C3a/C5a by removing C-terminal Arg	30 mg/L
S protein/vitronectin	84 kDa single chain	Binds C5b67 in fluid phase to inhibit MAC formation	250 mg/L
Clusterin	70 kDa heterodimer of 35 kDa chains	Binds C5b67 in fluid phase to inhibit MAC formation	150 mg/L
Membrane-bound			
CR1/CD35	220 kDa single chain, 30 SCRs,† TM	CP/AP convertase decay accelerator and fI cofactor	RBC, WBC, renal, others

DAF/CD55	70 kDa single chain, four SCRs, GPI	CP/AP convertase decay accelerator	Broadly distributed
MCP/CD46	60 kDa, single chain, four SCRs, TM	CP/AP fI cofactor	Broad, absent from RBCs
CD59	20 kDa globular protein, four S-S bonds, heavy glycosylation, GPI	Binds C5b-8 on membrane to inhibit MAC formation	Broad, all blood cells, etc.

AP, alternative pathway; Arg, arginine; CP, classical pathway; DAF, decay accelerating factor; fH, factor H; fI, factor I; GPI, glycosyl phosphoinositol; LHR, long homologous repeat; MAC, membrane attack complex; MASP-2, mannan-binding lectin-associated serine protease-2; RBC, red blood cell; SCR, short consensus repeat; TM, transmembrane; WBC, white blood cell.

*Common isoform; other oligomers of C4bp, α7β0, and α6β1, are also found in plasma.

†Common isoform; forms comprising 37 SCRs (gain of LHR) and, rarely, 23 SCRs (loss of LHR) occur.

The fH-related proteins 1 to 5 are omitted for simplicity and because their functions are unconfirmed.

TABLE 36.3 Receptors for Products of Complement Activation

Receptor	Structure	Ligand; Function	Cell Expression
C3/C4/C5 fragment receptors			
CR1 (CD35)	TM, single chain, 30 SCRs	C3b/C4b; binds immune complexes; B-cell activation	RBC, WBC, FDC, renal, others

CR2(CD21)	TM, single chain, 15 or 16 SCRs	iC3b/C3dg/C3d; sensitizes B cells for response to antigen	B cells, some T cells, FDC
CR3 (CD11b/CD18)	Integrin heterodimer, α 160 kDa, β 95 kDa, TM proteins	iC3b; phagocytic receptor, leukocyte migration	Myeloid cells, NK cells
CR4 (CD11c/CD18)	Integrin heterodimer, α 150 kDa, β 95 kDa, TM proteins	iC3b; phagocytic receptor, leukocyte migration	Myeloid cells, T cells, NK cells
CRIg	45 kDa single chain Ig super-family member	C3b/iC3b; phagocytic receptor	Tissue macrophages
C3a receptor (C3aR)	54 kDa heptaspan G protein-coupled receptor	C3a; activates cell responses	WBC, brain and renal cells, etc.
C5a receptor (CD88)	45 kDa heptaspan G protein-coupled receptor	C5a > C5adesArg; activates cell responses	Broadly expressed
C5L2	37 kDa heptaspan; G protein coupling uncertain	C5a/C5adesArg/C3a/C3adesArg; activates cell responses?	Broadly expressed
Receptors for C1q			
CR1 (CD35)	See above	C1q; uncertain	See above

C1qRp(CD93)	125 kDa single chain TM	C1q/MBL/SP-A; phagocytic receptor	Myeloid cells, endothelium
gC1qR	Tetramer 33 kDa subunits	C1q; phagocytic receptor	WBC, platelets
α2β1 integrin	Integrin, heterodimer	C1q, collagens, laminins, decorin, etc.; cell activation	Broadly expressed

CR1, complement receptor 1; CR2, complement receptor 2; CR3, complement receptor 3; CR4, complement receptor 4; CRIg, complement receptor of the immunoglobulin superfamily; FDC, follicular dendritic cell; Ig, immunoglobulin; MBL, mannan-binding lectin; NK, natural killer; RBC, red blood cell; SCR, short consensus repeat; TM, transmembrane; WBC, white blood cell.

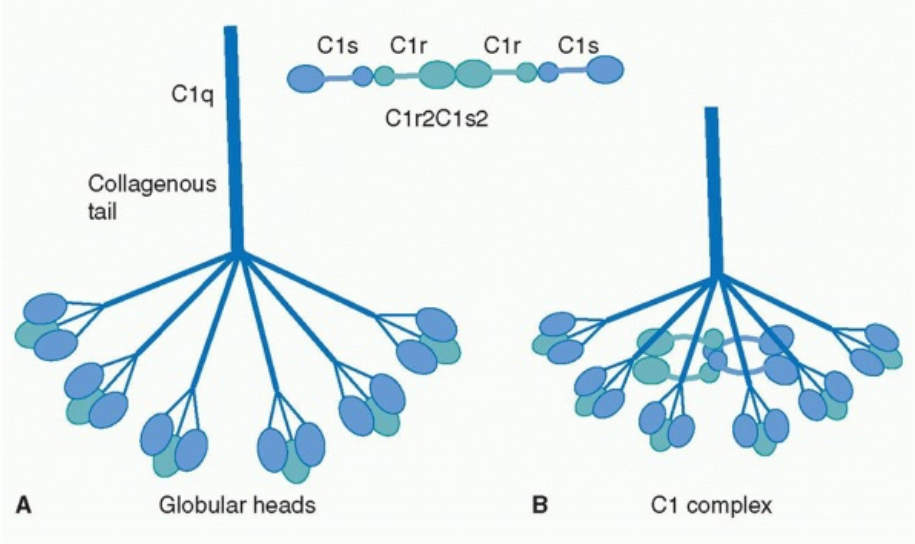

FIG. 36.1. Structure of C1. A: C1q comprises six units tightly associated through the collagenous tail, separating in the neck region to spread the globular heads out from the tail. Each unit is itself made up of three closely apposed subunits, C1q-A, -B, and -C. $C1r_2C1s_2$ is assembled in a linear complex in the order C1r-C1s-C1s-C1r. **B:** In the C1 complex, the $C1r_2C1s_2$ complex winds into a figure-of-eight conformation and binds among the globular heads in a calcium-dependent complex.

The C1s serine protease has two substrates, C4 and C2, the next two proteins in the classical pathway sequence. The illogical ordering here reflects the fact that complement components were named chronologically, according to the order of their discovery (C′1 > C′2 > C′3 > C′4), rather than according to their position in the reaction. **C4** is a relatively abundant protein, present in plasma at around 0.5 g/l. It is a large (210 kDa), disulphide-bonded

heterotrimer. Activated C1s captures C4 from the fluid phase, perhaps in part through interaction of its short consensus repeat (SCR) domains with C4, then cleaves the C4 α chain at a single site near the amino terminus, releasing a 77 amino-acid fragment, **C4a**, and exposing in the cleaved α′ chain of the large fragment **C4b** a labile thioester group (Fig. 36.2A). Although most of the nascent C4b formed will decay in the fluid phase through hydrolysis of the thioester, a small proportion will bind reactive hydroxyl or amino groups on the activating surface, creating a cluster of covalently bound C4b around the initiating IgG/C1 complex. Immobilized C4b binds the next component in the sequence, **C2**, in a magnesium-dependent complex. C2 is a single-chain plasma protein of mass 100 kDa and plasma concentration around 25 mg/L; it is the most heat-labile of the complement proteins, destroyed by brief incubation of plasma at 56°C. C4b-bound C2 is cleaved by activated C1s in an adjacent IgG/C1 complex, releasing a 30 kDa fragment **C2b**, while the 70 kDa **C2a** fragment, an active serine protease, remains associated with C4b on the surface.†,[20,21]

The magnesium-dependent **C4b2a** complex is the CP C3 convertase, the next activation enzyme in the sequence. C2a in the C4b2a complex is an active serine protease that cleaves **C3**, a two-chain 190 kDa protein, homologous to C4 and the most abundant of the complement proteins at around 1 g/l in plasma.[22] Cleavage releases a 77 amino-acid fragment, **C3a**, from the amino terminus of the α chain of C3, exposing in the large fragment, **C3b**, a labile thioester group essentially as described previously for C4b (Fig. 36.2B). Again, most of the C3b formed decays by thioester hydrolysis, but a small fraction covalently binds the activating surface, clustering around the site of activation. Some of the C3b formed will directly bind C4b2a through its thioester to form a trimolecular complex, **C4b2a3b**; this binding is not a random event but occurs at a single specific site in C4b, placing C3b in the correct orientation for succeeding steps of activation. The C4b2a3b complex contains a binding site for **C5** involving interactions with both C4b and C3b in the complex. C5, another homologue of C4 and C3, is a 200 kDa, two-chain molecule present in plasma at about 100 mg/L; importantly, C5 lacks the critical thioester group and so cannot bind covalently to targets. Once bound to C4b2a3b, the CP C5 convertase, C5 is cleaved by C2a in the complex, releasing a 74 amino-acid fragment, **C5a**, from the α chain of C5 and leaving the large fragment, **C5b**, loosely attached to the convertase. Cleavage of C5 is the final enzymatic step in the CP (Fig. 36.3).

Two features of CP activation are critical to its roles. First, amplification at each of the enzymatic steps is critical for efficient activation; thus, a single active IgG/C1 complex will deposit an abundance of C4b in the vicinity of the initiating

IgG/C1, each C4b2a complex formed will in turn cause deposition of many copies of C3b on the surrounding membrane, and each C5 convertase will also cleave multiple C5 molecules. Second, the nascent thioester groups in C4 and C3 are critical components of complement activation; without these entities, complement activation on surfaces would be an impossibility and the system would not function. The thioester group is formed from interaction between a glutamine and a cysteine residue that, in the intact molecule, are buried in the protein structure (Fig. 36.4).[17,18] When activated by the convertase, a major conformational change occurs that exposes the internal thioester bond in C3b and C4b, making it very unstable and highly susceptible to attack by nucleophiles such as hydroxyl groups (-OH) and amine groups

(-NH_2) in membrane proteins and carbohydrates, creating a covalent bond that locks C3b and C4b onto the surface.[23] The exposed thioester is highly labile and rapidly inactivated by hydrolysis, restricting binding of C3b and C4b to the immediate vicinity of the activating enzyme.

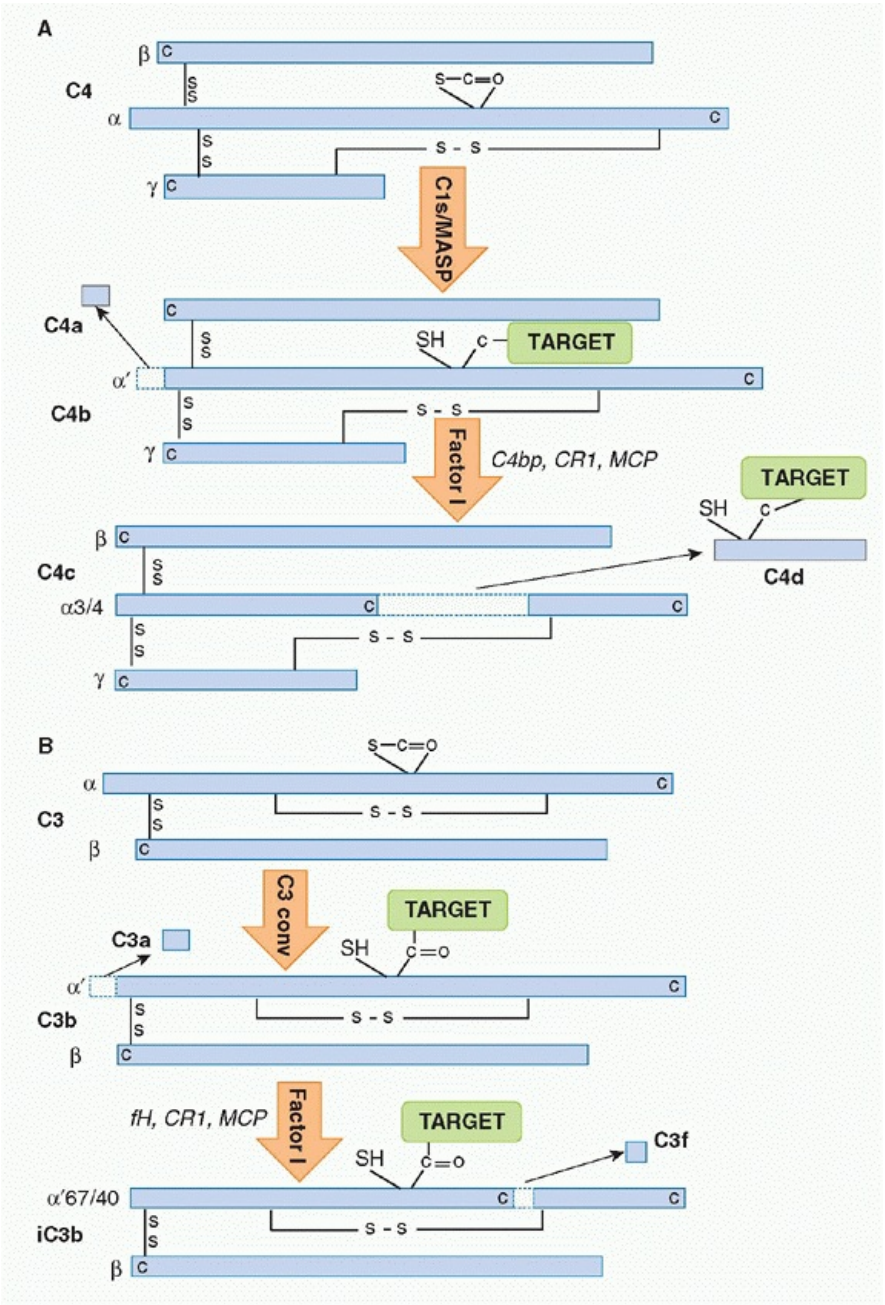

FIG. 36.2. Activation and Inactivation of C4 and C3. A: C4 is activated by cleavage of a 77 amino acid fragment, C4a, from the amino terminus of the α-chain, catalyzed by C1s in the classical pathway (CP) or MASP-2 in the lectin pathway (LP). Activation exposes the thioester in the α′-chain of C4b, enabling attachment to surfaces. The plasma enzyme factor I (fI) cleaves and inactivates C4b in the presence of appropriate cofactors, releasing the large, multichain C4c and leaving the C4d fragment attached to the surface. **B:** C3 is activated by cleavage of a 78 amino acid fragment, C3a, from the amino terminus of the α-chain, catalyzed by the C3 convertase of the CP/LP or

alternative pathway. Activation exposes the thioester in the α′-chain of C3b, enabling attachment to surfaces. The plasma enzyme fI cleaves and inactivates C3b in the presence of appropriate cofactors, releasing a small fragment, C3f, from the α′-chain, and leaving the iC3b fragment attached to the surface. Further cleavage events, not shown here, occur in the presence of CR1 as cofactor, releasing the large, multichain C3c and leaving the C3dg fragment attached to the surface. Finally, C3dg is further degraded by plasma proteases, releasing the small C3g peptide and leaving C3d attached to the target.

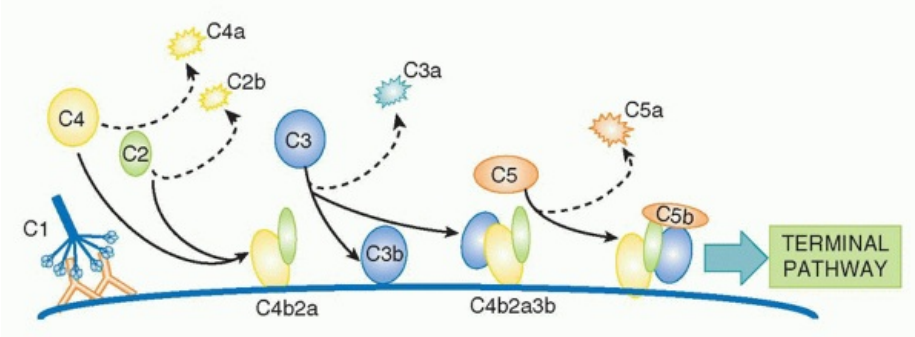

FIG. 36.3. Classical Pathway Activation. C1s in the activated C1 complex bound to immobilized antibody cleaves C4. C4b binds the surface through its thioester and acts as a receptor for C2, which is then cleaved by C1s to yield the C4b2a complex (classical pathway [CP] C3 convertase). C4b2a cleaves C3, depositing C3b on adjacent membrane. C3b binding in the C4b2a complex acts as a receptor for C5, presenting it for cleavage by C2a in the complex. Cleavage of C5 to form C5b is the last enzymatic step in the CP and initiates the terminal pathway.

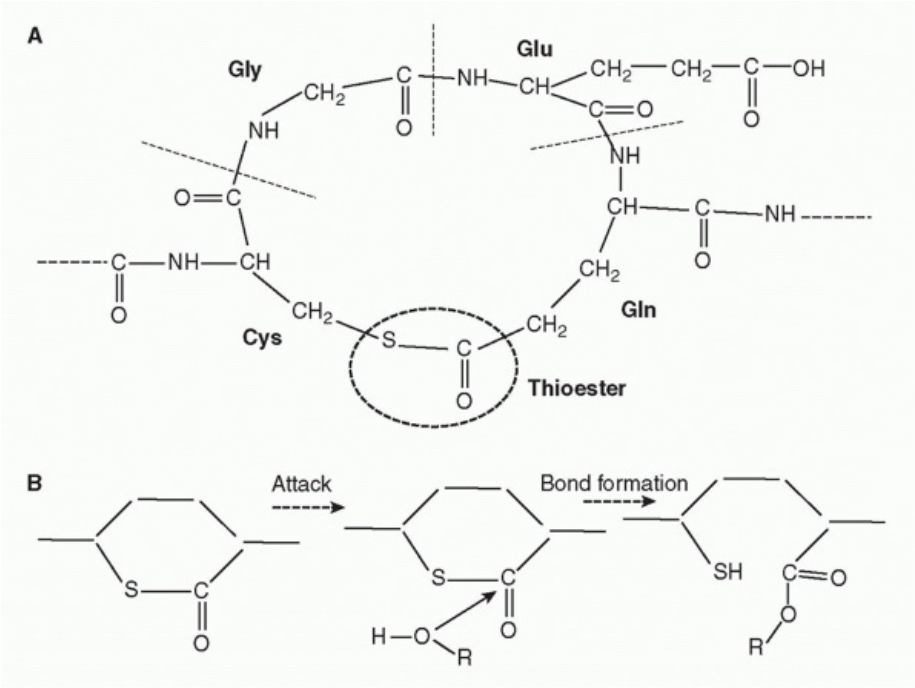

FIG. 36.4. Thioester Group Structure and Activation. A: The buried thioester in C3 and C4 is formed from the residues -Cys-Gly-Glu-Gln-. The bond is formed from a condensation reaction involving the Cys thiol group and the Glu carboxyl group in this four amino acid sequence. **B:** Hydroxyl groups on target proteins or sugars "attack" the exposed thioester in C3b or C4b in a reaction that is catalyzed by an adjacent histidine residue in the complement protein. The reaction creates a covalent bond, rigidly attaching C3b or C4b to the target.

The Alternative Pathway

The concept of an AP of complement activation grew out of the recognition that some pathogens activated complement without the need for antibody. The controversial history was briefly described previously, but today the existence of the AP is not in doubt, although whether it should be considered a separate pathway remains an area of debate. The AP functions in two interlinked ways, first as an efficient amplification loop to drive further complement activation whatever the initiating trigger, and second as an always-on pathogen sensor ready to attack foreign surfaces.[24,25] The trigger for AP activation is the presence of "activated" C3; this can be "classically activated" nascent C3b on membranes or in plasma, or C3 that has been hydrolyzed in plasma, **C3(H_2O)**. Spontaneous hydrolysis of C3 occurs under physiological conditions at approximately 5% of total C3 per day, driving a constant, low-grade "tickover" activation of the AP in plasma. **Factor B** (fB), a 110 kDa single-chain protein and structural homologue of C2, binds to form a magnesium-dependent complex, C3bB or C3(H_2O) B; in its bound state, fB is cleaved by a plasma serine protease, **factor D** (fD), releasing the 50kDa Ba fragment and leaving the serine protease fragment, Bb, in the complex to form the AP C3 convertase. The enzyme fD is a small (25 kDa) serine protease present in tiny amounts (1 mg/L) in plasma as an active enzyme with just one substrate, fB in complex with C3b/C3(H_2O). Bb in the C3bBb or C3(H_2O)Bb convertase cleaves C3 exactly

as occurs in the CP, releasing C3a and generating C3b that can bind to targets and/or bind more fB to continue the AP amplification cycle—a positive feedback amplification loop (Fig. 36.5). C3bBb on targets will catalyze the deposition of many C3b molecules as described for the CP convertase, and C3b binding to a specific site on C3b in the convertase will create a trimolecular C5 convertase in which C5 can be cleaved by the adjacent C2b, events that are analogous to those described in the CP. I have yet to mention the protein for which the AP was first named: **properdin**. This complicated molecule, an oligomer comprising two, three, or four copies of a 53Da single-chain protein, binds and stabilizes the AP convertases, reducing their inherent tendency to fall apart ("decay") and increasing markedly their capacity to perpetuate activation. Recently, a second role for properdin, binding to bacterial surfaces and forming a platform for AP convertase assembly, has been emphasised.[26]

The recognition that the AP is always on, in a constant tick-over state, explained how complement is so efficiently activated on pathogens. Tick-over ensures that all plasmaexposed surfaces are continuously showered with C3b; on self cells, inhibitory mechanisms described in the following sections ensure that no amplification occurs. However, on pathogens, lacking such protection, AP amplification kicks in, rapidly coating the surface with C3b. It is important

to note that the AP is inexorably linked to the CP in that C3b generated through the latter will feed into the former to amplify activation. It therefore does not matter whether the initial C3b is generated by the CP or AP (or, indeed, the LP that follows), the AP amplification loop will amplify the response, particularly when occurring on the intrinsically activating surfaces of pathogens.

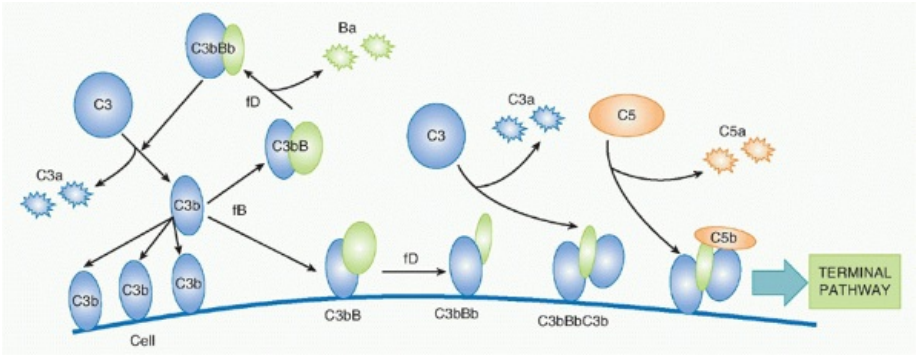

FIG. 36.5. Alternative Pathway Activation. The initiating activated C3 may be C3(H_2O) formed by spontaneous hydrolysis in the fluid phase, or C3b, formed from classical pathway/lectin pathway activation in the fluid or surface phase. Activated C3 binds factor B, rendering it susceptible to cleavage/activation by factor D. The resulting enzyme, C3(H_2O)Bb or C3bBb, cleaves more C3b, creating a positive feedback amplification loop in the fluid phase and depositing more C3b on the target. C3b binding into a target-bound C3bBb enzyme acts as a receptor for C5, presenting it for cleavage by Bb in the complex. Cleavage of C5 to form C5b is the last enzymatic step in the alternative pathway and initiates the terminal pathway.

The Lectin Pathway

The LP, first described only in 1987,[27,28] shares features with both the AP and CP. Like the AP, it provides antibody-independent "innate" immunity, activated by pathogens independent of antibody. Its similarities to the CP are legion; indeed, it only differs in the initiation step and is perhaps better considered as a different route to CP activation that bypasses the need for antibody.[29] The C1 complex is replaced by a structurally similar multimolecular complex, comprising a C1q-like recognition unit, either **mannan-binding lectin** (MBL) or **ficolin** (a family of three proteins in man), and **MBL-associated serine protease-2** (MASP-2) that provides the enzymatic activity. The recognition units bind carbohydrate epitopes, N-acetyl glucosamine for both ficolins and MBL, and mannose for MBL alone; these ligands are abundant in the cell walls of diverse pathogens, including bacteria, yeast, fungi, and viruses, making them targets for LP activation. Each MBL subunit comprises a homotrimer of 32 kDa chains, an amino-terminal collagen-like region responsible for trimerization in a triple helix, a short α-helical neck region, and a globular carbohydrate recognition domain. Subunits assemble into oligomers containing between two and six oligomers, the latter closely resembling the C1q hexamers. Indeed, C1q and MBL are members of the collectin family of proteins characterized by globular head regions with binding activities and long collagenous tail regions with diverse roles. Serum levels of MBL are highly variable in the population, from undetectable to 5 mg/L. **Ficolins** are novel lectins, structurally similar to C1q and MBL through the collagenous regions, but with head regions comprising fibrinogen-like domains.[30] Three ficolins are described in man, termed ficolin-1, ficolin-2, and ficolin-3.‡ Serum concentrations of all are low, ficolins-2 and -3 around 5 mg/L and ficolin-1 about 0.05 mg/L, although reported levels for each vary widely. **MASP-2** is a member of a family of homologous lectin-binding proteins, structural homologues of C1r/C1s, three of which express protease activity (MASP-1, MASP-2, MASP-3) while the other two do not (MAp19, also called sMAP; MAp44, also called MAP-1). After a decade of debate, claim and counterclaim, it is now generally agreed that MASP-2 is the critical enzyme of the lectin pathway: a MASP-2 dimer associates with the MBL or ficolin oligomer in a calcium-dependent manner to generate a complex that is necessary and sufficient to create the activation enzyme.[31] The biological roles of the other members of the MASP protein family remain obscure, although MASP-1 has recently been shown to be critical for AP activation in the mouse as it activates profD.[32] MASP-2 complexed with the MBL or ficolin oligomer captures C4 from the fluid phase, likely via its SCR domains, then cleaves C4 at a single site, identical to that targeted by C1s, to release C4a and generate C4b that binds through its thioester to the surface adjacent the initiating enzyme. The rest of the sequence mirrors that of the CP: C2 is captured onto C4b and presented for cleavage by MASP-2

in an adjacent complex, and the resultant enzyme, C4b2a, continues activation through C3 and C5.

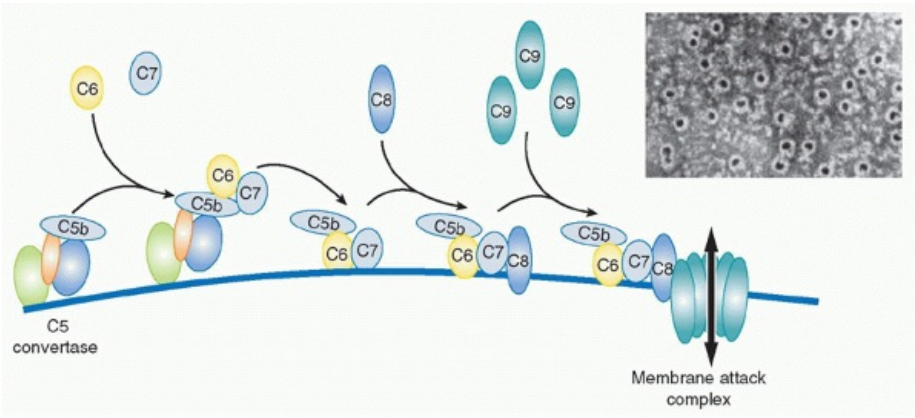

FIG. 36.6. Terminal Pathway. C5b, still attached to the convertase, binds C6, then C7. The trimolecular C5b67 complex is released to the fluid phase. A fraction of the complexes formed attach through hydrophobic interaction to the membrane. Membrane bound C5b67 recruits C8, then multiple copies of C9. C9 monomers unfold, insert into and through the membrane, and polymerize to form a transmembrane pore through which ions and water can freely flow. The inset shows an electron micrograph of a complement-lyzed cell; circular membrane attack complex lesions, a light protein rim surrounding a dark pore, are readily seen.

The Terminal Pathway

The terminal pathway (TP), sometimes referred to as the membrane attack pathway, is a final, common pathway for all activation routes. Cleavage of C5 is the last enzymatic step in the complement sequence and the final step of each activation pathway. The TP is a system almost unique in nature where five plasma proteins join to create an amphipathic membrane-inserted complex, the membrane attack complex (MAC), that creates a lytic pore in the membrane (Fig. 36.6).[33] The TP begins with the binding of the next component in the sequence, **C6**, to C5b still in the grip of the C5 convertase. C6 is a 100 kDa single-chain protein present in plasma at around 50 mg/L. Conformational changes during formation of the C5b6 complex weaken the grip of the convertase and create a binding site for the next component, C7, a 95 kDa single-chain molecule, plasma concentration about 90 mg/L. C6 and C7 are homologous molecules and are genetically linked, with genes adjacent on chromosome 5p. Incorporation of C7 causes further loosening of grip, releasing the trimolecular C5b67 complex into the fluid phase. The newly released C5b67 complexes shower down onto the lipid membrane surrounding the convertase and bind firmly to the surface via a hydrophobic site in the complex, thereby creating a nidus for continued assembly of the MAC. This is an inefficient process; the large majority of C5b67 complexes formed are inactivated in the fluid phase before they can bind membranes. Spontaneous inactivation occurs rapidly even when the C5b67 complex is assembled from pure proteins; in plasma, several proteins act as C5b-7 inhibitors to further accelerate inactivation. Those C5b67 complexes that do bind membranes then recruit the next protein in the sequence, **C8**, a heterotrimeric molecule (α and β chains each approximately 61 kDa, γ chain, 22 kDa; α and γ covalently linked, β noncovalently associated) present in plasma at about 80 mg/L. Binding of C8 introduces additional hydrophobicity, causing the resultant C5b-8 complex to embed

more firmly in the membrane. There is some evidence that the C5b-8 complex can cause membrane disruption and leakiness, but the major membrane disruption necessary to kill bacteria or other target cells requires the recruitment of multiple copies of the final component of the MAC, **C9**, a 70 kDa single-chain protein present in plasma at around 60 mg/L. The first globular C9 molecule binds C8 in the C5b-8 complex and undergoes major conformational rearrangement, unfolding to reveal a hydrophobic face that allows insertion into and through the membrane lipid bilayer. As additional C9 molecules are recruited, they in turn unfold and insert, aligning with the first C9, like barrel staves; with the recruitment of about 10 C9 molecules, the barrel is completed, creating a protein-lined channel through the membrane, the MAC (see Fig. 36.6). The C9 hydrophobic faces tightly lock the MAC in the membrane while the opposite, hydrophilic faces create a channel through which water and ions can flow, the MAC pore.** In electron micrographs of complement-lyzed targets, the MAC is readily visible as a

ring of about 10 nm internal diameter. The C5b-8 complex is displaced to the edge of the ring, resembling a pan handle.

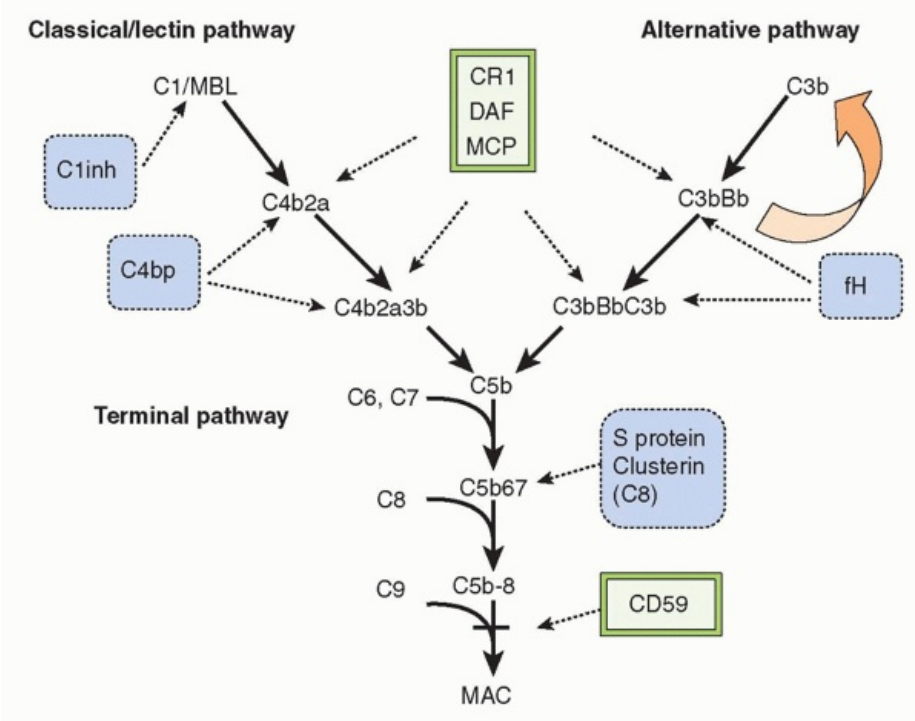

FIG. 36.7. Complement Regulation. Regulatory proteins are present both in plasma (*dotted boxes*) and on cell surfaces (*solid boxes*) to control complement activation at multiple stages in the activation and terminal pathways.

CONTROLLING COMPLEMENT ACTIVATION

Complement is designed to efficiently target and destroy pathogens and other foreign cells; however, the nature of the system dictates that it also targets host cells and thus has the potential to cause tissue damage and disease—a double-edged sword. Damage to self is minimized by the presence of numerous regulatory proteins and control mechanisms.

Complement regulatory proteins are present both on host cell membranes and in the fluid phase, collaborating to minimize activation and suppress amplification of complement. Each stage of each of the complement pathways is controlled through inhibition or accelerated decay of complement enzymes or by physical interference (see Table 36.2 and Fig. 36.7).

Control of Initiation of the Classical Pathway and Alternative Pathway

Activated C1 is regulated by a plasma serine protease inhibitor called **C1 inhibitor** (C1inh), a 100 kDa heavily glycosylated single-chain protein present in plasma at around 150 mg/L. C1inh binds C1r and C1s in activated C1 and forms a tight complex (C1inh-$C1r_2C1s_2$), simultaneously stripping them from the Ig-bound C1q. Like other serine protease inhibitors, C1inh undergoes an autocatalytic cleavage event during formation of the complex that stabilizes its binding to substrate; it thus behaves as a suicide inhibitor, inactivated during the process of inhibition. C1inh is the only plasma inhibitor for activated C1, but it has several other substrates, notably plasma kallikrein and the coagulation enzymes, factor XIa and factor XIIa.[34] C1inh also inhibits the LP, binding to and removing MASP-2 from the activated MBL/ficolin-MASP complex to switch off activation.

Control of the CP/LP C3 Convertase

The CP/LP C3 convertase, C4b2a, is regulated by inhibitors present in the fluid phase and on membranes. **C4b binding protein** (C4bp) is a complex, multi-chain plasma protein present in plasma at about 200 mg/L. The predominant structure for the C4bp oligomer comprises seven copies of an eight-SCR α-chain and one copy of a three-SCR β-chain (α7β1), locked together through disulphide bonds in the short, carboxy-terminal oligomerization domains, yielding a spider-like eight-armed structure (Fig. 36.8).††,[35] Oligomers missing the β-chain and containing seven (α7β0) or eight (α8β0) α-chains are found in various amounts in different individuals. Each of the α-chains in C4bp contains a binding site in its three amino-terminal SCRs that can bind C4b in the C4b2a complex. C4bp exerts two different inhibitory activities: first, it displaces C2a from C4b, termed “accelerated decay,” and second, it acts as a cofactor for enzymatic cleavage of C4b by the plasma enzyme **factor I** (fI), a two-chain (heavy, 50 kDa; light, 38 kDa), disulphide-bonded serine protease present at about 30 mg/L in plasma.‡‡ C4b is inactivated by cleavage at two sites in the α′-chain straddling the thioester, thereby releasing a large fragment, C4c, to the fluid phase and leaving the small C4d fragment attached to membrane (see Fig. 36.2A); neither C4c nor C4d are of particular biological

relevance. The β-chain of C4bp binds and inactivates Protein S, an important anticoagulation protein, one of many fascinating links between complement and coagulation.[36]

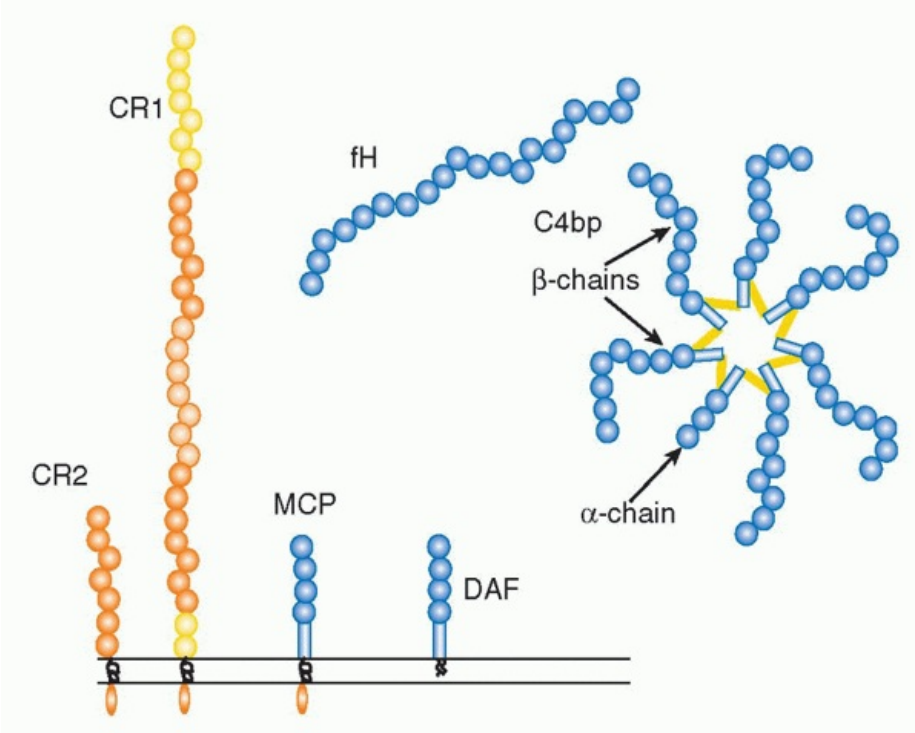

FIG. 36.8. Complement Regulators in the Regulators of Complement Activation Cluster. The complement regulators (and receptors) encoded in the regulators of complement activation cluster are all assembled from the same building block, the short consensus repeat (SCR) domain. The simplest, the fluid-phase regulator factor H, comprises just 20 SCRs arranged like beads on a string; C4bp is more complicated but is dominated by SCRs, the oligomer held together by short non-SCR joining sequences at their carboxy-termini. On the membrane, complement receptor 1 (CR1) is a very large molecule, comprising 30 SCRs in its most common isoform, with short transmembrane and cytoplasmic regions at its carboxy-terminus. The first 28 SCRs are arranged in four groups of seven called long homologous repeats, with repeating homology. Complement receptor 2 structurally resembles CR1 but comprises only seven SCRs in its most common isoform. Decay accelerating factor and membrane cofactor protein both comprise four amino terminal SCRs followed by a heavily carboxylated stalk and either a glycosyl phosphoinositol anchor (decay accelerating factor) or transmembrane and cytoplasmic regions (membrane cofactor protein).

Two homologous cell surface complement inhibitors act in tandem to regulate the C4b2a complex. **Decay accelerating factor** (DAF; CD55) is a broadly distributed glycosyl phosphoinositol (GPI)-linked membrane protein made up of four SCR domains and a heavily glycosylated stalk at the carboxy terminus that links to the GPI anchor.[37] As the name implies, DAF accelerates decay of the convertase; it binds membrane-associated C4b2a and displaces C2a, then releases because its affinity for C4b alone is low. Decay allows the second inhibitor, **membrane cofactor protein** (MCP; CD46), access to bind membrane-associated C4b. MCP, like DAF, is broadly distributed, though absent from erythrocytes, and comprises four SCR domains and a heavily glycosylated stalk, but differs in that it is a transmembrane protein with an intracellular domain that has important signalling roles,

described in a later section.[38] As its name implies, it is a cofactor for fI-mediated cleavage of C4b to C4c and C4d. This two-step regulation is important because decay alone leaves intact C4b on the surface, which can recruit more C2 and form a new convertase; in contrast, fI cleavage destroys C4b, thereby switching off activation. Another membrane protein, **complement receptor 1** (CR1; CD35), can also regulate the C4b2a enzyme through decay and cofactor activities. CR1 is an enormous molecule expressed on erythrocytes, the majority of leukocyte subsets, dendritic cells, glomerular podocytes, and a few other cell types. CR1 comprises, in its most common isoform, 30 SCRs, with a transmembrane region and short cytoplasmic domain at the carboxy-terminus.[39] The amino-terminal 28 SCRs are arranged in seven blocks, termed long homologous repeats (LHRs), in which the first SCR in each LHR is homologous to the first SCR in every other LHR, the second to every other second SCR, and so on. The functionally important parts of CR1 are the C3b-/C4b-binding sites contained in the first four SCRs of the first three LHRs; although differing in relative activities and ligand binding affinities, each of these sites can both decay the C4b2a convertase and bind C4b to catalyze its cleavage by fI. Because the functional sites are at the cell-distal end of a very large, elongated molecule, interaction with C4b or C4b2a on the same cell (intrinsic activity) is limited; however, interaction with C4b or C4b2a on adjacent surfaces (extrinsic activity), for example on circulating immune complexes, is favoured and is an important physiological role of erythrocyte CR1.[40]

Control of the Alternative Pathway C3 Convertase

The AP C3 convertase, C3bBb, is regulated in a very similar manner to the CP convertase. C4bp has only very low affinity for C3b or C3bBb, likely of no physiological relevance. Its role is taken by another plasma protein, **factor H** (fH), an elongated, single-chain protein made up entirely of 20 SCRs, present in plasma at about 300 mg/L.[41] The complement regulatory activity of fH resides in SCRs 1 to 4; these four domains bind the C3bBb convertase, displace Bb from C3b (accelerated decay), and act as cofactor for fI to cleave C3b at two internal sites in the α′-chain, generating the large membrane-bound fragment, iC3b, and releasing a small peptide, C3f. iC3b cannot drive further complement activation but is an important ligand for complement receptors, as described in a later section. On membranes, the C3bBb convertase is regulated by the same proteins that control C4b2a. DAF binds C3bBb, displaces Bb, and is then released (decay acceleration); MCP binds C3b and catalyzes its cleavage by fI to yield iC3b and C3f (see Fig. 36.2B). CR1, through its C3b-/C4b-binding sites, both decays C3bBb and binds C3b to catalyze its cleavage by fI. Importantly, CR1 catalyzes a second fI cleavage event, an additional cut that releases the large fragment, C3c to the fluid phase, leaving a small piece of the α′ chain, C3dg, attached to the membrane through the thioester. Plasma proteases then chew C3dg down further to C3d, an important ligand for complement receptors.

Control of the Anaphylatoxins

The fragments C3a and C5a released during activation of complement are extremely potent inflammatory mediators, attracting phagocytes to the site of activation (chemotaxis),

and activating them to release their cargoes of enzymes, reactive oxygen species, and other proinflammatory molecules. These powerful effects are limited in time and space by the rapid

inactivation of C3a and C5a in plasma and tissue fluids. The principal inactivator is **carboxypeptidase N** (CPN), a metallocarboxypeptidase made up of four noncovalently associated subunits, two identical 85 kDa regulatory subunits that stabilize the enzyme, and two identical 55 kDa catalytic subunits, present in plasma at 30 mg/L. CPN is a zinc-dependent enzyme that cleaves carboxy-terminal arginine or lysine residues from proteins or peptides; it removes the carboxy-terminal arginine (Arg; N) residue from both C3a and C5a.[42] The residual peptides, C5adesArg and C3adesArg have, respectively, much reduced or absent proinflammatory activities because of reduced or absent capacity to bind the receptors for the parent molecules. Plasma levels of these peptides can be measured and provide a useful index of ongoing complement activation in man and animal models. Although C3adesArg and C5adesArg are inactivated with respect to proinflammatory activity, they retain or acquire other activities that may be of equal biological importance. CPN also removes the carboxy-terminal Arg from bradykinin, altering receptor binding and biological properties of this important mediator.

Control in the Terminal Pathway

Control at the C3 convertase stage is the crucial pinch-point of complement activation; nevertheless, later stages are also subject to control. C5 convertases of both activation pathways are subject to the attentions of the same regulators described for the equivalent C3 convertases, limiting their lifespan through decay acceleration and cofactor collaboration with fI. As further insurance against damage to self, the TP is also regulated at multiple stages. Once released from the convertase, the C5b67 complex must make the perilous journey to the membrane—an entirely random migration that must be accomplished before the membrane-binding site decays or is blocked, all of a fraction of a second. The vast majority of the C5b67 complexes formed never bind membrane; the site is hydrolyzed or the plasma scavenger proteins **S-protein** (also called vitronectin) and/or **clusterin** bind and block the site.[43,44] Perhaps the most efficient fluidphase inhibitor of the TP is the next component in sequence, C8; if C8 binds C5b67 before it attaches to membrane, the binding site is lost. Because the process is so inefficient, large amounts of the waste product, the terminal complement complex (TCC) containing all the TP components, clusterin and S-protein, are found in plasma when complement activation occurs in vivo. TCC levels in plasma can be measured and provide an excellent index of ongoing complement activation. Despite the attention of these fluid-phase inhibitors, some C5b67 complexes will bind the membrane, usually on the same cell and close to the triggering convertase, but occasionally on adjacent, innocent bystander cells. C8 then binds, and with recruitment of multiple C9 molecules, the MAC forms. Membrane regulation of this process is provided by **CD59**, a small, compact GPI-anchored molecule widely expressed on most cell types.[45] CD59, by moving randomly in the membrane, will encounter the forming MAC at the C5b-8 stage and lock firmly to it, preventing the recruitment of multiple C9 molecules and the assembly of the MAC lytic pore (Fig. 36.9).

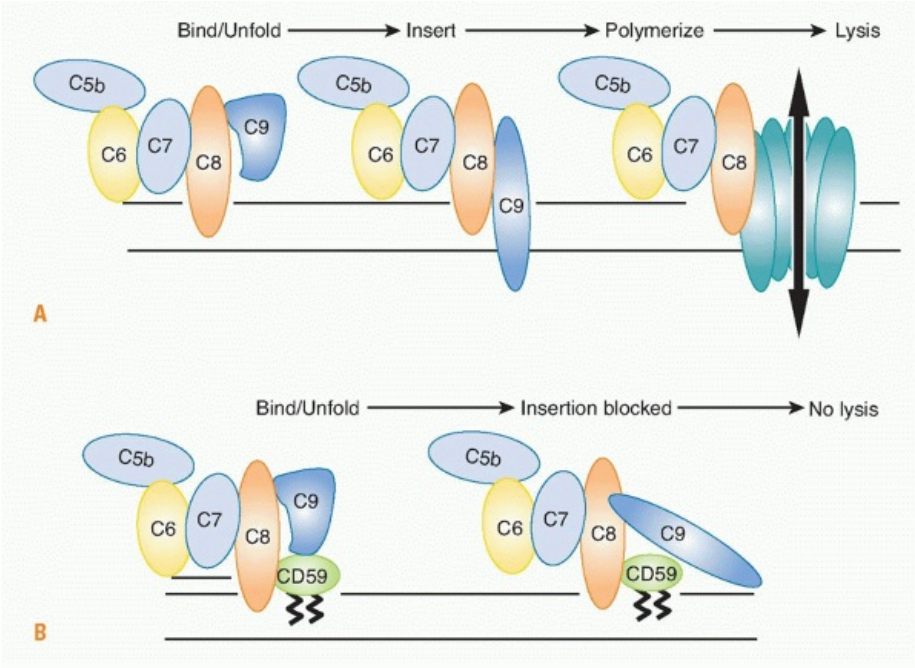

FIG. 36.9. Membrane Attack Complex Inhibition by CD59. A: In the absence of CD59, C5b67 bound to the membrane sequentially recruits C8 then multiple copies of C9 that unfold, insert, and polymerize to form the membrane attack complex pore. **B:** When CD59 is present on the membrane, it binds noncovalently into the C5b-8 complex. Although the first C9 can still bind, unfolding and insertion is sterically hindered, further C9 recruitment is halted and no pore forms.

Resistance and Recovery Mechanisms in Nucleated Cells

As a further failsafe to protect from MAC killing, metabolically active nucleated cells deploy recovery processes that eliminate the MAC lesion from the cell membrane. Recovery

was first described in neutrophils that, when attacked by complement, rapidly started to "bleb," releasing multiple vesicles to the fluid phase.[46] Electron microscopy and biochemical analyses showed that these vesicles were packed with MAC pores, while the rest of the cell membrane was free of lesions (Fig. 36.10). This packaging and removal was an active process and, when inhibited by metabolic poisons, neutrophil killing by MAC was increased. Similar mechanisms of MAC removal, either by shedding on vesicles or internalization, were soon discovered in many other nucleated cell lines and primary cells. Despite the fact that the recovery mechanism was discovered 25 years ago, the precise way in which the cell senses the MAC, packages MAC lesions into membrane patches, and sheds or internalizes the patches remain poorly defined. In neutrophils, calcium ion influx through the MAC pore is a key early event, but the downstream signaling pathways leading to recovery are unknown.

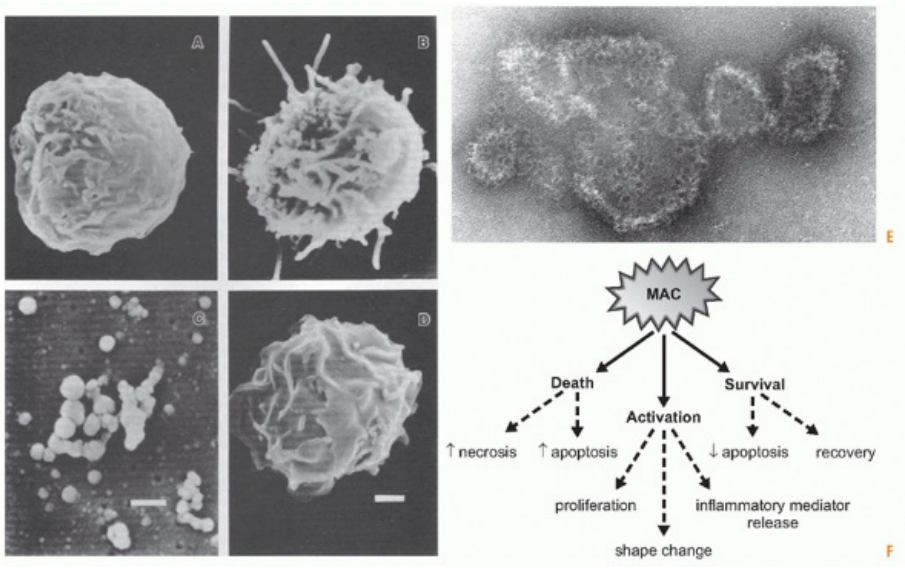

FIG. 36.10. Recovery Mechanisms in Nucleated Cells. A: Neutrophils prior to complement attack display a smooth, slightly ruffled appearance in scanning electron micrographs (SEMs). **B:** Within minutes of exposure to a nonlethal complement attack, the appearance is transformed: cells are covered in membrane projections. **C:** This frame shows SEM appearance of vesicles shed from attacked cells. **D:** After recovery, cells regain their tranquil appearance. **E:** This frame shows transmission electron micrographs of the same vesicles to show rich decoration with membrane attack complex (MAC) pores. **F:** Nonlethal MAC attack is not without consequences for the cell; changes in cell survival, proliferation, morphology, inflammatory mediator release, and many other events may be triggered in the cell.

COMPLEMENT RECEPTORS, OPSONINS, AND ANAPHYLATOXINS

Complement activation is a danger signal that alerts the host to infection or injury and initiates appropriate responses. Complement activation products flag danger by physically binding to pathogens, immune complexes, and other toxic bodies, and by their release into the surrounding milieu; subsequent events require the interaction of these fragments with specific receptors present on a variety of cell types (see Table 36.3).

Receptors for the Opsonic Fragments of C3 and C4

C3 is the most abundant complement component and the most important source of complement fragments. C3b and its degradation products iC3b and C3d coat the target, a process called opsonization, thereby tagging the target for recognition by cells bearing complement receptors.[47] **CR1,** described previously as a complement regulator, is an atypical receptor in that it modifies its own ligand. CR1 binds C3b (and C4b) coating immune complexes (ICs) via its binding sites in LHRs 1, 2, and 3, and catalyzes its cleavage by fI. Erythrocyte CR1 plays a critical role in IC handling; the C3b-coated IC binds CR1 on the erythrocyte and is held transiently until the ligated C3b is cleaved by fI to iC3b/C3dg; binding affinity is lost and the complex is released, only to bind again via another C3b.[40] This

dynamic binding permits the efficient sequestration of ICs on erythrocytes but without immobilizing them in a way that inhibits their efficient transfer to complement receptor-bearing tissue macrophages in the spleen and liver for final disposal. CR1 on other cell types also operates by binding and processing C3b-coated ICs. On dendritic cells, CR1 localizes opsonized ICs for presentation of antigen to T cells, while on B cells, C3b coating the IC binds CR1 and is cleaved to C3d, a ligand for another complement receptor, **complement receptor 2** (CR2; CD21), clustered with CR1 and the B-cell antigen receptor (BCR). Simultaneous engagement of CR2 and the BCR markedly lowers the threshold for antibody response.

CR2 is made up of either 15 or 16 SCR domains (alternative splicing removes SCR11 in the smaller isoform), a transmembrane region, and a cytoplasmic tail with important roles in signalling.[39] It is expressed on B cells, T-cell precursors and some mature T cells, dendritic cells, and some other cells involved in antigen presentation, basophils and epithelia. CR2 is a rather promiscuous receptor with numerous binding partners, including the IgE receptor (CD23), interferon-α, and the Epstein-Barr virus; its complement ligands are C3d or iC3b, binding at a single site in SCR1 and SCR2. The key role of CR2 is to enhance the immune response to antigens contained within the IC. On B cells, CR2 is clustered with the B cell-specific signaling molecule CD19 in a complex held together by the tetraspanin CD81; this tri-molecular complex interacts with the BCR to modulate the B cell response to antigen. CR2 on dendritic cells contributes to IC trapping in lymph node germinal centres.

Complement receptor 3 (CR3; CD11b/CD18) is a heterodimer comprising a 165 kDa α-chain (CD11b) and a 95 kDa β-chain (CD18); it is a member of the β_2-integrin family of leukocyte surface heterodimeric proteins sharing the common β-chain. CR3 is expressed on monocytes, neutrophils, mast cells, natural killer cells, dendritic cells, and some T cells.[48] It is notable for its promiscuity, binding adhesion molecules (intercellular adhesion molecule [ICAM]-1 and -2), coagulation proteins, microbial products, and carbohydrate antigens; its principal complement ligand is iC3b, although it binds weakly to C3d. Binding of an iC3b-coated particle to CR3 on phagocytic cells triggers the phagocytic process, leading to the elimination of the opsonized particle. Other phagocytic receptors, including the Ig Fc receptors and CD14, certainly contribute to the phagocytic process, and there is continuing debate around which of these triggers are required for and most important in the phagocytic process.

Complement receptor 4 (CR4; CD11c/CD18), another β_2-integrin expressed on myeloid cells, resembles CR3 with regard to distribution and complement ligand-binding properties. It is possible that CR4 plays important roles in some dendritic cell processes, although it remains something of an enigma.

Complement receptor of the immunoglobulin superfamily is a recently described receptor for C3b/iC3b expressed exclusively on tissue-resident macrophages, including Kupffer cells in the liver.[49] It plays important roles in the capture and clearance of opsonized ICs and pathogens from the circulation.

Receptors for the Anaphylactic Fragments of C3 and C5

Receptors for the small anaphylatoxin (AT) fragments released from C3 and C5 during activation are extremely important players in the recruitment of inflammatory cells and in a

growing list of other events. C3, C4, and C5 are structurally similar molecules and are all activated in similar ways: a single cut by the activating enzyme that releases a peptide, C3a, C4a, and C5a, respectively, from the amino terminus of the α-chain. Current opinion is that there are no receptors for C4a and that, as a consequence, it has no biological function. In contrast, specific receptors exist for the AT molecules C3a and C5a, which mediate important biological roles. Three AT receptors have been described to date, the **C3a receptor** (C3aR), the **C5a receptor** (C5aR; CD88), and the **C5a receptor-like 2** (C5L2).[50] They are homologous molecules, members of the G-protein-coupled receptor family of heptaspan membrane proteins. **C3aR** is expressed on all myeloid cells and some nonmyeloid, including activated T cells, astrocytes, endothelia, epithelia, and smooth muscle. C3aR binds C3a with nanomolar affinity but does not bind C3adesArg, C5a, or C5adesArg. Upon binding of C3a, intracellular signaling cascades are triggered through activation of heterotrimeric G-proteins that in turn cause increased intracellular free calcium and other downstream events. **C5aR** binds C5a with nanomolar affinity and C5adesArg with tenfold lower affinity; it does not bind C3a/C3adesArg. C5aR is expressed on all myeloid cells and numerous nonmyeloid including endothelia, neurones, and astrocytes; expression on lymphoid cells has been suggested but current evidence does not support this. Binding of C5a or C5adesArg triggers activation via heterotrimeric G-proteins, essentially as described for C3aR. **C5L2** was first described just 10 years ago and remains something of an enigma.[51] It is broadly expressed on myeloid and nonmyeloid cells and is often co-expressed with C5aR in many tissues. C5L2 binds both C5a and C5adesArg with nanomolar affinity, although the binding sites for these two ligands are not identical, suggesting that they may have different effects. Some researchers contend that C5L2 also binds C3a and C3adseArg, although this remains controversial. Critically, C5L2, unlike the other AT receptors, is not G-protein coupled and, as a consequence, is considered by many as a nonfunctional decoy receptor that dampens down local responses to C5a. In one specific site, adipose tissue, C5L2 appears to be functionally important, strongly implicated as the receptor triggering fat mobilization in response to locally produced C3adesArg (termed “acylation-stimulating protein” in this context).[52] Clarification will likely soon follow in this active research area.

Receptors for C1q

Identification of receptors for C1q has been a minefield of false leads because of the inherent stickiness of the protein. Several receptors have been reported over the years,

although many have not stood the test of time and the physiological relevance of the others remains uncertain. The most convincing candidate receptor is the **C1q receptor for phagocytic enhancement** (**C1qRp**; CD93), a heavily glycosylated 120 kDa transmembrane sialoglycoprotein expressed on myeloid cells and endothelia.[53] Its extracellular region comprises a collagen recognition domain followed by five epidermal growth factor (EGF) domains; the collagen recognition domain binds the collagenous regions of C1q, MBL, and another lectin molecule, surfactant protein A (SpA). It is suggested that this interaction is important in the clearance of apoptotic cells; these spontaneously bind C1q, MBL, and likely SpA, tagging them for binding C1qRp and phagocytic clearance. Antibodies against C1qRp inhibit apoptotic cell clearance in vitro, and mice deficient in C1qRp or C1q display delayed apoptotic cell clearance. Several members of the **integrin family** of cell adhesion molecules have been implicated as C1q binders; of the several collagen-binding integrins, α2β1 stands

out for its capacity to bind C1q and MBL.[54] A 60 kDa receptor for the collagenous tail of C1q, MBL, and other collectins, termed **cC1qR**, was shown to be identical to calreticulin, a cytoplasmic chaperone protein, raising questions about how this molecule could associate with membranes and act as a C1q receptor. It is now suggested that calreticulin binds the extracellular domains of CD91 to create a receptor. Other molecules suggested to act as receptors for C1q (± MBL) include CR1 (binding the collagenous region through its membrane-proximal SCRs) and a 33 kDa protein that binds the C1q globular heads (**gC1qR**).[55] The physiological roles of these interactions are uncertain.

COMPLEMENT ONTOGENY, GENETICS, AND PROTEIN FAMILIES

Complement is an evolutionarily ancient defense system; proteins with C3-like opsonic activities and fB-like enzymatic properties are present in the hemolymph of starfish, sea anemones, and even the horseshoe crab, but not in insects.[56,57] Early studies of primitive complement systems were limited because they relied upon the identification of opsonic or lytic activities in fluids derived from various species. A more recent approach to complement evolution has been to search for complement homologues in the genomes of primitive animals.[58] These studies confirm the very early arrival of C3- and fB-like molecules, show that C3 multiplication to yield C4 and C5 occurred prior to the emergence of cartilaginous fish, confirm that the fB/C2 duplication event preceded the split between Amphibia and Mammalia, and confirm the presence of C1q-like, MBL-like, and MASP-like proteins in lamprey. All four terminal components are present in all mammals, birds, and amphibians, but no genetic evidence for terminal components is found in sharks despite early claims of a C9-like molecule and lytic activity in shark serum.

Many of the complement components, regulators, and receptors share structural features with others, creating protein families within the complement system, usually a result of gene reduplication events during evolution.

The Thioester Protein Family

C3, C4, and C5, together with the abundant noncomplement plasma protease inhibitor, α2-macroglobulin (α-2M), comprise a family of homologous proteins each made up of multiple disulphide-linked chains derived from a single chain precursor and typified by the presence of an internal thioester, hence called the thioester protein family (TEP). These proteins have evolved from an ancestral protease inhibitor closely resembling α-2M[56] and have utilized the thioester, part of the α-2M protease inhibition machinery, to confer capacity to covalently bind surfaces. Loss of the thioester in C5, a requirement for the evolution of a lytic TP, is a relatively late evolutionary event. With some of the complement protein families, their common evolutionary origins are evidenced by conservation of genetic linkage— the duplicated genes remain adjacent in the genome; however, for the TEP family, gene linkage has been lost, with each gene on a different chromosome; *A2M* on chromosome 12, *C3* on chromosome 19, *C5* on chromosome 9, and *C4* on chromosome 6. The *C4* gene is particularly interesting. First, it is duplicated in man, the two genes, *C4A* and *C4B*, encoding highly homologous proteins, differing in just four amino acids clustered in the α-chain; second, it is situated in the major histocompatibility complex (MHC) on chromosome 6, linked to the genes encoding **C2** and **fB,** themselves homologous molecules, derived from a

common ancestor.[59] Co-location of these three genes into the MHC cluster is seen in all higher vertebrates, indicating that it was an early event and suggesting that the common ancestor of the TEP family proteins was linked to fB/C2 from the earliest origins of the complement system. Whether there is any functional consequence of the location of these complement genes in the MHC is unclear; however, the *C4* gene in zebrafish is not linked to MHC,[60] implying that its location within the MHC in higher vertebrates is an evolutionary accident of no functional importance.

The Terminal Pathway Protein Family

The TP components, **C6**, **C7**, **C8, and C9**, are structural homologues derived from a common C9-like ancestor protein and show increasing complexity as one travels back from C9 to C6. **C9** is the simplest, comprising, from the amino terminus, a thrombospondin (TSP) domain, a low-density lipoprotein-receptor A-type domain, a MAC-perforin domain, and an EGF domain. The **C8β** and **C8α** chains each contain the same domains as C9, but with the addition of an extra TSP domain at the carboxy-terminus; **C8γ** is a lipocalin family member with no homology to other complement proteins; **C7** contains all the domains present in the C8 chains, but has an additional four domains at its carboxy-end, two SCRs and two factor I-MAC domains, also found as a single domain in fI.[61] **C6** closely resembles C7 but has acquired an additional TSP domain at its amino terminus. The MAC-perforin domain in the T cell pore-forming protein perforin is homologous to that in C9 and the other TP proteins, and is also found in many bacterial cytolysins, suggesting that it is a common feature of pore-forming proteins in nature.[62] The genes encoding TP proteins are linked

in two groups. C6, C7, and C9 are linked on chromosome 5. The first two are immediately adjacent to one another, albeit in opposite orientations, while *C9* is more distantly linked. *C8A* and *C8B* are very closely linked and in opposite orientations on chromosome 1p.

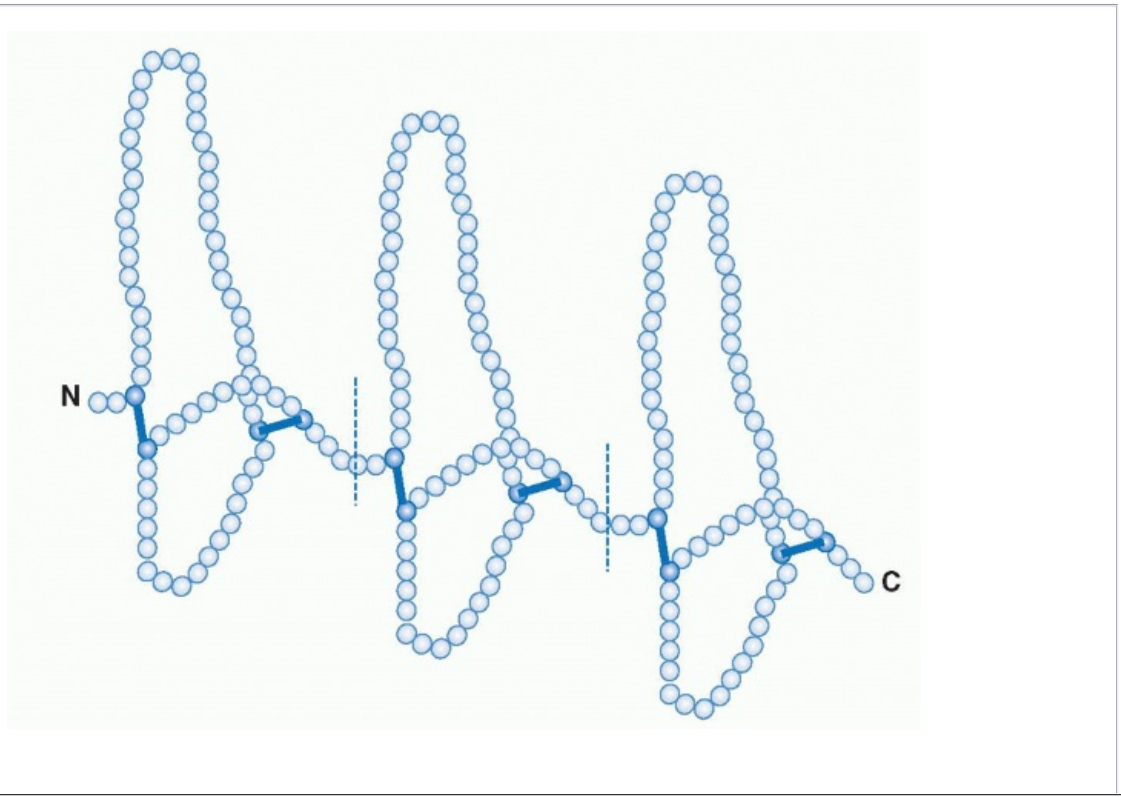

FIG. 36.11. Short Consensus Repeat Structure. The short consensus repeat comprises approximately 60 amino acids held in a rigid "bead" structure by intradomain disulphide bonds.

The Collectin Family

The **collectin** family includes C1q, MBL, and the ficolins. All have collagenous amino terminal stalks and globular recognition domains at their carboxy-termini.[63] Evolutionary tracking of this family is complicated by the frequency of collagenous proteins in nature, most of which are unrelated to complement. Clade analysis strongly suggests that lampreys (*agnathia*; jawless fish) have a *C1q* gene that is a likely ancestor of the mammalian *C1QA*, *C1QB*, and *C1qC* genes. This finding indicates that *C1q* predates the evolution of antibody and adaptive immunity, likely as a pathogen recognition molecule. MBL genes are found even in the earliest vertebrate genomes, but ficolin genes appear to be more recent, present in tetrapod genomes but not in lower vertebrates.[64] In man, the three *C1Q* genes are arranged in tandem in order A-C-B on chromosome 1p. The MBL gene resides on chromosome 10, clustered with the genes encoding the related collectins, surfactant proteins A and D (*SFTPA1*, *SFTPA2*, *SFTPD*). The genes encoding ficolins-1 and -2 are closely linked on chromosome 9q, while the ficolin-3 gene is on chromosome 1p.

The C1r/C1s/Mannan-Binding Lectin-Associated Serine Protease-2 Family

The initiating enzymes of the CP and LP comprise another family (MASPs-1, -2, and -3; C1r; and C1s) sharing the same domain structure comprising, from the amino terminus, a C1r/C1s/Uegf/Bmp1 (CUB) domain, an EGF domain, a second CUB domain, two SCRs, and a carboxy-terminal serine protease domain.[65] The *MASP1* gene, on chromosome 3, is alternatively spliced to yield MASP-1 itself, MASP-3 in which the serine protease domain is larger, and Map44, a product truncated after the first SCR. Alternative splicing of the *MASP2* gene, on chromosome 1, yields either MASP-2 itself or a truncated product, Map19, comprising the CUB and EGF domains with four unique amino acids at the carboxy-terminus. The common ancestor, present in ascidian worms, is a *MASP1* gene, although the precise pathway through which this gene reduplicated to yield the *MASP2*, *C1R*, and *C1S* genes is uncertain.[66] The *C1R* and *C1S* genes are adjacent in a tail-totail arrangement on chromosome 12p, suggesting that these two genes arose relatively recently from a common precursor.

The Regulators of Complement Activation Family

The last, and perhaps most interesting, of the complement protein families to be discussed in this section is the **regulators of complement activation** (RCA) family, characterized structurally by a preponderance of SCR domains and genetically by close linkage in the RCA cluster on chromosome 1q, suggesting that they have developed through serial duplication events.[67] The SCR domain, the signature of the family, is a globular domain of around 60 amino acids, including a number of highly conserved tryptophans, prolines, and cysteines that give the SCR its shape (Fig. 36.11). The conserved cysteines, four in each SCR, form two invariant disulphide bonds to lock the structure, and joining of domains end-toend creates the elongated, "beads on a string" appearance typical of this family. SCR domains

are also found in other complement proteins (C6, C7, fI, C1r, C1s, MASPs, etc.) and some noncomplement proteins (eg, selectins), but only in RCA proteins is the dominance of this domain seen. RCA proteins in lower vertebrates, though fewer in number (six in chicken, two in frog), are also made up of SCR domains, and their genes are clustered. The frog genes are orthologs of the human *DAF* and *C4BP* genes, indicating that these are the common ancestors of other RCA proteins. The RCA cluster comprises two blocks of genes encoding complement regulators and receptors, interspersed with a number of unrelated noncomplement genes (Fig. 36.12). The first block comprises, in sequence from telomeric end, the genes for MCP (*MCP*), a CR1-like pseudogene (*CR1-like*), CR1 (*CR1*), CR2 (*CR2*), DAF (*DAF*), a C4bp α-chain-like pseudogene (*C4BPA-like*), C4bp α-chain (*C4BPA*), and C4bp β-chain (*C4BPB*); the pseudogenes have no protein product. The second block, some distance from the first in a centromeric direction, comprises, in sequence, the genes for fH (*CFH*), fH-related 3 (*CFHL3*), fH-related 1 (*CFHR1*), fH-related 4 (*CFHR4*), fH-related 2 (*CFHR2*), and fH-related 5 (*CFHR5*). Alternative splicing of the *CFH* gene creates an additional protein product, fH-like 1 (fHL-1), comprising the first seven SCRs of fH and an additional six unrelated carboxy-terminal amino acids.[68]

Expression Patterns of Complement Proteins

The complement genes are not ubiquitously expressed; rather, they show cell type-specific expression patterns that are important in understanding how the system works.

Restricted expression of complement receptors, described previously, ensures that the appropriate cell types respond to complement activation products. Regulators are broadly expressed, on most host cells and particularly those exposed to plasma, to protect from damage; however, there are notable exceptions where one or more regulators are absent or nearly so; for example, erythrocytes lack MCP,[38] while some cells in the brain lack CD59.[69] Plasma contains an abundance of complement proteins, at concentrations varying from very high (1 g/L for C3) to very low (1 mg/L for fD). The major site of biosynthesis for most of these plasma components is the liver; abundant proteins like C3 and C4 are products of hepatocytes and, like the other hepatocytederived plasma complement proteins, behave as acute phase reactants, increasing in concentration in response to inflammatory cytokines. Hepatic synthesis of C3 and C4 can therefore increase two- or three-fold during inflammation, but plasma levels rarely increase as much because inflammation is also associated with increased complement activation and consumption of these proteins. A few complement proteins are mainly produced elsewhere; tissue macrophages are the major source of plasma C1q, adipocytes the primary source of fD, and leukocytes, likely neutrophils, the major source of plasma C7.[70] Other cell types and tissues can contribute to plasma complement protein production, and this local production is likely to be very important for complement activity within organs and tissues, particularly when inflammation is present. The kidney is a secondary source of many complement proteins; indeed, transplantation studies have shown that the kidney produces up to 5% of plasma C3, increasing to as high as 10% with renal inflammation.[71] There is very little complement synthesis in the noninflamed brain, fortunately so because brain cells are poorly protected from complement; however, inflammation switches on complement production in glia and neurons, contributing to brain cell loss in neurodegeneration.

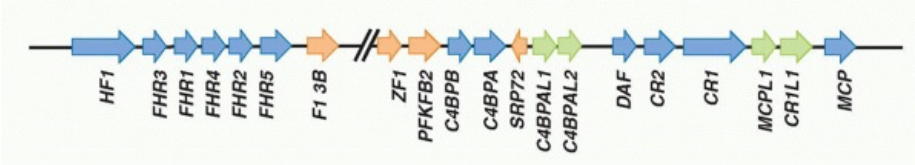

FIG. 36.12. The Regulators of Complement Activation Gene Cluster. The regulators of complement activation cluster comprise a long region (up to 7 Mb) on band q32 of human chromosome 1 that contains the genes for all the short consensus repeat-containing complement regulators and receptors. Two separate subclusters contain, respectively, the genes for factor H and the factor H-related proteins 1 to 5, and the genes encoding, in order, the β- and α-chains of C4bp, decay accelerating factor, complement receptor 2, complement receptor 1, and membrane cofactor protein. The "true" genes (*blue*) are interspersed with numerous pseudogenes (*green*) that have no protein product and several nonrelated noncomplement genes (*peach*).

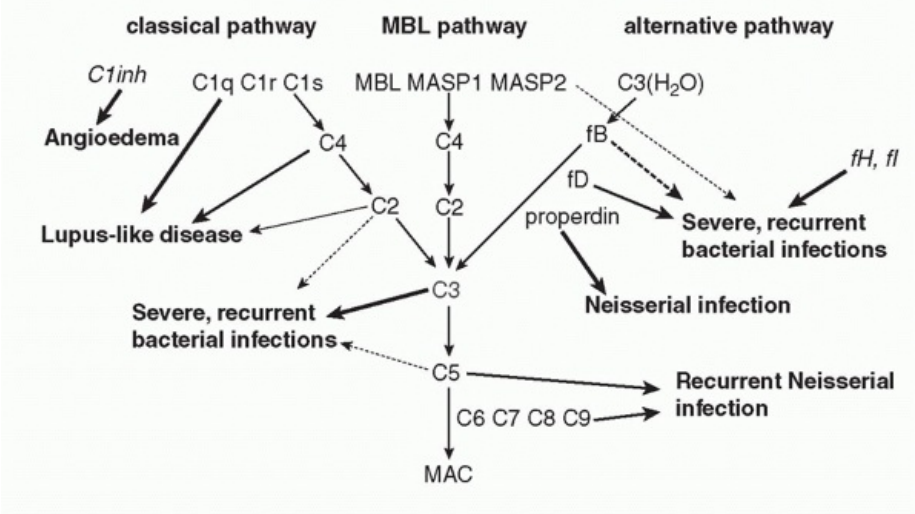

FIG. 36.13. Complement Deficiencies. Deficiencies of most of the components and plasma regulators of complement have been described in human subjects. The clinical presentations commonly associated with each of the deficiencies are summarized in this simplified figure.

COMPLEMENT MUTATIONS, POLYMORPHISMS, AND AUTOANTIBODIES

Mutations in complement proteins are rare events that can be catastrophic and cause partial or total deficiency of the protein, or more subtle, altering the expression level or functional

efficiency of the protein. Polymorphisms are common variations in protein composition that may or may not have functional consequences.

The most dramatic outcome of a mutation in a complement protein is **deficiency**, which may involve a loss of protein product (Type I deficiency) or the production of a functionally inactive protein (Type II deficiency). For almost every complement protein, regulator, and receptor, individuals totally and/or partially deficient in the component have been described, experiments of nature that have informed understanding of the biological roles of different complement pathways; indeed, deficiencies are best understood when grouped according to pathway or family affected (Fig. 36.13).

Classical Pathway Component Deficiencies

Deficiencies of **CP component** proteins (C1, C4, C2) remove the capacity for efficient activation of complement on ICs and are strongly associated with lupus-like IC disease and infections.[72] **C1q deficiency** is rare (only a dozen or so families have been described, and all affected homozygous individuals develop severe lupus-like disease with rashes, renal failure, and other sequelae before adulthood). Deficiencies of either **C1r** or **C1s** are similarly rare and often combined because of linkage and coordinate expression of the genes; symptoms and penetrance are as for C1q deficiency. **Total C4 deficiency** is also rare because there are two C4 genes (*C4A*, *C4B*) each with two alleles, requiring co-inheritance of four mutations for complete deficiency. These rare individuals will all develop lupus-like disease early. Mutations leading to loss of expression of one of more C4 alleles (null alleles) are relatively common in the population: 35% have one null allele, 8% two null alleles, and 1% three null alleles; these latter individuals will have low plasma C4 levels and an increased tendency to develop IC disease, greater in those with more null alleles and in those null at the *C4A* gene.[73] Genetic testing for C4 gene copy number is therefore a useful adjunct to measuring plasma levels in testing for C4 deficiency. **C2 deficiency** is the most common complement deficiency among Caucasians; C2 null alleles are present in some 1% of individuals, giving a predicted incidence of deficiency of 1:10,000 in the population. Although C2 deficiency does increase the risk of developing IC disease, the majority of C2-deficient individuals are healthy, detected at routine screening because their plasma lacks CP hemolytic activity.

The strong association of classical pathway deficiencies with lupus-like disease has led to the assertion that lupus, not only in complement deficiency but also in classical systemic lupus erythematosus (SLE), is caused by the defective clearance of immune complexes and apoptotic cells which then become sources of autoantigens.[74] This “waste disposal hypothesis” has altered perceptions of the disease and modified approaches to treatment.

Lectin Pathway Component Deficiencies

Deficiencies of **LP components**, partial and total, have been described. Plasma levels of MBL vary widely in the population due to a complex set of mutations and polymorphisms in the constituent chains.[75] Three mutations clustered in exon 1 of the *MBL* gene individually disrupt the capacity to form the higher oligomers necessary for MBL function and, in homozygosity or compound heterozygosity, result in complete deficiency of MBL. Complete MBL deficiency predisposes to bacterial infections, particularly in individuals who are

otherwise compromised (eg, neonates, the elderly, patients with cystic fibrosis, and patients with acquired immunodeficiency syndrome).[76] A number of common polymorphisms in MBL can also profoundly affect MBL plasma levels and oligomerization status, and those inheriting an extreme set of variants can have profoundly low MBL levels, with the same resultant problems as those totally deficient in MBL. Genetic mutations leading to deficiencies of **ficolin-2** and **ficolin-3** were recently reported and shown to cause defective LP activation in plasma.[30] Mutations in the *MASP2* gene leading to complete or subtotal deficiency of this key LP enzyme **MASP-2** were also described,[77] but their clinical relevance remains unclear.

C3 Deficiency

C3 is the most abundant and most critical of the complement proteins, essential for activation through all pathways. It is therefore not surprising that **total C3 deficiency**, a very rare finding restricted to a few dozen families, is devastating.[78] Individuals present in childhood with severe, recurrent bacterial infections that, if not promptly treated, will progress to uncontrolled sepsis and death. Supportive care and antibiotics can permit survival into adulthood, but IC disease and renal injury then become apparent.

Alternative Pathway Component Deficiencies

Deficiencies of the **AP components** are rare, with just a few individuals or families reported for each. Total deficiency of fB has not been reported, although a recent abstract described total or subtotal deficiency in a teenager with meningitis.[79] Each of the fD-deficient cases have presented with Neisserial infection, most often fulminant septicaemia, suggesting that AP amplification is particularly important in dealing with bacteria of this genus[80]; however, numbers of cases are small, and it is possible that AP deficiencies have broader consequences for susceptibility to bacterial infections. Deficiency of the AP stabilizer, properdin, is also associated with severe Neisserial infections, meningitis, and septicaemia.[81] Inherited in an X-linked manner, it is almost exclusively seen in young males, usually presenting in childhood. It is rare but probably underascertained. Properdin deficiency may be associated with a complete absence of the protein (Type I), presence of very low levels of normal protein (Type II), or presence of near-normal levels of a nonfunctional protein (Type III). Patients who survive the initial infectious episode tend to do reasonably well thereafter as anti-Neisserial antibodies develop, permitting recruitment of the CP in subsequent exposures.

Terminal Pathway Component Deficiencies

Deficiencies of **TP components** (C5, C6, C7, C8, and C9) are relatively common and all predispose to Neisserial infections. C5, though not a true TP component, is included here because consequences of deficiency are similar; **C5 deficiency** has been identified in a few dozen families from across the globe, perhaps more common in Africans and African Americans. Deficiency predisposes to Neisserial infections, including meningitis and septicaemia, and perhaps other infections[82]; unlike AP deficiencies, infections tend to be recurrent and often involve unusual serotypes of Neisseria. **C6 deficiency** is the second most common complement deficiency in Caucasians, predicted from null allele frequency to have an incidence of around 1:10,000 in the population; in African Americans, it may be even

more common, with a predicted incidence greater than 1:2,000.[83] C6 deficiency is

common among the Cape Coloured ethnic group in South Africa, believed to be the result of a founder mutation imported from Holland in the 17th century. Consequences are similar to those of C5 deficiency: recurrent Neisserial infections. Subtotal deficiency of C6 has also been described, with levels a few percent of normal and with or without linked deficiency of C7; the frequency and relevance of these is uncertain.[84] **C7 deficiency** is also common in some racial groups, with a predicted incidence of 1:10,000 in Israelis of Moroccan Jewish descent.[85] The frequency of total deficiency in Caucasians is not well defined, but personal experience suggests it is considerably less common that C6 deficiency in the United Kingdom. Clinical consequences are identical to C6 deficiency. Subtotal C7 deficiency is common in Caucasians, with a defined mutation at an allele frequency of about 1%.[84] A few cases of combined deficiency of C6 and C7 have been described as a consequence of the close linkage of the genes.[86] **C8-deficient** individuals can lack either C8αγ or C8β chain; the former is rare in Caucasians, the latter more common.[87] In all C8αγ-deficient individuals characterized to date, the mutation is in the *C8A* gene. Plasma contains no detectable C8αγ and very low amounts of C8β, indicating that this chain is labile in isolation in plasma. C8β-deficient individuals have no detectable C8β in plasma but variable amounts of C8αγ, often approaching normal. In either case, plasma haemolytic activity is completely lost. Presenting symptoms are identical to those of other TP deficiencies noted previously. **C9 deficiency** is rare in most ethnic groups with only a handful of cases reported in Caucasians, but it is by far the most common complement deficiency in Japanese and other Oriental races, the result of a single, ancient non-sense mutation (R95X) in the gene.[88] Frequency of the null mutation is about 2% in Koreans and 1% in Chinese; however, in Japanese, null allele frequency is 6.7%, giving a predicted incidence of C9 deficiency of about 1:260 of the population! This incredible frequency implies some selective advantage of the null allele in these populations; most compelling is the suggestion that C9 deficiency blunts the sometimes overvigorous complement response to infection, making C9-deficient individuals less susceptible to the development of sepsis.

Plasma Regulatory Protein Deficiencies

Deficiencies of many of the **complement regulatory proteins** have been described. The most common by far is **C1inh deficiency**, which has a prevalence in Caucasian populations of 1:50,000. Deficiency of C1inh is common primarily because it presents as an autosomal dominant, heterozygous deficiency is sufficient to cause disease.[89] Deficiency of C1inh causes the disease hereditary angioedema (HAE), characterized by recurrent, acute episodes of localized swelling of the skin and/or mucous membranes. As noted previously, C1inh is not only the sole plasma protease inhibitor of activated C1r/s and the MASP enzymes, but also inhibits enzyme cascades involved in coagulation, fibrinolysis, and the contact system. Inflammation or injury triggers activation of complement and these other proteolytic cascades in tissues, leading to the consumption of C1inh, a suicide inhibitor. In the presence of only a single normal *C1INH* gene, synthesis of C1inh cannot keep up with triggered consumption and plasma levels fall precipitously, leading to loss of control of the multiple cascades. Active products of the cascades, particularly the kinins, cause localized

tissue edema, the hallmark symptom of HAE. Many different mutations in *C1INH* have been described in patients with HAE.[90] In about 80% of cases, these are null mutations with no protein product (Type I); in about 20%, a protein is produced but is inactive (Type II). **Deficiency of fI**, the key enzyme responsible for the inactivation of the convertase enzymes of the AP and CP, is a rare but devastating problem.[78,91] Tickover complement activation and AP amplification proceed unchecked, leading to complete consumption of C3; this secondary C3 deficiency predisposes to bacterial infections and IC disease, precisely as in primary C3 deficiency. The plasma regulator of the AP convertase, fH, is essential for fluid-phase AP regulation. **Complete deficiency of fH** is rare and, like fI deficiency, results in uncontrolled AP amplification and consumption of C3.[78] Secondary C3 deficiency predisposes to infection and immune complex disease, but fH deficiency uniquely affects the kidney, causing a characteristic set of renal pathologies, including various subtypes of membranoproliferative glomerulonephritis and atypical hemolytic uremic syndrome (aHUS).[92] aHUS is much more strongly associated with mutations in the carboxy-terminal SCRs of fH that do not cause deficiency but do reduce or ablate the capacity of fH to bind surfaces; these binding mutants of fH are the most common genetic finding in aHUS, responsible for up to half of all cases and causing disease even in heterozygosity.[93] Deficiencies of other members of the fH gene family have recently been described and in some cases associated with disease. Combined deletion of the *FHR1* and *FHR3* genes is a common finding, present in about 5% of Caucasians and even more common in some racial groups. Absence of fHR1 and fHR3 is associated with aHUS, apparently because it predisposes to the development of anti-fH autoantibodies (described in the following)[94]; the same deficiency is protective for the common eye disease age-related macular degeneration (AMD). Deficiencies of other fHR proteins are much less common and of uncertain clinical relevance. **Deficiency of C4bp**, the fluid phase regulator of the CP, is extremely rare with only two case reports to date; in neither case were the presenting symptoms compatible with a complement defect, suggesting that they were ascertainment artifacts.

Membrane Regulatory Protein Deficiencies

Complete, global deficiencies of any of the cell surface regulators are very rare events. A single case of **complete deficiency of CD59** was reported, a young Japanese male who presented with a severe hemolytic syndrome.[95] A handful of families with **complete deficiency of DAF** have been described, apparently healthy apart from an apparent association with gut inflammation in some families.[96] Of note, both CD59 and DAF are GPI-anchored molecules and are missing from the GPI-negative hemopoietic clone in the hemolytic disorder **paroxysmal nocturnal hemoglobinuria** (PNH);

absence of these complement regulators is the cause of the erythrocyte lysis and activation of platelets and leukocytes that typify this disorder.[97] **Complete deficiency of MCP** has not been reported, perhaps reflecting the fact that this molecule plays key roles outside of complement regulation. Deficiencies of complement receptors are similarly rare or nonexistent. No complete inherited deficiencies of **CR1** have been described, although acquired deficiencies are common in those with IC diseases such as SLE. No deficiencies of **CR2** have been reported, although again, acquired low levels are found in SLE. A specific

deficiency of the **CR3** α-chain was described in one individual presenting with severe SLE; deficiency of the common β-chain causes loss of all four integrins that share this chain with profound consequences for leukocyte adhesion and immune function. No complete deficiencies of the AT receptors have been reported.

Complement Protein Point Mutations

Point mutations that affect function of a complement protein in more subtle ways are also sometimes of clinical importance. Perhaps the best example is that of fH mentioned previously, where the carboxy-terminal SCRs appear to be "hotspots" for point mutations that have no direct effect on the complementregulating capacity of fH, but profoundly reduce its capacity to bind surfaces.[98] Even in heterozygosity, these mutations predispose the individual to the development of aHUS, particularly when combined with other complement polymorphisms or mutations that alone have little effect. Another intriguing example is a recent report describing an unusual renal disease in Greek Cypriots; search for a genetic cause identified a mutation in **FHR5**.[99] The mutant protein was present in plasma but was dysfunctional, unable to bind efficiently surface-bound C3b; quite how this functional deficit in an apparently minor member of the fH family causes such major pathology remains to be determined.

Complement Protein Polymorphisms

Common polymorphisms in complement components and regulators have also been linked to disease, particularly chronic inflammatory diseases and infections. Among the inflammatory diseases linked to complement polymorphisms, two stand out; **AMD**, the most common cause of vision loss in the elderly in Western societies, and **dense deposit disease** (DDD), a rare renal disease. A common polymorphism in fH causing a single amino acid change in the seventh SCR (Y402H) was shown in many independent studies to be strongly linked to AMD, individuals homozygous for the less common H allele having a 6- to 10-fold higher risk of developing the disease than those homozygous for the more common Y allele.[100] Vision loss in AMD is caused by a buildup of an amorphous material called "drusen" beneath the retina that disrupts retinal architecture, causing loss of vision. Analysis of drusen shows that it contains an abundance of complement fragments, indicating that it is a site of complement activation, driving inflammation in the eye. Recent biochemical studies have suggested that the Y402 variant of fH binds better to drusen than the H402 variant—more fH binding will result in less complement activation, less inflammation, and less disease in Y402 homozygotes. A second fH polymorphism, V62I, is also linked to AMD, the I allele being protective. This polymorphism increases the C3b binding and cofactor activities of fH, making a more efficient inhibitor and thus restricting AP activation.[101] Other complement polymorphisms have also been linked to AMD; a common polymorphism in C3 (C3S/F; R102G) was associated with increased risk of AMD (two-fold higher for G allele homozygotes compared to R allele homozygotes), while a common polymorphism in factor B (R32Q) was associated with a near-two-fold decreased risk for Q allele homozygotes. The functional effects of the C3 and fB polymorphisms have been characterized[102,103]; in each case, the allele that is "risk" for AMD ($C3_{102G}$; factor B_{32R}) is more active in forming AP convertases and will hence drive more complement activation and inflammation in drusen. DDD is linked to both of the polymorphisms in fH described previously, Y402H (H allele risk, as for AMD

described previously), and V62I (I allele protective, as in AMD), and is also linked to the C3 R102G polymorphism.

The Complotype

The "set" of complement polymorphisms that an individual inherits can have dramatic effects on complement activity in his or her plasma. An individual inheriting in homozygosity the more active variants of C3 and fB and the less inhibitory variants of fH can have an AP activation loop in plasma that is 10-fold more active than that of an individual inheriting the less active components and more inhibitory fH variants.[103] This inherited **"complotype"** will markedly affect disease susceptibility—an individual with a more active AP will combat infection well but may be more susceptible to chronic inflammation, while those with a less active AP may be at risk of infection but protected from chronic inflammatory diseases (Fig. 36.14). To date, attention has focused on the AP; however, polymorphisms in any of the LP, CP, and TP components and regulators, that alter function and/or plasma levels, will impact upon the complotype of an individual.

Complement Autoantibodies

Autoantibodies against complement components, regulators, and complexes have been found in and linked with disease. **Nephritic factors** (NeFs) are autoantibodies that bind and stabilize the AP (and rarely CP) C3 convertase. They are, as the name implies, associated with renal disease, usually present in patients with DDD, and sometimes found in other types of membranoproliferative glomerulonephritis.[104] NeFs are also found in the rare disease partial lipodystrophy where peripheral adipose tissue is lost.[105] NeF stabilizes the convertase both by slowing natural decay and by preventing accelerated decay mediated by fH and other regulators. Complement is therefore consumed systemically and/or locally, and this in turn causes renal pathology. It is not at all clear why an immune response to the convertase enzyme occurs in NeF-positive individuals. One clue is provided by the demonstration that NeF are linked to the

convertase-stabilizing C3 polymorphism, $C3_{102G}$ (C3F)[103,106]; perhaps a more stable convertase is more likely to be immunogenic because it lasts longer? **Autoantibodies against fH** are increasingly recognized in association with renal disease, particularly aHUS.[94] Almost all anti-fH-positive aHUS patients lack fHR1 and fHR3; this appears to be necessary but not sufficient for anti-fH production because most individuals with this common gene deletion do not make anti-fH antibodies. The anti-fH antibodies predominantly target the carboxy-terminal SCRs of fH and inhibit fH binding to surfaces, mimicking the effects of the aHUS-associated mutations in fH. **Anti-C1q autoantibodies** are associated with a number of autoimmune and renal disease, notably lupus nephritis and poststreptococcal glomerulonephritis. Anti-C1q antibodies are a useful marker of disease activity, but their contribution to the disease process is uncertain. **Anti-C1inh autoantibodies** are associated with a rare, acquired form of angioedema mimicking HAE[107]; the autoantibodies target the reactive center of C1inh thereby blocking its function.

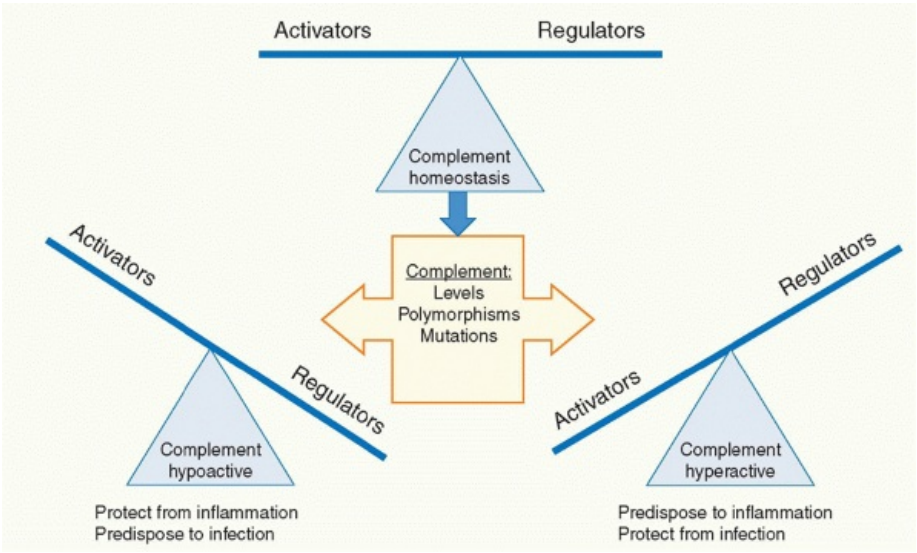

FIG. 36.14. The Complotype. Despite the tendency of complement to spontaneously activate, the balance of activators and regulators ensures that homeostasis prevails. Interindividual variability in terms of complement protein/regulator plasma levels, common polymorphisms, or rare mutations dictate that some individuals will have an intrinsically more active complement system (*right*), protective against infection but risk for chronic inflammation, while others have an intrinsically less active system (*left*), risky for infection but protective for chronic inflammatory disease.

COMPLEMENT IN DISEASE: ROLES AND TREATMENT OPPORTUNITIES

As noted previously, complement deficiencies, mutations in complement proteins, polymorphic variants in complement, and complement autoantibodies can all cause disease. In addition to these specific circumstances, complement contributes to a large number of diseases, triggered by diverse events, by driving inflammation and tissue damage. Some diseases are clearly complement mediated, while others present a mixed picture with multiple effectors contributing. The best example of the former is the hemolytic and thrombotic disorder **PNH**. A somatic mutation gives rise to a clonal population of hemopoietic cells that cannot make GPI anchors and thus lack all GPI-linked proteins from their surfaces.[97] Key among these are the complement regulators DAF and CD59. Absence of DAF and CD59 on erythrocytes, which intrinsically lack the other membrane regulator MCP, renders them highly susceptible to autologous complement activation and hemolysis, resulting in the cardinal signs anemia and hemoglobinuria. Platelets and leukocytes derived from the clone are also deficient in regulators and prone to complement activation and injury, resulting in increased platelet aggregation and leukocyte activation, which in turn predispose to thrombotic stroke.

Complement in Ischemia-Reperfusion Injuries

Ischemia-reperfusion (IR) injuries (eg, ischemic stroke, myocardial ischemia, or post-bypass) are highly dependent on complement activation. The ischemic tissue, when reperfused spontaneously or through clinical intervention, activates complement through the AP and likely also the LP, leading to injury and inflammation, increasing the extent of the injury.[108] Precisely why the ischemic tissue becomes an AP activator is still debated, although reactive

oxygen species generated during anoxia are implicated and the ischemic tissue shows decreased expression of complement regulatory proteins. The earliest studies of the efficacy of anticomplement drugs were performed in animal models of IR injury;

these, and many more since, have firmly demonstrated that complement inhibition is highly protective in this group of conditions.

Complement in Sepsis

Sepsis is a devastating disease for which there are few therapeutic options. The best available drug treatments, steroids, and/or activated protein C, only modestly impact outcome, and for most patients, all that can be offered is life support. As a consequence, mortality exceeds 25% of cases and has remained stubbornly unchanged for decades. The realization that sepsis was a consequence of overwhelming immune system activation provoked considerable interest and investment in anti-tumor necrosis factor and other agents targeting inflammatory cytokines; however, none have yet stood the test in clinical trials. There is an abundance of evidence implicating complement in sepsis. Serum complement levels fall, and complement activation products, including C3a, C5a, and TCC, are present at high levels and are predictive of outcome.[109] Animal models of sepsis have added to the evidence; in many studies, inhibition of complement activation improves the clinical outcome, animals genetically deficient in complement components have improved survival. The activation fragment C5a appears to be particularly important in driving the disease in man and models, at least in part because of its effects on neutrophils. Initially, a powerful attractant and activator, C5a in excess causes suppression of neutrophil phagocytosis and mediator release.[110] Antibodies that block C5a and several different agents that block the C5a receptor have been shown to be protective in sepsis models but have yet to be tested in man.

Complement in Transplant Rejection

The immune system treats transplanted organs in much the same way that it treats other foreign invaders: it attacks. Complement is no exception in this respect, although the full force of complement-mediated rejection is seen only when the organ is very foreign. When organs are transplanted across species barriers, **xenotransplantation**, the host response is instant: hyperacute rejection occurs, destroying the organ graft within minutes of initiating perfusion. The primary cause of this explosive rejection is activation of complement in the graft.[111] Pig-to-human transplantation is superficially attractive for anatomical, physiological, and ethical reasons; however, when pig organs are perfused with human blood, IgM natural antibodies in the plasma bind carbohydrate epitopes on the pig cells, activate complement, and destroy the graft. A decade ago, there was much interest in the production of pigs expressing transgenically the human complement regulators on their cells. This strategy, combined with a second genetic manipulation to modify the expressed carbohydrate epitopes, was successful in creating pig organs resistant to hyperacute rejection when perfused with human blood or transplanted into primates. This promising industry was mortally wounded by concerns about the transmission of pig viruses into the human population, but is slowly rising from the ashes on the back of even better pigs.[112]

Hyperacute rejection can also be seen in human-human (allo-) transplants where the donor and recipient are ABO blood group incompatible or where the recipient is presensitized to

donor antigens.[113] Here too, antibody binding activates complement in the graft, leading to its rapid destruction. As anticomplement drugs, described in the following, become more widely available, it is likely that they will be used to protect grafts transplanted into sensitized or incompatible individuals. Surprisingly, work in animal models suggests that even short-term complement inhibition can have long-term effects on graft survival, a phenomenon known as accommodation.

Allotransplants are also subject to acute vascular rejection, a slower process starting days or weeks after the transplant and taking days or weeks. Long considered a cell-mediated process, it is now clear that complement activation contributes; rejecting grafts stain for C4d, a marker of CP activation and inhibition of complement in animal models, is protective.

Complement in Autoimmunity

In many **autoimmune diseases**, although the initiating event is the generation of an immune response against self antigens, much of the observed pathology requires complement activation. In some diseases, complement activation is essential for pathology. **Myasthenia gravis** offers a particularly good example. The initial event is an autoimmune response against motor end plate sequestered antigens, notably the acetylcholine receptor. Binding of antibody in itself causes little damage, but the resultant activation of complement causes the destruction of the end plate and failure of neuromuscular conduction.[114] In the animal model, inhibition of complement completely prevents the development of weakness and paralysis.[115] In **multiple sclerosis**, an immune response against central nervous system-sequestered antigens leads to breaching of the blood-brain barrier, influx of inflammatory and immune cells, and the generation of antibodies that bind myelin and other structures. Complement activation in the brain is particularly harmful because myelin and many brain cell types are poorly protected by complement regulators and are thus easily damaged or destroyed.[69] Again, animal models have suggested that complement inhibition can suppress disease[116]; however, it is likely that multiple sclerosis is a heterogeneous disease, with complement as a major driver in only some patients.[117] A related autoimmune neurological disease, **neuromyelitis optica**, is associated with autoantibodies against aquaporin 4, a water channel expressed on astrocytes and some other cell types. Complement activation is a prerequisite for the myelin loss and cell damage that typifies this disease. In the autoimmune peripheral neuropathy, **Guillain-Barre syndrome**, antibodies target peripheral nerve myelin, fix complement, and drive axonal damage. **Recurrent fetal loss** is a distressing syndrome where women mount an immune response against fetal antigens leading to fetal rejection. Recent evidence has implicated antiphospholipid antibodies in a large proportion of affected women; evidence from human studies and mouse models implicates complement activation as the major effector of rejection in this syndrome.[118]

Complement in Renal Disease

Many **renal diseases** are associated with abundant complement activation in the kidney. Some of these are autoimmune in origin, with antibody or immune complex deposition in the glomerulus being the trigger for complement activation. The glomerular injuries associated with aHUS, fHR5 deficiency, and DDD were described previously. DDD, noted previously for

its association with anti-C3 convertase autoantibodies (NeF), is an archetypal disease of complement dysregulation, linked not only to NeF but also to mutations and polymorphisms in complement proteins that predispose to a loss of fluid-phase control of activation.[104] Precisely why these triggers target exclusively the kidney remains unknown. Other renal diseases in which complement activation plays a critical role include the various membranoproliferative glomerulonephritides, IgA nephropathy, antiglomerular basement membrane disease, lupus nephritis, and membranous nephritis.[119] In the last of these, MAC-induced activation of glomerular podocytes is the principal cause of the renal injury.

Complement in Degenerative Diseases

Complement also plays roles in many **degenerative disorders**, likely because of the accumulation of damage from low-grade complement activation over many years. The association of complement polymorphisms with AMD has been mentioned previously, a more active complement system increasing the risk of disease.[99,103] The brain and retina are particularly susceptible to this slow-burn injury, likely because these sites have poor waste disposal systems, allowing the accumulation of debris—drusen in AMD, plaques and tangles in Alzheimer's disease—that cause further complement activation thereby driving inflammation and injury. The recent demonstration that a common polymorphism in the AP regulator fH is the strongest known risk factor for AMD has focused attention; individuals homozygous for the risk allele (fH-H402) have up to 10-fold greater risk of developing AMD compared to those homozygous for the protective allele (fH-Y402).[99] Other AP protein polymorphisms have also been linked to AMD, leading many in the field to conclude that AMD is caused by AP dysregulation. Anticomplement therapies, described in the following section, are now being tested for treating AMD.

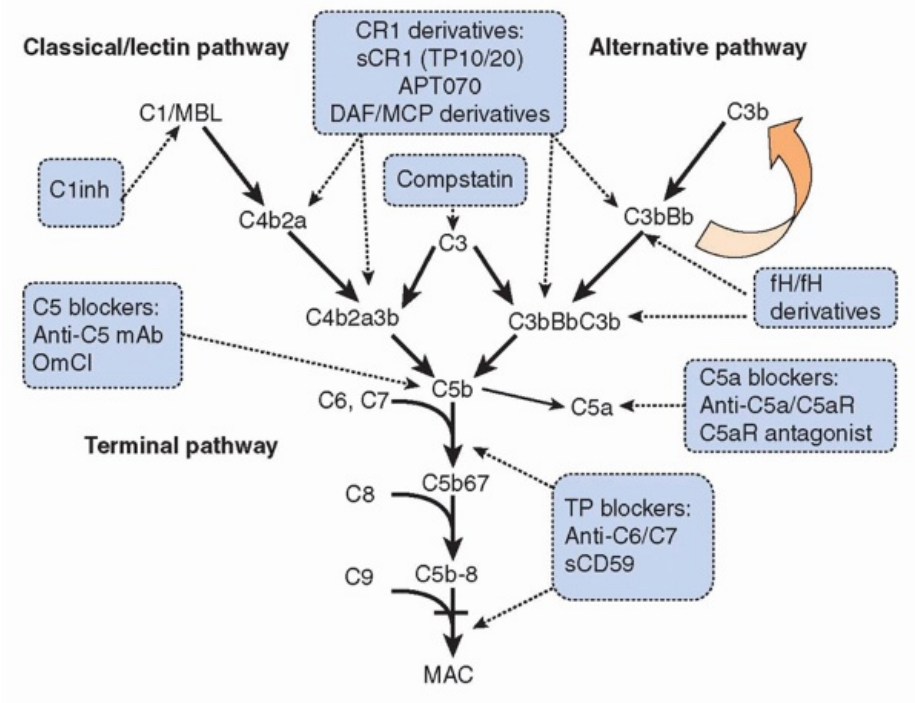

FIG. 36.15. Anticomplement Therapies. Drugs in the market place, in trials, or in development target each stage of complement activation. Agents are in *dotted boxes*;

dotted arrows illustrate primary targets in the complement pathways.

ANTICOMPLEMENT THERAPIES

General Principles

Drugs targeting the complement system have come of age in the last 10 years. Twenty years ago there were, with the exception of C1inh, described in the following, no clinically feasible ways of modulating complement activation in man. Cobra venom factor, a C3-like molecule that forms a stable AP convertase in serum and rapidly consumes all available complement activity, was used as a proof-of-concept in animal models of disease, but caused shock syndromes and occasional deaths in animals through precipitous release of activation products, making it unviable clinically. The scene has changed markedly in recent years with the arrival of an armory of agents that inhibit complement in different ways and in different parts of the pathway (Fig. 36.15; Table 36.4).

Modified Membrane Regulators as Anticomplement Drugs

The advent of clinically viable complement inhibitors came with the invention by Fearon and colleagues of the concept of modifying the naturally occurring membrane complement regulators to inhibit complement in plasma.[120] They expressed a soluble form of CR1 (sCR1) comprising the 30 SCRs of the extracellular portion and showed that it was a powerful fluid-phase inhibitor of C3 cleavage. When tested

in a myocardial ischemia model, sCR1 delivered at the time of reperfusion markedly reduced the size of the resultant infarct, effectively protecting the myocardium from further injury by complement. Soluble CR1 was tested in many other animal models of disease, spanning the spectrum from ischemia through autoimmune to degenerative, and proved effective in most conditions.[116,121] Despite its capacity to inhibit complement activation in vivo in man, clinical trials of sCR1 (developed latterly by Avant Therapeutics, Needham, MA, and known as TP10) have been disappointing. Development for the original application, adult respiratory distress syndrome, was abandoned after a single, small trial. Some success was obtained in use post-lung transplant where sCR1 treatment significantly shortened time on respirator postoperatively,[122] while in a large-scale trial in highrisk patients on cardiopulmonary bypass, sCR1 reduced the incidence of post-bypass myocardial infarction and death in men but not women—an unexpected finding confirmed in a second trial.[123] Although still in development for this and a few other applications, the history of sCR1 remains one of unfulfilled promise. Modified forms of sCR1, including addition of carbohydrate groups (sLex) to target sites of inflammation (TP20), and the engineering of small (three SCRs), membrane-localizing forms (APT070), may prove of more clinical benefit in the future. The success of sCR1, at least in animal models, led to the engineering of soluble forms of other membrane C3 convertase regulators, DAF, MCP, and hybrids of DAF and MCP (CAB-2), all of which have proved effective in at least some animal models, but none have progressed beyond the earliest stages of clinical testing. Similarly, attempts to develop soluble forms of CD59 as therapeutics have been unsuccessful, likely because of the small size of the molecule and its propensity to bind plasma proteins. Very recently, a fusion protein in which the C3d-binding

SCRs of CR2 are fused to the complement AP-inhibiting amino terminal SCRs of fH has been described.[124]

This agent, which binds C3d at sites of complement activation and there inhibits complement activation, has excellent AP-inhibitory activity in vitro and in vivo in monkeys, and is being fast-tracked for treatment of AP-mediated diseases.

TABLE 36.4 Complement Therapeutic Agents

Agent	Development Status	Mode of Action
Protease inhibitors		
Plasma-derived C1inh	Available for > 20 years for HAE, new formulations now FDA approved	Inhibitor of C1r/s, MASPs, kallikrein, and other plasma proteases
Recombinant C1inh	Made in Tg rabbits, in phase 3 trials for HAE (Rhucin)	As above
fD inhibitors; BCX1470, others	Models only, no significant human trials	Small molecules, specific inhibitors of fD protease activity
Soluble forms of natural complement regulators		
sCR1 (TP10; TP20)	Phase 2 trials CPB, early trials in stroke, MI, others	CP/AP C3 convertase regulator
APT070 (Microcept)	Preclinical in renal transplantation, development stages in others	SCR 1-3 of CR1 on membrane-targeting tail, convertase regulator
CAB-2 (MLN-2222)	Phase 1 trials in CPB	DAF:MCP hybrid, convertase regulator
Recombinant MBL	Preclinical as substitution	Replacement of deficient

	therapy	protein
Recombinant fH	Preclinical, substitution therapy in AMD	Increasing levels of “protective” fH; convertase regulator
TT30	Preclinical for AP-mediated diseases	CR2-fH hybrid, targeted convertase regulator
Antibodies		
Anti-C5 (Eculizumab)	Available for PNH, aHUS; other indications in development	Humanized mAb, C5 cleavage blocker; inhibits C5a production, MAC
Anti-C5 (Pexelizumab)	Short-acting variant of above; phase 2 for MI, CPB	As above
Anti-C5a (TNX-558)	Preclinical, inflammation	Humanized mAb, binds/blocks C5a
Anti-C5aR (Neutrazumab)	Preclinical, arthritis, stroke	Humanized mAb, blocks C5aR
Anti-fD (TNX-334)	Preclinical, AMD	Humanized mAb, blocks fD enzyme
Anti-fB (TA106)	Preclinical	Humanized mAb, blocks fB binding
Antiproperdin	Preclinical	Humanized mAb, blocks properdin
Complement protein blockers		
Compstatin (POT-4)	Phase 1, AMD	Cyclic peptide, binds C3, blocks cleavage
OmCI	Preclinical, AMD	Tick-derived C5-binder, inhibits C5a production, MAC
ARC1905	Preclinical, AMD	RNA aptamer; binds/blocks

		C5
PMX-53	Phase 2, arthritis, psoriasis	Peptide C5a antagonist
JPE-1375	Preclinical, inflammation	Peptide C5a antagonist

aHUS, atypical hemolytic uremic syndrome; AMD, age-related macular degeneration; AP, alternative pathway; CP, classical pathway; CPB, cardiopulmonary bypass; CR1, complement receptor 1; CR2, complement receptor 2; DAF, decay accelerating factor; fB, factor B; fD, factor D; FDA, U.S. Food and Drug Administration; fH, factor H; HAE, hereditary angioedema; MAC, membrane attack complex; MASP, mannan-binding lectin-associated serine protease; MBL, mannan-binding lectin; MCP, membrane cofactor protein; MI, myocardial infarction; PNH, paroxysmal nocturnal hemoglobinuria; RNA, ribonucleic acid; SCR, short consensus repeat.

Plasma Regulators as Anticomplement Drugs

The plasma regulators of complement activation are also potential therapeutics; indeed, the exception referred to previously is the enormous success achieved in treating HAE, caused by deficiency of C1inh, with plasma-derived C1inh. Frank and coworkers showed 30 years ago that C1inh purified from plasma could terminate acute attacks in patients with HAE.[125] Commercial preparations of pasteurized, purified C1inh were widely available within a few years and have been used since in Europe and some other locations to great effect, saving the lives of many sufferers. Unfortunately, use of C1inh in the United States fell foul of suspicions that it was a vector for transmission of hepatitis and other viruses, removing from use the best means of treating attacks. Events in the last few years have changed the scene. New formulations of plasma-derived C1inh, subjected to ultrafiltration to further reduce risk of virus contamination, and recombinant forms of C1inh are now approved by the U.S. Food and Drug Administration (FDA) and in use both for treatment of acute attacks and prophylaxis in HAE.[126] Both plasma-derived and recombinant fH are also in development as potential therapeutics, driven in large part by the strong genetic link, noted previously, between the fH-Y402H variants and AMD. Treatment of AMD patients with the “protective” Y402 variant, either local (intraocular) or systemic, is suggested but remains untested clinically.

Monoclonal Anticomplement Antibodies as Drugs

A number of blocking monoclonal antibodies, capable of switching off complement activation in vivo, have been tested with good effect in animal models of complementmediated disease. Monoclonal antibodies targeting either the AP (anti-fB, anti-fD) or TP (anti-C5, anti-C6) have proved particularly effective in models. Several of these reagents are being developed as human therapeutics; the first of these to reach the market is a humanized monoclonal anti-C5 antibody, eculizumab, marketed under the trade name Soliris™.[127] This monoclonal antibody binds human C5 with high affinity and prevents its cleavage by the convertase enzyme, thus blocking C5a generation and MAC assembly. Eculizumab was first approved for use in the rare hemolytic disorder PNH in which erythrocytes and other blood cells are rendered susceptible to complement damage because they lack the GPI-anchored regulators

DAF and CD59. Erythrocytes hemolyse spontaneously, releasing hemoglobin into the plasma and, via renal filtration, the urine, leading to the characteristic dark urine. Patients become anemic as erythrocyte loss exceeds rate of production and are often dependent on large, frequent blood transfusions. Thrombotic episodes and strokes can prove fatal. Administration of eculizumab dramatically reverses these symptoms; erythrocyte hemolysis ceases, patients become transfusion independent, and risk of stroke markedly decreases. Maintenance with twice-weekly dosing maintains this spectacular remission for many months or years.[128] In 2011, eculizumab was approved by the FDA for treatment of aHUS, a major advance for a disease that was previously untreatable except by dialysis.[129] Epidemic HUS, caused by infection with Shiga toxin-producing strains of *Escherichia coli*, closely resembles aHUS in terms of pathology but is an acute disease ending either in recovery or renal failure. Emergency use of eculizumab in a very large outbreak of HUS in Germany proved remarkably effective, rescuing many critically ill patients.[130]

Small Molecule Complement Inhibitors as Drugs

A limiting factor in the use of recombinant proteins and monoclonal antibodies as anticomplement agents is cost; eculizumab treatment of PNH currently costs in excess of $500,000 per patient per year, making it the most expensive FDA-approved drug! The quest for an inexpensive small molecule inhibitor of complement, preferably orally active, has been a long one, and there are still no ideal agents available. Most promising among the current candidates is a C3-/C3b-inhibiting peptide, compstatin, which tightly binds its ligand thereby blocking complement activation via all pathways.[131] Compstatin has been shown to be an effective complement inhibitor in vivo in primate models (it does not work in rodents). Compstatin is currently in phase I trials for treatment of AMD where local (intraocular), slowrelease formulations may prove particularly useful. A number of other synthetic and naturally occurring molecules have been shown to be effective inhibitors of complement activation in vitro and in models, but none have yet entered clinical trials. The G-protein-coupled heptaspan receptors for C3a and C5a are excellent drug targets, and a number of small molecule blockers of the C3a and/or C5a receptors have been reported.[132] In animal models, these act to reduce the inflammation associated with complement activation. A cyclic hexapeptide, F[OpdChaWR], blocks the C5a receptor and inhibits inflammation in a broad range of animal models and is in development for human use with sepsis likely to be the first target.[133]

NOVEL ROLES OF COMPLEMENT

In addition to its roles as innate immune effector, complement is increasingly being implicated as an important player in a number of other physiological and pathological processes. The list of novel roles is long and growing, and here I will briefly describe just a few as an illustration of this burgeoning field of interest.

Complement as a Regulator of B-Cell Responses

The first indication that complement influenced adaptive immunity came from the work of Pepys who, in the 1970s, showed that C3 depletion in mice treated with cobra venom factor or other complement activators caused a marked reduction in antibody response to a range of antigens.[134]

Although a number of mechanisms were suggested at the time, it was more than a decade before Fearon and coworkers showed that C3 fragment-coated (opsonized) antigen was a much more efficient activator of B cells than unopsonized antigen because it simultaneously engaged the BCR (surface IgM) and CR2, assembled in a signaling complex on the B-cell surface.[135] The signaling complex comprised surface IgM tightly linked to the phosphatase enzyme CD45, adjacent to CR2, and linked to the Ig superfamily member CD19 and the tetraspanin molecule tetraspanin CD81, which connects the complex to the intracellular signaling moiety PI-3 kinase (Fig. 36.16). Although antigen-binding BCR can alone cause B-cell activation, large amounts of antigen are needed; if the antigen is coated with iC3b/C3d, it binds both CR2 and the BCR, lowering the B-cell antigen response threshold by up to 1000-fold! CR1 on the B cell also plays an important role by first capturing C3b-coated antigen, then acting as cofactor for the fl-mediated cleavage of C3b into iC3b and C3d, the ligands for CR2. Recognition of the importance of CR2 in regulating B-cell responses led to a flurry of interest in using C3d, coupled to pathogen-derived antigens, as super-vaccines; promising results in animal models have yet to translate to humans.

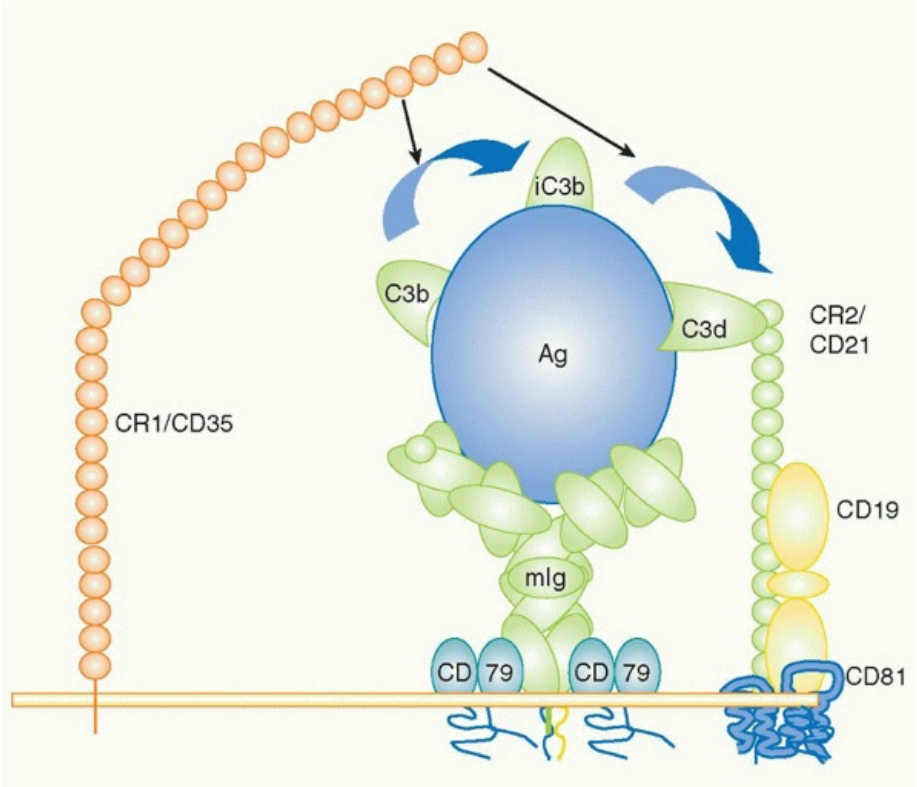

FIG. 36.16. The B-cell Signaling Complex. Antigen coated with C3 fragments (opsonized) binds the B-cell receptor (mIg) to trigger B-cell activation. C3d fragments on the antigen, produced by factor I degradation in the presence of complement receptor 1 as cofactor, bind complement receptor 2, present on the B cell in a signaling complex with CD19 and CD81. Co-ligation of the B-cell receptor and complement receptor 2 signaling complexes markedly lowers the threshold for B-cell response to antigen.

Complement and T-Cell Activation

Most published work suggests that T cells do not express classical complement receptors in significant amounts. Expression of CR2 is controversial, with some reporting expression, particularly on activated T cells, and suggesting that CR2 might play a role in driving T-cell activation. CD8 T cells certainly express receptors for C3a, and several studies have suggested that local activation of C3 and production of C3a, and C5a, might be an important part of T-cell help and a trigger to T-cell activation.[136] The complement regulator MCP (CD46) is expressed on T cells and also plays roles as a costimulator in T-cell activation; coligation of CD3 and CD46 in the presence of interleukin-10 drives T cells to differentiate into T regulatory cells that in turn dampen activation of bystander cells.[137] The natural ligand for MCP in this context is C3b, further implicating C3 products in T-cell control. Indeed, a growing body of evidence indicates that MCP and its ligand C3b are key controllers of T-cell fate and modulate T-cell cytokine production in health and disease.

Interactions with Toll-like Receptors

The toll-like receptor (TLR) family of pattern recognition molecules are an ancient immune defense system that act by sensing and signaling cell responses to infection. TLRs recognize a broad range of bacterial and viral products, present either outside or inside the cell, and set in train cytokine production and other appropriate cell responses to infection. Several of the pathogen TLR agonists, including lipopolysaccharide (from bacterial cell walls) and zymosan (from yeast cell walls) are efficient activators of complement; hence, these agonists trigger a double-hit through the TLR and through complement activation. Complement activation products, specifically C5a and, less strongly, C3a, enhance the cytokine response triggered by engagement of the TLRs, although the precise mechanism remains a subject of debate.[138] Some studies strongly implicate the C5L2 receptor in these events and, indeed, TLR activation of cells markedly increases their subsequent response to C5a in a C5L2-dependent manner.[139] Cross-talk between TLRs and complement via C5a has been implicated in T-cell

activation, and other complement molecules, including the gC1qR, CR3, and MCP, have been shown to independently interact with TLRs. The growing understanding of the interactions between these two innate immune effector systems will likely inform better approaches to therapeutic intervention in the future.

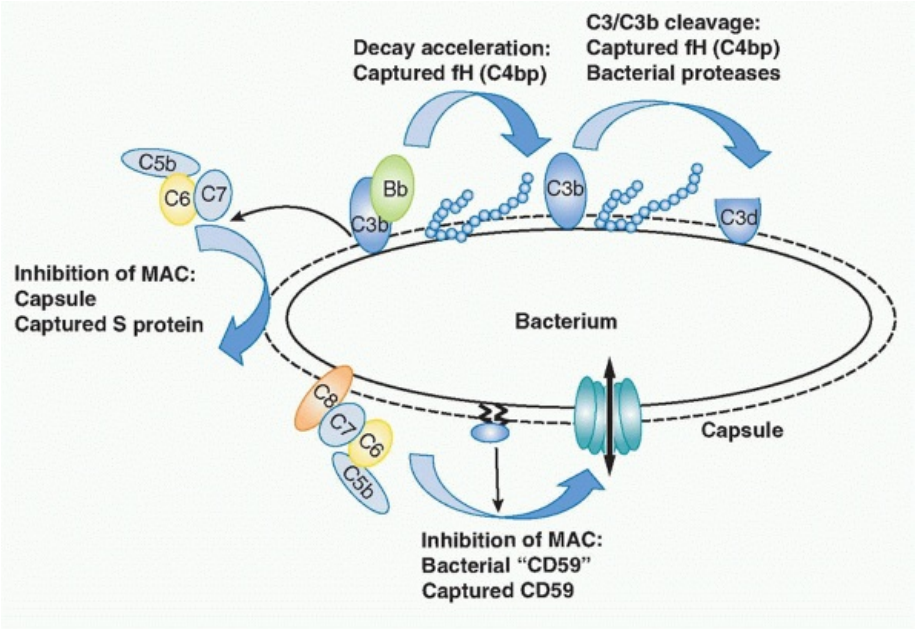

FIG. 36.17. Bacterial Complement Evasion Strategies. Many bacterial species have evolved elaborate defense strategies to protect against complement opsonization and killing; some of the more common are illustrated here. The capsule, where present, provides a physical barrier to bacterial membrane damage but may itself be a target for opsonization. C3 fragments and C3 convertases are targeted by secreted proteases and by C3 convertase regulators; they are either pirated from the host or expressed in the bacterial genome. Membrane attack complex formation is inhibited not only by capsule but also by terminal pathway regulators, either captured (such as S protein) or expressed by bacteria (CD59-like molecules).

Evasion and Hijacking of Complement by Pathogens

Complement exists to rapidly identify and destroy invading bacteria, a vital pillar of innate immune defense. Driven by this selective pressure, bacteria and some other pathogens have evolved numerous ways of evading complement activation and killing (Fig. 36.17).[140] First among these are the physical barriers; for example, gram-positive bacteria possess cell walls that protect from MAC killing. Many pathogens have evolved the capacity to mimic or steal the human complement regulators to subvert complement attack. Recruitment of host plasma complement regulators C4bp and/or fH is a particularly common occurrence and many pathogens, notably *Borellia*, *Neisseria*, and *Streptococcus*, have evolved specific membrane proteins, virulence factors that act to capture these regulators, thereby protecting the pathogen surface.[141] Some pathogens acquire membrane regulators such as CD59 and DAF from host cells, either by physical interaction with the cells, or for some viruses, during their release from infected cells. Several viruses have evolved soluble complement regulators that are structural and functional analogues of the human regulators; for example, vaccinia virus and smallpox virus both encode complement control proteins made up of SCRs that have both decay accelerating and cofactor activities,[142] while *Borellia burgdorferi* expresses a CD59- like MAC inhibitor.[143] Other pathogens have evolved enzymes that efficiently

degrade complement proteins or activation products as a means of avoiding complement damage; still others possess binding proteins that mop up complement proteins onto the pathogen surface. Among pathogens, *Staphylococcus aureus* stands out as an escape artist extraordinaire, expressing factors that inhibit complement activation, digest complement proteins, block complement receptors, and mimic complement regulators at multiple stages.[144]

Some viruses go one step further: not content with avoiding complement killing, they turn complement to their advantage. Several viruses use complement regulators and receptors as entry routes into the cell; the measles virus binds MCP, the Epstein-Barr virus binds CR2, and the Coxsackie virus binds DAF. MCP is used as a receptor by many different pathogens, leading to its colorful description as a "pathogen magnet."[145] Human immunodeficiency virus takes yet further liberties, inviting complement activation in order to acquire surface C3 fragments that are then used as a passport for cell entry by binding CR3 on host cells.[146]

Complement and Lipid Metabolism

In the late 1980s and early 1990s, two separate lines of research converged to implicate complement as a major regulator of lipid metabolism in adipose tissue. Speigelman's group showed that an adipose tissue-derived protein they termed adipsin, implicated in regulation of fat mass, was identical to the complement AP enzyme fD.[147] They also showed that adipocytes synthesized not only fD but also the AP components fB and C3, everything needed to generate AP activity locally. Meanwhile, Cianflone was investigating a remarkable plasma protein termed acylation-stimulating protein, which was a powerful stimulus for triacylglycerol synthesis in adipose tissue; molecular characterization showed that acylation-stimulating protein was identical to the complement activation product

C3adesArg, generated when the C3a anaphylatoxin is "inactivated" by carboxypeptidase-N.[148] It is now clear that local production of AP proteins and AP cycling in adipose tissue is a major regulator of lipid turnover through production of C3adesArg, which binds specific receptors (likely C5L2) on adipocytes to mediate its effects (Fig. 36.18).[149] The link between AP activation and adipose tissue activities might explain the association, between NeF-driven AP dysregulation and the loss of adipose mass in the disease partial lipodystrophy. The broader implications of the effects of complement products on lipid handling, adipose tissue mass, and atherosclerosis are now coming under the spotlight.[150]

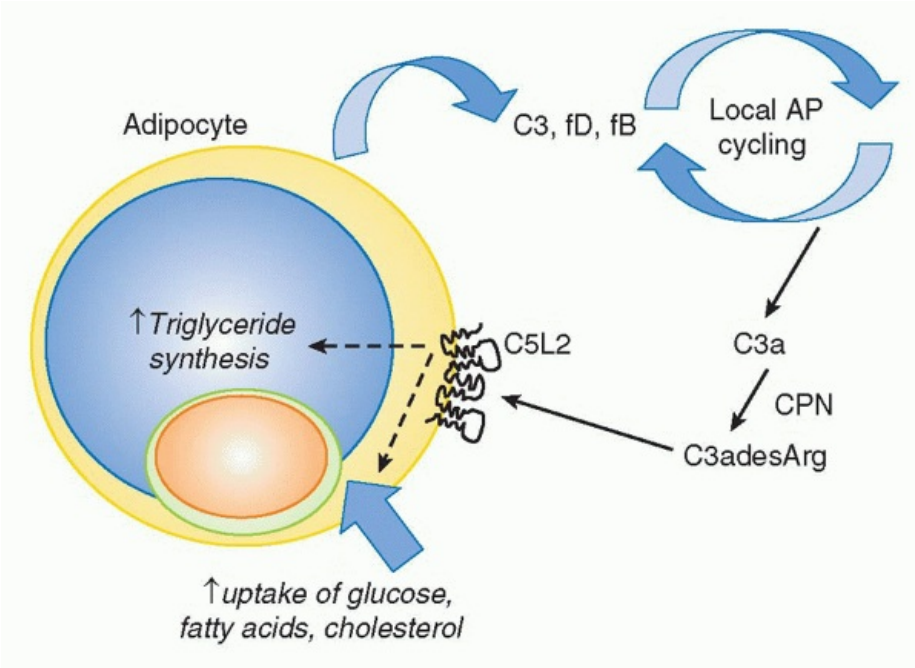

FIG. 36.18. Complement and Adipocyte Activation. Adipocytes synthesize and secrete the alternative pathway (AP) proteins factor D, C3, and factor B into the local environment. Local AP activation, initiated through tick-over or other triggers, generates C3a, which is rapidly processed to C3adesArg by carboxypeptidase N. C3adesArg binds C5L2 on adipocytes, initiating a signaling cascade that results in increased uptake of glucose, fatty acids, and cholesterol; increased triglyceride synthesis; and increased lipid accumulation in adipose tissue.

CONCLUSION

Complement, an evolutionarily ancient system discovered more than 120 years ago, continues to surprise with increasing realization of its importance in diverse diseases, growing capacity to regulate its activation in vivo, and expanding list of roles outside of innate immunity. The decades to come will likely bring further revelations. I hope that this brief chapter provides some of you with the background and enthusiasm to contribute to the quest.

Chapter 37

Cell-Mediated Cytotoxicity

Judy Lieberman

INTRODUCTION

The most effective way the immune system can control the threats of intracellular infection and cellular transformation is by destroying infected and cancerous cells.[1,2,3,4,5,6,7] When killer lymphocytes recognize harmful cells, they can target them for elimination by triggering programmed cell death. The main killer cells are natural killer (NK) cells of the innate immune sytem and cluster of differentiation (CD)8+ T lymphocytes of adaptive immunity, although some CD4+ T lymphocytes, particularly T_H1 and regulatory T (T_{reg}) cells, also express and deploy the specialized cell death machinery. All killer lymphocytes contain specialized secretory lysosomes, called cytotoxic granules, that are filled with deathinducing enzymes, called granzymes ("granule enzyme"). When the killer cell is activated, the cytotoxic granules move to the immune synapse formed with the target and fuse their membranes with the killer cell membrane, dumping their contents into the immune synapse in a process termed *granule exocytosis*. Perforin, a pore-forming protein in the granules, delivers the death-inducing granyzmes into the cytoplasm of the target cell to initiate its death. In this encounter, the killer cell remains unharmed.[8] It is a serial killer that can detach from one target to seek and destroy others.[9] Killer cells can also activate programmed cell death by using cell surface receptors to ligate cellular death receptors, such as Fas, on target cells. Granule-mediated cell death is key to control viral and intracellular bacterial infection and cancer because perforin-deficient mice and humans homozygous for perforin mutations or deficient in molecules needed for granule exocytosis are highly vulnerable to infection with intracellular pathogens and prone to develop spontaneous lymphomas.[10] The death receptor pathway regulates lymphocyte homeostasis. Patients genetically deficient in the death receptor Fas or its ligand FasL develop autoimmunity.[11] Target cells destroyed by cytotoxic granules or death receptor ligation die a highly regulated death (programmed cell death or apoptosis) rather than by necrosis. Programmed cell death minimizes inflammation and damage to nearby tissue as target cells undergoing programmed cell death are rapidly recognized and cleared by immune phagocytes, especially macrophages.[12] The topic of this chapter was reviewed in more depth in a recent issue of *Immunological Reviews*.[13]

In this chapter we first describe the killer cells: Which immune cells are able to kill and how they develop this capacity and are regulated. Because of its destructive potential, cytotoxicity needs to be carefully regulated. We next focus on the death machinery used for granule- and death receptor-mediated cytotoxicity and how it is mobilized and used to destroy the target

cell. We also discuss what is known about how killer cells are protected against their own weapons of destruction. Some granzymes are expressed without perforin in nonkiller cells. We also discuss the increasing evidence for noncytotoxic proinflammatory roles of killer molecules.

THE KILLER CELLS

The major killer cells are NK cells in innate immunity and CD8 T cells in adaptive immunity. Naïve T cells that have not previously seen antigen do not express either granule effector molecules or death receptors and are incapable of cell-mediated cytotoxicity.[14] Within about 5 days of activation, naïve CD8 T cells differentiate into effector cytotoxic T lymphocytes (CTLs) that express both types of cytotoxic molecules. At the same time, these cells downregulate adhesive and chemokine receptor molecules that retain them in lymph nodes and acquire receptors that allow them to traffic to tissue sites of infection and tumor invasion. Activation to cytotoxic effector cells is tightly regulated. It requires not only antigen-receptor activation but also costimulation, and is greatly enhanced when antigen-presenting cells are stimulated by danger and pathogen-associated pattern motif receptors or when naïve T cells are stimulated by exogenous inflammatory and antiviral cytokines, including type I interferons (IFNs), interleukin (IL)-1, and IFN γ. Upon activation, effector CD8 T cells also begin to express the Fcγ receptor CD16, also present on NK cells, which enables them to recognize and lyse target cells that have been coated with IgG antibodies in a process called antibody-dependent cell-mediated cytotoxicity.[15] In situations of persistent and extensive antigen, however, such as occur in tumors and chronic viral infection, many of the CD8 T cells that have the surface protein expression of CD8 effector cells no longer express perforin and are not cytotoxic.[16,17,18] Effector CD8 T cells that lack cytotoxicity have been termed "exhausted." Most effector cells in an immediate immune response die within a few weeks, but some survive and develop into memory cells. Memory cells downregulate expression of cytotoxic effector proteins, but the kinetics of downregulation varies with the molecule and with the particularities of the immunostimulatory environment.[14,19] In particular, activation of CD8 T cells without CD4 T-cell help leads to an unimpaired primary cytotoxic response but greatly impairs the development of antigen-specific memory cells.[20]

The immunosuppressive drug rapamycin directs antigenstimulated CD8 T cells to differentiate preferentially into memory cells rather than to effector CTLs.[21] Memory CD8 T cells rapidly reacquire cytotoxic capability within hours of restimulation. The molecular basis for this rapid response is not well understood, although recent studies suggest that in memory CD8 T cells, the chromatin of cytolytic effector gene promoters and of eomesodermin, the master transcription factor that regulates CD8 effector genes, bears epigenetic marks that poise them for transcription compared to naïve T cells.[22,23,24,25,26] These cells may also store messenger ribonucleic acids (mRNAs) for perforin and granzyme that can be rapidly translated upon activation. Some types of activated CD4 T cells, especially T_H1, NKT, and T_{reg} cells, also express granzymes and perforin and have cytotoxic activity. Murine T_{reg}s express granzyme B but probably not granzyme A.[27,28] Although immunosuppression by T_{reg}s is mediated by soluble factors, there is also a poorly understoood component that requires cell-to-cell contact. Direct lysis of cognate T cells and

potentially other immune cells by granule-mediated and death receptor pathways by T_{reg}s is likely an important mechanism for suppressing immune activation.[29,30,31]

Because it takes a week to 10 days for naïve CD8 T cells to proliferate and differentiate into a large population of antigen-specific CTLs, the immediate response to intracellular infection in individuals that have not been vaccinated or previously exposed is mediated by NK cells. Although freshly minted NK cells were previously thought to immediately express granzymes and perforin, it now seems clear that—at least in mice—resting NK cells have minimal cytotoxic activity.[32] They constitutively express mRNAs for granzymes A and B and perforin but only have granzyme A protein. Because they lack substantial perforin protein, cytotoxicity is limited. However, perforin and granzyme proteins and cytotoxicity are upregulated rapidly when NK cell-activating receptors are stimulated. Less differentiated NK cells that highly express the neural cell adhesion molecule or CD56 are poorly cytotoxic, whereas more differentiated $CD56^{dim}$ NK cells are potent killer cells.[33] In the circulation, $CD56^{dim}$ NK cells have about a log more perforin than $CD56^{bright}$ NK cells. NK-activating receptors recognize cell surface changes in tumors, stressed cells, and infected cells, such as downregulation of major histocompatibility complex/human leukocyte antigen molecules or cell surface expression of nonclassical major histocompatibility complex molecules, such as MICA and MICB, which are induced by stress. A longstanding dogma of innate immunity is that innate immune responses are not altered by antigen exposure. However, it is now clear that NK cytotoxicity to infection and other stimuli can be greatly increased by previous antigen exposure.[34] NK cell memory of prior exposure probably results from the expansion of NK cells bearing activating receptors specific for different important pathogens. These receptors, many of which are poorly conserved during mammalian evolution, may have coevolved with important pathogens. The link between individual NK receptors and pathogen recognition remains to be defined.

CYTOTOXIC GENE EXPRESSION

There are 5 human granzymes and 10 mouse granzymes expressed from three gene clusters that arose by gene duplication. In humans, the genes encoding granzymes A and K, tryptases that cleave after basic amino acids, are clustered on chromosome 5; the genes for granzyme B, which cleaves after aspartic acid residues such as the caspases; and granzyme H (or C in mice), which cleaves after hydrophobic residues, are clustered with myeloid cell proteases like mast cell chymase on chromosome 14; and the gene for granzyme M, which is highly expressed in NK cells and cleaves after Met or Leu, is found on chromosome 19 (Fig. 37.1). The mouse granzyme B cluster is uniquely expanded by multiple gene duplications to encode, in addition, granzymes D, E, F, G, L, and N. Nothing is known about these mouse-specific enzymes, but they may have evolved to defend against specific common mouse pathogens.[1] Granzyme A and B are the most abundant granzymes and the most studied. Killer cells, including NK cells, cytotoxic CD4 and CD8 T cells, and even some T_{reg} cells, express highly individualized and tightly regulated patterns of granzymes that depend on both cell type and mode of activation.[35,36]

Expression in Noncytolytic Cells

Perforin is only expressed by cytotoxic cells. Although granzymes were previously also

thought to have similarly restricted expression, noncytotoxic cells can express granzymes without perforin.[37] Granzyme transcripts can be amplified from prothymocytes in fetal liver and double negative thymocytes.[38] Although granzyme A transcripts are detected in thymocytes with the potential to develop into CD8+ cells, granzyme A activity is detected only in the most mature CD4-CD8+ thymocytes. These results suggest posttranscriptional regulation of granzyme translation (see the following for additional examples). Granzyme B, but not granzyme A, is expressed in T_{reg} cells and plays an important perforin-dependent role in T_{reg} function in mice. Benign and transformed B cells can be induced to express granzyme B by IL-21 alone or when combined with anti-B-cell receptor antibody.[39] Granzyme B is also expressed without perforin in many different types of myeloid cells. Within the immune system, granzyme B is expressed in human plasmacytoid dendritic cells (pDCs).[40] There are comparable levels of granzyme B transcripts in resting and activated pDCs but significantly higher amounts of granzyme B protein in activated cells, suggesting posttranscriptional regulation of expression. Granzyme B is also expressed in both normal and neoplastic human mast cells in vitro and in vivo.[41] It localizes to mast cell granules and is secreted when they are activated. In mice, skin-associated mast cells and bone marrow-derived in vitro differentiated mast cells express granzyme B but lung mast cells do not.[42] Neither granzyme A nor perforin are detected in mouse mast cells. The granzyme B gene is encoded within a few hundred kilobases of mast cell proteases. Thus, the granzyme B/mast cell chymase and tryptase genomic region is likely open and active in mast cells. In human basophils, IL-3 induces granzyme B, but not granzyme A or perforin,

expression.[43] Expression of granzyme B in mast cells and basophils suggests a role of granzyme B in mediating allergic disease. In fact, granzyme B has been found in bronchoalveolar lavage fluid after allergen exposure. Several studies have suggested that granzyme B and perforin are expressed in human neutrophils, but this is controversial.[44,45,46,47]

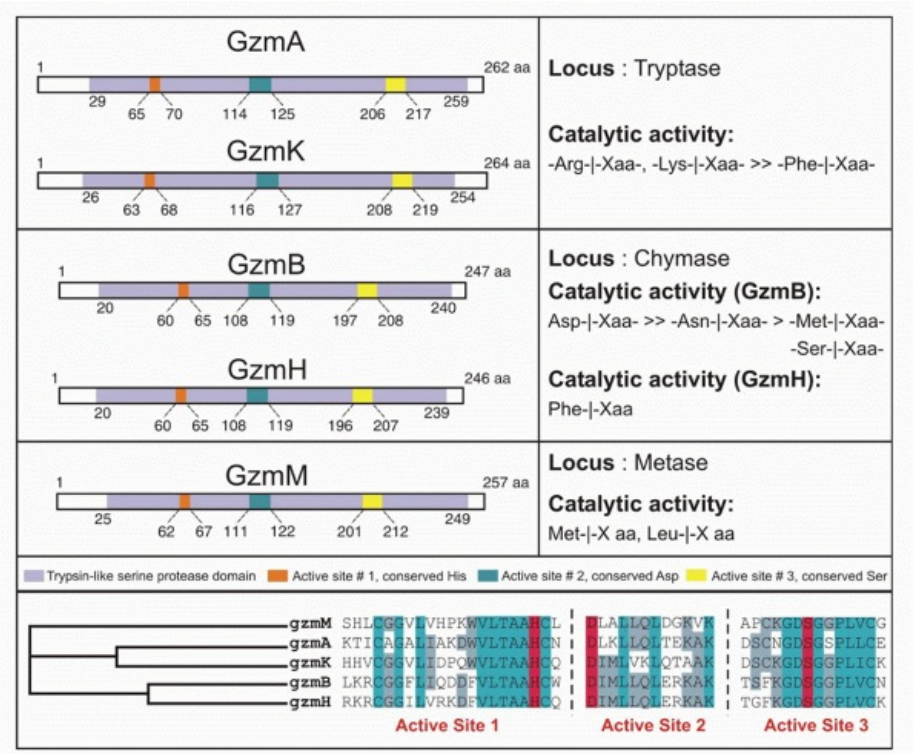

FIG. 37.1. The Human Granzymes are Encoded in Three Clusters. (Figure reprinted with permission from Chowdhury D, Lieberman J. Death by a thousand cuts: granzyme pathways of programmed cell death. *Annu Rev Immunol*. 2008;26: 389-420.)

Granzyme B is also expressed in the absence of perforin in the human reproductive system in developing spermatocytes and in placental trophoblasts[48] and by granulosa cells of the human ovary in response to follicle stimulating hormone.[49] In addition, granzyme B has been detected in a subset of primary human breast carcinomas and in chondrocytes of articular cartilage.[50] The granzyme M transcript is expressed at low levels in the photoreceptor cells of the retina in the mouse.[51] An alternatively spliced form (aGM) is exclusively expressed in these cells at much higher levels. Like granzyme M, granzyme K has an alternatively spliced form exclusively expressed in the brain.[52] The physiologic significance of the alternative transcripts of granzymes M and K is unclear.

Extracellular Signals Regulating Granzyme Expression

The kinetics and expression of the individual granzymes and perforin vary in different clonal populations in vitro and in vivo and depend on how they are activated.[53,54,55] Most circulating CD8+ T lymphocytes that express any granzyme express both granzyme A and granzyme B, but some cells are positive for only one granzyme. Single-cell expression profiles of granzymes, perforin, and IFNγ have been investigated in in vitro or in vivo activated CD8+ T cells using reverse transcription-polymerase chain reaction in mice[35] and intracellular staining and flow cytometry in humans.[56] Individual T cells show diverse expression of these genes. Although some pairs of genes (perforin and IFNγ) are coexpressed more frequently than others, no specific combination of genes is consistently

coexpressed. During in vitro activation of mouse naïve lymphocytes with antibodies to CD3, CD8, and CD11a and IL-2, the expression of granzyme A and granzyme C is delayed compared with cytolytic activity and expression of perforin and granzyme B.[35] When mouse CTLs are activated in vivo by influenza virus infection, most antigen-specific CD8 T cells found in the lung 1 week after infection express both granzymes A and B, and about a third of them also express perforin. Moreover, there is no in vivo difference in the kinetics of induction of granzyme A, granzyme B, or perforin. Granzyme C is not induced by influenza infection in vivo. The diversity of expression of individual granzyme and perforin genes suggests that each gene is regulated independently, although it is likely that these genes will share some common transcription factor recognition sites and epigenetic changes. Differences in T-cell receptor (TcR) avidity, costimulatory and inhibitory receptor engagement, danger and innate immune receptor activation, cytokine milieu, type and state of activation of the antigen-presenting cell, and presence of helper or regulatory CD4 T cells will likely influence the induction of the granzyme and perforin genes. Moreover, the cell's prior history of activation will affect cytolytic gene expression during subsequent encounters with antigen. Surprisingly, little is known about this subject.

The perforin and granzyme genes are induced during T-cell activation. However, the only signal shown consistently to upregulate granzyme A and B and perforin is IL-2.[57] IL-2 regulates perforin and granzyme expression directly and independently of its effect on CD8+ T-cell survival and proliferation.[58] Mice genetically deficient in IL-2 retain the ability to elicit a CTL response against many viruses, tumors, and allografts,[59,60] although there are deficiencies in cytotoxicity under certain conditions.[61] The other γ_C-dependent cytokines (IL-4, IL-7, IL-9, IL-15, and IL-21) likely substitute for IL-2 in its absence. IL-15 is particularly important because it also shares the γ-chain with the IL-2 receptor. IL-15 induces the expression of perforin, granzymes A and B, IFNγ, and Fas ligand in primary mouse lymphocytes.[62] IL-21 works synergistically with IL-15 to upregulate granzyme A and B expression in mouse CD8 T cells.[63] In vivo in mice, IL-21 exhibits potent antitumor function by enhancing NK and CD8 T-cell cytotoxicity.[64] Similarly in human peripheral blood CD8 T cells, IL-15 and IL-21 both activate granzyme B and perforin expression, but IL-21 does so without inducing CD8 T-cell proliferation.[65] Members of the IL-6/IL-12/IL-27 family also can upregulate granzyme and perforin expression.[66,67]

Transcriptional Regulation of Perforin and Granzymes

Two key transcription factors, T-bet (*TBX21*) and eomesodermin (*EOMES*), which belong to the T-box family, are the key master regulators of cytotoxic gene expression and survival of committed CD8 memory cells.[68,69,70,71] After naïve CD8 T-cell activation, T-bet is induced before eomesodermin.[72] Notch signaling and the Runx3 transcription factor upregulate eomesodermin, but also directly upregulate expression of perforin and granzyme B genes.[72,73] Mice deficient in both T-bet and eomesodermin genes are unable to control tumors and intracellular infection.[74,75,76] They develop a wasting syndrome caused by anomalous differentiation to IL-17-secreting cells, suggesting that these two genes not only

positively regulate cytotoxic gene expression and other genes required for CTL survival and function but also suppress differentiation to alternate lineages.

Chromosome transfer experiments have shown that expression of the perforin gene (*PRF1/prf1*) is regulated by cis-regulatory regions extending about 150 kb around the gene.[72,77,78] These include a core promoter located 120 bp upstream of the transcription start site and two enhancer regions and a locus control region (LCR) that are altered during T-cell differentiation and activation. The LCR is open for transcription specifically in cytotoxic cells. The region around the presumed LCR is more accessible to deoribonuclease (DNase I) digestion (and therefore its chromatin is open) in murine CD8 CTLs than in CD4 T_H1 cells, likely explaining their approximately 20-fold increase in *prf1* mRNA. Increased IL-2 does not enhance the accessibility of the LCR. The enhancers are both activated by IL-2R signaling mediated by signal transducer and activator of transcription (STAT)5 binding to two sites in each enhancer. Other STAT family members activated by alternate cytokines can also activate them. Activation of the more proximal enhancer also depends on IL-2-activated NF-κB binding. Both enhancers also contain binding sites for AP-1 and ETS transcription factors, whereas the distal enhancer has an E-box and NFAT binding site, and the proximal enhancer contains eomesodermin, Ikaros, and CREB binding sites. Recruitment of ribonucleic acid (RNA) pol II to the transcription start site and activation of transcription increase with IL-2 stimulation. The key factors involved in activating transcription at the prf1 promoter are Runx3 and eomesodermin. T-bet does not appear to play a direct role in activating prf1 transcription but likely acts indirectly by increasing IL2-Rβ expression and enhancing IL-2 signaling. The current model suggests that Runx3 is needed to open the extended prf1 locus during T-cell differentiation, whereas eomesodermin plays a more direct role in activating transcription near the promoter. Other transcription factors also likely participate in transactivating the perforin promoter, including an ETS transcription factor, probably myeloid elf-1-like factor (MEF).

Much less is known about the details of gene regulation of the granzymes. Enhancers or other long-range regulatory region of granzyme genes remain to be defined. Granzyme B is the only granzyme whose expression has been studied. A distal DNase hypersensitivity site 3.9 kb upstream of the granzyme B transcription start site is accessible only in activated, but not resting, CD8 T cells.[79] Inclusion of this region in a GFP reporter in transgenic mice enhances CTL-specific expression, suggesting that this region may have enhancer activity. Induction of the expression of granzyme transcripts requires at least two independent stimuli: activation of the TcR and costimulation by cytokines of the γ_c family. The signals from several distinct signal transduction pathways are integrated in the nucleus in the form of transcription factors that bind to granzyme gene regulatory elements and activate transcription. Early studies identified a 243-bp fragment upstream of the mouse granzyme B transcription start site that potentially regulates granzyme B transcription.[80] This region contains binding sites for two ubiquitous transcription factors: activating transcription factor/cyclic AMP-responsive element binding protein and activator protein-1, and two lymphoid specific factors, Ikaros and core-binding factor (PEBP2).[81] Several of these transcription factor binding sites are evolutionarily conserved between the human and mouse granzyme B promoters.[82,83] Analysis of reporter assays using promoters that had been systematically mutated at these sites in primary cells and cell lines revealed subtle differences in the importance of some

transcription factors in primary cells versus cell lines. For example, activator protein-1, cyclic AMP-responsive element binding protein, and core-binding factor were not as important for transcription in primary cells as they appeared to be in cell lines.[82,84] These studies suggested that combinations of transcription factors (particularly, activator protein-1 and corebinding factor) activate granzyme B expression in primary cells. The most compelling difference between the mouse and human granzyme B gene promoter is the importance of the Ikaros site only in human granzyme B expression.[82,84] Studies in *Stat1*-deficient mice indicate that STAT1 mediates

granzyme B induction by IFNα or IL-27.[67,85] IL-27-induced augmentation of granzyme B expression also depends on T-bet.[67] Eomesodermin also drives granzyme B expression.[71] Direct binding of T-bet and eomesodermin to the granzyme B promoter has not been examined.

Posttranscriptional Regulation

Several examples of cells expressing perforin and/or granzyme transcripts, but not protein, were described previously, including resting NK cells, thymocytes, and unactivated pDCs and mast cells. Murine memory CTLs also express abundant granzyme B mRNA but no protein.[86] All these results point toward a general mechanism of "prearming" cytotoxic lymphocytes with effector mRNAs, allowing these cells to rapidly respond to external stimuli. This type of gene regulation is well known to regulate cytokine expression, presumably for the same purpose. Two recent studies provide evidence for negative regulation of granzyme B and perforin expression by microRNAs miR-27* and miR-223 in NK cells.[87,88] It will be interesting to see if expression or processing of these micro RNAs declines rapidly after NK cell activation.

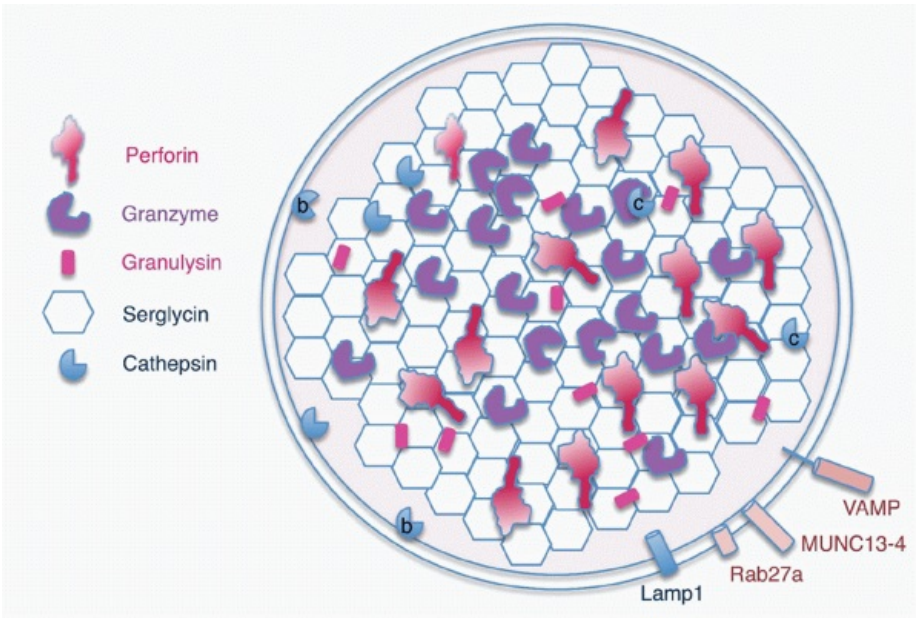

FIG. 37.2. Key Components of Cytotoxic Granules. The cytolytic effector molecules, perforin, granzymes, and granulysin, are bound to the serglycin proteoglycan. Cytotoxic granules also contain molecules found in all lysosomes, such as Lamp1 (CD107a) and

cathepsins, as well as membrane-associated proteins specific to secretory lysosomes, such as vesicle-associated soluble N-ethylmaleimide-sensitive factor accessory complex component (VAMP)7 or VAMP8, Munc13-4, and Rab27a, which are essential for granule exocytosis. Cathepsins B and C play a special role in cytotoxic granules: Cathepsin C processes the progranzymes to the active enzyme, and membrane-associated cathepsin B helps protect the killer cell from membrane damage in the immune synapse by perforin. Other cathepsins may substitute for these cathepsins when they are absent or mutated.

GRANULE-MEDIATED CELL DEATH

Killer Cell Granules

Killer cells contain cytotoxic granules that are acidic, electron-dense, specialized secretory lysosomes[89] (Fig. 37.2). These granules are mobilized like secretory vesicles in other secretory cells, such as neurotransmitter-containing vesicles near the synapses of neurons and melanin-containing vesicles of melanocytes. Cytotoxic granules contain the granzymes, trypsin-like serine proteases, whose major job is to initiate programmed cell death in cells marked for immune elimination. Cytotoxic granule proteins also regulate the survival of activated lymphocytes and may also cause inflammation by acting on extracellular substrates. The granzymes are trypsin-like serine proteases that use a classic histidine, serine, aspartic acid catalytic triad to cleave their substrates. Human granzymes A, B, C, and M; rat granzyme B; and human progranzyme K have all now been crystallized with high resolution.[90,91,92,93,94,95] The active granzymes are produced by cleavage of a dipeptide from the N-terminus of the proenzyme. Activation is accompanied by a radical conformational change. Progranzyme K has a more rigid structure lacking an open active site than the active granzymes.

Detailed information about the conformation surrounding the active sites of granzyme A and B has provided the structural basis for understanding how subtle differences in the active site conformation lead to substantial differences in substrate specificity. As a consequence, mouse granzyme B is preferentially able to cleave mouse procaspase-3, whereas human granzyme B is better able to cleave the human orthologue. Granzyme A differs from the other granzymes in forming a covalent homodimer; the other granzymes are monomeric. Dimerization creates an extended site for substrate binding that is believed to confer a high degree of specificity to granzyme A for its substrates.[90,96] In particular, because of the extended exosite for substrate binding, granzyme A substrates do not share a common short peptide sequence around the cleavage site.

The cytotoxic granules also contain perforin, a poreforming molecule that delivers the granzymes into the target cell. Another pore-forming molecule, granulysin, which is homologous to the saposins, is cationic and selectively active at disrupting negatively charged bacterial and possibly fungal and parasite cell membranes. Granulysin is expressed in humans and nonhuman primates, and orthologues are found in some other species (pigs, cows, and horses), but not in mice. The positively charged cytotoxic effector molecules are bound in the granule to an acidic proteoglycan, called serglycin, after its many Ser-Gly repeats.[97,98] In addition to these specialized molecules, the cytotoxic granules also contain

lysosomal enzymes, the cathepsins, and internal lysosomal membrane proteins, such as CD107 (Lamp1). The outside of the granule membrane binds soluble N-ethylmaleimidesensitive factor accessory protein receptor (SNARE) proteins, synaptotagmins and Rab GTPases, which regulate vesicular trafficking and cytotoxic granule release. Some of these molecules, including Rab27a and Munc13-4, which are important for granule exocytosis, are only incorporated into cytotoxic granules as they mature by fusion of cytotoxic granules with specialized exocytic vesicles, formed in secretory cells by fusion of late endosomes and recycling endosomes. Some of the granule-associated molecules associate with lysosomes in all cells, whereas some have a specialized function in killer cells.

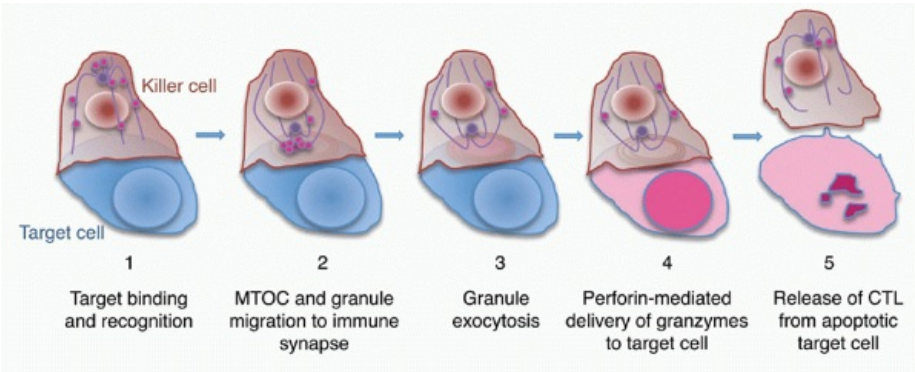

FIG. 37.3. Steps in Granule-Mediated Cytotoxicity. After the killer cell recognizes a target cell ***(1)***, an immune synapse is formed at the interface and the microtubule organizing center (MTOC) moves to the synapse, reorganizing the microtubule network ***(2)***. Cytotoxic granules move along microtubules to dock at the killer cell membrane in the central supramolecular activation complex (c-SMAC) of the immune synapse. Granule membranes fuse with the killer cell plasma membrane, releasing their contents *(magenta)* into the immune synapse ***(3)***. Perforin delivers the granzymes into the cytosol of target cells **(*4*) where they initiate apoptotic death *(5)*. The granzymes concentrate in the nucleus of target cells. The killer cell then detaches from the dying cell and is free to seek out additional targets.**

Steps in Granule Exocytosis

When CTLs and NK cells form an immune synapse with a target cell, engagement of activating receptors, including the TcR, NK cell-activating receptors, and Fc receptors, stimulates the killer cell to destroy the target cell[7] (Figs. 37.3 and 37.4). Activation for cytolysis is enhanced by binding of CD8 or CD4, costimulatory receptors, and adhesion molecules such as LFA-1, which cluster in well-defined concentric rings within the immune synapse. Killer cell activation causes a calcium flux that induces lytic granules to cluster around the microtubule organizing center and then align along the immunologic synapse.[99,100,101,102,103] Granules move to the immune synapse via both the microtubule network and actin cytoskeleton. The latter interaction is via myosin IIA in NK cells.[104] The actin meshwork thins around the site of the synapse to make room for granules to move through it.[105,106,107] Cytotoxic granules then dock to the killer cell plasma membrane in the

central region of the immune synapse (c-SMAC). In T cells, granule docking and fusion may localize to a distinct (secretory) region of the central cluster (c-SMAC) of the immune synapse that is separate from the signaling domain containing the T-cell receptor and associated kinases.[108] Recent studies did not observe a separation of signaling and secretory domains in the c-SMAC of NK cells. Cytotoxic granule docking is orchestrated by binding

of Rab27a on the cytosolic side of the mature granule membrane with synaptotagmin-like proteins, SLP1 or SLP2, which are anchored in the cell membrane. Docked granules are then primed for fusion by the interaction of Munc13-4 on their surface with syntaxin 11 on the killer cell membrane. This triggers the formation of a SNARE complex, the molecular machine for granule membrane fusion, between a cytotoxic granule vesicle-associated SNARE complex component (VAMP) protein with syntaxin 11 and SNAP23 on the cell membrane. Of the seven human VAMP proteins, studies in cytotoxic T cells have suggested that VAMP8 is required, whereas in NK cells both VAMP4 and VAMP7 are needed for different steps leading to granule exocytosis.[109,110] Granule membrane fusion also requires participation of Munc18-2 to trigger the conformational activation of the SNARE complex. Although the general mechanism of granule exocytosis described previously is used by all killer cells, some of the details of granule trafficking and fusion at the synapse may differ between killer T cells and NK cells (although apparent differences may disappear when the same high-resolution techniques are applied to both types of killer cells). Cytotoxicity and granule fusion may occur even in the absence of a stable synapse.[111]

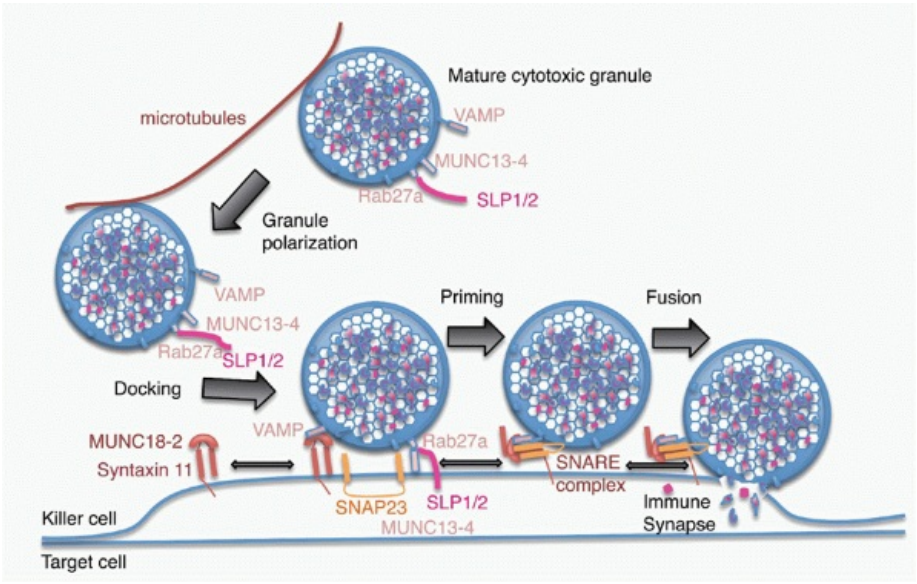

FIG. 37.4. Model of Granule Exocytosis. In response to antigen recognition, the mature cytotoxic granule moves along microtubules, probably with assistance from the actin-myosin cytoskeleton (*not shown*) to dock at the cell membrane at the immune synapse. A cytotoxic granule vesicle-associated soluble N-ethylmaleimide-sensitive factor accessory (SNARE) complex component (VAMP) protein binds to Munc18-2, which is associated with plasma membrane syntaxin 11. Cytotoxic granule proteins Rab27a and Munc13-4, in association with a synaptotagmin SLP1 or SLP2, help anchor the granule to the membrane. A SNARE complex forms between plasma membrane SNAP23 and

syntaxin 11 and granule membrane VAMP to initiate fusion of the granule membrane to the plasma membrane. Following membrane fusion, the cytotoxic granule contents are released into the immune synapse. After fusion, granule membrane-associated cathepsin B (*not shown*) is displayed on the killer cell membrane and protects it from perforin membrane damage. Figure adapted from de Saint Basile et al.[7]

Genetic Diseases Caused by Defects in Perforin or Granule Exocytosis

Inherited deficiencies in perforin or the genes encoding syntaxin 11, Munc13-4, and Munc18-2 that orchestrate cytotoxic granule trafficking and release are linked to defective cytotoxicity and profound immunodeficiency.[112,113,114,115,116,117,118] Patients with mutations in these genes develop the familial hemophagocytic lymphohistocytosis (FHL) syndrome. These patients are handicapped in controling viral infections and develop a severe immune activation syndrome that is often fatal in childhood unless treated with bone marrow transplantation. Some patients with milder perforin mutations that do not completely eliminate cytotoxic function are not diagnosed until adulthood. These adult patients with FHL not only have impaired antiviral immunity but are also more prone to develop lymphoma (such as perforin-deficient mice). The most prominent and sometimes fatal clinical manifestation of FHL is an inflammatory syndrome caused by uncontrolled activation and expansion of CD8 T cells, often in response to poorly controlled herpes virus infections, which leads to systemic activation of macrophages, which infiltrate tissues and overproduce proinflammatory cytokines. Macrophage activation is driven by excessive production of IFNγ by activated CD8 T cells.[10,119] Sequencing

of perforin mutations in patients with FHL has identified nonsense, frameshift, and missense mutations that disrupt perforin synthesis, folding, or activity.[5,120] The importance of some of these have been validated by testing cytolytic function of rat basophilic leukemia cells engineered to express mutant perforin and granzyme B. Defects in genes encoding the AP-3 adaptor—needed to shuttle cargo from the Golgi to secretory lysosomes—the lysosomal trafficking regulator LYST, or Rab27 lead to human syndromes (Hermansky-Pudlak syndrome type 2, Chediak-Higashi syndrome, and Griscelli syndrome type 2, respectively) and corresponding mouse models (*pearl*, *beige*, and *ashen* mice, respectively) in which cytotoxicity as well as other processes involving secretory lysosomes are defective. In fact, mice and humans with defects in these genes have defects in pigmentation due to defective melanosome transport.

Lessons from Knockout Mice

Mice genetically deficient for granzymes A, B (and the granzyme B cluster), and M and perforin provide important tools for probing the importance of these effector molecules in immune defense.[1] Perforin-deficient mice[112] closely recapitulate the symptoms of humans with genetic perforin deficiency. They are severely immunodeficient and compromised in their ability to defend against viruses and tumors and develop the inflammatory syndrome of FHL when infected with mouse cytomegalovirus.[121] Mice deficient in any 1 of the 10 granzymes, or even of the granzyme B cluster, only have subtle differences compared to wild-type

animals. These experiments highlight the functional redundancy of the granzymes. While only one molecule (perforin) effectively delivers the granzymes into target cells, each of the granzymes can trigger cell death. However, target cells may be selectively resistant to one or another of the granzymes (ie, by bcl-2 overexpression or by expression of viral serpins). Requirements for a single granzyme have been shown in some cases by specific immune challenges. For example, granzyme A-deficient mice are more susceptible to the poxvirus ectromelia[122] and granzyme B-deficient mice have less GvHD.[123] In constructing genetically deficient mice, genetic alterations of one gene can affect the expression of nearby granzyme genes. In the original granzyme B knockout mice, the PGK-neo cassette remaining in the granzyme B locus impedes the expression of other granzyme cluster genes (granzymes C, D, and F). The granzyme B gene has also been deleted keeping the expression of granzymes C, D, and F intact.[124] Cytotoxic T cells from the granzyme B-specific deletion mouse are significantly more effective at inducing apoptosis than those from the granzyme B-cluster knockout animal, underlining the importance of the other granzyme B cluster granzymes, especially when granzyme B is absent.

Because granzyme A and B are the most abundant granzymes in T cells, granzyme A/B doubly deficient mice are more immunodeficient than the single knockouts.[125,126,127] CTLs from granzyme A/B-deficient mice, although somewhat impaired in cytotoxicity relative to wild-type cells, nonetheless largely retain the ability to kill target cells.[128,129,130] However, the timing of key molecular events during apoptosis, such as externalization of phosphatidylserine (annexin V staining), is delayed during cell death induced by granzyme A/B-deficient CTLs versus wild-type CTLs.[131] Cytotoxic T cells lacking granzyme A and B induce a modified form of cell death that seems morphologically distinct from either perforin-mediated necrosis or wild-type CTL-mediated apoptosis.[131] Granzyme A/B-deficient animals do not develop spontaneous tumors and clear many viruses normally. The likely explanation of these results is that the other “orphan” granzymes (particularly H/C, K, and M),[132,133,134] substitute for granzyme A and B.

Although granzyme M is highly expressed in innate immune killer cells, including NK cells, NKT cells, and γδ T cells, granzyme M-deficient mice have normal NK and T cell numbers and NK activity against tumors.[135] Defense against the mouse poxvirus ectromelia and implanted NK-sensitive tumors is unimpaired in granzyme M-deficient mice compared to wild-type mice. Deficient mice are somewhat impaired in responding to mouse cytomegalovirus infection as they have higher viral levels, but they are eventually able to clear the infection. Thus, granzyme M does not appear to be essential for NK cell-mediated cytotoxicity.

Perforin Delivery of Cytotoxic Molecules into Target Cells

When the granule membrane fuses with the killer cell membrane, the granule contents are released into the synapse. Granzymes and perforin probably dissociate from serglycin in the immune synapse before they enter target cells.[136] Granzymes bind to the target cell membrane by electrostatic interactions (granzymes are very positively charged and the cell surface is negatively charged)[137,138,139] and also by specific receptors, such as the cation-independent mannose-6-phosphate receptor.[140] However, specific receptors are not required for binding, internalization, or cytotoxicity.[137,139,141,142] The lack of a receptor

enables all types of cells to be eliminated and limits escape from immune surveillance. The granzymes are delivered into the target cell (but not the killer cell) by perforin where they initiate at least three distinct pathways of programmed cell death. Although perforin is essential for granule-mediated cytotoxicity to deliver the granzymes into cells, the granzymes are redundant, as each granzyme can independently activate cell death. Although genetic deficiency of one or a few granzymes does not lead to severe immunodeficiency, mice lacking one or another granzyme display subtle differences in their ability to control specific viral infections. Why are there so many granzymes? The immune system needs to contend with a wide variety of tumors and infections, some of which have elaborated strategies to evade apoptosis and immune destruction. Some of the granzymes may have evolved to disarm specific intracellular pathogens. The interplay between granzyme B and H and adenovirus illustrates how multiple granzymes may have evolved to eliminate important pathogens.[143,144,145] Although both enzymes can cleave and inactivate at least two adenoviral proteins, the virus has also developed a way of inactivating granzyme B. Granzyme H potentiates the effect of granzyme B by destroying an adenoviral granzyme B inhibitor.

Perforin delivers granzymes and other effector molecules into the target cell cytosol.[146,147] At high concentrations,

perforin multimerizes in a cholesterol- and calcium-dependent manner in the plasma membrane of cells to form 5- to 30-nm pores.[148,149,150,151,152] Recent cross-linking and biophysical studies suggest that perforin may form at least two types of pores in membranes: small pores composed of about seven monomers that are not stable and much larger stable pores.[153,154] Cryoelectron microscopy reconstructions suggest that the large pores are composed of approximately 19 to 24 subunits and have a lumen large enough for granzyme monomers or granzyme A dimers to readily pass through. The precursor of human perforin is a 555 amino acid protein synthesized with a 21 amino acid leader sequence. The N-terminal region of the mature 67-kDa protein (residues 44-410 of the human protein) is homologous to domains in complement proteins C6, C7, C8a, C8b, and C9 that form the complement membrane attack complex (MAC). The crystal structure of monomeric mouse perforin was recently solved.[152] The complement homology domain, termed the *MAC/perforin domain* (MACPF), is similar in structure to that of bacterial pore-forming cholesteroldependent cytolysins, although they insert into membranes in opposite orientations. The MACPF domain of perforin is followed by an epidermal growth factor (EGF)-like domain; a C2 domain, a domain present in synaptotagmins and other calcium-dependent proteins, which becomes able to bind to lipid membranes after a conformational change in response to calcium; and a short 12 amino acid C-terminal peptide. The docking of the calcium-bound C2 domain is the first step in pore formation. Docking likely triggers both multimerization and a major conformational change in which two clusters of α-helices in the MACPF domain jackknife into the membrane. It is unclear whether multimerization to form a pore occurs before or after this conformational change. Perforin is glycosylated at two sites: one in the MACPF domain and one in the C-terminal peptide. Glycosylation of at least one site is needed for targeting perforin to cytotoxic granules, probably via binding of the glycan to the mannose-6-phosphate receptor.[155] En route to or in the granule, the glycosylated C-terminal peptide is removed from human (but not mouse) perforin by an undefined cysteine protease to produce the

mature active protein.[156]

The original model for how perforin delivers granzymes into cells was that granzymes entered cells through perforin pores in the target cell plasma membrane. This model predicts that granzymes directly pass and disperse into the target cell cytosol. However, granzymes do not directly enter the cytosol but instead are first endocytosed into clathrincoated vesicles and transported to endosomes.[154,157,158] Thus, the original model is not correct. Current data suggest that perforin indeed forms target cell plasma membrane pores, but these pores are small and transient (Fig. 37.5). However, calcium flows into the target cell through these pores and remains elevated for a few minutes. Because intracellular calcium is low in cells with an intact cell membrane, the cell senses a calcium influx as a sign of disruption of the plasma membrane. The elevated calcium triggers a cellular membrane damage response (also known as cellular wound healing) in which intracellular vesicles move to the plasma membrane and fuse their membranes to patch holes, and any damaged membrane is rapidly removed and internalized into endosomes.[158,159,160,161] At the same time, membrane-bound granzymes, granulysin, and perforin are endocytosed. Elevated cytosolic calcium activates endosomal fusion, and granzyme- and perforin-containing endosomes fuse to form giant endosomes approximately 10 times larger than normal endosomes that have been termed gigantosomes. In the endosomal membrane, perforin forms larger and more stable pores through which granzymes begin to leak out into the cytosol. About 15 minutes after cell death has been triggered, the gigantosomes rupture, releasing any remaining cargo to the cytosol where they begin to activate programmed cell death. When the membrane repair response is inhibited, because the cell remains leaky, target cells die by necrosis instead of by slower, regulated, and energy- dependent programmed cell death.

Although perforin is the major molecule responsible for granzyme delivery, under some circumstances other molecules might serve that function. For example, bacterial and viral endosomolysins can substitute for perforin in vitro (and are widely used as laboratory reagents for intracellular delivery[162]) and potentially might play a similar role in vivo. The heat shock protein (Hsp)70, which chaperones some peptides across cell membranes, can also carry granzyme B (and presumably other granyzmes) into cells.[163] Hsp70 is on the surface of some stressed cells or tumor cells and might help to remove these cells from the body.

Programmed Cell Death Pathways Activated by Granzymes

Once in the cytosol, the granzymes independently activate several parallel pathways of programmed cell death[6] (Table 37.1). Granzyme B cleaves and activates the caspases and also directly cleaves many important caspase substrates. Granzyme B can activate cell death that mimics caspase activation, even when the caspases are inhibited or in cells in which the caspase mitochondrial pathway is deficient. Granzyme A activates a distinct programmed cell death pathway that does not involve the caspases or disrupt the mitochondrial outer membrane. The substrates of the two major granzymes are largely nonoverlapping. The exceptions, lamin B and PARP-1, may indicate common features needed for cells undergoing all forms of programmed cell death, such as disruption of the nuclear membrane, inhibition of deoxyribonucleic acid (DNA) repair, or maintaining cellular adenosine triphosphate levels. What is known about cell death executed by the other (so-called orphan) granzymes is briefly

described in the following. The orphan granzymes may be more highly expressed under conditions of prolonged immune activation.[164] The orphan granzymes are functionally important as mice genetically deficient in the whole granzyme B cluster are less efficient at clearing allogeneic tumors than mice deficient in just granzyme B.[124] Although some key granzyme proteolytic substrates are in the cytosol (ie, Bid, caspase-3, and ICAD for granzyme B), other important targets are in other membrane-bound cellular compartments, especially the nucleus and mitochondrion. In the cytosol, granzymes B, H, and possibly K also directly cleave the proapoptotic BH3-only Bcl-2

family member Bid to initiate the classical mitochondrial apoptotic pathway that leads to mitochondrial outer membrane permeabilization (MOMP) and release of cytochrome c and other proapoptotic proteins from the intermembrane space.[165,166,167,168,169,170,171] Granzymes A and B (and possibly other granzymes) enter mitochondria through an unknown mechanism to cleave important substrates including electron transport proteins.[172,173,174] Granzyme C (in mice) and granzyme H (in humans) activate caspase-independent cell death with a pronounced mitochondrial phenotype. All of these events cause mitochondrial depolarization and production of superoxide anions and other reactive oxygen species, which is a key first step in killer lymphocyte-mediated death, as superoxide scavengers block granzyme-mediated cell death.[173] Granzyme A and B rapidly translocate to and concentrate in the nucleus,[175,176] where proteolytic cleavage of key substrates is important to induce programmed cell death by both granzyme A (SET, Ape1, lamins, histones, Ku70, PARP-1) and B (lamin B, PARP-1, NuMa, DNA-PK_{cs}). Nuclear translocation of the granzymes may be mediated by importin-α.[177]

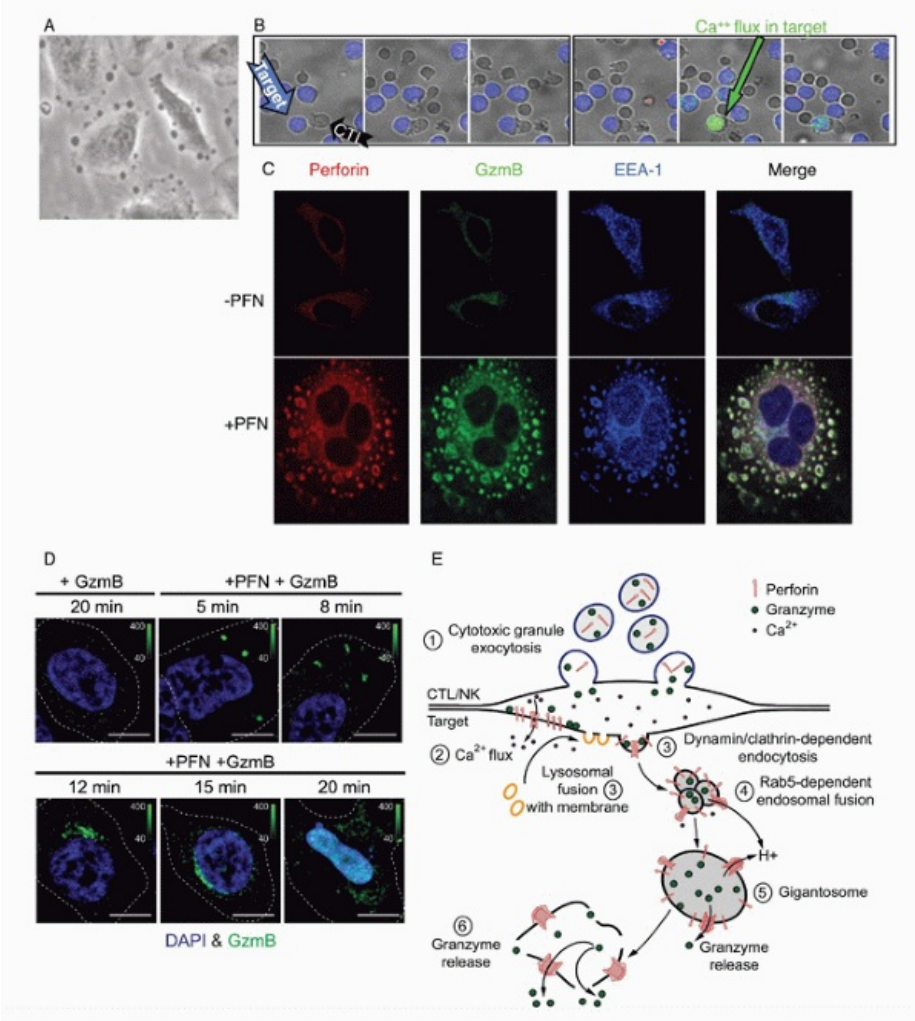

FIG 37.5. Current Model of Perforin Delivery of Granzymes into the Target Cell. **A:** Perforin treatment of HeLa cells causes dramatic membrane perturbation and blebbing. **B:** Killer cell degranulation causes a transient calcium influx in target cells that persists for a few minutes. In this experiment from Keefe et al.,[157] PHA-activated human cytotoxic T lymphocytes were incubated with Fura-2-loaded, anticluster of differentiation three-coated U937 cells, and images were obtained every 30 seconds. The Fura-2 indicator dye is *blue* when calcium is low and *green* when it is elevated. **C:** Perforin and granzyme B are endocytosed into giant EEA-1-staining endosomes (image courtesy of Jerome Thiery). **D:** When HeLa cells are treated with perforin and granzyme B, within 5 minutes, granzyme B (*green*) concentrates in gigantosomes and is released beginning after about 12 minutes. The released granzyme concentrates in the target cell nucleus. **E:** Model for perforin delivery. After cytotoxic granule exocytosis into the immunologic synapse *(1)*, perforin multimerizes in the target cell membrane to form small transient pores through which calcium enters *(2)*, triggering a plasma membrane repair response *(3)* in which lysosomes fuse with the damaged plasma membrane and perforin and granzymes are rapidly internalized by endocytosis. Perforin and granzyme-containing endosomes then fuse in response to the transient calcium flux *(4)* to form gigantosomes. Within gigantosomes, perforin continues to multimerize to form larger pores, preventing acidification and causing some granzyme release *(5)* before inducing endosomal rupture and complete granzyme release into the target cell cytoplasm *(6).* (**D,E:** Reprinted from

Table modified from Chowdhury and Lieberman.6

Granzyme A

Granzyme A induces caspase-independent cell death, which is morphologically indistinguishable from apoptosis[178,179,180] (Fig. 37.6). Granzyme A is the most ancient of the granzymes; tryptases homologous to granzyme A are found in cytotoxic cells in bony fish.[181] Granzyme A was the first granzyme described and is the most widely expressed. Cells treated with granzyme A and perforin die rapidly: Within minutes, they undergo membrane blebbing and have evidence of mitochondrial dysfunction (increased reactive oxygen species, loss of mitochondrial transmembrane potential [$\Delta\Psi_m$], disruption of mitochondrial morphology).[172,173] Within half an hour, externalization of phosphatidyl serine (measured by annexin V staining) occurs; and DNA damage, chromatin condensation, and nuclear fragmentation become apparent within 1 to 2 hours. DNA is damaged by single-stranded cuts into megabase fragments that are much larger than the oligonucleosomal fragments generated during caspase or granzyme B-activated cell death.[182] Because the DNA fragments are too large to be released from the nucleus, assays that measure DNA release into culture supernatants are typically negative. Mitochondria are damaged without MOMP or release of proapoptotic mediators, such as cytochrome c, from the mitochondrial intermembrane space.[173] In mitochondria, granzyme A cleaves Ndufs3 in electron transport chain complex I to interfere with mitochondrial redox function, adenosine triphosphate generation and maintenance of $\Delta\Psi_m$ and to generate superoxide anion.[129,172,173] The superoxide generated

by damaged mitochondria drives an endoplasmic reticulum (ER)-associated oxidative stress response complex, called the SET complex, into the nucleus where it plays a critical role in

granzyme A-induced nuclear damage.[173,182] The SET complex contains three nucleases (the base excision repair endonuclease Ape1, an endonuclease NM23-H1, and a 5′-3′-exonuclease Trex1), the chromatin modifying proteins SET and pp32, which are also inhibitors of the tumor suppressor protein phosphatase 2A, and a DNA binding protein that recognizes distorted DNA, HMGB2.[183,184,185,186,187] One of the normal functions of the complex is to repair abasic sites in DNA generated by oxidative damage. Recent studies also implicate the cytosolic SET complex as binding to the human immunodeficiency virus preintegration complex and facilitating human immunodeficiency virus infection.[188] The SET complex exonuclease Trex1 digests cytosolic DNA produced by endogenous retroviruses and infectious viruses to inhibit the innate immune response to cytosolic DNA.[189,190,191,192] Mutations in *Trex1* that inactivate its nuclease activity or cause its mislocalization are linked to human inflammatory and autoimmune diseases, including Aicardi-Goutiere syndrome and systemic lupus erythematosis.[193,194,195,196,197] Granzyme A, which traffics to the nucleus by an unknown mechanism, converts this DNA repair complex into an engine for DNA destruction by cleaving SET, an inhibitor of the endonuclease NM23-H1.[185] This allows NM23-H1 to nick DNA; the exonuclease Trex1 then extends the break.[184] At the same time, granzyme A cleaves and inactivates HMGB2 and Ape1 to interfere with base excision repair.[186,187] In addition to disabling base excision repair, granzyme A also interferes with DNA repair more generally by interfering with the recognition of damaged DNA by cleaving and inactivating Ku70[198] and PARP-1.[199] Within the

nucleus, granzyme A also opens up chromatin by cleaving the linker histone H1 and removing the tails from the core histones, making DNA more accessible to any nuclease, and disrupts the nuclear envelope by cleaving lamins.[200,201]

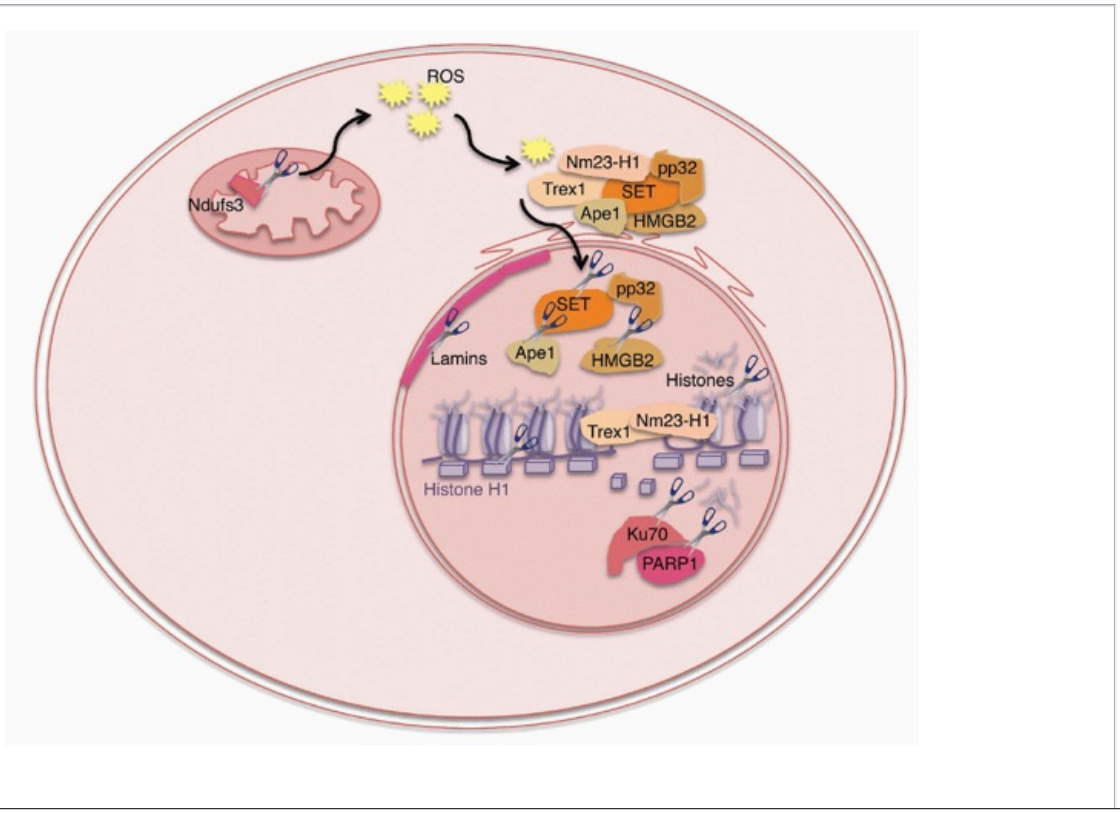

FIG 37.6. The Granzyme A Pathway of Cell Death. Reactive oxygen species generated by granzyme A (represented by *scissors*) cleavage of Ndufs3 in electron transport complex I in mitochondria drives the endoplasmic reticulum-associated SET complex into the nucleus. Granzyme A enters the nucleus by an unknown pathway. In the nucleus, Granzyme A cleaves three components of the SET complex (SET, HMGB2, and Ape1) to activate two nucleases in the complex to make single-stranded deoxyribonucleic acid (DNA) lesions; NM23-H1 makes a nick, which is extended by the exonuclease Trex1. Granzyme A also degrades the lamins and the linker histone H1 and removes the tails from the core histones, opening up chromatin and making it more accessible to these nucleases. DNA repair proteins Ku70 and PARP-1 are also targets.

Granzyme B

Granzyme B is unique among serine proteases because it cleaves after aspartic acid residues like the caspases[202,203] (Fig. 37.7). It induces target cell apoptosis by activating the caspases, particularly the key executioner caspase, caspase-3.[204,205] Human granzyme B, but not the mouse enzyme, also activates cell death by directly cleaving the key caspase substrates, Bid and ICAD, to activate the same mitochondrial and DNA damage pathways, respectively, as the caspases.[92,166,167,168,206,207,208] As a consequence, caspase inhibitors have little effect on human granzyme B-mediated cell death and DNA fragmentation while the same inhibitors significantly block the action of the mouse enzyme. Thus, human CTLs and NK cells may be more effective than mouse killer cells at eradicating virus-infected cells or tumors that have developed methods for evading the caspases. Both human and mouse enzymes cleave many of the same substrates as the caspases (including PARP-1, lamin B, NuMa, DNA-PK$_{CS}$, tubulin) and have substrate specificity close to that of caspases-6, -8, and -9.[209] However, human granzyme B cleaves optimally after the tetrapeptide IEPD, whereas mouse granzyme B has somewhat different peptide specificity, preferring to cleave after IEFD.[92,206] Moreover, other regions including the P' region (C-terminal to the cleavage site) and more distal regions contribute to substrate specificity. Because of subtle

differences in sequence, the human and mouse granzyme B can differ in important ways with respect to their substrates and the efficiency with which they are cleaved.

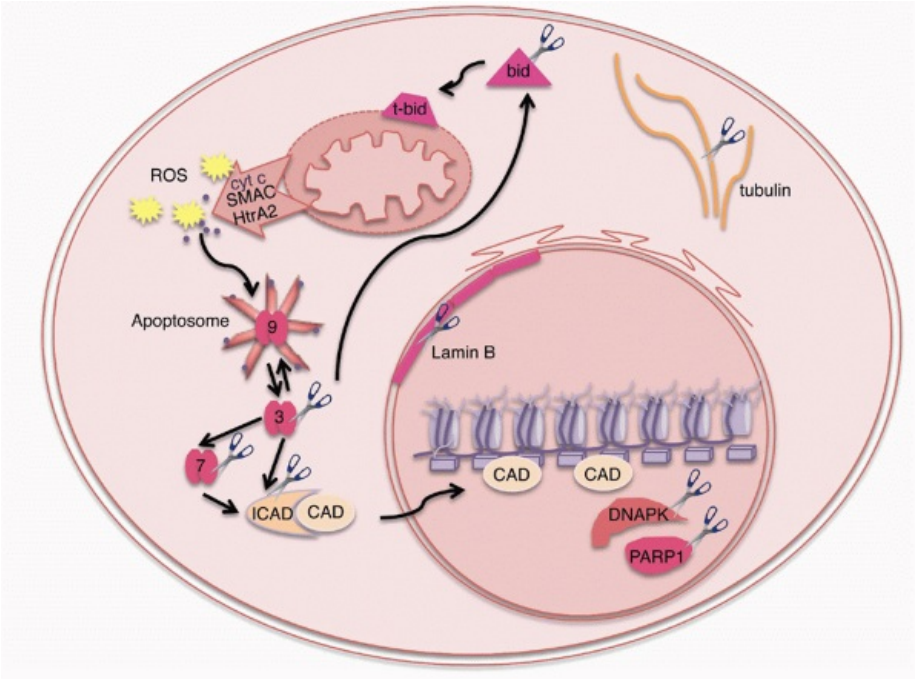

FIG 37.7. The Granzyme B Pathway of Cell Death. Human granzyme B (represented by *scissors*) cleaves Bid to produce truncated Bid (tBid), which initiates the classical mitochondrial apoptotic pathway characterized by reactive oxygen species generation, loss of the mitochondrial transmembrane potential, and disruption of the mitochondrial outer membrane to release proapoptotic mediators in the intermembrane space, including cytochrome c (*blue balls*, cyt c), SMAC/Diablo, and HtrA2/Omi. Cytochrome c binds to apoptotic protease activating factor 1 (Apaf-1) to form the apoptosome that activates caspase-9. Caspase-9 activates caspase-3 and the apoptotic cascade that includes cleavage of ICAD, the inhibitor of the caspase-activated DNase (CAD), allowing CAD to enter the nucleus and make oligosomal DNA double strand breaks. Human granzyme B on its own can directly activate caspase-3 and some key downstream caspase targets, including ICAD, lamin B, tubulin, and the DNA repair proteins DNA-PK_{CS} and PARP-1. Mouse granzyme B lacks direct proteolytic activity on some important substrates (see text).

The granzyme B (and caspase) mitochondrial pathway leads to reactive oxygen species (ROS) generation, dissipation of $\Delta\Psi_m$, and MOMP with release of cytochrome c and other proapoptotic molecules from the mitochondrial intermembrane space. Human granzyme B activates this pathway directly by cleaving Bid, whereas mouse granzyme B activates it indirectly. However, granzyme B targets mitochondria in other ways, including by cleaving antiapoptotic Mcl-1 and Hax-1, a protein that helps maintain the mitochondrial transmembrane potential.[174,210] Loss of $\Delta\Psi_m$, but not cytochrome c release, occurs in the presence of pancaspase- inhibitors (even using mouse granzyme B) and in mice genetically deficient for Bid, Bax, and Bak (the latter two Bcl-2 family members are required for Bid-induced mitochondrial damage).[132,169,211,212] Granzyme B can also activate ROS by activating extramitochondrial nicotinamide adenine dinucleotide phosphate-oxidase.[213] DNA damage by granzyme B is mediated primarily by the activation of the caspase-activated

DNase (CAD) following proteolytic cleavage of its inhibitor ICAD either directly by human granzyme B or indirectly by executioner caspases, such as caspase-3.

In humans, there is a common polymorphism of granzyme B in which three amino acids (Q^{48}, P^{88}, Y^{245}) are mutated to $R^{48}A^{88}$ H^{24}.[214] This polymorphism does not seem to affect cytotoxicity and does not have any known clinical significance.[215]

Granzymes C and H

Mouse granzyme C and human granzyme H, homologous granzymes encoded downstream from granzyme B, are predicted to cleave after aromatic residues.[133,216] Granzyme H arose during primate evolution, independently of granzyme C, in an intergenic recombination event between granzyme B and a mast cell chymase.[217] Both induce caspase-independent death with hallmarks of programmed cell death: ROS generation, dissipation of $\Delta\Psi_m$, chromatin condensation, and nuclear fragmentation.[133,216] DNA destruction by granzyme C (and probably granzyme H as well) is via single-stranded nicks and does not involve CAD. Rapid mitochondrial swelling and disruption of mitochondrial ultrastructure are particularly striking in cells treated with granzyme C. The mitochondrial pathways activated by granzyme C and H may be different; granzyme C triggers cytochrome c release, a sign of MOMP, whereas granzyme H does not.[133,216]

Granzyme H cleaves two adenoviral proteins: a DNA binding protein (also a granzyme B substrate) and the adenovirus 100K assembly protein, a previously described inhibitor of granzyme B.[143,145] Cleavage of DNA binding protein interferes with viral DNA replication, whereas cleavage of 100K restores granzyme B function in adenovirus-infected cells. Granzyme H also cleaves the cellular La protein, an RNA binding protein that participates in the posttranscriptional processing of mRNAs transcribed by RNA polymerase III and some transfer RNA (tRNA) and viral RNAs.[218] Cleavage mislocalizes La from the nucleus and decreases translation of hepatitis C virus proteins. Therefore, granzyme H may play a special role in immune defense against certain viruses. Because granzyme H is expressed in NK cells, it may help eliminate these viruses early in infection before adaptive immunity has had a chance to develop.

Granzyme K

Granzyme K is another tryptase in mice, rats, and humans that is encoded downstream near granzyme A on human 5q11 to 5q12 (or the syntenic region of mouse chromosome 13). It is much less expressed than granzyme A, and unlike granzyme A, is a monomer, not a dimer. Mice genetically deficient in granzyme A express granzyme K, which may explain the lack of a significant phenotype of granzyme A-/- mice, except when challenged with some viruses.[219,220] Purified rat and recombinant human granzyme K have been available for some time,[221,222] but little was known about its cell death activation until recently. Like granzyme A, purified rat granzyme K efficiently induces caspase-independent cell death, characterized by mitochondrial dysfunction without MOMP (ROS and loss of $\Delta\Psi_m$, but without cytochrome c release).[132] However, unlike granzyme A, rat granzyme K-induced cell death was originally reported to be inhibited in cells overexpressing Bcl-2.[132] This finding

was surprising, as Bcl-2 inhibits MOMP, which leads to cytochrome c release, which was not detected in granzyme K-treated cells. In fact, a more recent study found that cell death by recombinant human granzyme K did not activate caspase-3 and was unaffected by caspase inhibitors or Bcl-x_L overexpression.[171] Granzyme K mimics granzyme A DNA damage [171]: It causes caspaseindependent nuclear fragmentation and nuclear condensation and single-stranded DNA breaks by targeting the SET complex. Like granzyme A, granzyme K causes SET complex nuclear translocation and hydrolyzes and inactivates SET, Ape1, and HMGB2 in the SET complex.[171] Presumably, cleavage of SET, the inhibitor of NM23-H1, triggers DNA damage by the granzyme A-activated DNases, NM23-H1, and Trex1 in the SET complex.[184,185] The same group recently reported that granzyme K causes mitochondrial damage that includes not only ROS generation and dissipation of $\Delta\Psi_m$ but also Bid cleavage (to a fragment that appears to be the same size as is generated by granzyme B) and MOMP with release of cytochrome c and endonuclease G (endoG).[171] This needs to be verified because rat granzyme K does not cause cytochrome c release,[132] and this same group showed that caspases are not activated by granzyme K, and overexpression of Bcl-x_L does not interfere with human granzyme K-induced cell death,[171] as would be expected if MOMP is triggered. Although granzyme K appears to duplicate the nuclear damage pathway of granzyme A, further studies are needed to determine whether the mitochondrial granzyme K pathway resembles that activated by granzyme A (no MOMP) or granzyme B (Bid cleavage, MOMP), or is a hybrid of both. A proteomics analysis that compared granzyme A and K suggested that although the two enzymes share many substrates, some may be unique to granzyme K.[223] In fact, recent studies suggest that granzyme K cleaves and inactivates p53, which should interfere with cellular repair pathways, and interferes with the ER unfolded protein response by cleaving multiple components of the ER degradation complex.[224,225]

Granzyme M

Granzyme M is the most distinctive of the granzymes. It likely arose from a gene duplication of a neutrophil protease, as it is encoded near a cluster of other neutrophil proteases in human chromosome 19p13.3 (or a synteic region of mouse chromosome 10) and is slightly more homologous to one of them (complement factor D) than to the other granzymes.[226] Unlike the other granzymes, granzyme M cuts after Met or Leu.[227,228] None of the serine protease inhibitors that block the other granzymes, including the pan-granzyme inhibitor 3,4-dichloroisocoumarin, effectively inhibit granzyme M.[229] Moreover, granzyme M appears to function primarily in innate immunity, as it is expressed mostly in NK cells and γδ T cells and only in the subset of CD56+ T cells.[230,231] Until recently, it was not clear whether granzyme M induces cell death.[134] Granzyme M-/- mice have unimpaired NK- and T-cell development and NK cell-mediated cytotoxicity but are less able to defend against mouse cytomegalovirus infection.[135]

The literature does not agree about the type of cell death activated by granzyme M. Kelly et al.,[134] using recombinant human granzyme M expressed from baculovirus in insect cells, found that granzyme M induced rapid, caspase-independent cell death that looked like

autophagic death and did not find evidence for DNA fragmentation, mitochondrial depolarization, phosphatidyl serine externalization, or caspase activation. On the other hand, using human granzyme M expressed in yeast, the Fan laboratory argued that granzyme M activated caspase-dependent cell death, in part by cleaving and inactivating both the apoptosis inhibitor survivin and ICAD, with phosphatidyl serine externalization, caspase activation, CAD activation with oligonucleosomal DNA laddering, PARP cleavage, and mitochondrial disruption with MOMP (mitochondrial swelling, dissipation of $\Delta\Psi_m$, ROS generation, cytochrome c release).[232,233,234] This group also suggested that another granzyme M substrate may be TRAP75, a Hsp that inhibits granzyme M-induced ROS generation.[233] However, one aspect of this study that may not be completely consistent with what is known about granzyme M is that the Fan paper[232,233] claims that granzyme M cleaves ICAD after a Ser residue, whereas peptides containing Ser at the P1 site are not substrates of granzyme M expressed in yeast. Therefore, further work will be needed to determine whether granzyme M activates granzyme B- like caspase-dependent cell death or a novel pathway distinct from that activated by the other granzymes. The mouse and human isoforms may also have diffeent substrates.[235] Examining cell death induced by native purified granzyme M may be necessary to determine what type of cell death is induced by these enzymes. One intriguing other activity of granzyme M might be to cleave and inactivate the granzyme B serpin inhibitor SerpinB9 (PI-9), which it has been shown to do in vitro.[228] If this proves to be a physiologically relevant substrate in cells, then one function of granzyme M might be to potentiate the activity of granzyme B. Mice genetically deficient in granzyme M are more susceptible to cytomegalovirus infection, and granzyme M cleaves a cytomegalovirus structural protein and inhibits its replication.[236] Thus, an important function of granzyme M may be to help protect us from this important human pathogen.

Granulysin

Human cytotoxic granules of cytotoxic T cells and NK cells also contain another effector molecule: the membrane perturbing saposin-like molecule granulysin.[237] The granulysin gene (*GNLY*) was first identified as a late activation gene expressed 3 to 5 days after T-cell activation, which coincides with the expression of the other cytotoxic effector molecule genes in naïve T cells.[238] Granulysin is synthesized as a 15-kDa protein that is cleaved at both ends to produce a 9-kDa peptide. Both forms can form membrane pores in membranes. The larger form is secreted by NK cells and cytotoxic T cells, whereas the 9-kDa form is stored and released from cytotoxic granules during NK-cell or cytotoxic T-cell attack. Granulysin preferentially disrupts bacterial membranes and has been postulated to play a role in immune elimination of bacteria, fungi, and parasites.[239,240,241,242] It may also have some antitumor activity, but this requires very high granulysin concentrations in vitro that may not be physiologically relevant. There is also some evidence that secreted granulysin can act as a chemoattractant for dendritic cells and other immune cells and can induce them to express proinflammatory cytokines.[243,244] Purified granulysin is only active as a cytotoxic agent against bacteria and other pathogens when experiments are performed at high micromolar concentrations of granulysin under hypotonic or acidic conditions that are not found extracellularly. Thus, granulysin's membrane perturbing activity likely only operates within cells, perhaps to target intracellular bacteria and other pathogens located in acidic

intracellular vesicles, such as phagolysosomes. Perforin is needed to deliver granulysins into target cells.[239,245,246] Understanding the importance of granulysin in antibacterial defense and immunopathology (it is overexpressed at sites of immune activation and in blistering skin diseases) will be facilitated by the recent generation of transgenic mice that express granulysin.[247]

How is the Killer Cell Protected from its Cytotoxic Molecules?

The killer cell is not injured by its own granules. It delivers the "kiss of death" and escapes the encounter with the cell targeted for elimination unharmed and then can find and destroy other targets. How the killer cell determines that it has killed its target and is ready to detach is unknown. Several mechanisms ensure that the killer molecules are inactive during protein synthesis, processing, and storage within the granule. Within the killer cell, the cytotoxic molecules are synthesized as proenzymes that are only processed to their active form within the granule. The granzymes and perforin are expressed with a signal sequence that directs them to the ER. The high concentration of calreticulin in the ER likely serves as a sink for free calcium, which prevents perforin activation.[248,249,250,251] Cleavage of the signal peptide of the granzymes produces an inactive proenzyme that contains an N-terminal dipeptide that needs to be removed to produce an active protease. During synthesis, perforin is also rapidly transported from the ER to the Golgi. This is facilitated by a conserved C-terminal tryptophan residue by an unknown mechanism.[155] Mutation of the terminal tryptophan leads to enhanced death of the killer cell. In the Golgi, mannose-6-phosphate-containing glycans are added

to progranzymes and perforin, which serve as sorting signals for transport to lysosomes. Within the cytotoxic granule, the N-terminal dipeptide on all progranzymes is removed by cathepsin C (dipeptidyl peptidase I) to generate the active enzyme.[252] However, mice and humans genetically deficient in cathepsin C have only partially reduced granzyme activity and cytolytic function and modestly reduced immune defense against viral infection.[253,254] This suggests that alternate ways can activate progranzymes. In fact, IL-2 treatment stimulates cathepsin C-independent dipeptide cleavage in NK cells from patients with Papillon-Lefevre syndrome, who have loss of function of cathepsin C.[255] Cathepsin H and probably other cathepsins can process progranzyme B.[256] Granzymes, which are highly basic, are bound, as are perforin and presumably granulysin, to the acidic serglycin proteoglycan within the granule, which helps keep them inactive. Serglycin is responsible for the electron dense core and may also enhance effector protein storage in the granules.[257] Granzyme proteolytic activity and perforin pore formation is also negligible at the acidic pH (pH 5.1 to 5.4) of the granule.

Although granzyme and perforin trafficking within cytotoxic cells minimizes leakage of active death effector molecules out of granules, any stray molecules in the cytoplasm could cause cell death.[258] During granule exocytosis, some granzymes might inadvertently reenter effector cells. Because CTLs typically kill several targets in succession without harming themselves, an important question is how CTLs protect themselves from their own cytotoxic molecules. An important protective mechanism against killer cell suicide is serpin expression

in the killer cell cytoplasm.[259] Serpins are members of a superfamily of protease inhibitors with more than 1,500 family members.[260,261] Serpins inactivate their target proteases either by covalently and irreversibly binding to the active site of the enzyme or by forming noncovalent complexes that are so strong they resist the denaturing conditions of sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE).[261,262] Serpins that inactivate granzyme B (SerpinB9, also known as PI-9, in human cells[263] or its ortholog Spi6 in mouse cytotoxic cells[264]) are expressed in killer cells. Mice genetically deficient in *Spi6* have reduced numbers of memory CD8 T cells, suggesting that CTL survival is compromised by their own granzyme B.[265] In fact, cytotoxic T cells from these mice show granule membrane instability and have increased cytosolic granzyme B and apoptosis.[266] However, no killer cell serpins are known that inactivate the other granzymes. A recent report suggests that SerpinB4 is a potent granzyme M inhibitor that may render some tumors resistant to granzyme M.[267] However, NK cells or activated killer lymphocytes are not known to express this serpin.

When perforin and granzymes are released into the immune synapse, why is killing unidirectional? How is the killer cell membrane protected from perforin damage? During granule exocytosis, the cytotoxic granule membrane fuses with the killer cell plasma membrane, exposing internal granule membrane-associated proteins. These include cathepsin B, which inactivates by proteolysis perforin redirected toward the killer cell.[8] However, killer cells genetically deficient in cathepsin B survive unscathed when they kill targets.[268] This suggests that other membrane-bound granule cathepsins (or perhaps other CTL surface proteases or other perforin inhibitors) might also inactivate perforin redirected at the killer cell.

Cellular Resistance to Granule-Mediated Death

The human granzyme B SerpinB9 is not only expressed by lymphocytes[259,269] but also by dendritic cells,[270] cells at immune privileged sites (testis and placenta),[48,271,272] endothelial and mesothelial cells,[273] and mast cells.[274] Similar results hold for Spi6 in mice.[264,265,275] Modulators of inflammation such as LPS, IFNγ and IL-1β[276,277] induce *SerpinB9* expression. SerpinB9 expression is enhanced by estrogen and hypoxia because of estrogen responsive elements and hypoxia-inducible factor 2 binding sites, respectively, in its promoter.[278,279] In particular, SerpinB9 is induced by hypoxia in neuroblastomas.[280] This expression pattern suggests that SerpinB9 not only protects killer cells and myeloid cells that express granzyme B from autodestruction but also may protect antigen-presenting cells, bystander cells at sites of inflammation, and cells in immune privileged sanctuaries from granzyme B-mediated killing. It may also be a mechanism for tumor evasion of immune surveillance.

No intracellular inhibitors of granzyme A have yet been identified. However, some trypsin inhibitors also inhibit granzyme A. Granzyme A is bound and irreversibly inhibited in the circulation by two trypsin inhibitors, α-2 macroglobulin and antithrombin III.[281] Extracellular granzyme A complexed to proteoglycans is resistant to these two protease inhibitors.[282] A

recent study identified another granzyme A inhibitor, pancreatic secretory trypsin inhibitor, from pancreatic secretions.[283] Pancreatic secretory trypsin inhibitor is found in the blood, particularly in patients with severe inflammation and tissue destruction.[284,285] Unlike the other two granzyme A inhibitors, pancreatic secretory trypsin inhibitor inhibits granzyme A complexed to proteoglycans.[283] It is unclear whether any of these granzyme A inhibitors are expressed in cytotoxic lymphocytes.

Viral Granzyme Inhibitors

A number of viruses produce inhibitors of apoptosis or Bcl-2-like proteins that inhibit caspase-mediated apoptosis, which consequently also inhibit granzyme B-mediated cell death. The pox virus-encoded cytokine response modifier A gene (CrmA) inhibits granzyme B.[286] CrmA directly binds and inhibits granzyme B both in vitro and in vivo. Overexpression of CrmA in target cells inhibits CTL-mediated cell death. CrmA also strongly binds and inhibits caspases-1 and -8 and weakly inhibits other caspases such as caspase-3.[287] Parainfluenza virus type 3 specifically inhibits granzyme B by degrading granzyme B mRNA in infected T cells.[288] Importantly, granzyme A transcripts are not affected by this virus. The mechanism of virus-mediated granzyme B mRNA decay is not known.

Human granzyme B is inhibited by the adenoviral assembly protein (Ad5-100K) by a unique "unserpin"-like mechanism.[143] Ad5-100K rapidly complexes with granzyme B and gets cleaved very slowly at specific sites. Granzyme B that enters the infected target cell during killer cell attack is

saturated by the abundant Ad5-100K protein. Importantly, the slow kinetics of the cleavage reaction ensures that there is always a molar excess of Ad5-100K protein relative to granzyme B. Ad5-100K, which is also needed for virus assembly,[143] does not inhibit caspases or other apoptotic pathways.[144] In fact, the inhibitory activity of Ad5-100K is specific for human granzyme B and not its mouse or rat ortholog.

EXTRACELLULAR ROLES OF GRANZYMES

Although most research has focused on the cell death-inducing properties of granzymes, there is increasing evidence of extracellular functions of granzymes in promoting inflammation and coagulation and degrading extracellular matrix. Low amounts of granzymes A, B, and K are detected in the serum of healthy donors.[289] During inflammation and infection, elevated levels of granzymes are found in serum and other bodily fluids, including the serum of patients undergoing acute cytomegalovirus infection and chronic human immunodeficiency virus infection, the joints of patients with rheumatoid arthritis, and the bronchoalveolar lavage fluid of allergen-challenged patients with asthma and patients with chronic obstructive pulmonary disease.[43,282,290,291,292,293,294] Elevated granzyme levels have also been found in the serum of patients with endotoxemia and bacteremia, reflecting the fact that granzymes (but not perforin) are expressed and secreted by activated myeloid cells and a few other cell types, not just by lymphocytes.[41,44,45,295,296,297,298] In fact, in patients with sepsis, not only is serum granzyme K elevated, but its natural inhibitor (inter-α protein) is depleted, so the free active form of the enzyme is circulating and might cause damage.[299]

Granzyme B has also been detected in macrophages of atheromatous lesions and rheumatoid joints.[296] Proteolysis by extracellular granzymes will be inhibited by serum and extracellular protease inhibitors, such as the trypsin inhibitors, antithrombin III and α-2 macroglobulin.[282] Some conditions that induce extracellular granzymes may also increase the release of intracellular serpins.[300]

Extracellular granzymes might arise from direct secretion —bypassing granule exocytosis—or by leakage from the immune synapse or by release from necrotic cells. Most directly secreted granzymes are secreted as proenzymes, which are inactive.[301] However, some of the proenzymes might be activated extracellularly by serum proteases. It is not known whether the immune synapse forms a perfectly tight gasket that completely prevents granzymes from leaking into the extracellular space during degranulation. Asymmetric synapses termed *kinapses*, which are less stable and less tight, and are formed by cytolytic CD4 T cells and probably under circumstances where the integrated activating signal from the target cell is weaker, may be leakier than the canonical stable synapse.[302] Although extracellular granzymes are not likely to get into the cytoplasm of cells to induce cell death without a high local concentration of perforin, they can proteolyze cell surface receptors or extracellular proteins. Recent studies suggest extracellular granzymes A and K activate macrophages to produce and secrete inflammatory cytokines, although the mechanism for this is not known.[303,304,305] These experiments performed with recombinant and purified granzymes need to be confirmed using cytotoxic cells because macrophages are exquisitely sensitive to immune activation by endotoxin, and it is not possible to verify the absence of endotoxin in preparations of these trypsin-like enzymes because the endotoxin assay measures trypsin activity.[180] Some of the reported extracellular functions/substrates of the granzymes are summarized subsequently, but it is likely that these proteases, despite their high degree of substrate specificity, could have multiple, as yet unappreciated, destructive effects, particularly if present at high concentrations at inflamed sites in the absence of natural inhibitors. The physiologic significance of these extracellular activities is still unclear. One provocative study found a dramatic increase in granzyme B-sufficient versus granzyme B-deficient mice in the rate of rupture of aortic aneurysms in atherogenic mice (deficient in apolipoprotein E [Apo E]) that were also perforin deficient.[306] This result suggests that extracellular granzyme B contributes to the pathogenesis of atherosclerosis.

The known extracellular activities of granzymes suggest a proinflammatory effect. Granzyme A can activate the proinflammatory cytokine IL-1β directly,[307] and granzyme B can convert pro-IL-18 to its active form.[308] Granzyme K can activate proinflammatory cytokine production from lung fibroblasts, probably by cleaving their surface protease-activated receptor-1.[309] Granzymes also degrade extracellular matrix. Granzyme A may be able to degrade heparin sulfate proteoglycans, collagen type IV, and fibronectin.[310,311,312] Granzyme B can remodel the extracellular matrix by cleaving vitronectin, fibronectin, and laminin.[313] Proteolysis of the extracellular matrix might facilitate lymphocyte migration to sites of infection or inflammation or cause tissue destruction at sites of inflammation.[313,314] Granzyme A may also inhibit clotting by cleaving the thrombin receptor and von Willibrand factor[315,316,317] or by activating prourokinase to activate plasminogen.[318] In the central nervous system, granzyme B cleaves

a glutamate receptor (GluR3), potentially contributing to immunoneurotoxicity, excitation, and autoimmunity in the brain.[319,320] Granzyme B on its own causes death of neurons in a pertussis toxin-sensitive manner, suggesting possible cleavage or involvement of G protein-coupled receptors.[321] Other potential granzyme B receptor targets are Notch1 and fibroblast growth factor receptor 1 (FGFR1), which might inhibit growth signals to developing or malignant cells.[322]

DEATH RECEPTOR PATHWAYS

NK cells and cytotoxic T cells can also trigger apoptosis by ligating and activating cell surface tumor necrosis factor (TNF) receptor family members that contain a cytoplasmic approximately 80 amino acid long death domain on target cells[323,324] (Fig. 37.8). Death-by-death receptor ligation can be distinguished from granule-mediated cell death because it is calcium independent and is not inhibited by calcium chelation. The death receptors on target cells form trimers when they are activated. In humans, six members of the larger TNF receptor family contain death domains: Fas (CD95, activated by Fas ligand [FasL, CD95L]), TNFR1 (activated by TNF), DR3 (activated by TNF ligand-related molecule 1 [TL1 or TNFS15]), DR4 and DR5 (activated by TNF-related apoptosisinducing ligand [TRAIL]), and DR6 (unknown ligand). There

are mouse orthologs for all of these, except DR5. The death domains recuit one of two adapter molecules, Fas-associated death domain (FADD) or TNF receptor-associated death domain (TRADD), which serve as a platform for recruiting signaling complexes. Depending on the cellular context, signaling by the death receptors can either trigger caspasemediated apoptosis or proliferative and proinflammatory responses. In general, the receptors that predominantly recruit FADD (Fas, DR4, and DR5) are more likely to trigger apoptosis, whereas signaling from the TRADD-associated receptors (TNR1, DR3, and possibly DR6) is more likely to activate cell survival and proliferation pathways via activation of the NF-κB transcription factor and the JNK and p38 MAP kinase pathways. When cell death is triggered in cells in which the caspase pathway is inhibited, targeted cells undergo an alternate programmed cell death pathway termed necroptosis, mediated by a kinase (receptor-interacting protein 1 [RIP1]) that is recruited by TRADD.[325,326]

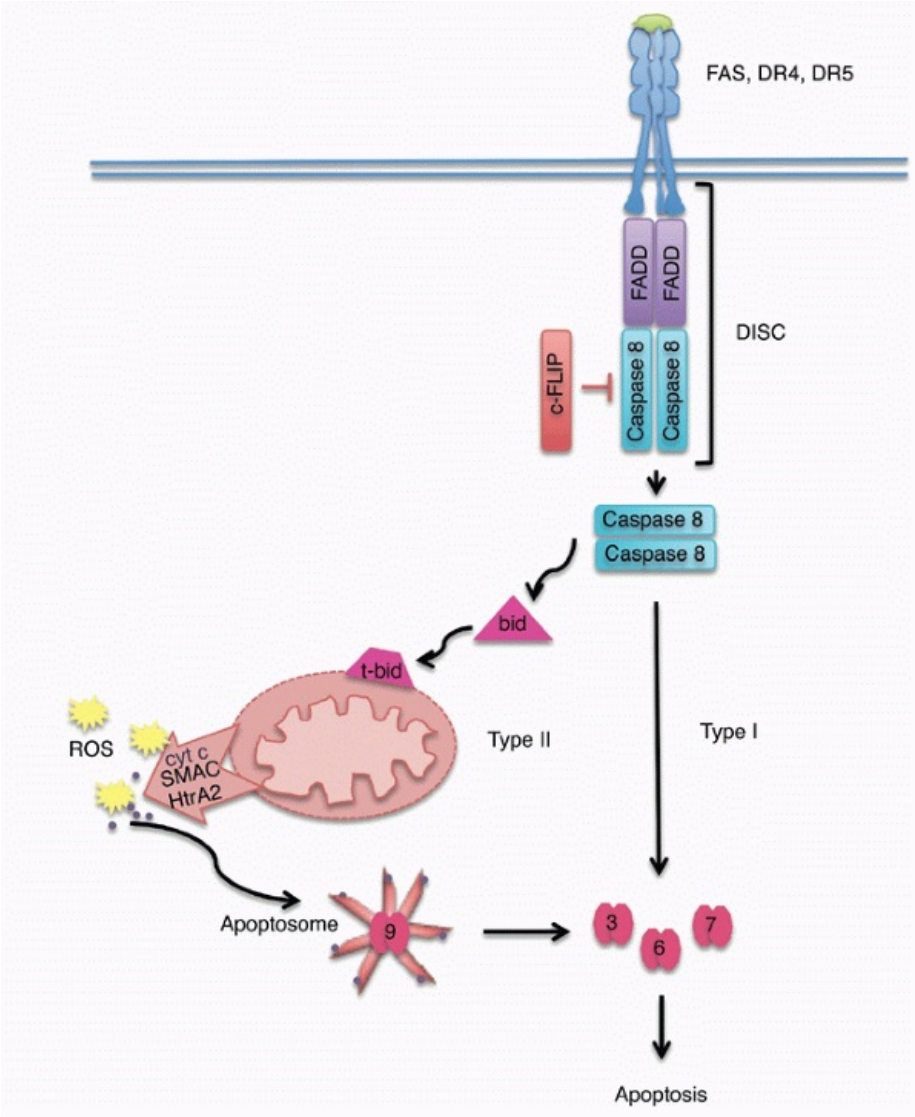

FIG. 37.8. Death Receptor Pathways of Apoptosis. Ligation of a death receptor trimer on target cells recruits the deathinduced signaling complex, which activates caspase-8, releasing it to the cytoplasm where it can cleave Bid to activate mitochondrial apoptotic pathways and cleave and activate the effector caspases-3, -6, and -7. In type I cells, apoptosis does not require mitochondrial amplification, whereas type II cells die only if mitochondrial mediators of apoptosis are released. The caspases activated downstream of caspase-8 are represented by numbered dimers. Cytochrome c required for caspase-9 activation in the apoptosome is represented by a *blue ball*. Caspase-8 activated by death receptor signaling and granzyme B-mediated death are very similar, although the granzyme B-mediated death is much more rapid. Fas-associated death domain can also recruit an alternate signaling complex that leads to cell activation rather than apoptosis (*not shown*).

After death receptor activation and recruitment of FADD, FADD recruits the apical caspases-8 and/or -10 (the latter has no mouse ortholog) to form the death-induced signaling complex (DISC) at the cell membrane. Within the DISC, these caspases are autoproteolyzed and activated. The activated caspases are then released to the cytoplasm where they can cleave

the Bcl-2 family member Bid to activate mitochondrial damage and also cleave and activate the executioner caspases (3, 6, and 7). The mitochondrial pathway amplifies caspase activation by activating caspase-9. Some cells (called type I [eg, thymocytes]) undergo apoptosis without requiring activation of the mitochondrial pathway, whereas others (type II cells [eg, B lymphocytes]) are resistant to cell death if the mitochondrial pathway is blocked.

Humans and mice that are genetically deficient in either FAS or its ligand are able to defend against intracellular pathogens but develop an autoimmune syndrome called autoimmune lymphoproliferative syndrome.[11,327] Fas-mediated death is required to eliminate chronically activated T cells and contributes to elimination of self-reactive immune cells. Mice with genetic deficiencies in these genes develop similar symptoms. Although caspase-8 is considered the main initiator caspase that associates with and is activated by death receptor signaling, humans bearing caspase-8 mutations have defects in T-cell activation and immunodeficiency rather than autoimmunity, which highlights the importance of the nonapoptotic signaling that results from death receptor engagement.[328] Of note, humans with caspase-10 mutations develop autoimmune lymphoproliferative syndrome, suggesting that under certain circumstances, caspase-10 substitutes for caspase-8 in initiating death receptor-mediated apoptosis.[329] Nonapoptotic death receptor signaling, mediated by activation of NF-κB, JNK, and MAP kinase pathways, not only promotes cell proliferation but also has a proinflammatory effect, which involves activating chemokine and cytokine production by macrophages and dendritic cells. The relative strength of proapoptotic and nonapoptotic signaling is determined in part by cellular expression of c-FLIP, an inhibitor of caspase- 8, which is recruited to the DISC and promotes recruitment of RIP1 and TNF receptor-associated factor 2 (TRAF2) to activate nonapoptotic pathways. The c-FLIP mRNA can be spliced into alternate isoforms: c-$FLIP_L$ (long) and c-$FLIP_S$ (short). DISC recruitment of c-$FLIP_S$, which is homologous to caspase-8 but is enzymatically inactive, inhibits apoptosis, whereas the concentration of c-$FLIP_L$ determines whether it is proapoptotic (at low concentrations) or antiapoptotic (at high concentrations). Some tumor cells as well as some activated T cells and NK cells overexpress c-$FLIP_L$, which renders them insensitive to death receptor-mediating apoptosis and promotes their survival.

Mouse studies suggest that DR5 (the ortholog of human DR4 and DR5) and its TRAIL may play an important role in innate immune tumor surveillance.[330] TRAIL may also participate in eliminating activated CD8 CTLs that were primed in the absence of effective CD4 help.[20] Immature NK cells express TRAIL, and DR5-deficient mice are prone to develop tumors and metastases in several endogenous mouse tumor models. As a consequence, soluble TRAIL and agonistic antibodies to DR4 or DR5 are currently being developed for potential tumor immunotherapy.[331,332]

CONCLUSION

Killer lymphocytes in the innate and adaptive immune responses protect us from infection and cellular transformation by releasing cytotoxic granules and help control immune cell proliferation and autoimmunity by both cytotoxic granule release and death receptor-activated cell death. Killer cells trigger multiple programs of cell death, which ensures that the immune system can control pathogens that have devised strategies to resist individual cell death pathways. Lymphocyte-targeted cells are recognized by scavenger cells such as

macrophages that rapidly engulf them and remove them to limit inflammation that occurs when cells die by necrosis. Research in the next few years should provide a better understanding of how cytotoxic gene expression is regulated, how killer cells are protected from their own molecules of destruction, the alternate cell death pathways activated by the multiple granzymes, and how the granzymes overcome the strategies by which viruses and tumors try to evade elimination. Further research will clarify the mechanisms and physiologic importance of inflammatory noncytotoxic effects of killer cell enzymes.

ACKNOWLEDGMENTS

I thank members of the Lieberman laboratory past and present for many useful discussions. This work was supported by National Institutes of Health grant AI45587. Parts of this chapter were modified from a recent review article on the granzymes.[6]

PARASITES AND THE IMMUNE SYSTEM

Distinct Features and Global Health Importance of Parasitic Pathogens

The term "parasite" is formally used as a designation for eukaryotic protozoan and metazoan pathogens residing within or upon their hosts. The origin of this usage is not clear but almost certainly relates to the common historical period and tropical disease context in which many of these agents were identified. Indeed, parasites are the most phylogenetically diverse category of pathogens and at the lower end of their evolutionary tree are often difficult to distinguish from fungi and other protista in both their morphology and genomic organization.

Although the taxonomic basis of their classification into a single group is under question, parasites as infectious agents do share many biologic characteristics. They frequently (although not always) display complex life cycles consisting of morphologically and antigenically distinct stages and produce long-lived or chronic infections to ensure transmission between their hosts. The induction of severe morbidity or mortality is an atypical outcome. However, in the tropical and subtropical regions where transmission is high, the low frequency of disease translates into a major global health and economic problem because of the sheer numbers of people exposed and because of the confounding issues of malnutrition and coinfection. As illustrated by outbreaks in the past decades of disease caused by the protozoa *Giardia*, *Cryptosporidia*, *Cyclospora*, and *Toxoplasma*, parasites also represent a continuing threat to populations in wealthier countries. Indeed, all of the major food- and water-borne protozoa have been classified as Category B bioterrorism pathogens because of their potential to cause acute epidemic illness. The human immunodeficiency virus (HIV)/acquired immune deficiency syndrome epidemic has also increased the impact of parasitic disease in both developed and developing regions because immunocompromised hosts become highly susceptible to some normally tolerated parasites such as *Cryptosporidia*, *Toxoplasma gondii*, and *Leishmania*. The danger also exists for many of these organisms to spread into new geographical regions, as environmental degradation and climate change become ever-increasing threats. Finally, parasitic disease remains an important problem in livestock, causing annual economic losses in the billions of dollars and, in the case of trypanosomiasis, limiting the agricultural development of huge areas of potential grazing lands on the African continent.

The immune system plays a central role in determining the outcome of parasitic infection establishing a critical balance meant to ensure both host and pathogen survival. As with other infectious agents, disease emerges when the scales tip toward either a deficient or excessive immune response. Manipulation of that response by means of vaccination or immunotherapy remains a key approach for global intervention in parasitic disease. A list of the most important parasitic infections of humans, along with estimates of their prevalence, annual mortality, and current control methods, is presented in Table 38.1. The data testify to the continued enormity of the problem reflected in the numbers of people annually infected and dying of diseases such as malaria, schistosomiasis, and trypanosomiasis as well as the high level of morbidity in those surviving. A striking situation reflected in the data is the complete absence of effective vaccines for protecting human populations. In the case of malaria, the need for a global immunization strategy has become particularly acute as drug resistance spreads worldwide. Clearly, the development of vaccines to prevent parasitic diseases remains one of the major unachieved goals of modern immunology and one of its greatest and most difficult challenges. The scientific challenge lies with the extraordinary complexity of parasites as immunologic targets and their remarkable adaptability to immunologic pressure. The field of immunoparasitology is focused on developing a basic understanding of this important host-pathogen interface for

the ultimate purpose of intervention. At the same time, the work in this area—particularly in recent years—has provided immunology with a series of major insights concerning effector and regulatory responses as they occur in vivo. Indeed, because of their years of close encounter with and adaptation to the vertebrate immune system, parasites can be thought of as the "ultimate immunologists," and there is much to be learned from them about the fundamental nature of immune responses.

TABLE 38.1 Global Impact of Parasitic Disease and Current Control Measures[a]

	Estimated Prevalence (Millions)	Annual Deaths (Thousands)	Control Methods Currently Used
Malaria	216	1200	Vector control, chemotherapy
Schistosomiasis	207	20-280	Chemotherapy, hygiene
Soil-transmitted helminths[b]	1200	12-135	Chemotherapy, hygiene
Leishmaniasis	12	50-80	Vector control, chemotherapy
African trypanosomiasis	0.3-0.5	10-48	Vector control
Chagas disease	10	10	Vector control
Lymphatic filariasis	120	0	Vector control, chemotherapy
Onchocerciasis	18	0	Vector control, chemotherapy

a Data compiled from World Health Organization Fact Sheets (www.who.int/mediacentre/factsheets/en/) and other miscellaneous sources.

b Hookworm, ascariasis, and trichuriasis. The data are combined values for all three infections.

Some Hallmarks of the Immune Response to Parasites

The interaction of parasites with the immune system has several distinguishing features that

are of special interest to fundamental immunologists. Most parasitic pathogens are able to survive the initial host response and produce longlasting or chronic infections designed to promote transmission. In the case of many protozoa (eg, *Toxoplasma*, *Leishmania*), *chronicity* is characterized by a state of *latency* in which replication of the parasite is minimal and infection cryptic. The development of chronicity depends not only on the ability of the parasite to escape protective immune responses (*immune evasion*) but also on the generation of finely tuned mechanisms of *immunoregulation* that serve both to prevent parasite elimination and suppress host immunopathology. As discussed in detail later in this chapter, the study of these immunomodulatory pathways in both human and experimental parasitic infections has yielded important insights concerning the mechanisms by which regulatory cells and cytokines control immune effector functions in vivo.

An additional prominent feature of the immune response to parasites is *Th1/Th2 polarization.* For reasons that are not entirely clear, parasitic infections often induce cluster of differentiation (CD)4+ T-cell responses that are highly polarized in terms of their Th1/Th2 lymphokine profiles. This phenomenon is particularly striking in the case of helminths, which in contrast to nearly all other pathogens, routinely trigger strong Th2 responses leading to high immunoglobulin (Ig)E levels, eosinophilia, and mastocytosis. At the opposite pole, many intracellular protozoa induce CD4+ T-cell responses with Th1-dominated lymphokine secretion patterns. This striking difference presents a beautiful example of immunologic class selection. Interestingly, in murine *Leishmania major* infection, CD4+ cells polarize to either Th1 or Th2 depending on the strain of parasite or strain of mouse infected, and the association of these responses with healing or exacerbation provided the first demonstration of a functional role for this dichotomy.[1,2] Parasite models have also been used to reveal new effector functions, such as the ability of eosinophils to kill pathogens and, as discussed subsequently, are now being used extensively to study microbial innate recognition and immune response initiation. This ability to uncover and investigate basic immune and immunopathogenic mechanisms while studying the host response to a group of phylogenetically unique pathogens of global importance is perhaps the most engaging and rewarding aspect of research in immunoparasitology.

INNATE RECOGNITION AND HOST DEFENSE

Innate recognition plays an important role in determining the outcome of the host-parasite encounter by both providing an initial barrier to infection and by influencing the magnitude and class of the subsequent adaptive immune response. At the same time, from the parasite's point of view, innate immune defenses must be subverted for infection to be established; it is clear that many parasitic pathogens have evolved specific mechanisms for evading them, and these evasion mechanisms can also provide an explanation for virulence differences amongst parasite strains. Moreover, in some cases, parasites appear to actually hijack the process of innate recognition to deviate adaptive immunity to facilitate their own persistence.

Humoral Mechanisms

Innate resistance against parasitic infection is mediated in part by preexisting, soluble factors that recognize and destroy invading developmental stages or target them for killing by effector cells. The alternative pathway of complement activation provides a first line of defense against extracellular parasites and because of this, the infective stages of parasitic protozoa and helminths have developed a various strategies to subvert complement-mediated attack. In some instances, blood and tissue parasites have evolved redundant mechanisms to ensure their survival

during serum exposure. For example, infective metacyclic and bloodstream trypomastigotes of *Trypanosoma cruzi* express multiple stage-specific surface glycoproteins, such as gp160 and the 87-93kDa trypomastigote decay accelerating factor, which are actively released by the parasite and are functional homologues of human decay accelerating factor that interferes with assembly of C3 convertases by binding to C3b.[3] Another trypomastigote glycoprotein, gp58/gp68, inhibits alternative pathway C3 convertase assembly by binding to factor B. *T. cruzi* trypomastigotes have also been found to continuously shed acceptor molecules with covalently bound C3 fragments, thought to be due to an endogenous phospholipase that cleaves glycosylphosphatidylinositol (GPI)-anchored membrane proteins. In addition, trypomastigotes export calreticulin to the parasite surface where, by binding C1, the protein can both inhibit activation of the classical pathway and promote parasite invasion.[4] *T. cruzi* amastigotes, on the other hand, have been shown to resist complement lysis by preventing membrane insertion of the membrane attack complex (MAC), C5b-9. An analogous mechanism of resistance has been observed for the infective metacyclic promastigote stage of *Leishmania*, which expresses an elongated form of the major surface and released glycolipid on *Leishmania* promastigotes, lipophosphoglycan (LPG), such that it behaves as an effective barrier to membrane insertion and pore formation by MAC.[5] Metacyclics also increase expression of the surface metalloproteinase gp63,[6] which can cleave C3b to the inactive iC3b form, thus preventing deposition of MAC.[7] Both C3b and iC3b effectively opsonize the complement resistant forms for uptake by macrophages, its host cell of choice. Tissue-invasive strains of *Entamoeba histolytica* also activate the alternative complement pathway but are resistant to lysis due to the action of a Gal/GalNAc lectin, which mediates adherence of trophozoites to host cells and binds to C8 and C9 terminal components.[8] Interestingly, the lectin shares sequence similarities with CD59, a membrane inhibitor of MAC in human blood cells.

The damage caused to worms as a consequence of alternative pathway activation is due primarily to the bound C3 activation products that act as ligands for cellular adherence and killing by eosinophils, neutrophils, and macrophages. In addition to synthesizing their own complement regulatory proteins to subdue the activation cascade, helminths also acquire endogenous regulatory molecules from the host. For example, schistosomes can inhibit complement activation through surface-expressed parasite proteins that bind C2, C3, C8, and C9 but also do so by acquiring decay accelerating factor from the host and incorporating it into their teguments.[9] Similarly, the infective L3 stage larvae of *Onchocerca volvulus*, the causative agent of river blindness, were shown to bind the main human fluid phase regulator factor H, thereby promoting C3b inactivation.[10] Other parasitic nematodes such as *Toxocara canis*, *Brugia malayi*, and *Trichinella spiralis* appear to block complement attack by secreting proteases that attack the complement pathway[11] or regulatory proteins that inhibit its function.[12]

A well-characterized set of soluble mediators providing a barrier to parasitic infection are the primate-specific trypanosome lysis factors (TLF1 and TLF2) present in serum that contribute to the innate resistance of humans to *Trypanosoma brucei* infection.[13] The key active components of these serum complexes are haptoglobin-related protein and apoliprotein L (ApoL)-1 that together are cytotoxic to *T. b. brucei* and act synergistically to provide enhanced trypanosome killing when assembled into the same high-density lipoprotein (HDL) particle. Haptoglobin-related protein and ApoL-1 have different proposed activities; ApoL-1 is able to form ion pores in lysosomal membranes, whereas haptoglobin-related protein is able to accelerate lysosomal membrane peroxidation.

Whereas the TLFs are capable of killing *T. brucei*, the species that infect humans, *T. b. gambiense* and *T. b. rhodesiense*, are both refractory to TLF-mediated cytolysis. This property has been correlated with the expression of a serum resistance-associated gene that is homologous to the variant surface glycoprotein. Importantly, transfection of serum resistance -associated gene from *T. b. rhodesiense* into *T. brucei* confers resistance to lysis by human serum, arguing that its expression may have been a critical step in the adaptation of the former parasite for infection of primates.[14] Interestingly, mice cotransfected with TLF components display enhanced resistance to *T. brucei* infection, suggesting that such a genetic modification strategy might be useful in protecting livestock against this parasite, which still is a major impediment to cattle farming in many parts of Africa.[15]

Cellular Mechanisms

Phagocytosis by macrophages represents an innate first line of defense against protozoan pathogens. Macrophages possess primary defense mechanisms, including activation of

oxidative metabolism, which are induced by the attachment and engulfment of microbial agents, and the early survival of intracellular parasites will depend on their ability to avoid or withstand oxidative stress conditions. The major source of reactive oxygen species is the multimeric enzyme complex, nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. Early studies suggested that *Leishmania* parasites avoid triggering the oxidative burst by actively inhibiting macrophage (PKC) activation,[16] which is required for phosphorylation of several sites on the cytosolic oxidase subunit, p47phox. The inhibition of the respiratory burst has also been linked to leishmanial LPG, which is rapidly transferred to the inner leaflet of the phagosomal membrane and prevents translocation of the NADPH oxidase cytosolic components.[17,18] As some LPG-deficient *Leishmania* strains still manage to survive in macrophages, it is clear that redundant mechanisms exist for the parasite to avoid macrophage triggering. These include opsonic ingestion through receptors that are uncoupled from the activation of NADPH oxidase. A number of "silent" entry receptors have been described that are variably used by different species and developmental stages of *Leishmania*, including complement and mannose receptors,[19] and receptors for apoptotic cells.[20,21]

In contrast to *Leishmania*, *Toxoplasma* enters all nucleated cells, including macrophages, by an active invasion mechanism that excludes most host cell proteins, including membrane components of the NADPH oxidase, from the

parasitophorous vacuole.[22] Malaria parasites are also sensitive to oxidative stress, and knockout mice lacking NADPH oxidase suffer more rapid increases in malaria parasite densities than wild-type mice.[23] In this case, reactive oxygen species are generated primarily as a result of the degradation of host hemoglobin within parasitized red blood cells (RBCs).[24] The detoxification of reactive oxygen species is achieved with a range of low-molecular weight antioxidants, including the tripeptide glutathione, and a number of host- and parasite-encoded enzymes.[25]

The maturation of phagosomes into digestive organelles represents the heart of the defensive machinery of macrophages, and intracellular parasites have evolved diverse strategies to avoid, escape from, or withstand the acidified, hydrolytic environment of phagolysosomes. For *Toxoplasma*, the integral membrane proteins that are excluded from the nascent vacuole include those involved in acidification and fusion with the endosomal network.[26] If instead the parasite is forced to enter the cell by a phagocytic pathway, as a consequence of, for example, antibody opsonization, it is targeted through the normal phagolysosomal system and is killed.[27] For *T. cruzi*, which trigger a wound repair pathway involving lysosome exocytosis to enter into cells,[28] the early vacuole is acidified and potentially fusogenic. Intracellular survival of *T. cruzi* is dependent on its ability to escape from the vacuole, a process facilitated by its expression of a putative pore-forming protein that is immunologically cross-reactive with human C9, and that can disrupt the phagosome membrane allowing egress of the parasite into the cytoplasm.[29] *Leishmania* promastigotes, again via transfer of their surface LPG which increases the periphagosomal accumulation of F-actin and disrupts phagosome microdomains, transiently inhibit normal phagosome maturation.[30] The delay in phagosome maturation may be necessary to allow sufficient time for metacyclic promastigotes transmitted by the sand fly to differentiate into more acidophilic, hydrolase-resistant amastigotes. The various strategies employed by parasitic protozoa to evade the innate defenses of host macrophages are depicted in Figure 38.1.

Neutrophils have been an understudied component of the innate cellular response to protozoan pathogens, despite the fact that they are rapidly and massively recruited to the site of parasite delivery by the bites of arthropod vectors. They have been clearly revealed by intravital two-photon microscopy to be the first cells to take up *Leishmania* in the skin during the first hours of infection following inoculation by needle or vector sand flies.[31,32] Their localized recruitment is triggered by the vascular damage caused by the needle injection or the sand fly bite in addition to signals derived from sand fly saliva and the parasite.[33,34] The survival of *Leishmania* following their phagocytosis by neutrophils, similarly to macrophages, is dependent on their ability to inhibit fusion of tertiary granules with the parasite-containing phagosome, which was again shown to be linked to the expression of the promastigote surface LPG.[35,36] Interestingly, macrophages have been observed to phagocytose infected neutrophils in vitro,[35,37] and the exploitation of the apoptotic cell clearance function of macrophages is the basis for the "Trojan horse" infection model whereby infected, apoptotic neutrophils are proposed to silently deliver *Leishmania* to host macrophages to initiate productive infections in these cells. At later stages of infection, neutrophils may help to defend against *Leishmania*, in part, by releasing fibrous deoxyribonucleic acid (DNA)-based extracellular traps that ensnare and kill the parasite.[38] DNA-based extracellular traps are also elicited by *T. gondii* tachyzoites, with evidence that they exert direct microbicidal effects and interfere with host cell invasion and parasite spread.[39] Although neutrophils are not required to control malaria infections (and may, indeed, contribute to tissue damage), their oxidative burst is severely compromised following exposure to the heme detoxifying enzyme heme oxygenase, leaving malaria patients at increased risk for systemic, gram-negative, bacterial infections.[40]

Unlike protozoa, helminths are too big to be engulfed by phagocytes and can only be killed by these cells when the latter have been activated by products of the adaptive immune response. Instead, eosinophils, which frequently accumulate in tissues soon after worm invasion, may mediate innate cellular defense against helminth larvae by means of discharge of the major basic protein and cationic proteins present in the granules of these cells.[41,42]

In contrast to intracellular killing by phagocytes and extracellular killing by eosinophils, some innate cellular defenses do not eliminate parasites directly but instead trigger other effector cells to do so. Perhaps the best studied example of this form of innate immunity is the natural killer (NK) cell pathway of cytokine production. NK cells become activated as a consequence of various parasitic infections; *Leishmania* promastigotes; *Plasmodium falciparum* -infected RBCs; components of *T. gondii*, *T. cruzi*, *E. histolytica*, and *Cryptosporidium parvum*; and excretory-secretory proteins of the hookworm *Necator americanus*[43] all activate human peripheral blood NK cells to produce interferon (IFN)γ. Despite occasional reports of direct binding of parasite ligands to NK-cell receptors, the emerging consensus is that NK-cell activation is secondary to pattern recognition receptor (PRR)-mediated activation of myeloid dendritic cells (DCs) and monocyte/macrophages and requires both contact-dependent and cytokine-mediated (interleukin [IL]-12, IL-18) signals.[44] Moreover, in the absence of Th2 responses, NK cells may become an important source of the protective type-2 cytokine, IL-13, during murine gastrointestinal nematode infections.[45] These findings suggest that NK cells may provide a T-lymphocyte independent pathway for cytokinemediated defense and as such serve to prevent parasites from overwhelming the host prior to the development of adaptive responses. Nevertheless, there is increasing evidence that NK responses are markedly enhanced by T-cell-derived IL-2, revealing a novel pathway by which adaptive immune responses may augment innate responses.[46,47] Trafficking of NK cells to parasite-infected tissues is critically dependent upon chemokines binding to CCR5.[48] Both IL-10 and transforming growth factor (TGF)-β have been shown to serve as negative regulators of NK cell IFNγ production by means of their suppression of monokine and B7 expression by antigen-presenting cells (APCs) or, in the case of TGF-β by directly affecting NK-cell function.[49] Such suppression

may be important in protecting the host against the tissue damaging effects of excessive NK-cell-derived IFNγ and tumor necrosis factor (TNF)-α. NK-cell responses are further regulated by calibration of signals from activating and inhibitory receptors for major histocompatibility complex (MHC) molecules; moderation of NK responses to malariainfected RBCs by inhibitory receptors such as NKG2A/CD94 and polymorphic killer-cell Ig-like receptors has been proposed.[50] Although NK-cell-derived IFNγ can limit the initial phase of protozoal replication[51] and may a play a role in the polarization and expansion of Th1 cells, in some

situations, adaptive T-cell immunity is sufficient to control infection even in the absence of this early NK response.[52,53] The role of NK-cell cytotoxicity in resistance to protozoan infection is less well understood; for murine malaria, it is not required for NK-mediated resistance to blood stages,[52] but cytotoxic NK killing of malaria-infected liver cells has been reported.[54]

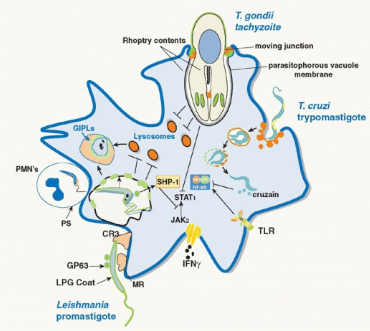

FIG. 38.1. Evasion of Innate Immune Mechanisms in Infected Macrophages by Parasitic Protozoa. Macrophages possess potent antimicrobial functions that are initiated by uptake of pathogens. Receptor-mediated phagocytosis of *Leishmania* promastigotes is accomplished by CR3 or mannose receptors that are unlinked from the signaling pathways involved in induction of reactive oxygen intermediates or proinflammatory cytokines. Silent uptake using receptors for apoptotic, phosphatidyl serine positive neutrophils delivering viable promastigote has also beeen described. The transfer of surface lipophosphoglycan to the phagosome membrane results in delayed fusion with lysosomes. Following transformation to amastigotes, which are more hydrolase resistant due to an abundance of surface glycoinositolphopsholipids, phagosome maturation proceeds. Host cell phosphatases such as SHP-1 can be directly activated by *Leishmania* surface and released molecules, including GP63, to inactivate janus kinase 2 (JAK2) and inhibit interferon (IFN)γ-inducible macrophage functions. *Toxoplasma* actively invades by rapid discharge of adhesive proteins from secretory organelles called rhoptries, then by inserting and squeezing past a moving junction in the plasma membrane that acts as a molecular sieve, excluding from its vacuole host proteins required for acidification and fusion with the endosomal network. Various *Toxoplasma*-induced defects in IFNγ signaling have been described, including proteolysis of signal transducer and activator of transcription 1. *T. cruzi* trypomastigotes enter the macrophage by inducing the recruitment of lysosomes to the plasma membrane; they only transiently reside in the vacuole before escape into the cytoplasm via secretion of a pore-forming molecule. *T. cruzi* inhibits toll-like receptor-mediated macrophage activation by directly targetting nuclear factor-kappaB (NF-κB) p65 for cleavage by a released protease, cruzain.

Two other cell populations that may function to provide a rapid cytokine response to invading parasites are γδT cells and NK T cells. These "unconventional T lymphocytes" express T-cell receptor chains of limited diversity, which may be designed for innate recognition of microbial structures or self-components revealed by infection of host cells. Although the function of NK T cells in innate resistance to parasites is currently under debate, there is considerable evidence supporting a protective role for γδT cells. Although representing a small percentage of lymphocytes in the periphery, γδT cells are abundant in epithelial and mucosal tissues, the sites of initial host invasion by many parasites. Moreover, their numbers increase in peripheral blood in response to a number of protozoan infections[55] where they can contribute effector cytokines or, in the case of extracellular *P. falciparum* merozoites, mediate direct granulysin-dependent killing.[56] Nevertheless, rather than being essential for host resistance, it is likely that γδT lymphocytes (in common with NK cells) provide an adjunct to conventional αβ CD4+ and CD8+ T cells in restricting parasite growth during the vulnerable period when the adaptive responses mediated by these lymphocyte subsets is emerging.[57,58]

A recently discovered group of effectors in the early cellular response to parasites are the innate lymphoid cells (ILCs). This cell population belongs to a heterogeneous family of innate non-T, non-B cells that are not antigen restricted. However, as they express CD45 and are dependent on traditional T-cell growth factor signaling pathways, they have been called ILCs. In common with NK cells, which themselves have now been reclassified as ILC, ILC2 produce cytokines important in T-cell subset differentiation and amplification. In the case of ILC2, these cytokines are IL-4 and IL-13, which promote Th2 development and function. As outlined later in this chapter, ILC2 (which may comprise as many as four distinct cell populations) play an important role as a major source of IL-13 in the intestinal response to nematodes and in worm expulsion.[59] Also as discussed subsequently, basophils can provide an innate source of IL-4, thereby driving Th2 differentiation, and have been proposed to do so while simultaneously serving as APCs for T-cell activation.

TABLE 38.2 Parasite Molecular Patterns Recognized by Toll-Like Receptors

MAMPs	Parasite	Structure	TLR Stimulated	Reference
GPI anchors	*Leishmania* ssp.	LPG	TLR2	60
	Trypanosoma cruzi	GPI anchors containing unsaturated alkylacylglycerol		
TLR2				
		GIPLs containing ceramide	TLR4	
	Trypanosoma brucei	GPI anchors of VSG	Undefined	
	Plasmodium falciparum	GPI anchors of MSPs	TLR2	118
			TLR4	
	Toxoplasma gondii	GIPLs and GPI anchors	TLR2	

			TLR4	
Genomic DNA	*T. brucei*	Contain unmethylated CpG motifs	TLR9	472
	L. major	Contain unmethylated CpG motifs	TLR9	64
	L. braziliensis	Leishmania RNA virus-1	TLR3	65
	T. cruzi	Contain unmethylated CpG motifs	TLR9	61
	P. falciparum	AT-rich stem-loop DNA motif	STING, TBK1, and IRF3-IRF7	80
Hemazoin	*P. falciparum*	Polymerized heme from degradation of hemoglobin	TLR9	
Protein	*T. gondii* (and related apicomplexa)	Profilin molecules	TLR11	68
Phospholipid	*Schistosoma mansoni*	Lysophosphatidylserine in tegument	TLR2	73
Phosphorylcholine	Filarial nematodes	Phosphorylcholine-containing glycoconjugates on ES-62 glycoprotein	TLR4	72
RNA	*S. mansoni*	Double-stranded RNA in parasite ova	TLR3	74

DNA, deoxyribonucleic acid; ES-62, filarial excretory-secretory antigen; GlPL, glycoinositolphospholipid; GPI, glycosylphosphatidylinositol; LPG, lipophosphoglycan; MAMP, microbe-associated molecular pattern; MSP, merozoite surface protein; RNA, ribonucleic acid; TLR, toll-like receptor; VSG, variant surface glycoproteins. Role of Pattern Recognition Receptors in Innate Recognition of Parasites

The innate immune system, in addition to providing a natural barrier that limits infection, also plays a critical role in the initial recognition of parasites and the triggering of adaptive immunity. Invading parasites, such as other pathogens, are sensed by host PRRs that recognize microbe-associated molecular patterns shared by different groups of organisms (Table 38.2). These PRRs are highly expressed

on both epithelial cells and APCs and, when ligated, trigger cytokine and costimulatory signals that initiate both innate and adaptive cellular responses.

Toll-like receptors (TLR) are, so far, the major group of PRRs known to be triggered by parasites. The study of TLR involvement in parasitic infection began with the identification of parasite ligands that stimulate cytokine production from macrophages and DCs. In the case of protozoa, important classes of such ligands are the GPI lipid anchors present on many parasite surface proteins and phosphoglycans, and the membrane-associated glycoinositolphospholipids. Thus, GPIs from *T. brucei*, *Leishmania*, *T. gondii*, and *P. falciparum* can stimulate macrophages to upregulate inducible nitrogen oxide synthase expression and produce proinflammatory cytokines. Similarly, the GPI anchor fraction of mucin-like molecules from *T. cruzi* trypomastigotes triggers macrophage production of IL-12 and TNF. Glycoinositolphospholipids from *T. cruzi* and *T. brucei* possess similar agonist activities.[60] Studies employing reporter cell lines transfected with specific TLRs, or TLR-specific knockouts, have demonstrated that the responses induced by these parasite glycolipids are due to stimulation of TLR2 and to a lesser extent TLR4 (preferentially triggered by glycoinositolphospholipids in the case of *T. cruzi*).

Parasite nucleic acids also represent important ligands for TLR recognition. Thus, genomic DNAs from several protozoan species have been shown to stimulate host proinflammatory cytokine production presumably through the recognition of unmethylated CpG motifs by TLR9. A major role for nucleic acids in stimulation of host resistance to *T. cruzi* is evidenced by the diminished host resistance of both TLR9 and TLR2/TLR9 double knockout animals[61] and by more recent studies on mice deficient in UNC93B1, a protein that mediates translocation of TLR3, 7, and 9 to endolysosomes. These animals showed greater susceptibility to infection than TLR9-deficient mice, a finding that points to an additional role for TLR7 recognition of parasite RNA in the innate response to *T. cruzi*.[62] TLR9 signaling also contributes to host resistance to *Leishmania* apparently through DNAd-riven activation of both DCs and NK cells, although there is debate as to whether this stimulation also plays a role in Th1 response development.[63,64] *Leishmania* strains isolated from patients with mucocutaneous leishmaniasis were found to harbor high amounts of a ribonucleic acid virus that induced a TLR3-mediated hyperinflammatory response in mice that may explain the destructive metastatic lesions associated with mucosal disease.[65] In the case of *P. falciparum*, hemazoin, a product of malaria-induced hemoglobin degradation is a TLR9 agonist,[66] although at present there is controversy as to whether this results from contamination with immunostimulatory DNA fragments of parasite origin.[67]

A chemically different class of TLR ligands are the profilin proteins expressed by apicomplexan protozoa. These molecules are unique to eukaryotes and are typically associated with intracellular actin. Profilins from *T. gondii*, *Eimeria*, and *C. parvum* potently trigger IL-12 production from murine DCs as well as systemically following in vivo inoculation.[68] Experiments in the murine *T. gondii* model established that this response is due to the stimulation of TLR11, a TLR that although present in mice and other small animals is not functionally expressed in primates. Recent studies have demonstrated that UNC93B1 is required for triggering of TLR11 activation and IL-12 production by *T. gondii* profilin in mice, thus revealing an endosomal localization for this TLR.[69] Nevertheless, whereas UNC93B1-deficient mice are highly susceptible to *T. gondii* infection, animals deficient in TLR11[68] (as well as TLR3, 7, and 9) show no or only partial impairment of resistance, indicating that UNC93B1 must serve additional functions in innate immunity to the parasite beyond its role in TLR11 localization and activation.[70]

Helminth parasites also express TLR ligands, although as discussed subsequently, their role in the immune response has been harder to define than those characterized in protozoa. Moreover, in many studies, the possibility of contamination by bacterial or viral TLR ligands from symbionts has not been systematically ruled out. Indeed, *Wolbachia* symbionts confer strong TLR4 and TLR2 agonist activity on filarial parasites due to their endotoxin-like components.[71] Well-studied examples of helminth TLR microbe-associated molecular patterns include the phosphorylcholine containing moieties of the filarial glycoprotein ES-62[72] and the lysophosphatidylserine components of schistosome membranes[73] that trigger TLR4 and TLR2, respectively. In addition, schistosome eggs possess double stranded

ribonucleic acid molecules that stimulate TLR3 in DCs.[74]

The role played by TLRs in the host response to parasites is complex and not fully delineated in any of the host-parasite models studied. The main evidence for TLR involvement comes from experiments in mice deficient in myeloid differentiation primary response gene 88 (MyD88), a major adaptor protein required for signaling by most TLRs as well as by the IL-1 and IL-18 receptors. MyD88-deficient animals exhibit a loss in resistance to *T. gondii*, *T. cruzi*, *L. major*, *T. brucei*, and—in the case of *Plasmodium berghei*—decreased immunopathology[60] that likely reflects the role of TLR signaling in accessory cells (eg, DCs, epithelial cells) in the initiation and maintenance of Th1 responses. However, the altered susceptibility of these mice could also involve non-TLR-related effects of MyD88 deficiency and/or T-cell intrinsic functions of the gene, as demonstrated in the *T. gondii* mouse model.[75] Significantly, no major alterations in helminth-induced immune responses have as yet been described in MyD88- deficient hosts on susceptible genetic backgrounds, arguing against a significant role for TLR signaling in Th2-dependent host resistance and pathology in worm infections.

In contrast to the dramatically increased susceptibility often observed in MyD88-/- mice following protozoan infection, mice deficient in single TLRs exposed to the same parasites rarely show pronounced changes in resistance, even when such animals display major immune response impairments. For example, while TLR11-/- mice infected with *T. gondii* develop severely blunted IL-12 responses both in vitro and in vivo, they nevertheless survive the acute-phase infection and show only a minor increase in parasite load in comparison to fully susceptible IL-12-deficient animals.[68] Such findings may reflect redundant functions for different TLR or a requirement for multiple MyD88-dependent TLR (or IL-1/IL-18) signals in host resistance. An additional

complexity is that mice deficient in single TLRs may show unaltered (or even enhanced) resistance because the TLR in question controls an immunopathologic response or downregulates host effector functions.[76] Moreover, as exemplified by recent studies in the peroral *T. gondii* infection model, TLR signals triggered by host commensal flora (presumably as a result of intestinal barrier breakdown) can also influence the outcome of parasitic infection.[77] A major challenge of current research in this area is to decipher such positive and negative TLR signals triggered by parasite, commensal, or host ligands and establish how their integration governs host resistance.

There is also a dearth of knowledge concerning the function of PRR signaling pathways outside the TLR family. A topic of particular interest in this regard is the role of inflammasome activation in parasite-induced immunopathology. Two recent studies have demonstrated that malaria hemazoin is a potent activator of the NLRP3 inflammasome in vitro but have yielded conflicting results on the involvement of this pathway in cerebral malaria in vivo.[78,79] Most recently, sensing of AT-rich malarial DNA by an an unknown receptor that signals via the stimulator of IFN gene (STING), TANK-binding kinase 1 (TBK1), and interferon regulatory factor (IRF)3 to IRF7 signaling pathway has emerged as an entirely novel pathway of pattern recognition.[80]

DCs play a major role in linking parasite pattern recognition signals to the induction of both NK-mediated innate responses and T-cell-dependent adaptive immunity. As discussed previously, in the case of many protozoa, DC-derived IL-12 provides a major stimulus for the initiation of host defense pathways. The critical role of DCs is underscored by the impaired IL-12 production as well as impaired control of protozoan (*T. gondii*) infection[81] in mice in which CD11c+ DC populations have been genetically depleted. Such DC-depleted mice are also unable to generate CD8+ cytotoxic T-lymphocyte responses against *Plasmodium yoelii* sporozites.[82] The requirement for protozoan invasion in DC activation is complex and depends on the parasite species and DC subset in question. Indeed, as discussed subsequently, infection of DCs can result in suppressed responsiveness to activation stimuli. Nevertheless, infection of DCs with, for example, live *Leishmania*[83] or *T. gondii* appears to be important for efficient priming of CD8+ T cells despite the sequestration of many of the protozoa in question within parasitophorous vacuoles physically removed from the class I MHC antigen presentation machinery of the host cell.[84] In addition, it appears that under certain situations (eg, immunization with irradiated malarial sporozoites[85]) infected, apoptotic host cells are taken up by DCs as a mechanism of CD8+ T-cell priming. Thus, although live infection is clearly important for efficient T-cell response induction, direct infection of DCs (as opposed to other host cells) may not be required in vivo. The failure to observe parasite-containing DCs engaged in long-lived contact with T cells in in vivo imaging studies lends credence to this hypothesis but is subject to alternative interpretations.[86,87]

In addition to their role in initiating immune responses, DCs appear to be efficient vehicles for dissemination of parasites into different tissues as illustrated by studies in the *T. gondii* mouse model.[88] Infection of DCs can also serve as a survival strategy for protozoa and as a means for maintaining cryptic infection, as suggested by recent studies in which DCs from mice with rodent malaria were found to be capable of initiating infection when inoculated into naïve hosts.[89]

Downregulation of Innate Signaling Pathways by Parasites: Role in Virulence Determination

In addition to upregulating APC function, parasite products can also dampen their activity either as a mechanism of immune evasion or for the purpose of protecting the host against the pathology associated with an uncontrolled immune response. *Leishmania*, *T. cruzi*, and *Toxoplasma* have in common their ability to inhibit proinflammatory and IFNγ inducible responses in infected macrophages, such that the parasites might not only prevent or delay the induction of Th1 responses but also render infected macrophages unresponsive to activation signals during the effector phase of the immune response (see Fig. 38.1). In many cases, the parasites exploit the presence of host cell phosphatases whose normal role is to temper the magnitude and duration of the proinflammatory response. For *Leishmania*, the inhibition is due in part to activation by the *Leishmania* metalloproteinase gp63 of host cell protein tyrosine phosphatases, including SHP-1 and other nonreceptor protein tyrosine phosphatases, which inactivate Janus kinase (JAK) family members involved in the IFNγ inducible phosphorylation cascade.[90] Other host cell phosphatases were found to be activated by *Leishmania* cysteine proteinases to regulate the Mitogen-activated protein kinase (MAPK) family members p38 and extracellular signal-regulated kinase (Erk)1/2, resulting in the upregulation of IL-10 and downregulation of nitrogen oxide (NO) and TNF-α production.[91] *T. cruzi* trypomastigotes, via expression of GPI-anchored mucin-like molecules, also activate macrophage phosphatases that target downstream elements of the TLR pathway, including MAPK and nuclear factor-kappaB (NF-κB), to establish a state of tolerance in the infected cells.[92] Furthermore, NF-κB p65 was found to be targeted directly for cleavage by the *T. cruzi* protease cruzain, and cruzain-deficient parasites rapidly activated macrophages via NF-κB p65 for IL-12 expression.[93] A homologue of cruzain, cysteine peptidase B, is expressed in *Leishmania mexicana* and was likewise found to degrade NF-κB p65 to inhibit IL-12 production by infected macrophages.[94] The need to counterbalance the excessive inflammation that can be triggered by *T. gondii* infection extends to the modulation of IFNγ-induced responses, and in particular the signal transducer and activator of transcription (STAT)1 signaling cascade that is critical for resistance to *T. gondii*. \arious defects in IFNγ-initiated STAT1 signaling have been described in *T. gondii*-infected cells, including proteolytic cleavage of STAT1, dephosphorylation, and prevention of nuclear translocation.[95] Thus, although both *T. cruzi* and *T. gondii* initiate strong proinflammatory responses in host macrophages, these signaling pathways appear to be subsequently impaired to avoid reaching pathologic levels that may be detrimental to the host and/or lethal to the parasite during the adaptive phase of the immune response.

The differential ability of parasites to dampen cellular activation signals appears to be a major factor in virulence

determination. This has been elegantly studied in recent work on *T. gondii* examining the basis of the marked virulence differences in mice between Type I, Type II, and Type III strains of the parasite. By examining the progeny of genetic crosses between Type I and III or Type II and III parasites, two highly polymorphic genes ROP18 and ROP16 were identified as major virulence determinants.[96,97] Both genes encode serine-threonine kinases associated with a parasite organelle known as the rhoptry. During the process of invasion, rhoptry proteins are discharged into the host cell. Studies with ROP18 indicate that in Type I strains the kinase inactivates effectors known as immunity-related GTPase (IRG) proteins (discussed subsquently) that mediate parasite killing by disrupting the parasitophorous vacuole.[98] By contrast, the Type 1 variant of ROP16 transits to the host cell nucleus where it phosphorylates and activates STAT3 and STAT6, which in turn downregulate the proinflammatory IL-12, IL-6, and inducible NO synthase response to the parasite via their roles as positive regulators of silencers of cytokine signaling and/or IL-10.[96] Recently, a third virulence factor has been identified, in part, through a new genetic cross between Types II and I. ROP5 is a pseudokinase and serves as a scaffold to enable ROP18 activity.[99,100] The mechanism(s) by which these three rhoptry proteins interact in suppressing host cellular function is a major area of interest in the field. A current model of the function of the major *T. gondii* virulence determinants is presented in Figure 38.2.

In addition to their suppressive effects on macrophages and other host cells, parasites or their products can negatively regulate DC function, both as a means to delay the onset of the adaptive response or to restrain an ongoing response to prevent immunopathology. For example, IL-12 production by splenic DCs is rapidly suppressed following initial in vivo stimulation with soluble *T. gondii* antigen and cannot be restimulated for approximately 1 week thereafter. The antiinflammatory outcome appears to result from the induction, by parasite products, of lipoxin A4, an arachadonic acid metabolite that upregulates silencers of cytokine signaling-2 to inhibit soluble *T. gondii* antigen-induced DC migration and IL-12 production.[101] Similarly, in murine malaria, the initial burst of proinflammatory cytokines is down regulated as DCs become refractory to further TLR signaling.[102] The ligands implicated in these interactions include a conserved domain of *P. falciparum* erythrocyte membrane antigen and hemozoin that has been shown to directly inhibit the maturation of human DCs.[103] This TLR tolerance is similar to that induced by endotoxin and may explain the prevalence of "regulatory" $CD11c^{low}CD45RB^{high}$ DCs later in infection that have been shown to induce IL-10-secreting T cells as a negative feedback mechanism to control immunopathology.[104] The relevance of these findings to human disease is supported by the observation that the interethnic differences in malaria infection outcome in Malian children are associated with reduced expression of activation markers and reduced TLR-induced responses in DCs from *P. falciparum*-infected Dogon children who experience more severe disease.[105] Also, the percentage of human leukocyte antigen-DR + DCs has been reported to be significantly lower in Kenyan children with severe or mild malaria compared to healthy controls, and they also had increased frequencies of DCs expressing BDCA-3, a marker that is upregulated on IL-10 treated monocyte-derived dendritic cells (MDDC).[106] In Chagas disease, compromised DC function has been linked to immune suppression in chronically infected mice. *T. cruzi* blood stages inhibited the lipopolysaccharide (LPS)-induced activation of mouse bone marrow-derived DCs, with both IL-10 and TGF-β important in the induction of the regulatory DC phenotype.[107,108] Together, these studies involving *T. gondii*, malaria, and *T. cruzi* suggest that parasites drive DC activation and proinflammatory reactions during the acute stages of infection, followed by the emergence of regulatory DCs that modulate the adaptive response, limiting both immunopathology and pathogen clearance.

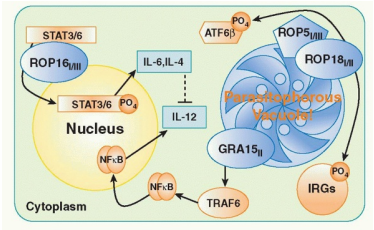

FIG. 38.2. Proposed Cellular Roles for *Toxoplasma gondii* Secretory Proteins in Determining Acute Parasite Virulence. The diagram depicts a cell infected with *T. gondii* showing the major tachyzoite secretory proteins implicated as virulence factors and the host functional pathways they regulate. The rhoptry protein ROP16 is secreted into the host cell and accumulates in the nucleus. There, it is thought to phosphorylate signal transducer and activator of transcription (STAT)3 and STAT6 transcription factors that upregulate interleukin (IL)-4- and IL-6-dependent responses, leading in turn to impaired IL-12 production. The granule protein GRA15 is also released following invasion and associates with the parasitophorous vacuole membrane (PVM). In the case of Type II strains, this results in the induction of IL-12 through a TNF receptor associated factor 6 (TRAF6), NF-kB-dependent pathway. ROP18 is secreted into the host cell where it remains tethered to the PVM and can directly phosphorylate immunity-related guanine triphosphatase (GTPase), blocking their recruitment to vacuoles resulting in impaired parasite clearance. ROP18 has also been shown to phosphorylate activating transcription factor 6 beta (ATF6b), an endoplasmic reticulum (ER) stress response transcription factor involved in control of *T. gondii*-induced dendritic cell function. Recent genetic studies indicate that ROP5, a polymorphic, tandemly duplicated pseudokinase, also plays a major role in acute virulence, likely through interaction with ROP18. See Fentress and Sibley[470] for a recent review. (Adapted from Sibley LD, Boothroyd JC. Genetic mapping of acute virulence in *Toxoplasma gondii*. In: Sibley LD, Howlett BJ, Heitman J, eds. *Evolution of Virulence in Eukaryotic Microbes.* Hoboken, NJ: Wiley Blackwell; 2012, with permission.)

By comparison, studies with *Leishmania* suggest that for most strains their initial encounters with DCs fail to activate these cells and, as a consequence, proinflammatory responses and cell-mediated immune mechanisms are effectively inhibited or delayed even during the acute stage of infection. In the case of *Leishmania major*, the infective

promastigotes deposited in the skin by vector sand flies were found to be poorly taken up by DCs in vitro. However, later in infection, efficient uptake of amastigotes by DC in vitro and in vivo is dependent on parasite-reactive IgG binding to FcγRI and FcγRIII; this primes DCs for efficient production of IL-12.[109] Furthermore, the initial encounter of other *Leishmania* species associated with nonhealing infections in mice not only failed to activate DC but also inhibited their subsequent responses to activation signals.[110] For example, DCs with clear regulatory properties and bearing the phenotype of $CD11c^{lo}$ CD45RB+ CD11b+ IL-10-producing cells, emerge as the predominant DC subset in the spleen of *Leishmania donovani*-infected mice and induce antigenspecific tolerance in vivo.[111]

Mechanisms Underlying Th1/Th2 Response Selection

Because parasites often stimulate CD4+ T-cell responses that are highly polarized in either the Th1 or Th2 direction, parasitic infection models have become important tools for studying the cellular basis of Th1/Th2 response selection. DCs are thought to be an important source of the signals that determine CD4+ T-cell effector choice, and their role is best understood for Th1 responses. *T. gondii*, *T. cruzi*, and *Plasmodium* have been shown upon their initial encounter with DCs to upregulate expression of IL-12 and costimulatory molecules. The

nature of these encounters has been extensively studied for *T. gondii*, whose possession of important Th1-inducing TLR ligand(s) has been inferred by the high susceptibility to infection of mice lacking MyD88[112] and shown to be selectively acting on DCs.[93] Importantly, the high susceptibility of MyD88-/- mice is comparable to that observed in IL-12-/- mice and is not due to the absence of IL-1/IL-18 signaling.[113] As noted previously, the stimulation of TLR11 by parasite profilin appears to be the major MyD88 pathway that triggers this IL-12 response in the murine model.[56] *T. cruzi* induces a delayed, although ultimately strongly and persistently polarized, Th1 response in infected mice that is also MyD88 dependent and, as already mentioned, appears to be induced largely by nucleic acid ligands.[91] The Th1 responses that contribute to immunopathology during blood-stage malaria infections are driven, at least in part, by TLR ligands as MyD88-/- mice have decreased production of IL-12 and attenuated pathology,[114] whereas—in acutely infected mice and humans—hyperresponsiveness has been linked to IFNγ-induced enhancement of TLR expression on DCs.[115] As previously discussed, hemozoin or a hemozoin-DNA complex hemozoin acting through TLR9, and GPI binding to TLR2, appear to be the main malaria component(s) that activate mouse and human blood DCs to secrete IL-12.[116,117,118]

Unlike the protozoan pathogens just described, *Leishmania* appears to trigger TLR signaling in DC poorly, and in most cases, their ability to activate these APCs—for upregulated expression of costimulatory molecules and especially for IL-12 production—requires additional signals that are host derived. For example, the interaction of CD40L on T cells with CD40 on infected DCs enhances IL-12p70 secretion in vitro[119] and is essential for *L. major* -specific Th1 activation and immunity in vivo.[120] In addition to IL-12, there are signals delivered by other cytokines, including IL- 18, IL-27, IFN α, and IL-1, which have been shown to bias *Leishmania*-specific CD4+ T-cell priming toward a Th1 cell fate. Mouse strains with intrinsic deficiencies in host factors necessary to augment Th1-polarized responses against *Leishmania* are highly susceptible to infection, and as noted previously, the first direct demonstrations of the relevance of the Th1/Th2 balance to the regulation of disease outcome in vivo were based on studies of *L. major* infection outcome in different inbred mouse strains. The Th2 polarization that determines the extreme susceptibility of BALB/c mice to *L. major* is due, at least in part, to an intrinsically poor Th1-differentiating capacity, as even in the absence of IL-4 or IL-4 receptor signaling, IFNγ responses remain relatively weak.[121,122] An additional strain difference that may influence Th subset development relates to the finding of very rapid dissemination of parasites from the site of inoculation to the draining lymph nodes and spleen in BALB/c mice, whereas early parasite containment is observed in resistant mice.[123] These differences in parasite dissemination raise the possibility that distinct populations of DCs, with the capacity to induce preferential priming for either Th1 or Th2 cells, are present in different tissue environments and become differentially activated in resistant versus susceptible mice. In support of this hypothesis, targeting to selective DC subsets can be achieved by altering the site of antigen delivery; *L. major* parasites delivered intravenously, intranasally, or even to different skin environments can elicit Th2 responses and nonhealing infections in normally resistant mice.[124,125]

Although *L. major* infection in BALB/c mice remains an extraordinary tool for investigating the factors controlling Th2 response selection in vivo, the fact that the model reflects an aberrant response arising, at least in part, from inherent Th1 developmental defects suggests that these defects might not reflect the mechanisms underlying the Th2 polarization that is a hallmark of helminth infections in virtually all mammalian hosts. Furthermore, although Th2 immune deviation is clearly an inappropriate host response to an intracellular pathogen such as *Leishmania*, Th2 responses are an evolutionarily driven, integral aspect of acquired resistance to most parasitic worms or to the containment of the immunopathologic reactions that worms or their products can provoke.

DCs conditioned by exposure to helminth products polarize naïve T cells toward a Th2 phenotype.[126,127] Importantly, Th2 polarization driven by most helminth antigens is MyD88 independent,[128] whereas Th1 differentiation is in most instances MyD88 dependent. Furthermore, activation of DCs by helminth antigens appears to be minimal as judged by the absence of upregulated MHC and costimulatory markers, cytokine production, and transcriptional or proteomic signatures.[129] In the case of DCs exposed to schistosome egg antigens (SEAs) or *Fasciola hepatica* (liver fluke) tegumental antigen, their maturation and IL-12 p70 production in response to TLR ligands become severely impaired, associated with defective MAPK and NF-κB activation.[130,131,132] In human filariasis, live microfilariae of *B. malayi* modulate DC function by altering TLR3 and TLR4 expression and function.[132] The major component of *Schistosoma mansoni* eggs responsible for conditioning DCs for Th2 polarization

is a secreted T2 ribonuclease omega-1 that is hypothesized to act by limiting conjugate formation between DCs and CD4+ T cells.[133,134] N-glycans containing fucose and binding to DC-specific intercellular adhesion molecule 3-grabbing nonintegrin on DCs have also been implicated in the induction of Th2 responses by schistosomes.[135]

Many of these observations would seem consistent with a model of Th2 induction by DCs that, in the absence of a threshold of instructional, positive signals for Th1 priming occurs via a default pathway. However, defaulting to Th2 is not observed when IL-12-deficient mice are infected with either *T. gondii* or *Mycobacterium avium*.[136] Furthermore, in the case of DCs exposed to SEA, there remains a requirement for NF-κB signaling and costimulation (CD40 and OX40L) for the induction of Th2 responses.[137] Therefore, it is more likely that helminth-conditioned DCs, rather than initiating a default pathway in naïve T cells, provide a set of active, instructive signals that result in Th2 priming. The exact nature of these instructive signals is, however, currently unclear.

Surprisingly, IL-4 does not appear to provide an essential instructive signal for Th2 differentiation, as helminth-conditioned DCs will polarize a Th2 response in vitro in the absence of IL-4,[126] and mice deficient in IL-4, IL-4R, or STAT 6 develop diminished but still physiologically significant Th2 responses when infected with *Nippostrongylus brasiliensis* or *S. mansoni*.[138,139] Using T-cell-specific gene ablation of Notch1 and 2 receptors, it was revealed that Notch is required for Th2 responses to *Trichuris muris*[140] and also drives IL-4R/STAT 6 independent Th2 differentiation in vitro in response to SEAs.[141] Although DC expression of the Notch ligand, Jagged-2, has been shown to be required for Th2 differentiation in response to SEA in vitro, it is apparently not required for Th2 polarization induced by SEA-pulsed DCs in vivo.[142]

Although IL-4R/STAT 6 signaling is not essential for priming of IL-4+CD4+ T lymphocytes in many helminth infection models, it is clear that IL-4 plays a critical role in the maturation and stabilization of Th2 cells once their phenotype has been decided. In this context, Th2 cells need not be the only source of IL-4 for maturation of the Th2 response; basophils committed to express IL-4 are recruited to the liver and lungs of mice infected with *N. brasiliensis*,[143] and a direct role for basophils in helminth-induced type 2 immunity was confirmed by the capacity of adoptively transferred IL-4 producing, adult-derived basophils to restore the ability of juvenile mice to expel *N. brasiliensis*.[144] It has been argued that basophils rather than DCs are the critical cells responsible for helminth-induced Th2 polarization (see following discussion), but this hypothesis has been challenged and may be limited in validity to those experimental models where IL-4 appears necessary for Th2 priming.

EFFECTOR MECHANISMS OF HOST RESISTANCE

Once parasites have successfully evaded innate host defenses and their antigens have been processed and presented by APCs, adaptive cellular and humoral immune responses are invariably induced, usually against a wide array of antigenic constituents of each pathogen. The problem is that because of the nature of the host-parasite adaptation, these responses are rarely orchestrated in a manner that will completely eliminate the parasite or restrict its growth. The design of successful immune intervention strategies depends on the identification of relevant target antigens but even more importantly on an understanding of

the type of immune responses and protective mechanisms that must be induced. These effector mechanisms can be broadly classified based on the type of parasite (intracellular or extracellular) against which they are directed.

Intracellular Parasites

Because of their primary habitat within host cells, intracellular parasites are thought to be particularly susceptible to cell-mediated immune effector mechanisms, often involving a mixture or succession of CD4+ and CD8+ T-cell responses. The extent of CD8+T-cell involvement appears to be related to the degree of class II versus class IMHC expression on the host cells infected. CD8+ T cells are especially critical effector cells for the control of *T. cruzi* or *T. gondii* infections, as well as the liver stages of malaria, as these parasites infect nucleated cell types that express only MHC class I molecules. Although slow to develop during the early stages of *T. cruzi* infection, CD8+ T cells with specificity for immunodominant antigens encoded by the trans-sialidase gene family reach enormous numbers in mice (30% of the total CD8+ T-cell population) and following a contraction phase, persist throughout the chronic stage of infection.[145] Unlike some chronic viral infections, *T. cruzi* -specific CD8+ T cells in chronically infected mice do not appear to become exhausted and bear the phenotype of effector memory cells that require persistent antigen to be maintained.[146] In mice chronically infected with *T. gondii*, an effectormemory population of CD8+ T cells is especially critical for long-term resistance to toxoplasmic encephalitis.[147] Even in *Leishmania* infection, where parasites reside almost exclusively in macrophages, CD8+ T cells can be highly protective against both primary infection and reexposure.[148,149] In addition to their contribution of IFNγ to the effector response, CD8+ T cells might also control intracellular parasitic infection through the lysis of host cells. In every protozoan infection analyzed, however, including *T. gondii*,[150] malaria,[151] and *T. cruzi*,[152] mice deficient in the lytic molecules perforin or granzyme B showed no or minimal loss of host resistance. In fact, perforin-mediated lysis of vascular endothelial cells was found to contribute not to protection but to the severity of experimental cerebral malaria in mice.[153] These observations suggest that, as already noted for NK cells (see previous discussion), the protective functions of CD4+ and CD8+ T cells against intracellular parasites are mediated primarily through cytokine production rather than target cell lysis.

IFNγ is the key cytokine involved in control of intracellular protozoan parasites, as demonstrated by the extreme susceptibility of IFNγ-deficient mouse strains to infections with *Leishmania*,[154] *T. cruzi*,[155] *T. gondii*,[156] *Plasmodium*,[157] and even *C. parvum*,[158] which dwells in epithelial cells inside the

gut. Its mechanism of action is perhaps clearest in the case of *Leishmania*, which replicate primarily in macrophages— a cell type readily activated by this cytokine. The major function of IFNγ in restricting parasite growth appears to be the induction of inducible nitrogen oxide synthase (also known as NOS2) and the subsequent generation of toxic reactive nitrogen intermediates (RNI) within infected macrophages. Thus, disruption of the NOS2 gene in a normally resistant strain leads to a susceptible phenotype, and macrophages from the same knockout strain show defective IFNγ-induced control of parasite growth.[159] In addition to IFNγ, optimal production of RNIs is dependent on costimulation with TNF-α or triggering by alternative signals such as IFN-αβ or by CD40L produced or expressed by activated CD4+ T cells.[160] The production of RNI by IFNγ-activated macrophages is inhibited by IL-4, IL-10, IL-13, and TGF-β,[161] and this is likely to be a major mechanism by which the Th2 response prevents healing in *Leishmaniasis*.

Cytokine-mediated control of intracellular *T. gondii* infection involves a more complicated mechanism than induction of RNIs. The immunity induced cannot be attributed solely to activated macrophages as originally thought, as the parasite infects multiple host cell types and host resistance requires IFNγ signaling in cells of both hemapoietic and nonhemapoietic origin.[162] Accordingly, the role of RNIs in resistance has been shown to be limited, functioning predominantly in the chronic stage of infection, although the outcome may vary following oral infection with *T. gondii*. An important clue concerning the mechanism controlling acute infection came from studies in mice deficient for members of the p47 GTPase family, now referred to as IRG genes. The IRG proteins involved are induced by IFNγ in a variety of hemapoietic as well as nonhemapoietic cell types. Mice deficient in either Irgm3 (IGTP) or a second family member, Irgm1 (LRG-47), were found to be highly susceptible to infection with *T. gondii* while developing a normal IFNγ response.[163] Upon IFNγ stimulation of *T. gondii*-infected cells, Irgm3 has been shown to traffic from the endoplasmic reticulum to the parasitophorous vacuole where it participates in a process involving disruption of the vacuole, stripping of the tachyzoite membrane, and autophagic elimination of the parasites in the host cell cytosol.[164,165] Although Igrm1 is similarly required for effective IFNγ-dependent control of *T. gondii*, it is not recruited to the parasitophorous vacuole and is thought instead to serve as a negative regulator protecting immune cells from a variety of cytotoxic functions.[166] In this regard, Irgm1 also plays a major role in IFNγ-dependent host resistance to *T. cruzi* where, in addition to regulating intracellular killing of the parasite, it is required for a normal hematopoietic response to the infection.[143] As noted previously, IRG proteins (eg, Irgm3) are targeted by *T. gondii* virulence factors, and thus, the IRG system may be coevolving in response to pathogen pressure.[98,166] Another IFNγ-dependent mechanism of intracellular parasite killing that limits *T. gondii* replication in human but not mouse nonhemapoietic cells is the induction of indolamine 2,3-dioxygenase, an enzyme that catabolizes tryptophan, an essential amino acid for growth of this protozoan.[167] These examples underscore the complexity of the effector pathways triggered by IFNγ, which act against different parasites in different host cells.

Although resistance to the erythrocytic stages of malaria is largely mediated by antibodies, they likely act in concert with T cells. Thus, even when the primary role of antibody is clear, as with the passive transfer of immune serum, the extent of protection is reduced by prior splenectomy or T-cell depletion. The relevant pathways seem to function through cytokine (eg, IFNγ, TNF-α) activation of macrophages that phagocytose and destroy infected RBCs in the spleen. This process is augmented when infected RBCs are opsonised by Fc receptor (FcR)-binding antibodies, providing an excellent example of cooperation between cellular and humoral arms of the immune response. In support of this concept, resistance to human malaria has been correlated with T-cell production of IFNγ[168] and generation of NO[169] in vitro and with FcR-binding antibody subclasses.[170] Moreover, blood-stage immunity can be established in the absence of antibody, for example, after infection in B-cell-deficient mice, and can be transferred with defined CD4+ T cell lines and clones, indicating that cellmediated effector mechanisms can operate independently of antibodies.[171] Experimental infection studies in humans further support this idea. Ultra-low dose challenge with *P. falciparum*-infected RBCs[172] or sporozoites[173] confer immunity to reinfection; Th1 cell responses are induced, but little or no malaria-specific antibody was detected. However, experimental vaccines designed to induce potent T-cell responses have been associated with high levels of immunopathology. For example, 60% of mice receiving a vaccine designed to induce CD4+ Th1 responses to an immunodominant blood stage antigen of *Plasmodium yoelii* died despite being able to effectively eliminate infected erythrocytes.[174]

Intracellular protozoa live briefly in the extracellular milieu during initial host infection and when they invade new cells during their in vivo multiplication. During this period, they are vulnerable to attack by antibody. In addition, while not directly killing free parasites, antibodies can block their invasion of new cells, thereby suppressing infection. These forms of humoral immunity are of special interest in vaccine development. After repeated infection, humans living in areas endemic for *P. falciparum* gradually develop immunity to asexual blood stages, preventing high-density parasitemia, and thereby preventing clinical disease. The contribution of antibody to this resistance was demonstrated in experiments in which serum from highly immune adults was transferred to acutely infected children, resulting in a temporary but highly significant reduction in parasitemia.[175] The generally accepted explanation for slow acquisition of immunity to malaria is that it is strain specific, and that an individual becomes immune only after being exposed to the strains circulating in his or her

community. Furthermore, humoral immunity to malaria is likely to depend upon an array of antibodies of differing antigen specificities and functions, including agglutination of sporozoites, merozoites, or parasitized RBCs; inhibition of parasitized RBC cytoadherence to small blood vessels; and/or blocking of hepatocyte or red cell invasion by sporozoites or free merozoites.[176] For the latter mechanism, the fine specificity of the

antibody is crucial as some antibody specificities are able to block merozoite invasion into erythrocytes, whereas others, with distinct but overlapping specificities, either have no effect or, in the worst case, impede the activity of invasion inhibitory specificities.[177]

A well-studied example of antibody-mediated protection is the response to the circumsporozoite (CS) protein present on preerythrocytic stages of malaria.[178] Monoclonal antibodies directed against the CS protein prevent invasion and development of sporozoites in cultured hepatocytes and in vivo, in passive transfer studies, confer protective immunity against *P. berghei*, *P. yoelii*, *Plasmodium vivax*, or *Plasmodium knowlesi* sporozoite challenge.[179] With the advent of intravital imaging techniques, it has become apparent that sporozoites are initially inoculated into dermal connective tissues where they may take up to 30 minutes to locate and invade a blood vessel. In immunized animals, or those that have been passively transfused with anti-CS antibodies, sporozoites become immobilized within minutes and fail to invade blood vessels (see Vanderberg and Frevert[180] for excellent video footage of these effects). Although incomplete sporozoite neutralization or inhibition of hepatocyte invasion allows the development of forms that can infect red cells, reducing the number of developing hepatic schizonts can significantly reduce the size of the blood inoculum, delay the onset of patent parasitemia, and may allow the host more time to develop effective anti-blood-stage immunity. Sporozoite antigens can confer significant protection in their own right (as described subsequently, see vaccines) and may also prove to be very valuable components of a multivalent vaccine.

Extracellular Parasites

Extracellular parasites are a highly diverse group of pathogens that include nematoda (round worms) and platyhelminthes (trematode and cestode flat worms) as well as some extracelluar protozoa such as *Giardia* spp. and African trypanosomes. Unlike bacteria, viruses and protozoa that replicate within their hosts and most helminth parasites require an intermediate host or a period outside the mammalian host to replicate and complete their life cycle. Extracellular parasites exhibit variability in size, tissue tropism, and mechanism of immune evasion; helminths, in particular, often live in their definitive host for several years, hiding out in the gut, blood, lymphatics, and a variety of other host tissues. Together, these life history traits likely explain why a distinct set of complementary immune effector mechanisms are required to combat these large, multicellular pathogens. A variety of specialized innate and adaptive immune cells and mediators are triggered during infection including ILCs, T cells, eosinophils, mast cells, basophils, macrophages, and antibodies, and together these effectors mount a multipronged attack. Thus, immunity is achieved through a variety of mechanisms that include antibody-dependent cellular cytotoxicity, mucus secretion, alterations in gut physiology, and exposure to toxic mediators produced by epithelial cells, eosinophils, and alternatively activated macrophages (AAMs). Intestinal microflora have also been shown to influence parasite fecundity[181] and host immunity.[182]

Most extracellular helminth parasites induce highly polarized CD4+ Th2 cell responses (IL-3, IL-4, IL-5, IL-9, IL-10, and IL-13) that promote immunity by triggering mast cell, eosinophil, giant cell, IgG1/IgE/IgA, and mucosal cell responses. Mice deficient in the IL-4 receptor alpha-chain (IL-4Rα), STAT6, or the transcription factor GATA-binding protein 3 (GATA3) display increased susceptibility to a wide variety of helminths, identifying a critical role for the IL-4 and IL-13 signaling cascade in antihelminth immunity.[183,184] In addition to antigen-specific adaptive immune responses, it has become clear that type 2 cytokines secreted by ILCs are also involved in the development of resistance to some helminth parasites.[59,185,186,187,188]

Although the mechanisms that trigger the differentiation and development of Th1 and Th17 type responses are well defined,[189,190] the mediators that drive Th2 development appear to be more complex, although DCs,[191] select parasite antigens,[133,134,192] basophil-derived IL-4,[193,194] and epithelium-derived alarmins such as thymic stromal lymphopoietin (TSLP), IL-25, and IL-33 released during parasite invasion[188,195,196,197,198] are all involved to varying degrees depending on the particular helminth. Whereas basophils were recently reported to be the critical drivers of Th2 responses during helminth infection—by serving both as APCs and by producing IL-4[199,200]—subsequent studies have questioned the ability of basophils to serve as APCs[201] and instead identified DCs as the primary APCs and basophils as the dominant source of IL-4.[144,191,194,202,203,204,205,206] Thus, conventional DCs and basophils are both involved in the development of helminth-induced Th2 immunity.

Many helminths cause significant tissue damage as they migrate through tissues, triggering the release of alarmins by mucosal epithelial cells. One of the first epithelial-derived alarmins shown to play a role in helminth-induced Th2 immunity was epithelial cell-derived TSLP,[197,207,208] with a recent study demonstrating that TSLP can elicit a unique population of basophils that promotes Th2 cytokine-mediated immunity.[209] Nevertheless, other studies have suggested that the contribution of TSLP to Th2 response development may be limited to *T. muris* infection.[196,198] Indeed, several Th2-promoting helminth antigens have been shown to bypass the need for TSLP in the induction of Th2 immunity because they can directly inhibit the production of IL-12 p40 in DCs.[196,210,211] IL-1R4 (T1/ST2) and its ligand IL-33, an alarmin released from the nucleus of necrotic epithelial and endothelial cells and fibroblasts, have also been shown to contribute to Th2 response development,[212] again by suppressing the Th1 arm of immunity.[213] A similar role has also been identified for the IL-17 family cytokine IL-25 (IL-17E).[214,215,216] Studies conducted with IL-25-/- mice showed that by controlling the downstream actions of IL-13,[217] epithelial cell-derived IL-25 is required for the development of immunity to both *T. muris* and *N. brasiliensis*.[215,216] Thus, multiple alarmins released by epithelial cells are involved in the generation of protective IL-4/IL-13 responses during helminth infection, with the relative contribution of each mediator being largely dictated by the pathogen and its site of infection.

When these alarmins are released during parasite invasion, they induce the recruitment of ILCs called nuocytes or

innate helper cells, which are poor producers of IL-4 but secrete large quantities of IL-13, thus quickly activating downstream protective type 2 effector responses.[59,186,187,188] Their rapid production of type 2 cytokines also provides a feedforward mechanism to activate the adaptive immune response, further amplifying type 2 immunity. The combined innate and adaptive type 2 response activates a broad range of downstream antiparasite effector mechanisms. Epithelial cells and goblet cells in the gut express the type II IL-4 receptor,[218] which binds IL-4 and IL-13, triggering goblet cell differentiation and mucus secretion.[219,220,221] Indeed, the mucins Muc2 and Muc5AC were recently shown to be critically required for the development of resistance to several intestinal nematodes.[222,223] Intestinal epithelial cells also secrete resistin-like molecule-β (Relmβ),[224] which regulates both the spontaneous and IL-4-induced expulsion of the luminal dwelling parasites *N. brasiliensis* and *Heligmosomoides bakeri* (formerly called *Heligmosomoides polygyrus*).[225] IL-4 and IL-13 also have effects on intestinal physiology, causing decreased peristalsis, increased mucosal permeability, reduced sodium-linked glucose absorption, and decreased chloride secretion in response to 5-hydroxytryptamine and acetylcholine,[226,227] which facilitates the expulsion of nematodes from the gut. IL-4Rα signaling also stimulates intestinal smooth muscle contractility and epithelial cell proliferation and turnover,[228,229] which operate together with epithelial secretions to promote parasite entrapment in mucus and

ultimately expulsion from the gut via a combined “weep and sweep” mechanism.[230,231] Intestinal permeability and smooth muscle contractility are also regulated by the actions of mast cell-derived proteases and protease-activated receptors that are expressed throughout the small intestine. An overview of antihelminth effector mechanisms is shown in Table 38.3.

TABLE 38.3 Major Antihelminth Effector Mechanisms

Parasite[a]	CD4+Th2 cells	Eosinophils	Mast Cells	Basophils	ILC2[b]	M2 Mø[c]	M1 Mø/NO[d]	Neutrophils	IgE	Mucins goblet cells	Relm β	TSLP	IL-25	T1/ST2[e]-IL-33	IL-4/IL-13	IL-5	IL-9	IL-10	IFN-gamma

CD, cluster of differentiation; IFN, interferon; Ig, immunoglobulin; IL, interleukin; NO, not needed; TSLP, thymic stromal lymphopoietin; YES, required; ?, indicates not investigated.

a Effector mechanisms involved in parasite clearance/expulsion determined from animal studies.

b ILC2: innate lymphoid cells producing Th2 cytokines (IL-13).

c M2 Mø: M2 alternatively activated macrophages.

d M1 Mø: M1 classically activated nitric oxide-producing macrophages.

e T1/ST2: IL-33 receptor.

f Decreases parasite fecundity only.

g No role in immunity in rodents but strong correlative evidence of a role in acquired immunity in humans.

h Only a minor role observed in some animal studies.

Several worms have been studied in detail in this regard: *T. muris*, a natural parasite of the mouse and closely related to human whipworm, *H. bakeri*, *Litomosoides sigmodontis*, *T. spiralis*, *N. brasiliensis* (the rat hookworm), and *Strongyloides stercoralis*. Although Th2 cytokines are clearly involved in resistance to many of the intestinal nematodes, the importance of Th2 immunity is less certain with many of the filarial (*B. malayi*, *Wuchereria bancrofti*, *L. sigmodontis*)[231,232,233] and schistosome species,[234] as discussed in detail in the following text.

T. muris and *H. bakeri* are both transmitted by the oralfecal route independently of an intermediate host; in some strains of mice, they are capable of establishing chronic infections. In the case of *T. muris*, development of immunity is dependent on the genetic background and sex of the definitive host, with resistant animals rejecting the parasite shortly after exposure and susceptible animals developing chronic infections.[235,236] With this parasite, resistant mice develop type 2 responses, whereas susceptible mice mount type 1 responses, with a variety of immunoregulatory cytokines and mediators influencing this decision. For example, in susceptible strains of mice, IFNγ, IL-12, MyD88, and TLR4 deficiencies[235,237] can promote the expansion of type 2 cytokine responses and facilitate the clearance of the parasites.

For *N. brasiliensis*, *H. bakeri*, and *T. muris*, primary immunity in most strains of mice depends on the development of a parasite-specific CD4+T-cell response,[238,239] with recent studies demonstrating that a broad T-cell receptor repertoire is needed for the development of efficient immunity to *N. brasiliensis*.[240] However, exogenous IL-4 or IL-13 can cure

primary *N. brasiliensis*, *T. muris*, and *H. bakeri* infections in T-cell-deficient mice.[241] Recent studies demonstrated that IL-25 and IL-33 induce IL-13-expressing nuocytes that are capable of mediating immunity independently of CD4+T cells, suggesting that the production of IL-13 by these ILC may be sufficient, particularly during primary infections.[59] The rapid immunity that develops during secondary infections, however, is likely facilitated by antigen-specific CD4+T cells. Interestingly, the individual roles of IL-4 and IL-13 in these infections appear to be dependent on the genetic background of the host as C57BL/6 IL-4 knockout mice are susceptible to *T. muris* infection, whereas BALB/c IL-4 knockout mice are resistant.[242,243] These latter studies and other comparative studies conducted in IL-4Rα-, STAT6-, and GATA3-deficient hosts revealed an IL-4-independent role for IL-13 in resistance,[183,184] which was confirmed by treating BALB/c IL-4-deficient mice with a soluble IL-13 inhibitor. IL-13- and IL-13Rα1-deficient mice also develop chronic infections despite generating relatively normal IL-4 responses,[244] further emphasizing the critical role of IL-13 in antinematode immunity.[242]

In contrast to *T. muris* where the requirement for IL-4 depends on the genetic background of the host, development of immunity to *N. brasiliensis* appears to be almost entirely IL-4 independent, as demonstrated in experiments with IL-4-/- and anti-IL-4 monoclonal antibody (mAb)-treated mice.[183] The IL-4-independent mechanism was, however, dependent upon IL-4 receptor and STAT6 signaling, again identifying a critical role for IL-13, which was confirmed in IL-13 blocking studies. IL-13- and IL-4/IL-13-deficient mice are also more susceptible to *N. brasiliensis* than IL-4-/- mice, further emphasizing the dominant role of IL-13.[245] Type 2 immunity was suggested to be controlled predominantly by an innate, IL-13-expressing, noneosinophil type cell of hematopoietic origin,[185] which has subsequently been hypothesized to be one or more of the recently described lineage-negative (CD4-CD127+IL-1RL1+ IL-17RB+RoRgt-) innate lymphoid cell populations: natural helper cells or fat-associated lymphoid clusters, nuocytes, innate natural helper type 2 cells, multipotent progenitor type 2 cells, and/or basophils.[59,186,187,188,203,204] Studies are ongoing to decipher the relative contributions of each of these populations in antinematode immunity.

Unlike infections with *N. brasiliensis* and *T. muris*, most mouse strains are susceptible to primary *H. bakeri* infections, but following drug clearance, the animals develop strong type 2 responses and become highly resistant to secondary infection. The maintenance of immunity during recall infections is crucially dependent on the presence of memory CD4+ Th2 cells at the site of infection,[246] with the lung being an important location for the initial priming of

memory CD4+ T cells.[247] The Th2 response triggers the development of arginase-1-expressing AAMs, which help clear primary *N. brasiliensis* and secondary *H. bakeri* infections.[218,248] The relative importance of AAMs in immunity to other nematode infections, however, remains less clear.[249]

Other cytokines, chemokines, and signaling pathways, including TNF, IL-18, IL-1, IL-10, IL-21, IL-27R (WSX-1), CCL2, Notch, and the NF-κB family have also been identified as important regulators of protective IL-13 responses during intestinal nematode infection. For example, mice treated with neutralizing antibodies to TNF develop relatively normal Th2 responses following infection with *T. muris*, yet they fail to expel their parasites, illustrating a critical downstream role for TNF in the mechanism of IL-13-mediated immunity.[250] IL-1α and IL-1β are also protective, although unlike TNF deficiency, which does not affect the Th2 response, IL-1 deficiency has a profound inhibitory effect on IL-13 production, thus identifying a unique role for IL-1 in the development of Th2-dependent antinematode immunity.[251,252] IL-21 also appears to play a critical role by augmenting Th2 cytokine production and the differentiation of AAMs.[253,254,255] Resistance to *T. muris* is also highly dependent on IL-10, which actively downregulates expression of the antagonistic type 1 cytokines IL-12 and IFN-γ .[220,256] IL-10-deficient mice also display marked morbidity and mortality following *T. muris* infection, identifying an additional role for IL-10 in the suppression of immune-mediated pathology during nematode infection. Interestingly, broad-spectrum antibiotics were found to partially protect *T. muris*-infected IL-10-deficient mice from morbidity and mortality, suggesting that an outgrowth of opportunistic bacteria in the gut exacerbates disease.[220]

Immunity to *T. spiralis* also requires STAT6-[257] and IL-4R signaling but not IL-4,[231] again identifying a dominant role for IL-13-mediated signaling in the development of immunity.[258] The fact that exogenous IL-13 can promote resistance in immunodeficient hosts suggests that a non-bone marrowderived cell in the gastrointestinal tract expressing the IL-4R is required for immunity, which was confirmed in elegant bone marrow chimera experiments.[259] The contribution of IL-13-producing innate effector cells in immunity to *T. spiralis*, however, has not yet been examined. Mast cells, which have been linked with IL-4/IL-13-induced changes in intestinal physiology, also play an important role in immunity to *T. spiralis*, as mice treated with mAbs against stem cell factor (a non-T-cell-derived cytokine) or c-kit (both of which play a central role in mast cell development) are unable to expel the parasites.[260] In these experiments, there was no inhibitory effect on the CD4+ Th2 cell response, and once the mAb treatment was stopped, the parasites were quickly expelled. These studies suggested that the CD4+ Th2 cell response cooperates with stem cell factor to promote mastocytosis, which in turn facilitates parasite expulsion by secreting proteases that degrade tight junctions, leading to increased fluid production in the gut.[261] Several cytokines made by CD4+ T cells, including IL-3, IL-4, IL-9, and IL-10, have been implicated in the development of the protective mast cell response during *T. spiralis* infection.[256,262,263,264,265,266] IL-9 is particularly important as high concentrations of IL-9 can accelerate the clearance of *T. spiralis*[267] and *T. muris*,[268] whereas anti-IL-9 mAb treatment significantly inhibits immunity to *T. muris*.[269] IL-9-producing DCs also generate protective CD4+ Th2 responses,[270] raising the possibility that IL-4 derived from mast cells operates in a feedback loop to enhance Th2 cell differentiation.[268] Mast cell-derived tryptases (eg, mMCP-6) are also be involved in the development of anti-*T. spiralis* immunity.[271]

Eosinophils are frequently associated with helminth infections, and AAMs have been shown to play an important role in eosinophil recruitment to peripheral sites.[272] Surprisingly, however, eosinophils do not appear to play

a significant role in immunity to *T. muris*, *H. bakeri*, *T. spiralis*, or *N. brasiliensis*.[273] Nevertheless, there is evidence from experiments with anti-IL-5 mAb treated, IL-5 transgenic, and IL-5Rα-chain knockout mice that these cells participate in immunity against tissue-invasive larval forms of *Strongyloides* spp. and *Angiostrongylus cantonensis*.[274,275,276,277] One study suggested that eosinophils promote immunity by serving as APCs.[277] There is also a large body of literature, primarily from studies in rats and humans, which suggests that eosinophils play a critical role in protection against (non-gut dwelling) schistosomes,[278,279] although anti-IL-5-treated and eosinophil-deficient mice displayed similar parasite burdens as their wild-type counterparts, possibly suggesting host-specific roles for eosinophils in the development of immunity.[278,280] In contrast to *S. mansoni* infections, immunity against primary *T. spiralis* infection in mice is impaired in IL-5-deficient mice and associated with decreased muscle hypercontractility.[281] However, recent studies conducted with eosinophil-deficient mice suggested that eosinophils promote the survival of muscle stage larvae in chronic *T. spiralis* infection by suppressing IFNγ and NO production.[282] Overall, despite the prevailing dogma, the majority of studies have failed to support a critical function for eosinophils as direct effector cells in immunity to intestinal helminths and instead suggest more of an immunoregulatory role for these cells.[283,284,285] In addition, because tissue eosinophils have been shown to produce IL-4 and IL-13,[280,286] one of their primary functions may be to participate in type 2-cytokine-mediated wound repair,[287,288] which appears to be a critical determinant in the successful establishment of chronic infections by many tissue-destructive helminths.[289]

A similar Th2-inducing mechanism has also been proposed for tissue basophils, which were identified as an important source of IL-4 in schistosome, filarial, and hookworm infections in both mice and humans.[143,290,291] In individuals infected with filarial parasites, the presence of antigen-specific IgE appears to be critical for the secretion of IL-4 by basophils.[291] Transgenic mice with constitutive and selective deletion of basophils are highly susceptible to secondary but not primary *N. brasiliensis* infection,[203] suggesting that the activation of basophils by antigen-specific IgE is critically required for the development of secondary immunity. Thus, CD4+ Th2 cells, ILCs (eg, nuocytes), eosinophils, mast cells, IgE, and basophils all contribute to the generation of protective type 2 responses to varying degrees.

Not withstanding the clear results in mice, the relative importance of the type 2 effector response in the development of immunity in humans remains uncertain. The most straight forward hypothesis, and one predicted for many years, that Th2-induced increases in IgE antibody production is protective against intestinal helminths, has either been refuted following intensive investigation using mouse models, or at least received little direct confirmation.[273,292] Indeed, B cell- and Ig-deficient mice display only modest increases in susceptibility to most helminth infections,[293] although parasite-specific IgG and IgA antibodies have been found to inhibit the fecundity of adult *H. bakeri*.[294] There is, however, a great deal of epidemiologic evidence that type 2 antibody responses, particularly in the form of antigen-specific IgE, mediate the resistance that develops with age in endemic areas. The possibility exists that there are host species differences in this regard because in rats the rapid expulsion of a secondary *T. spiralis* infection is easily transferred to naïve animals with IgE.[295] IgE-/- mice also expel adult *T. spiralis* worms at a much slower pace and develop nearly twice as many muscle larvae as their wild-type counterparts.[296] Although the exact mechanism by which IgE mediates protection is unclear, it is possible that parasitespecific IgE cooperates with eosinophils or macrophages in an antibody-dependent cellular cytotoxicity-type antiworm effector mechanism.[297,298,299] It may also play an important role in the production of IL-4 and IL-13 by mast cells and basophils. IgE-primed basophils secreting IL-4 may also enhance immunity by promoting the differentiation of CD4+ Th2 cells.[143,290,291] Consistent with the potential protective role of IgE, carriage of the human leukocyte antigen-DRB1*13 class II allele is associated with increased posttreatment IgE levels against *S. mansoni* antigens and decreased reinfection levels.[300] Further support for this mechanism comes from field studies in Brazil, where it was discovered that resistance to schistosome infection is controlled by a major gene that localizes to a region of chromosome 5, which

encodes the type 2 cytokines.[301] IgE and eosinophils are also both required for vaccine-mediated immunity against larval *O. volvulus* in mice immunized with irradiateiated larvae. Thus, in the case of secondary helminth infection, IgE, eosinophils, and basophils all collaborate to enhance immunity. Further work is required to elucidate the precise roles of these effector mechanisms in primary versus secondary infections and in different host species, with particular attention being paid to testing of hypotheses derived from model organisms in naturally infected hosts and vice versa.

In contrast to the intestinal parasites, where immunity is clearly dependent on type 2 cytokines, immunity to filarial parasites appears to be dependent on both type 1- and type 2-associated effector mechanisms.[302] In the *Brugia* mouse model of filariasis, B cells are also required for the development of immunity,[303] with IgM antibodies participating in the clearance of both primary and secondary infections and IgE assisting in clearance of primary but not secondary infections.[304] Parasite-specific IgA also plays a protective role in human bancroftan filariasis.[305] Genetic polymorphisms in genes encoding endothelin-1 and TNF-RII have also been correlated with the development of chronic human disease,[306] whereas studies in mouse models have identified important roles for IL-10 and possibly TGF-β1 in the establishment of chronic infections with *B. malayi*.[307] Eosinophils and antibody are required for resistance to primary *Brugia pahangi* infection,[308] suggesting an antibody-dependent cellular cytotoxicity-type effector mechanism is required for parasite clearance. However, studies with *Onchocerca ochengi*, a filarial parasite of cattle related to *O. volvulus*, have suggested that eosinophil degranulation on the parasite cuticle can in some cases actually promote worm viability.[309] Worm viability is also increased by endosymbiotic *Wolbachia* bacteria, which play a critical role in the growth, development, and survival of *B. malayi*.[310] *Wolbachia* also convert potentially deleterious eosinophil responses into neutrophildominated responses, which are incapable of contributing to

antifilarial immunity.[309] In the *L. sigmodontis* model of filariasis, IL-4 blocks nematode development in resistant hosts but not in susceptible strains of mice, further suggesting that Th2- dependent and Th2-independent mechanisms are involved in resistance.[311] Some studies have also identified important synergistic activity between IFNγ and IL-5 in antifilarial immunity, although the role of the Th1-associated cytokine IFNγ remains unclear.[312] Finally, IL-10-expressing CD4 +Foxp3+regulatory T cells have been shown to suppress immunity to *L. sigmodontis*, identifying a critical role for regulatory T cells in the establishment of chronic filarial infections.[313]

As with many of the extracellular parasites, resistance to protozoan trypanosomes requires elements of both cell-mediated and humoral immunity. The African trypanosomes are tsetse-transmitted parasites that inhabit the extracellular compartment of their host's blood and avoid detection by the humoral immune system by switching among antigenically distinct variant surface glycoproteins (VSGs) (see following discussion). Trypanosome-infected hosts typically do not produce antibodies that destroy the parasite, other than those that are VSG specific. Parasitemias manifest as recurring waves, with each wave of parasites expressing a different VSG, and are cleared following development of VSG-specific antibodies. Before an effective antibody response can be generated, however, the host develops quite high parasitemia, severe trypanosomiasis-associated pathology, generalized immunosuppression, and, in some circumstances, debilitating secondary infections.[314] It is clear that overproduction of IL-12, IFNγ, and NO is the primary trigger for these deleterious side effects[315] while also contributing to host resistance,[316] as parasite control within the extravascular tissue compartment requires a parasite antigen-specific Th1 response, associated with IFNγ-dependent activation of macrophages.[317,318] Type I IFNs have also been shown to play a role in early resistance to African trypansomes, although they may contribute to downregulation of IFNγ production and subsequent loss of host resistance later in infection.[319] In humans, resistance to most African trypanosomes, including *T. b. brucei*, is mediated by the TLFs, as previously discussed.[320] Interestingly, the higher rates of kidney disease in infected Africans compared to Americans of European descent appears to be linked to the expression of disease-associated variants of the apolipoprotein L (Apo L) components in TLF that are able to lyse *T. b. rhodesiense* in vitro.[321]

Another important extracellular protozoan, *Giardia*, is a flagellated intestinal parasite that causes both acute and chronic diarrheal disease. Despite its intestinal habitat, *Giardia* appears to be controlled by mechanisms distinct from those mediating resistance to most gastrointestinal nematodes, although recent studies suggest that mast cellderived IL-6 maybe important for the rapid elimination of *Giardia* in mice.[322,323] While a T-cell-dependent mechanism involving TNF-α is essential for resistance to acute infections,[324] numerous studies have suggested that antibodies, particularly the IgA isotype, are required to control chronic *Giardia lamblia* infections.[325] Moreover, it has been proposed that neuronal NOS (NOS1) might facilitate clearance of *Giardia* from the gut by increasing gastrointestinal motility and parasite-induced diarrhea.[326]

These examples clearly demonstrate that although intracellular and extracellular parasites often stimulate distinct immune responses, their immune control may involve overlapping immunologic effector arms.

MECHANISMS OF IMMUNE EVASION

Pathogens that rely on an insect vector to complete their life cycle, or are only sporadically transmitted from one host to another, are under strong evolutionary pressure to prolong their survival within their host. As the adaptive immune response is the principal barrier to the persistence of pathogens in mammalian hosts, parasites have evolved diverse strategies to evade immune control, either by evading immune recognition or by suppressing immune effector mechanisms. The former strategy refers to the ability of some parasites to sequester within sites that are inaccessible to immune attack, to mask themselves with host antigens, to shed their own target antigens, or most notably, to undergo antigenic variation. The latter strategy refers to the active suppression of established, ongoing immune responses that may contribute to the state of equilibrium that is established between host and parasite in sites of chronic infection.

Evasion of Immune Recognition

The asexual, blood stage of malaria would seem the most obvious example of a well-hidden parasite. Its ability to invade mature erythrocytes, which lack both class I and II histocompatibility molecules, in theory at least should protect it from recognition by antibodies or effector T cells. However, because parasitized erythrocytes are efficiently cleared by the spleen, additional immune evasion strategies (ie, antigenic variation) are required (described subsequently). Other intracellular protozoa appear to hide within immunologically privileged sites. The persistence of *T. cruzi* within heart or skeletal muscle, which is believed to underlie the pathogenesis of Chagas disease, occurs despite the fact that parasites are cleared from most other tissue.[327] Infected muscle cells may be only poorly recognized as targets for cytotoxic T lymphocytes, poorly accessible to their homing, or they may have intrinsic defects in immune-mediated killing mechanisms. A similar form of sequestration has been proposed to explain the long-term persistence of *Leishmania* within fibroblasts and dendritic cells following their efficient killing by activated macrophages during the acute stage of infection.[328] While persistent low-level infection of host cells has been proposed as an explanation for latency in *T. gondii* infection, the major parasite reservoir during chronic infection is undoubtedly provided by the tissue cyst, essentially a modified host cell carrying a specialized dormant parasite stage, the bradyzoite. Helminths (with the exception of *Trichinella*, which develop long-lived muscle stage larvae) do not invade host cells and, therefore, cannot use this strategy for evading immune recognition. Furthermore, because most multicellular helminth parasites do not replicate within their mammalian hosts, they are not equipped to evade immune recognition by undergoing antigenic variation. Instead, they employ alternative mechanisms

such as disguising their surfaces with host molecules and rapidly shedding membrane (tegument)-bound immune complexes.[329] In addition, helminths have evolved a series of elaborate processes for inactivating antibody, complement, and cellular effector elements that threaten the parasite surface.[330] Interestingly, recent data suggest that helminths may take advantage of host T lymphocyte and cytokine signals as developmental triggers; if these signals are in low abundance or lacking in vivo, parasite growth may be aborted or severely attenuated.[331,332,333] In the case of schistosomes, development of female parasites is not directly influenced by the adaptive immune system, whereas male development is.[334] In this sequential model, adaptive immune signals trigger development of mature males, which subsequently stimulate development of mature females.

Although the need for antigenic variation might be obvious for extracellular protozoa such as trypanosomes and *Giardia*, it is less obvious why malaria parasites—hiding inside RBCs—should have evolved a similar strategy of immune evasion.[335] The most plausible explanation is as follows. Developing schizonts cause erythrocyte distortion, loss of flexibility, and abnormal surface exposure of various membrane components, all of which make infected erythrocytes vulnerable to clearance from the circulation during passage through the spleen in a manner very similar to that by which normally aged red cells are removed and destroyed. In order to avoid passage through the spleen, the parasite exports to the red cell surface a number of molecular anchors—of which the best characterized is *P. falciparum* erythrocyte membrane protein-1 (PfEMP-1)—that bind to endothelial receptors, allowing the parasite to sequester in peripheral tissues. Parasite sequestration contributes to malaria pathology, clogging blood vessels and triggering focal inflammation, giving rise to cerebral, respiratory, and renal symptoms; sequestration in the placenta gives rise to pregnancy-associated malaria. Because these molecular anchors are parasite-derived, they are recognized by the immune system; antibodies bind to them, prevent endothelial sequestration (and ameliorate disease), and allow parasitized RBCs to be cleared in the spleen.[336] Thus, in order for the parasite to establish a chronic infection, a system of clonal antigenic variation is required. The importance of these molecular anchors as a parasite survival strategy is demonstrated by the fact that there are upward of 50 copies of the gene for PfEMP-1 (*var* genes) per parasite, more than 200 copies of other clonally variant surface protein genes,[337] and innumerable allelic variants of each gene in the global parasite population.

Evasion by Immune Suppression

Generalized immunodepression, which is a feature of many chronic parasitic infections, including malaria, African trypanosomiasis, and visceral leishmaniasis, appears in most instances to be secondary to other immune evasion strategies and results from the need to control inflammation (see the next section) or from a variety of immune dysfunctions that high-systemic parasite burdens can produce. These dysfunctions include disruption of normal lymphoid architecture, such as occurs in the mouse spleen during acute malaria infection[338] and during chronic infection with *L. donovani*.[339] In the case of *T. cruzi*, which can express and secrete multiple members of the highly polymorphic surface sialidase superfamily at one time, epitope-specific T-cell responses are suppressed either by altered peptide ligand inhibition or because immune recognition is impeded by a flood of competing targets.[340] Similarly, lymphocyte polyclonal activation, which can result in depression of antigen-specific responses, is a feature of many parasitic protozoan infections, including blood and tissue trypanosomes, *L. donovani*, *T. gondii*, and rodent malarias, but again, a causal link between polyclonal activation and immune evasion has not been established. The original hypothesis—that these organisms possess mitogenic or superantigenic moieties[341]— has been substantiated only in the case of *T. cruzi* from which the B-cell mitogen has been cloned and characterized as a eukaryotic proline racemase.[342]

Regulatory T Cells and Parasite Persistence

The modulation of ongoing immune responses in sites of chronic infection, such as the gut or the skin, may in many instances reflect not only parasite survival strategies but also normal mechanisms of immune homeostasis that operate to control immunopathology. Accumulating evidence has implicated a crucial role for regulatory T cells in the dynamic equilibrium that is established between parasites and their hosts. Regulatory T cell is the name given generally to the subsets of CD4+ T cells, and more recently CD8+ T cells, which negatively regulate multiple immune functions. Among the different subsets of CD4+ regulatory T cells that have been described, the best characterized are the so-called naturally occurring CD4+CD25+Foxp3+ T cells (nT_{reg}) that are present in naive animals. T cells with suppressive function can also be generated from conventional naïve cells, and include induced regulatory T cells (iT_{reg}), which are converted from activated CD4+ CD25-Foxp3- T cells to CD25+Foxp3+ suppressor cells following encounter with antigen and TGF-β in the periphery, and adaptive regulatory T or Tr1 cells, also generated from antigen activated cells in the periphery but which remain Foxp3- and secrete high levels of IL-10. There is data linking one or more of these populations to the suppression of immune responses to all of the major classes of pathogenic protozoa and helminths.

The evidence that nT_{reg}s contribute to pathogen persistence was initially demonstrated in the *L. major* mouse model, in which CD4+CD25+ T cells accumulated in the dermal lesion and promoted subclinical persistence of amastigotes following clinical cure in resistant mice.[343] Similarly, in a model of mouse malaria characterized by extremely rapid parasite growth (*P. yoelii* YM or 17XL), very early induction of TGF-β and IL-10 appears to inhibit the development of responses that are required for parasite clearance. Neutralization of IL-10 and TGF-β[344]—or, in some studies, depletion of nT_{reg}[345]—at the onset of infection allows parasite replication to be contained and mice are able to resolve their infections and survive. A similar scenario has been observed in experimental human infections within the context of malaria vaccine trials.[346] More recently, however, it has

begun to be appreciated that classical Foxp3+ regulatory T cells and adaptive IL-10-producing T cells have rather different roles in malaria-infected hosts. Thus, the major role of Foxp3+ regulatory T cells seems to be in maintaining immune homeostasis during asymptomatic infection, whereas IL-10-secreting cells are required to restore immune homeostasis after acute clinical infection.[347,348]

The role of IL-10-producing T cells in controlling immunopathology and parasite persistence is especially striking in the case of *T. gondii* and *Leishmania*. IL-10 production by CD4+CD25-Foxp3- T cells that also produced IFNγ was required for the control of Th1-driven immune pathology associated with *T. gondii* infection in mice[349] (discussed in more detail in the following section). A similar phenotype of IL-10-producing Th1 cells was associated with the inability to heal infection with a substrain of *L. major* that induces a polarized Th1 response in C57Bl/6 mice.[350] The clinical data has consistently supported an association of human visceral leishmaniasis with elevated levels of IL-10, which in the visceral leishmaniasis spleen was found to be expressed primarily by CD25-Foxp3-T cells.[351] It is important to emphasize that even in patients with active visceral leishmaniasis in whom systemic infections go uncontrolled, their elevated levels of IL-10 are accompanied by augmented production of IFNγ, which in the visceral leishmaniasis spleen is also expressed primarily by CD25-Foxp3-T cells. Together, these data suggest that in sites of strong inflammation, IL-10-producing Th1 cells may be activated as a powerful mechanism of feedback control to prevent collateral tissue damage. The regulation of IL-10 expression in these inflammatory settings has recently been described. IL-27, an IL-12 family member, was shown to upregulate IL-10 expression by Th1 cells in *T. gondii*-infected mice in a STAT1- and STAT3-dependent manner.[352] Accordingly, *IL-27ra*-/- mice developed lethal inflammation that was associated with defective IL-10 production by Th1 cells isolated from the brains of infected mice. *IL-27ra*-/- mice efficiently control *P. berghei* NK65 infections but have reduced capacity to produce IL-10 and develop severe, frequently fatal, Th-1-mediated liver pathology.[353] *IL-27ra*-/- mice infected with *L. major* also developed more severe pathology, which in the case of nonhealing *L. major* infections is associated with fewer numbers of T cells coexpressing IL-10 and IFNγ, and an increased frequency of Th17 cells.[354] The *L.*

major mouse model has also revealed a potential role for suppression mediated by IL-10 and TGF-β produced by macrophages following uptake of Ig-opsonized parasites.[355,356] Thus, redundant mechanisms of homeostatic control, including innate cells, natural and adaptive regulatory T cells, appear to be activated to control persistent immune pathology associated with antimicrobial immune responses in tissues that are especially susceptible to injury (eg, the liver, brain, skin, and mucosa).

IMMUNOPATHOLOGIC MECHANISMS AND THEIR REGULATION

If the appropriate protective response fails to develop or if the host is not able to achieve sterile immunity, then inflammation and other pathologic changes may be unavoidable consequences of persistent infection. This is the situation for many parasitic diseases. This does not mean that all infections with the same parasite species lead to the same immune pathology. One of the most striking features of human parasitic disease is the great variability in clinical outcome, ranging from asymptomatic infection to fatal disease. Esophageal disease due to *T. cruzi*, liver fibrosis, portal hypertension, and hepatosplenomegaly due to *S. mansoni*, and cerebral malaria due to *P. falciparum* are a few examples of the many immunopathologic complications that may occur in some individuals but not others. Part of this variability is determined by host genetics, whereas other potential determinants include parasite virulence factors, infection intensity, and the prior level of immunity. The picture is further complicated in individuals that are coinfected with other pathogens: For example, the severity of *P. falciparum* malaria is increased by concomitant bacteremia but reduced by concomitant *P. vivax* infection.[357] Antiretroviral drugs also impair CD36-mediated cytoadherence and nonopsonic phagocytosis of parasitized erythrocytes by human macrophages, which may lead to severe malaria disease outcomes in antiretroviral treated coinfected individuals.[358] The pathology associated with chronic *S. mansoni* infections reduces the CD4+ T cell-count, which can exacerbate the effects of HIV-1 infection.[359] *S. mansoni* infection also increases susceptibility to HIV infection, transmission, and replication in nonhuman primates,[360] and similar observations have been made in malaria-infected patients.[361] Concomitant exposure to malaria can affect the regression of hepatosplenomegaly in drug-cured *S. mansoni* patients.[362] Coinfections of *T. gondii* and *S. mansoni* in mice are also more lethal,[363] whereas preexisting infections with *N. brasiliensis* have been shown to inhibit innate pulmonary antituberculosis defense by activating the IL-4 receptor pathway in murine macrophages.[364] Finally, although endosymbiotic *Wolbachia* bacteria are believed to increase the fitness of filarial parasties, *Wolbachia* LPS is believed to be the principle driver of river blindness in chronic filariasis.[365]

It is difficult to do justice to the remarkably broad range of immunologic mechanisms that contribute to the pathology of parasitic disease. Twenty-five years ago, much of the research in this field concerned the role of immune complexes, complement, and anaphylaxis. These areas remain important, but the focus has shifted to the molecular basis of cellular processes such as inflammation, granuloma formation, wound repair, and immune regulation. An important issue that is the focus of intensive research is how the host maintains the fine balance between a protective immune response and one that causes pathologic complications. It is becoming increasingly clear that achieving balance in the immune response is the most critical determinant in the establishment of a long-term host-parasite relationship and, therefore, should be of considerable interest to vaccinologists. Interestingly, in many chronic parasitic infections, this balance appears to be regulated by the coordinated actions of several distinct immunoregulatory mediators, including regulatory T cells, IL-10-expressing regulatory B cells, and AAM, to name just a few.

Achieving Balance between the Anti-infective Immune Response and Host Pathology

Whereas Th1 responses are required to control intracellular-infections, there is a need to balance these potentially tissue-destructive responses. The harmful effector molecules induced by Th1 responses include NO, reactive oxygen intermediates, and TNF, which operate in a synergistic fashion to promote antimicrobial immunity but are often associated with undesired inflammatory and toxic side effects. Proinflammatory Th17 responses have also been shown to contribute to the acute pathology seen in some schistosomeinfected mice.[366,367] IL-10, TGF-β, arginase-1, and IL-4, produced by distinct subsets of regulatory cells including myeloid-derived suppressor cells, AAMs, regulatory T cells, IL-4/IL-13-producing Th2 cells, IL-10-producing regulatory T cells (Tr1), FoxP3-expressing conventional Th1, and IL-10+IFNγ+Foxp3- CD4+ T cells, may all help prevent Th1 and Th17 immune responses from overshooting and becoming pathologic during infection with intracellular pathogens.[349,368,369,370,371] There are also several examples in which persistent helminth-induced Th2 responses appear to be detrimental to the host. Strong antibody responses can lead to the formation of antigen-antibody complexes or complement activation resulting in bystander lysis.[372] Eosinophils, typically associated with the Th2 response, are involved in hypersensitivity reactions to the filarial worm *O. volvulus* and promote Th2 pathology in schistosomiasis.[280] Th2 cytokines are also important drivers of hepatic fibrosis and morbidity in chronic schistosome infections.[373] Similar to chronic Th1 and Th17 responses, a variety of regulatory mediators including IFNγ, IL-12, IL-10, the IL-13 decoy receptor, regulatory T cells, regulatory B cells, and silencers of cytokine signaling proteins have all been shown to contribute to the suppression of pathogenic Th2 responses.[374,375,376] In summary, the successful resolution of infection typically requires precise titration of the specific T helper cell response induced by the pathogen. This is not just in terms of amount but also where, when, and for how long the polarized Th1, Th2, or Th17 response persists.

Pathogenesis of Chronic Th1 Responses

As discussed previously, control of intracellular pathogens such as *Leishmania* spp., *T. gondii*, and *T. cruzi* requires the coordinated activation of both antigen-specific cells (T lymphocytes) and less specific responses (NK cells, neutrophils, and macrophages) with IFNγ and TNF playing critical roles by upregulating macrophage activation and nitric oxide production. Interestingly, IL-10-deficient mice inoculated with a normally avirulent *T. gondii* strain or with a virulent strain of *T. cruzi* succumb to infection within the first 2 weeks of infection.[377,378] In both of these infections, animals lacking IL-10 show increased suppression of parasite growth and, in the case of *T. cruzi*, inflammation and necrosis within the endocardium and interstitium of the myocardium is reduced. The increase in mortality is caused by systemically high levels of IL-12, IFNγ, and TNF produced in large part by activated CD4+ T lymphocytes and macrophages. The livers of both *T. gondii*- and *T. cruzi* -infected mice show numerous and prominent necrotic foci together with dramatically increased mononuclear cell infiltration. Similarly, macrophages from the mutant mice activated in vitro or in vivo with *T. gondii* secrete higher levels of TNF, IL-12, and inducible NO than macrophages from IL-10-sufficient animals. The combined clinical manifestations suggest that the IL-10-/- mice die in response to an overwhelming systemic immune response, resembling that observed during septic shock. In support of this conclusion, administration of anti-CD4, anti-IL-12, or anti-TNF mAbs reduces mortality in IL-10-/- mice.[377,378] Thus, in these models, IL-10 plays a major role in protecting the host against an excessive and lethal type 1 cytokine response.

Much has been written about the protective versus pathologic consequences of proinflammatory cytokine production in malaria (Fig. 38.3[379]). During the preerythrocytic stage in the liver, when parasite burden is relatively low and the infection is clinically asymptomatic, there is evidence that IFNγ and NO each play an important role in preventing the infection from progressing further.[380] Once the parasites invade erythrocytes and grow to large numbers, the riskbenefit equation is less clear. At this stage, the inflammatory cytokine response is systemic, and some pathologic side effects are inevitable. The most common clinical consequence in humans is fever, whereas life-threatening complications such as profound anemia and cerebral malaria occur in a proportion of infections. Depending on the specific host-parasite combination, mice may develop anemia, fatal neurologic

symptoms, or multiorgan failure; IL-1, IL-6, TNF, and, more recently, lymphotoxin-α have been the cytokines most consistently associated with severe pathology in these models.[381,382]

Conversely, experimental studies suggest that IL-10 and TGF-β cooperate to downregulate potentially pathogenic proinflammatory cytokine responses in malaria.[348] IL-10-deficient mice have increased mortality compared with normal littermates; this results not from fulminant parasitemia but from a sustained and enhanced proinflammatory cytokine response[383] and severe liver necrosis. Immunopathology in IL-10-/- mice can be prevented simply by adoptive transfer of wild-type (ie, IL-10 competent) CD4+ T cells, indicating that they are a sufficient source of IL-10 to prevent severe disease in the latter stages of acute infection.[383] Similarly, treatment of infected mice with a neutralizing antibody to TGF-β exacerbates the virulence of *P. berghei* and *Plasmodium chabaudi* infection; it was concluded that the protective effects of this cytokine are also due to downregulation of inflammatory responses.[384] However, as described previously, very early induction of TGF-β and IL-10 can inhibit the effector response that is required for parasite clearance[344,345]; thus, the outcome of malaria infections is determined, in part at least, by the sequence and timing of proinflammatory and anti-inflammatory (immune regulatory) responses. This is likely to depend upon sequential activation of innate immune cells, such as NK cells and γδ T cells, then Th-1 CD4+ T cells, and finally IL-10-secreting T cells. Preliminary evidence suggesting that CD4+ T cells that secrete both IFNγ and IL-10 may be a signature of

protection against severe malaria in African children clearly needs to be explored further.[385]

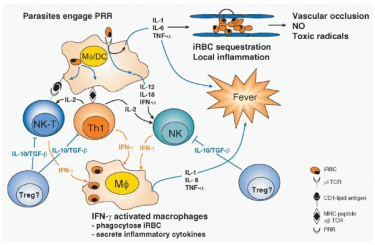

FIG. 38.3. Immunopathogenesis of Malaria. Parasitized red blood cells (pRBC) and parasite products bind to pattern recognition receptors (PRRs; eg, toll-like receptor [TLR]2 and TLR9) on monocytes and dendritic cells, and induce a cascade of proinflammatory cytokines (most importantly interleukin [IL]-12, interferon-γ, and tumor necrosis factor [TNF]-α). These inflammatory signals initiate numerous pathologic processes. They cause upregulation of endothelial adhesion molecule expression on vascular endothelium, promoting vascular sequestration of pRBCs, which clogs the vessels, reduces blood flow, and simultaneously raises intracranial pressure. The pRBC products also bind to PRRs in tissue, initiating local inflammatory loops, which amplify pRBC sequestration. Vascular occlusion and subsequent tissue damage contribute to cerebral malaria, respiratory distress, and multiorgan failure. Other cytokines such as IL-1, TNF-α, and IL-6 induce the fever response, which includes elevated temperature, nausea, headache, prostration, and muscle pain. The actions of inflammatory cytokines are antagonized by anti-inflammatory cytokines, principally IL-10 and transforming growth factor-β, which inhibit both production of, and cellular responses to, inflammatory signals.

Pathogenesis of Chronic Th2 Responses

During nematode infection, the protective Th2 response can cause significant pathologic changes in the intestine including inflammation, epithelial cell damage, excess mucus production, and diarrhea. However, these effects are often transient and resolve quickly once the parasite is expelled from the gut. If the parasites are not expelled, the immune response typically shifts to a more Th1/Th17-polarized reaction,[386] which can lead to an even more severe inflammation with characteristics similar to Crohn disease.[387] Thus, there are only a few chronic helminth infections where persistent Th2 reactions are established. Perhaps the most widely studied experimental model in this regard is the mouse model of schistosomiasis. Upon infection, adult parasites of *S. mansoni* migrate to the mesenteric veins where they live up to 10 years or more, laying hundreds of eggs per day. Some of the eggs become entrapped in the microvasculature of the liver and once there, they induce a granulomatous response.[388] Subsequently, hepatic fibrosis, portal hypertension, hepatosplenomegaly, and bleeding from esophageal and gastric varices may develop, which in some cases may ultimately lead to the death of the individual. Consequently, much of the symptomatology of schistosomiasis is attributed to the egg-induced inflammatory response and associated fibrotic pathology.[389,390]

Granulomas are pathogenic, not because they cause hepatic failure in the short-term, but rather because they induce hepatosplenomegaly and contribute to liver scarring.[390,391] CD4+ Th2 cells are essential for granuloma formation, whereas many other lymphocytes appear less critical including B cells, CD8 cells, NK T cells, and γδ T cells. B cell-deficient (μMT) mice, however, fail to downmodulate granuloma formation in the latter stages of the disease, suggesting that B cells and/or antibody might play an important immunoregulatory role in chronic infections.[392] In support of regulatory role for B cells and antibody, perinatal exposure to specific anti-SEA idiotypes has been shown to regulate survival, pathology, and immune response patterns in mice

subsequently infected with *S. mansoni*.[393] Cross-reactive regulatory idiotypes can also been used to predict clinical outcomes in chronically infected mice.[394]

Th2 cells also play an important role in the pathogenesis of schistosomiasis.[283] Indeed, a critical role for Th2 cells was confirmed in experiments in which mice vaccinated with egg antigen plus IL-12 to induce an egg-specific Th1 response upon subsequent infection developed smaller granulomas and less severe fibrosis than did nonvaccinated infected controls.[395] The decreased pathology was associated with a diminished Th2 and increased Th1 response. IL-4-/-, IL-4Rα-/-, and IL-13Rα1-/- mice as well as anti-IL-4 mAb-treated wild type (WT) mice were also shown to develop smaller granulomas and less fibrosis than similarly infected WT mice, further emphasizing the critical role of Th2 immunity in the pathogenesis of chronic schistosomiasis.[138,244,396,397]

Although the Th2-driven granulomatous response is widely believed to be detrimental in chronic infections, it is clear that IL-4-driven granuloma formation also serves an important host-protective role, particularly during acute infections with *S. mansoni*. During infection, the schistosome eggs that are produced in large quantities by adult parasites provide a continuous antigenic stimulus for the immune response. If these antigens are not sequestered or neutralized effectively, toxic components produced by the eggs are known to damage hepatocytes and reduce barrier immunity in the intestine.[396,398] Indeed, T cell-deprived, nude, severe combined immunodeficiency defect, and egg-tolerized mice infected with *S. mansoni* all die earlier than comparably infected immunologically intact mice because they are incapable of mounting a protective CD4+ Th2 cell-driven granulomatous response.[399] Widespread microvesicular hepatic and intestinal damage induced by toxic egg products contributes to the poorer survival of the infected immunosuppressed mice. IL-4R signaling is also required for the efficient passage of eggs through the intestine into the lumen.[398] Consequently, increased numbers of eggs are trapped in the intestinal wall when IL-4 is deficient, causing localized inflammation and increased systemic exposure to bacterial

toxins such as LPS. This response combined with the decreased Th2- and enhanced Th1-type response results in increased proinflammatory cytokine production that contributes to weight loss in and death of IL-4-deficient animals.[388] Therefore, although Th2-driven granuloma formation and fibrosis are detrimental in the long-term, they are also critically important in the short-term because they allow the establishment of a successful host-parasite relationship.[400]

Many of the pathologic complications associated with chronic helminth infections (portal hypertension, bleeding collateral vessels, anemia, mucosal barrier dysfunction, lymphatic blockage, etc.) do, however, result from the persistent expression of type 2 cytokines.[283] Whereas IL-4 was identified as the principle inducer of the protective Th2 response during acute schistosome infection,[396] IL-13 has been identified as the key driver of hepatic fibrosis and the fibrosis-associated complications observed in chronically infected mice.[374,398,401] In mice, the progression of hepatic fibrosis correlates with the intensity of the type 2 cytokine response,[402] and immunologic interventions that impair IL-13 activity have been shown to reduce collagen deposition and improve survival during chronic infection[374,398,401] as long as IL-4 production is preserved. Mediators produced during polarized type 1 cytokine responses have been shown to inhibit IL-13-dependent fibrosis, including TNF-α, IL-12, and NO.[403,404] Because macrophages and DCs are important sources of these mediators and have been shown to be important drivers of Th2 immunity in vivo, a major effort has been undertaken to elucidate the roles of distinct myeloid cell populations in the pathogenesis of schistosomiasis and other helminth infections.[191,400]

Numerous studies have shown that IL-4/IL-13-induced macrophages are found in many helminth infections. Gordon[405] first noted that macrophages treated with IL-4 and IL-13 develop an alternative activation state that is distinct from "classically activated macrophages" exposed to IFNγ. In vitro, the AAM or M2 phenotype[405] is characterized by elevated MHC class II, mannose receptor (CD206), YM1, Fizz1/Relm-α, and arginase (Arg) activity.[406,407,408,409] Studies of murine schistosomiasis have found that 20% to 30% of the cells in granulomas are AAMs,[410] and studies conducted with IL-4Rα conditional knockout mice have suggested that AAMs actively suppress the development of IL-12/IL-23p40-driven intestinal pathology during acute infection with *S. mansoni*.[371,411] Related studies conducted in conditional Arg1-deficient mice have also identified an important role for Arg1-expressing macrophages in the suppression of hepatic fibrosis during chronic *S. mansoni* infection.[407] These findings were supported in studies with mice deficient in cationic amino transporter-2, which imports L-arginine for use in NO production in macrophages. Cationic amino transporter-2-/- mice develop exacerbated liver fibrosis following schistosome infection associated with decreased NO production and increased Arg1 activity in AAMs and fibroblasts.[412] Together, these studies support the hypothesis that the phenotype of the macrophage plays a critical role in the pathogenesis of schistosomiasis. Similar studies are now underway to dissect the role of AAMs in other helminth infections.

PARASITE VACCINE STRATEGIES

Aside from the recent encouraging results involving the RTS,S malaria vaccine (discussed subsequently), there is still no safe, uniformly effective vaccine against any human parasitic infection. The lack of progress in this field is due to many factors, including the low priority that has historically been given to development of vaccines against diseases confined mainly to the developing world. By contrast, the perceived economic benefit to the agricultural industry of vaccines against livestock parasites has led to the licensing of several antihelminthic vaccines for veterinary use.[413] The greater impediments, however, may be related to the nature of parasitic infections themselves. In contrast to those bacterial and viral infections for which highly effective vaccines exist, and for which there is complete immunity induced by primary infection, most antiparasite vaccines will need to outperform the immune response to natural infection. Further, virtually all bacterial and viral vaccines that are currently in use mediate their protection by inducing a strong, long-lived,

humoral response that inhibits attachment or invasion, promotes clearance, or neutralizes released toxins. By contrast, there are no vaccines that are uniformly effective against diseases caused by intracellular pathogens that require cellular immunity to mediate protection. Thus, the manner in which potentially protective antigens can be administered to generate and maintain appropriate T-cell responses has yet to be proven in a clinical setting. Consequently, for the development of vaccines against intracellular protozoa (eg, malaria, *Leishmania*, *T. cruzi*, *Toxoplasma*), it will not be sufficient to simply identify target antigens; novel and rational approaches to vaccine design and delivery will need to be explored. In fact, from the examples discussed in the following, it is clear that ample numbers of potentially protective antigens have been identified and cloned from most of the major human parasitic disease agents, and the completion of their genomic sequences has already led to the identification of additional vaccine candidates based on their predicted developmental stage specificity, surface expression, secretion, or virulence associations.[414,415] The vaccination strategies that are currently being explored to meet the challenge of both antigen selection and delivery will be considered in the general context of B- and T-cell antiparasite vaccines. Note that the examples provided are by no means exhaustive but reflect general principles of vaccination against extracellular and intracellular targets.

B-Cell Vaccines

Vaccination Against Intestinal Protozoa

Parasitic protozoa that have an exclusive extracellular lifestyle in their mammalian hosts and are sensitive to antibody-mediated control include the intestinal pathogens *E. histolytica* and *G. lamblia*. Most deaths from *E. histolytica* arise from amebic liver abscess, the major extraintestinal manifestation of disease. Clinical studies suggest that the presence of mucosal antibodies to the surface Gal/GalNAc lectin of *E. histolytica* capable of blocking amebic adherence to intestinal epithelial cells, correlate with reduced risk of recolonization.[416] Furthermore, active immunization with the Gal/GalNAc lectin can induce IgA antilectin antibodies and provide protection against intestinal amebiasis in a mouse model of disease.[417] An amebic serine-rich protein (SREHP) and an alkyl hydroperoxide reductase (Eh29) are also highly immunogenic surface antigens of *E. histolytica* that can protect against amebic liver abscess in animal models via induction of intestinal IgA antibodies and together with the Gal/GalNAc lectin, represent the most promising candidates for oral vaccines against amoebiasis.[418] Specific serum and mucosal antibodies targeting surface antigens are also known to be important in elimination of *Giardia* from the host intestine. *Giardia* vaccines containing whole trophozoite preparations protected animals even when challenged with heterologous strains,[419] suggesting that an immune response to variant surface proteins, which are known to be targets of cytotoxic antibodies, are not essential for control of acute infection. However, by interfering with the mechanism controlling variant surface protein switching in *Giardia*, it was more recently shown that primary infection with trophozoites expressing many variant surface proteins was necessary to protect gerbils from subsequent infection.[420] More importantly, such genetically manipulated parasites might be used as cross-protective vaccine. Genes coding for *Giardia* cyst wall proteins, which could be used for developing a transmission-blocking vaccine, have been cloned, and a recombinant protein induced IgA antibodies such that immunized mice shed fewer cysts following challenge with live cysts.[421]

Vaccines Targeting Extracellular Stages of Malaria

Because both preerythrocytic- and erythrocytic-stage malaria parasites are at least transiently exposed to humoral antibody, vaccine strategies based on eliciting high-titered antibodies that can inhibit their invasion of RBCs or hepatocytes have long been favored (Fig. 38.4). As discussed previously, antibodies to sporozoite surface proteins can immobilize invading parasites, preventing them from reaching or invading hepatocytes; such antibodies can be protective, and the dominant antibody epitope is represented by the CS central repeat

sequences (NANP *n* in *P. falciparum*). These observations have made the CS protein the most extensively studied of all the malaria vaccine candidates.[422] The latest version of the vaccine—RTS,S—comprises a recombinant CS polypeptide fused to the surface protein of hepatitis B virus and administered together with an adjuvant containing LPS (monophosphoryl lipid A) and a water-soluble glycoside obtained from tree bark (*Quillaja saponaria*).[423] The vaccine has been designed to induce both antibodies and T cell-mediated effector mechanisms, and it is not clear which of these mechanisms is most important in conferring immunity. This vaccine is discussed in more detail in a following section.

Antibodies that inhibit the invasion of erythrocytes by the extracellular merozoite stage of malaria in vitro are found in many, but not all, individuals living in malaria endemic regions. Although the significance of these inhibitory antibodies to naturally acquired resistance remains unclear, their target antigens nonetheless remain prime candidates for asexual malaria vaccines[422] (see Fig. 38.4). Numerous antigens that form the surface coat of the merozoite or that are essential components of the parasite's cell invasion mechanism (apical complex and rhoptry proteins) have been evaluated as potential vaccine candidates. Although antibodies to several of these antigens have been found to be able to inhibit parasite development in vitro, or are associated with clinical immunity in vivo, the results of these studies tend to be rather inconsistent,[424] and the results of vaccine trials have been disappointing.[422] One of the problems seems to be that when one pathway of merozoite invasion into an erythrocyte is blocked by antibody, the parasite is able to switch to an alternative pathway using entirely different proteins. Recently, however, a novel receptor-ligand interaction has been identified that seems to be absolutely essential for merozoite invasion. *P. falciparum* rhoptry protein-5 (PfRh5) binds to the blood group antigen basigin on the red cell surface; blocking of this interaction with antibasigin antibody completely prevents parasite invasion and replication.[425] Just as importantly, antibodies to PfRh5 also block invasion and PfRh5 seems to

be a remarkably conserved protein among different parasite isolates, raising hopes that PfRh5 might be a credible new candidate for a blood stage malaria vaccine. Despite their extreme polymorphism, the variant surface antigens present on infected erythrocytes that mediate adhesion to endothelial cells are potential vaccine candidates.[426] Epidemiologic data suggest that the risk of severe manifestations of the disease is reduced after only a very few clinical episodes,[427] and that parasites causing severe disease tend to express a subset of variant surface antigens.[428] Thus, a finite number of variant antigens might be sufficient to elicit broad immunity against severe disease. Similarly, relatively few PfEMP-1 variants appear to mediate parasite sequestration in the placenta, and a pregnancy malaria vaccine might work by targeting the domains that bind to chondroitin sulphate, the major placental ligand for parasitized red blood cell (pRBC) sequestration.

Antimalarial transmission-blocking immunity works primarily by antibody-mediated, complement-dependent lysis of extracellular sexual stages of the parasite within the midgut of a blood-feeding mosquito[429] (see Fig. 38.4). Transmission-blocking immunity has been induced in vivo by immunization with gametes of avian, rodent, and monkey malarias. Several potential transmission-blocking vaccine candidates have been identified, and the genes encoding these surface proteins have been isolated and sequenced, but their production as recombinant proteins is hampered by failure to recreate the highly complex tertiary structures that are the targets of inhibitory antibodies. Furthermore, for those antigens expressed only by invertebrate stages of the parasite, lack of natural boosting may prevent maintenance of sufficiently high antibody titers.

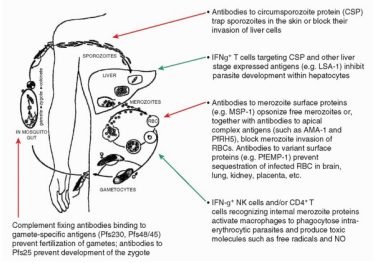

FIG. 38.4. Stage-Specific Vaccine Targets in Malaria Parasites. The *left* figure depicts the life cycle of malaria and the immune effector mechanisms that target the different developmental forms of the parasite (reproduced from Malaria Vaccine Initiative Web Site [www.malariavaccine.org/mal-what_is_malaria.htm]). (Adapted from Richie TL, Saul A. Progress and challenges for malaria vaccines. Nature. 2002;415:694-701, with permission.).

Clearly, an optimal vaccine against malaria would need to target multiple antigens and induce immunity against all stages. However, by targeting certain antigens confined to asexual blood stages, the induction of an adult-like immune status among high-risk infants in sub-Saharan Africa could greatly diminish severe disease and death caused by *P. falciparum*.

T-Cell Vaccines

Vaccination Against Leishmaniasis

Vaccines against intracellular parasites will need to induce long-lived cellular immune responses. As already discussed, for diseases such as Leishmaniasis, Chagas disease, and toxoplasmosis, Th1 and/or CD8+ T-cell responses are the effector mechanisms required for protective immunity. An inherent problem with most nonliving vaccines is their relative inefficiency in generating and/or sustaining these sorts of cellular responses. A major advance in T-cell vaccine development was the demonstration that proteins derived from *L. major* could elicit a powerful Th1 response and protective immunity if given with recombinant IL-12 as adjuvant.[430] IL-12 or IL-12-inducing adjuvants such as BCG, CpG-oligodinucleotides, or CD40L have since been used extensively in animal models to potentiate the efficacy of whole cell killed or a diversity of recombinant protein *Leishmania* vaccines.[431] A polyprotein containing several

Leishmania antigens (TSA, LmSTI1, and LelF), formulated with the TLR4 agonist MPL®, a detoxified derivative of 4'-monophosphoryl lipid A of LPS, is the only defined, subunit vaccine against leishmaniasis currently being tested in human trials.

The gold standard of the protection that can be achieved by vaccination in mice, and the only vaccination strategy against leishmaniasis that has worked so far in humans is "leishmanization," which is based on the lifelong convalescent immunity that is acquired following induction of a lesion at a selected site with a cutaneous strain of *L. major*. The nature of the acquired resistance that develops following healing of a primary lesion seems especially important to consider as only healed mice were protected against *L. major* transmitted by sand fly bites, whereas mice vaccinated with killed parasites plus CpG-oligodinucleotides were protected against needle but not sand fly challenge.[432] Importantly, the strong and durable protection against secondary challenge conferred by live vaccination in mice and humans is associated with the persistence of parasites long after clinical cure. The presence at the time of the challenge exposure of a population of effector memory cells that are rapidly tissue homing and readily secrete IFNγ upon encounter with antigen in the

challenge site appears to be critical for the full expression of acquired immunity.[432,433] The maintenance of effector memory T cells in live vaccinated hosts, and the loss of these cells following antigen clearance in antigen vaccinated hosts, likely explains the failures of a large number of human trials involving whole cell killed vaccines to significantly reduce the incidence of cutaneous leishmaniasis in individuals living in areas of relatively low transmission, where natural boosting is unlikely to have occurred.[434] The requirement for persistent antigens reinforces the rationale for live attenuated *Leishmania* vaccines, a number of which have been generated by targeted deletion of genes involved in parasite survival or virulence. Although the efficacy of live attenuated vaccines against needle challenge in mice has been shown,[431] none have been evaluated using infected sand flies and more generally pose greater difficulties in standardization and delivery in field settings.

Similar to *Leishmania*, a diversity of protein-, DNA-, and viral vector-based vaccines have been developed that successfully induce protective immunity against an experimental *T. cruzi* infection in mice, typically measured as a CD8+ T-cell-dependent reduction in acute-phase parasitemia or associated mortality.[435] In contrast to an anti-*Leishmania* vaccine, however, a prophylactic vaccine for human Chagas disease would almost certainly have to provide sterile immunity in order to be effective, as the cardiac pathologies are associated with persistent infection. Whereas a number of experimental vaccines were shown to reduce the tissue inflammation and parasitism associated with late chronic phase infections, it does not seem that infection itself, or even infection and drug cure, confers sterilizing immunity against reinfection,[146] and there is so far no evidence that a vaccine can achieve a better result. Furthermore, the immune response seems to be focused on epitopes encoded by genes of the large and strain variant trans-sialidase gene family,[436] which would require that a massive number of target epitopes be included in an effective vaccine. Thus, the rationale for the development of a safe and effective vaccine against human Chagas disease remains suspect, particularly as vector control methods have proven to be so highly effective.

Vaccines to prevent toxoplasma infection are needed primarily to protect livestock and prevent transmission to humans from felines. As with *T. cruzi*, CD8+T cells working in conjunction with IFNγ-producing CD4+T cells appear to provide optimal immunity to challenge infection and so far this type of protection is best induced by live attenuated strains of the parasite.[437] Recently, modern tetramer sceening and bioinformatic approaches have been used to identify dominant CD8+ epitopes for both mice[438] and humans[439] and in the latter case have been tested for their vaccine potential in transgenic mice expressing supertype human leukocyte antigen-A molecules. These findings offer new promise to peptide-based approaches for vaccination against *T. gondii*.

Vaccination Against Malaria Liver Stages

Because malaria parasites infect and replicate in hepatocytes, which express MHC class I, infected hepatocytes are potential targets of CD8+ T-cell responses (see Fig. 38.4). Irradiated or genetically attenuated *Plasmodium* sporozoites, which can infect hepatocytes but do not progress to a blood-stage infection, have been shown to protect rodents, monkeys, and humans against malaria and are believed to work by inducing IFNγ-producing CD8+ T cells specific for preerythrocytic antigen.[440] Overirradiation of sporozoites, or attenuation of sporozoites very early in their development inside the hepatocyte, negates their ability to immunize, suggesting that the targets of protective mechanisms are novel antigens expressed only if sporozoites are to undergo partial differentiation within hepatocytes. Efforts to mimic the protection generated by irradiated sporozoites using nonliving protein- and DNA-based vaccines have yielded encouraging results. A recombinant polypeptide representing the central repeat and C-terminal portions of the *P. falciparum* CS protein and fused to hepatitis B surface antigen (HBsAg) elicits IL-2-secreting CD4+ T-cell responses as well as antisporozoite antibodies in human volunteers, particularly when given with the GSK proprietary adjuvant AS01 (containing liposomes, MPL and QS21). The vaccine, RTS,S, induced antibody and T-cell responses in adults already primed to CS by preexposure to malaria. Most significantly, in this first phase II trial, vaccine efficacy during the first 9 weeks of follow-up was 71% but decreased to 0% over the next 6 weeks.[441] In the intervening decade, more than 50 clinical trials of RTS,S have been undertaken—many of them in Africa—refining the dose, the adjuvant, the immunization schedule, and age of vaccination,[442] and a phase III trial (the very first for a malaria vaccine) was begun in 2009. The preliminary results of this trial confirm that the vaccine has approximately 50% efficacy against clinical malaria attacks and against malaria-related hospital admissions,[443] but the duration of protection is still an area of concern. Moreover, as there are still no clear immunologic

correlates of vaccine-induced immunity, refinement of the vaccine to enhance its efficacy may mean that clinical trials need to continue for many years to come.

Despite initial enthusiasm that DNA vaccination strategies might improve the durability and potency of the cellular response, clinical trials have been disappointing, and the use of sequential immunizations using various heterologous prime/boost protocols are being tested to enhance the effectiveness of preerythrocytic vaccines.[178] Priming with plasmid DNA encoding CS and various liver stage-specific proteins and boosting with recombinant adenovirus or pox virus, such as modified vaccinia virus Ankara or fowlpox, has induced complete protection and very high levels of IFNγ-secreting CD8+ T cells in mice. Although protection in human trials has been less convincing, delays in time to emergence of blood-stage parasites have been consistently obtained, suggesting that the vaccination substantially reduces, but does not eliminate, liver stage parasites.

Vaccination to Prevent Pathology

In many parasitic infections, disease is a consequence of the host immune response. Because these pathogens are so well adapted to their hosts, it may be easier and more efficient to design immune interventions that prevent parasite-induced immunopathology rather than eliminate the infection itself. Although this approach will not lead to eradication of the parasite, it would likely reduce or alleviate the health consequences of infection. The feasibility of antipathology vaccines was demonstrated in a murine models of schistosomiasis.[395] Because disease in schistosomiasis is largely due to the granulomatous pathology that develops around parasite eggs trapped in target host tissues, a valid approach toward immunoprophylaxis for schistosomiasis is to vaccinate to minimize granulomatous pathology[395] or reduce parasite fecundity.[444,445] In mice, granuloma size and collagen deposition are correlated with the intensity of the type 2 response, and immunologic interventions, such as the administration of IL-4 and IL-13 antagonists, reduce both the size of granulomas and magnitude of fibrosis (discussed previously).[401,446] In extensions of these studies, mice immunized with parasite egg antigens plus IL-12[447] or CpGoligonucleotides[448] to induce an egg antigen-specific type 1 response, upon subsequent infection, exhibited far less severe egg-associated liver disease than did infected nonimmunized controls. Importantly, several immunodominant egg antigens have been described;[449,450] thus, it may be possible to design recombinant antipathology vaccines that duplicate the promising results produced with crude parasite extracts.

Parasite-derived GPI has been implicated in much of the pathology of malaria,[451] binding to TLRs on DCs and macrophages, and inducing release of TNF-α and other proinflammatory cytokines. As a proof of principle that GPI might serve as a target of an antidisease vaccine, mice immunized with synthetic GPI were protected against the acute immune pathology associated with *P. berghei* infection; however, as the mice were not immune to the parasite itself, they were unable to control parasite replication and eventually died of overwhelming parasitemia.[452] These observations suggest that although malaria vaccines that prevent immune pathology might reduce some aspects of morbidity, they are unlikely to be deployed in the absence of vaccine components that also limit parasite burden.

Vaccines Against Helminths

Infection with helminthic parasites remains a significant health problem in many tropical

countries. Whereas control measures are available in some areas, in most cases, patients living in endemic regions are quickly reinfected. Therefore, vaccines that reduce parasite and/or egg burdens would be a valuable tool to complement existing disease prevention programs and could represent a less costly and more practical approach than repeated chemotherapy. Although many subunit vaccines have been described and tested in various animal models, suboptimal levels of protection have hindered the development of all but a few of these candidate vaccines.[453] Significant advances in vaccination technology over the past decade have made it possible to identify novel targets using immunomics[454] and engineer vaccines that elicit strong cellular and humoral immunity.[455] Novel DNA vectors, improved delivery systems, new adjuvants, and immunomodulatory cytokines allow significant augmentation of the immune response to vaccines and preferential induction of specific effector mechanisms, including antibody isotypes, T helper cell subsets and cytotoxic T cells. However, in order to effectively harness and implement these advances, it will be necessary to fully understand the mechanisms of resistance to helminth parasites.

Vaccine models using radiation-attenuated larval parasites have provided the best examples of successful immunization against helminths. With the irradiated schistosome vaccine, although complete sterilizing immunity appears to be an unachievable goal, immunity approaching 60% to 80% is possible with the addition of adjuvants such as IL-12.[456] This model has served as the gold standard for schistosome vaccine development.[457] The cumulative evidence from vaccine studies conducted in numerous gene knockout mice suggests that irradiated parasites induce protection via both Th1- and Th2-dependent pathways,[234] and that both humoral and cellular mechanisms will be required for the generation of optimal immunity against most helminth parasites.[458,459]

While there has been extensive research on defined vaccines against helminth infection,[460,461] none of the candidate antigens have been shown to induce protective immunity in humans, although a few are actively being tested in clinical trials.[462] At least one of the antigens—glutathione-S-transferase (P28/GST)—has moved through a phase I trial, and phase II trials are now underway in Africa. Other antigens of interest include paramyosin (Sm97), Irv5 (myosin-like 62-kDa protein), triose phosphate isomerase, Sm23, the integral membrane protein tetraspanin-2, and Sm14, a fatty acidbinding protein.[463,464] With the recent advances in schistosome genomics, proteomics, and immunomics,, a new panel of vaccine antigens is being identified, and these antigens will warrant further investigation in animal models.[465,466]

A number of filarial vaccine candidates have also been described and are being tested, including chitinase, tropomyosin, paramyosin, and several larval antigens called the "abundant larval transcript family."[460] Finally, several experimental antihookworm vaccines are also being investigated.[467] While these accomplishments represent a significant advance for the field of helminthology, it is important to note that all of the candidate antihelminth vaccine antigens will at best provide only partial protection. It is hoped, however, that ongoing improvements in vaccination technology, combined with greater knowledge of the mechanisms controlling resistance, will allow development of more efficacious and better defined vaccines for these complex organisms.

CONCLUSION

In the 4 years since the publication of the last edition of *Fundamental Immunology*, studies on the host-parasite interaction have contributed important advances to our understanding of the immune response and its regulation. Interestingly, many of these discoveries emerged from the study of worm infection models and led to new insights into the mechanism of Th2 polarization, the orchestration of mucosal immune responses, and the function of ILCs, basophils, and AAMs in promoting adaptive immunity. Indeed, although once regarded as a less sophisticated topic than protozoan immunology, the study of immunity to helminths has undergone a major resurgence in part because of the growing appreciation of the phylogenetic uniqueness of worm pathogens and their host interaction. Research on the immune response to helminths has also been stimulated by the growing interest in neglected tropical diseases, where worm infections account for the most affected individuals. Finally, there has been a growing awareness of the important evolutionary role played by helminth infection in conditioning the mammalian immune system, in the maintenance of immunologic homeostasis at mucosal tissue barriers, and of the likely impact of the loss of this symbiotic relationship on immune function due to modern improvements in human hygiene.[468]

A second trend in immunoparasitology in recent years has been the widespread use of genetic and genomic screening technologies to identify genes with functional roles in the host-parasite relationship. Interestingly, many of these projects[98,438,439] have brought together molecular and immunoparasitologists with the common goal of simultaneously identifying both parasite epitopes/virulence determinants and their host receptors and signaling pathway targets. The findings gained from such studies should provide important groundwork for future systems biology approaches that seek to develop a broader vision of the interaction of parasites with the immune system.

Another important development since the publication of the last version of this chapter is the increased emphasis on the study of the human immune response to parasitic infection. The most notable advances have occurred in the field of malaria, which benefits from a wealth of clinical material and the ability to use peripheral blood as a physiologically relevant source of immune cells. The study of human malaria is yielding novel insights into the nature of B-cell effector and memory responses to the parasite as well as the role of innate cellular function in regulating disease outcome. Similarly, as noted previously in this chapter, human visceral leismaniasis has proved a fertile ground for the study of the role of T cells and cytokines in immunosuppression and, in the case of the disease itself, implicated IL-10 production as target for immunotherapeutic intervention.

Perhaps the most heralded recent advance in the field of immunoparasitology has been the success of the field trials of the RTS,S vaccine for falciparum malaria.[442] While still clearly limited as a tool for controlling malaria because of its partial efficacy, important lessons have been learned from the experience of bringing the RTS,S vaccine to its current stage of development. Ironically, although RTS,S was originally designed to simultaneously trigger humoral and cell responses to the circumsporozoite protein (CSP) Ag, it is not all clear that the protection induced by the vaccine depends on this multipronged response. Instead, its improved efficacy appears to have stemmed from changes to the GlaxoSmithKline (GSK) adjuvant formulations and dosing regimen employed.[441] Indeed, the vaccine construct itself has not changed significantly from the time of the earlier unsuccessful trials. Thus, the RTS,S trials have both affirmed the importance of antigen delivery and presentation in the induction of parasite immunity while emphasizing our continued ignorance of the rules linking these parameters to the induction of host resistance. Nevertheless, having a defined antigen vaccine in which at least a proportion of the immunized individuals become protected offers a rare opportunity to identify correlates of immunity to malaria triggered by a single immunogen through the use of a "systems vaccinology" approach.[469] Such studies, in addition to providing valuable information needed for the design of a more effective RTS,S vaccine, could supply an important precedent and platform for analyzing human immunity to parasitic pathogens at a wider level. It is hoped that exciting new approaches and opportunities of this kind will bring us closer to our ultimate goal of protecting human populations against the scourge of parasitic disease.

Chapter 39

Immunity to Viruses

Hildegund C.J. Ertl

INTRODUCTION

Veni, vidi, vici—I came, I saw, I conquered. If viruses could talk or see, this would be their hendiatris. Although viruses are minute particles composed only of a genome surrounded by a few proteins, they have a fiendish way of wreaking havoc not only on humans, as everyone who ever had the flu knows, but also on animals, plants, and even bacteria. Each year, more people die of viral infections than of natural disasters such as hurricanes, earthquakes, and tsunamis combined, or even manmade tragedies such as war. For example, it is estimated that variola major, the causative agent for smallpox, killed nearly half of the population of Native Americans after the virus was introduced into the western hemisphere by European colonizers. The Spanish Flu caused by an H1N1 influenza A virus caused the death of 50 to 100 million humans between 1918 and 1919, which is well in excess of the 16 million casualties of World War I. Human immunodeficiency virus (HIV)-1 has killed more than 25 million humans since 1981 and continues to spread, threatening the already frail economic structures of the most afflicted countries in sub-Saharan Africa, where more than 30% of the adult population carries the virus.

Not only do viruses cause acute or chronic infections with potentially fatal outcome, but they also contribute to other diseases. Viruses are associated with 20% of cancers, they have been implicated in the pathogenesis of human arteriosclerosis and autoimmune diseases, and they are linked to an overall reduction in life expectancy.

How can something so small be so deadly? Viruses, which range in size from 10 to 300 nm in diameter with genomes of minimally 2 kilobases to over 1.2 megabases, are unable to propagate themselves, but require a host cell to replicate. Once a cell becomes infected, viruses hijack its transcription and translation machinery to promote their own replication. The physiologic functions of the infected cell are disrupted as it is being turned into a virus production facility. However, the cell fights back as soon as it senses the virus. This fight initially takes place intrinsically within the infected cells but then rapidly spreads extrinsically once the immune system has been alerted. In turn, many viruses mount defenses against the attack from their host by encoding proteins that actively subvert innate and adaptive immune responses. In acute virus infections, the fight between virus and host literally lasts until the death of one of the adversaries. In chronic infections, a truce is eventually reached where virus and host coexist, generally at the expense of the well-being of the latter.

Fewer than 200 viruses are known to cause disease in humans. Over the last 50 years, on average two new species of human viruses have been discovered annually; one can expect that this number will continue to rise.[1] Where does this ever-increasing number of viruses come from? We are not certain about the origin of viruses, although we know from ancient texts as well as more modern data-driven genomic analyses that viruses have been around for a very long time.[2] Whether they originated from cells, concomitantly with cells, or even primordially from some genetic soup remains debated.[3] No matter how they evolved, their lack of common genes argues for a polyphyletic rather than monophyletic evolution. The constant discovery of new viruses may simply reflect improvements of detection technologies

that traditionally were based on cell culture and that are now being replaced with high-throughput genomics. Notwithstanding, many of the newly discovered viruses seem to evolve from animal reservoirs through mutations that allow for an extension of their host range. Of importance is that viral genomes have far higher mutation rates than, for example, mammalian genomes as they fail to correct errors during replication; such errors most commonly lead to loss of viral fitness but occasionally benefit the virus in its quest for replication. One example of a stable host range altering mutation that caught global attention was that of a coronavirus, which caused the outbreak of severe acute respiratory syndrome (SARS) in 2003 and 2004. This virus, termed SARS-CoV, which in its wild-type form infects civets, a cat-like carnivore, mutated and became infectious to humans and then within this host rapidly underwent further positive selection.[4] Other viruses such as pathogenic H5N1 avian influenza viruses have been isolated since the late 1990s repeatedly from humans, who commonly died as sequela of the infection. Pathogenic H5N1 viruses, which were, and by some still are, feared to evolve into pandemic viruses, have thus far failed to mutate to achieve sustained human-to-human transmission, while concomitantly, another influenza A virus arose from a triple reassortment between viruses that naturally infect humans, avians, and swine, and caused the 2007 influenza pandemic. Considering that our knowledge of animal viruses remains limited, the sudden emergence of new and potentially deadly viruses from other species continues to threaten global health.

While most other deadly disease can be treated with drugs such as antibiotics to resolve bacterial infections or can be prevented by lifestyle choices, our arsenal to combat viral infections remains limited. Vaccines, which can be effective

in preventing viral infections, and even achieved the eradication of small poxvirus, are only available for 15 viruses. Drugs to specifically treat infections are only effective for some viruses such as HIV-1, herpes, hepatitis B and C, and influenza viruses. Our main defense thus remains the immune system. Over eons, it has evolved to sense viruses as pathogens, to produce factors that stop viral replication, and to develop lymphocytes that destroy those cells that serve as viral production factories. Like an elephant, the immune system never forgets. Nevertheless, this defense like that in every war, even if victorious, comes at a price: a runny nose at best and death due to insufficient or overwhelming responses at worst.

BASICS IN VIROLOGY

Virus Classification

According to the International Committee of Taxometry of Viruses, all viruses are classified into order, family, subfamily, genus, and species. Names of serotypes, genotypes, strains, variants, or isolates of virus species or artificial viruses are not ruled by the International Committee of Taxometry of Viruses. A species is defined as a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecologic niche. A genus defines a group of species that share common characteristics, while subfamilies and families define a group of genera with common characteristics. An order, in turn, defines families with shared characteristics. Currently, 6 orders, 87 families, 19 subfamilies, 348 genera, and 2288 species of virus have been defined.[5] The Baltimore classification differs and divides viruses according to their genome or their mode of replication. Viruses contain either a deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) genome, which can be single stranded (ss) or double stranded (ds). SsRNA viruses carry either a negative- or positive-stranded RNA. During their lifecycle, some DNA and RNA viruses undergo an intermediate step in which the RNA genome is converted by reverse transcription (RT) into DNA or vice versa their DNA genome into an RNA genome. Accordingly, viruses are classified into dsDNA viruses (eg, adeno or poxviruses), ssDNA viruses (eg, parvoviruses), dsRNA viruses (eg, reovirus), positive-sense ssRNA viruses (eg, picornaviruses), negativesense ssRNA viruses (eg, rhabdoviruses), positive-sense ssRNA-RT viruses (eg, retroviruses), or dsDNA-RT viruses (eg, hepadnaviruses). Other classifications are based on host range (Holmes

classification) or structural characteristics (Lworff-Horne-Tournier [LHT] system).

The viral genome can be linear (eg, poxvirus), circular (eg, papillomaviruses), or segmented (eg, influenza virus). Viruses are further classified into enveloped (eg, rhabdoviruses) or naked (eg, picornaviruses) viruses. Viruses can also be divided according to their morphology, which can be polymorphic or structured, the latter having either icosahedral or helical symmetry.

To give an example of the taxonomic division of viruses: the 2007 pandemic H1N1 virus belongs to the species of influenza A virus, the genus of influenza virus, the family of Orthomyxoviridae with a negative-stranded ssRNA genome covered by a helical envelope. A list of common human viruses and additional viruses repeatedly referred to in this text and their classification is shown in Table 39.1. Other characteristics of virus families, such as their genomes and surface structures, are shown in Table 39.2.

Virus Transmission

Viruses have a single-track mind; their only goal is to replicate. The goal of their unwilling hosts is to get rid of them by mounting an immune response. Viruses have evolved a multitude of mechanisms to evade this immune response, and their hosts have adapted countermeasures accordingly, as only those that survived the onslaught of infections reached reproductive age. Highly contagious viruses can afford to not be overly concerned if their hosts, which are essential for their replication, survive, die, or mount a rapid and successful immune response because their ease of transmission ensures their continued existence. A typical example for such a virus is influenza virus, which is transmitted by aerosols before its host becomes sufficiently ill to seek solace in bed, which would limit contact with others and thus reduce the chance for the virus to spread. An example for a virus that is not overly contagious is rabies virus; it is transmitted by the bite of an infected animal, and it ensures its transmission by literally driving its host into an insane rage so that it will randomly attack and bite everyone in sight. Other viruses evolved to ensure the continued survival of their hosts, which enables their own continued replications without necessitating rapid transmission to a new individual. Such viruses are usually more complex, as much of their genome is devoted to combat immune responses.

Many viruses can only replicate in one species and therefore human infections require human-to-human contact. For viruses that are heat labile, such contact needs to be close, while more stable viruses can remain on surfaces or in water until the opportunity for infection arises. Viruses that only replicate in humans can potentially be eradicated once a vaccine becomes available as exemplified by smallpox virus. Other viruses are less discriminatory, and they replicate in multiple species, not necessarily only mammals but also birds or invertebrates. For example, influenza viruses can infect aquatic birds, chicken, swine, horses, humans, and even cats. Although they are most commonly transmitted to humans from other humans, spread from infected animals can occur, such as infections of humans with pathogenic H5N1 from chickens or ducks. Some viruses, such as rabies virus, infect all warm-blooded mammals, while other viruses alternate between mosquitoes and vertebrate animals. An example for the latter is Japanese encephalitis virus, which, in addition to mosquitoes of the *Culex tritaeniorhynchus* species, can infect humans, birds, most domestic animals, snakes, and frogs. The host range of a specific virus affects the mode of transmission, which is further influenced by the tissue tropism of the virus and its resistance to environmental factors like temperature or water.

One of the main protections against virus invasion is healthy skin; the upper layer of the keratinized epidermis effectively prevents entry of viruses. Mucosal surfaces,

although they are commonly bathed in antiviral proteins present in saliva and tears, in acids found in the female outer genital tract or the stomach, or in destructive enzymes such as those present in the upper intestinal tract, provide a more permissive port of entry for viruses

and, consequently, most viruses are transmitted through the mucosal surfaces of either the airways, the intestines, the genital tract, or the eye. Influenza viruses, parainfluenza viruses, some types of adenoviruses, and rhinoviruses spread through the airways and are transmitted by aerosolized droplets expelled by coughing or sneezing.

TABLE 39.1 Taxonomy of Viruses

Order	Family	Subfamily	Genus	Species (Alternative Names)	Abbreviation
Herpes virales	Herpes virideae	Alphaherpes virinae	Simplex virus	Human herpesvirus 1 (Herpes simplex virus-1)	HHV1
				Human herpesvirus 2 (Herpes simplex virus-2)	HHV2

TABLE 39.2 Characteristics of Viruses

Family	Genome	Virion	Capsid
Herpesvirideae	dsDNA	Enveloped	Isocahedral
Filoviridae	Negative-sense ssRNA	Enveloped	Helical
Paramyxoviridae	Negative-sense ssRNA	Enveloped	Helical
Coronaviridae	Positive-sense ssRNA	Enveloped	Helical
Adenoviridae	dsDNA	Enveloped	Isocahedral
Arenaviridae	Negative-sense ssRNA	Enveloped	Complex
Flaviviridae	Positive-sense ssRNA	Enveloped	Isocahedral
Hepadnaviridae	ds-DNA-RT	Enveloped	Isocahedral
Orthomyxoviridae	Negative-sense ssRNA	Enveloped	Isocahedral
Papillomaviridae	dsDNA, circular	Naked	Isocahedral
Parvoviridae	ssDNA	Naked	Isocahedral
Poxviridae	dsDNA	Complex	Complex
Reoviridae	dsRNA	Naked	Isocahedral
Retroviridae	RT-positive-sense ssRNA	Enveloped	Isocahedral
Togaviridae	Positive-sense ssRNA	Enveloped	Isocahedral

DNA, deoxyribonucleic acid; RNA, ribonucleic acid.

Viruses that spread through aerosols tend to be highly contagious, such as influenza viruses, which cause annual epidemics and occasional pandemics that within a few months can spread throughout the world as was shown in the 2009 swine flu pandemic. The new pandemic influenza virus was first identified in Mexico on March 18th, 2009; reached California by March 28th; was detected in Canada, New Zealand, the United Kingdom, Israel, and Spain by April 28th; in Germany by the 29th; in Austria, Switzerland, and the Netherlands by April 30th; in other European countries, as well as in Asia, by May 2nd; in South America by May 5th; and on June 11th was officially declared as a pandemic virus by the World Health Organization. The total death toll of this pandemic was rather modest with approximately 5700 reported deaths by August 10th, 2010, when the World Health Organization announced the official end of the pandemic. Another highly contagious virus is varicella virus, which causes chickenpox. This virus is also spread by droplets from person to person, but, unlike influenza virus, which is fairly stable and can thus infect individuals that touch an infected surface and then their nose, varicella virus is very heat labile and, as a rule, requires direct person-toperson contact.

Other viruses are transmitted by oral ingestion and are then spread by shedding into feces.

These viruses are generally stable, allowing them to resist the acidic environment of the stomach or the digestive enzymes of the intestinal tract. Many of them, such as influenza viruses that predominantly infect aquatic birds through the oral route or rotaviruses that cause severe diarrheal disease in children, can also survive for a prolonged time in water. Improperly treated drinking water can spread a number of other viruses, such as enteric adenovirus, calicivirus, astrovirus, poliovirus, or hepatitis A virus.

Sexually transmitted viral infections include herpes simplex virus (HSV) type 2, HIV-1, and several types of human papilloma viruses (HPV). Interestingly, all of these viruses establish sustained infections. HSV-2, after a replicative phase, persists latently in root ganglia from where it is periodically reactivated causing local sores that shed virus. HIV-1 first causes an acute flu-like infection and then persists mainly in CD4+ T cells while constantly dodging a vigorous antiviral immune response through mutations and immune evasion strategies. Although oncogenic types of HPV such as HPV-16 or -18 are commonly eliminated after genital infection, their persistence can over time cause transformation of the infected cells due to the activity of the two viral oncoproteins E6 and E7, which disrupt key cell cycle checkpoints and then lead to cervical cancer in women or penile or anal cancer in men. Although some of the sexually transmitted viruses (eg, HSV-2) are highly contagious, others (eg, HIV-1) transmit poorly and the average rate of HIV transmission has been estimated at 0.0082 per coital act in humans without comorbidities.[6]

Some viruses literally need to be injected into the body to cause an infection. These viruses are either transmitted by blood sucking insects or animal bites. Three flaviviruses, Dengue virus, West Nile virus, and Japanese encephalitis virus, are spread by mosquitoes, whereas Kyasanur forest disease virus, another flavivirus, is spread by ticks. Rabies virus, another vector-borne virus, is generally transmitted by the bite of an infected animal, most often a dog. The virus replicates in the central nervous system and is then transported to peripheral organs such as the salivary glands from where it is secreted into the saliva ready to spread to its

next victim. Although the vast majority of rabies infections are caused by bites, mucosal transmission[7] and transmission by transplantation of tissues from an infected individual have been reported.[8]

Virus Cell Entry and Replication

Most viruses enter cells upon binding to a receptor, some of which are broadly expressed while others are specific for a certain cell type. In some instances, viruses bind with high avidity to one receptor but are also capable of infecting cells that lack expression of the high-affinity receptor through low avidity binding to an alternative molecule. Other viruses require binding to a receptor and a coreceptor. Receptor usage determines tissue tropism of many viruses and in some cases it also influences their host range.

For example, the hemagglutinin (HA) of influenza A viruses that can spread in humans binds to sialyated glycan receptors with a terminal α2-6 linked N-acetylneuraminic acid. In contrast, α2-3 linked sugar residues are used as receptors for influenza A viruses that circulate in birds. Once the HA has bound to its receptor, it is cleaved. A trypsin-like enzyme present only in the lung cleaves HA into two subunits, which allows the virus envelope to fuse into the cell membrane. Some of the more pathogenic strains, such as the 1918 H1N1 virus or pathogenic 2006 H5N1 viruses, activate HA through a trypsin-independent mechanism.[9] These strains have a multibasic cleavage site that can be digested by furin and furin-like proteases, which are more ubiquitously present in human tissues than the trypsin-like enzymes, allowing these viruses to infect tissues other than lung.

The fiber knob of adenoviruses preferentially binds the coxsackie adenovirus receptor, which is expressed on epithelial cells. In addition, an Arg-Gly-Asp (RGD) motif present within the viral penton can bind α(v)-integrins with lower avidity. The fiber of adenoviruses of subfamily

B2, on the other hand, binds CD46, a ubiquitously expressed complement component that also facilitates entry of measles virus and human herpesvirus (HHV)6. The herpes virus mediator (HVEM) is a bimodal switch that can provide both immunostimulatory and immunoinhibitory signals to the immune system. Upon binding to LIGHT (lymphotoxin [LT]-like, exhibits inducible expression and competes with HSV-1 glycoprotein D [gD] for HVEM), HVEM submits stimulatory signals. Upon binding to the B- and T-lymphocyte attenuator (BTLA), it acts as an immunoinhibitor. HVEM also binds HSV-1 gD, thus facilitating entry of this virus. Binding of gD to HVEM takes place on a site that overlaps with the BTLA binding site; therefore, gD can be used to inhibit an immunoinhibitory pathway. HSV-1 may have evolved to block such a pathway, as activation of NF-κB promotes viral replication and assists in transcription of some of the early viral genes.[10]

The envelope protein of HIV-1 binds cluster of differentiation (CD)4 expressed mainly on T-helper cells. Upon binding, the protein undergoes structural changes that allow for its binding to a coreceptor, which for transmitting virions is CCR5, but following mutations, viruses circulating in an organism can also use CXCR4.[11] A mutant allele of CCR5 termed CCR5d32, which results in lack of CCR5 expression on the cell surface and which is found in 10% of Caucasians of European descent, provides resistance to infections with HIV-1.[12] Other viral receptors include the nicotinic acetylcholine receptor for rabies virus, heparan sulfate for dengue virus, adeno-associated viruses, and some of the herpes viruses, CD155 for poliovirus, CD81 for hepatitis C virus, CD21 for Epstein-Barr virus (EBV), C-type lectins, such as dendritic cell (DC)-specific intercellular adhesion molecule-3-grabbing nonintegrin (DC-SIGN) and liver/lymph node-specific intercellular adhesion molecule-3-grabbing integrin for Ebola virus, integrin-β3 for Hantan virus or intercellular adhesion molecule (ICAM)-1 for rhinoviruses. Examples for viral receptors including their physiologic functions are listed in Table 39.3.

Upon binding to a receptor, viruses not only need to gain access into the cell, but most of them then have to traverse to the nucleus to initiate their replication. Viruses enter the cell either through endocytosis[31] or fusion.[32] Clathrin-mediated endocytosis is used by enveloped as well as nonenveloped viruses including adenoviruses, influenza viruses, poxviruses, or rabies virus. In cadherin-mediated endocytosis, the virus-receptor complexes cluster into a cadherin-coated pit on the cell membrane that becomes invaginated, eventually closes, and detaches from the cell membrane. The clathrin-coated vesicles then deliver their cargo to early endosomes from where it travels to late endosomes. Other viruses such as coxsackie B virus, respiratory syncytial virus (RSV), and others enter cells by caveolar endocytosis. Caveolae are invaginations in the plasma membrane that are rich in cholesterol, glycosphingolipids, and claveolin, which are used for uptake of macromolecules into endosomes. In addition, caveolar endocytosis allows for transcytosis of molecules from the basal to the apical side of a cell or vice versa. Human enterovirus has been described to enter cells through a lipid raft dependent pathway, rotavirus infects through a cholesterol- and dynamin-dependent but clathrin-and caveolae-independent pathway, while other viruses enter cells by micropinocytosis or phagocytosis.

Enveloped viruses such as paramyxoviruses, some herpes viruses, or HIV-1 invade cells by direct fusion of the virus envelope with the cell membrane. Fusion is promoted by hydrophobic sequences within a viral surface protein and causes release of the viral genome into the cytoplasm.

Viruses that enter cells through endocytosis end up in endosomes. Mechanisms of escape from endosomes differ for enveloped and nonenveloped viruses. The decrease in pH between early and late endosomes favors conformational changes of viral surface proteins by exposing their hydrophobic residues, which allow for fusion of the viral envelope with the endosomal membrane. This in turn permits escape of the viral core or the genome into the cytoplasm. Nonenveloped viruses disrupt the endosomal membrane either by a pathway called carpet mechanism or by forming pores. In carpet-like disruption of endosomal

membranes, viral peptides act like a detergent and thus interrupt the hydrophobic interactions between membrane lipids allowing for the development of micelles and for transient formation

of holes within the membrane.[33] Other viruses carry proteins, which form amphipathic α-helices that assemble into a pore within the lipid membrane of the endosome where the hydrophobic parts interact with the lipid bilayer while the hydrophilic parts of the coils form the inner wall of the pore.[34] Picornaviruses, parvoviruses, and reoviruses utilize this strategy.

TABLE 39.3 Viral Receptors

Receptor	Virus	Viral Antigen	Physiological Function	References
Herpes virus entry mediator	Herpes simplex virus-1	Glycoprotein D	Receptor for costimualtors/coinhibitors	13,14
Coxsackie adenovirus receptor	Adenovirus C	Fiber	Cell adhesion molecxule	15
	Coxsackie B virus			
CD46	Adenovirus B2	Fiber	Complement regulatory protein	16
	Measles virus	Hemagglutinin		17
CD55	Enteroviruses	Hemagglutinin	Complement regulatory protein	18
CD155	Poliovirus	Virus proteins 1-3	Cell adhesion molecule	19
CD4	Human immunodeficiency virus-1	Glycoprotein 160	T-cell receptor coreceptor	20
Nicotinic acetylcholine receptor	Rabies virus	Glycoprotein	Forms ion channels in neuronal membranes	21
CD81	Hepatitis C virus	Glycoprotein E2	Signal transduction	22
ICAM-1	rhinovirus	Viral proteins 1-4	Cell adhesion molecule	23
CD21	Epstein-Barr virus	Glycoprotein 350/220	Complement component	24

DC-SIGN	Ebola virus	Glycoprotein	C-type lectin, adhesion molecule	25
	Dengue virus	Glycoprotein E		26
	Hepatitis C virus	Glycoprotein E2		27
P-selectin glycoprotein ligand-1	Enterovirus 71		Selectin receptor; mediates leukocyte rolling	28
SLAM/CD150	Measles virus	Hemagglutinin	Signal transduction	29
Transferrin receptor 1	Lassa fever virus	Glycoprotein	Import of iron	30

CD, cluster of differentiation; DC-SIGN, dendritic cell-specific intercellular adhesion molecule-3-grabbing non-integrin; ICAM, intercellular adhesion molecule; SLAM, signaling lymphocytic activation molecule.

Once within the cell, viruses may be broken down by autophagy,[35] a catabolic process involving the degradation of a cell's own components to convert unneeded pieces into nutrients. During this process, so-called autophagosomes form from membrane structures containing autophagiarelated gene products (Atg), such as the ubiquitin-like Atg8, the Atg4 protease, and the Atg12-Atg5-Atg16 complex. The outer membrane of the autophagosome fuses with a lysosome to allow for degradation of its contents. Formation of autophagosomes is initiated by PI3K and Beclin-1. Most viruses block this pathway by inhibiting PI3K activation, but rhinoviruses and poliovirus sponsor formation of early autophagosomes but block their fusion with lysosomes and then use the structures to egress the cells.[36]

Once a virus has reached the cytoplasm, it must deliver its genome to the nucleus. Many viruses such as herpesviruses and adenoviruses use microtubules to reach nuclear pores. Very small genomes can diffuse passively though pores into the nucleus, while larger genomes or particles require an energy-dependent process. Some viruses use viral proteins to facilitate nuclear entry. For example, cytomegalovirus (CMV) encodes two proteins, pUL69 and pUL84, that facilitate the transport of its genome to the nucleus. pUL69 binds to UAP56, which facilitates nuclear export of unspliced RNA; pUL84 binds to importin-alpha proteins,[37] which can dock to nuclear pores and then be transported through it.

Most viruses initiate their replication in the nucleus as they depend on nuclear enzymes for transcription. Poxviruses and some of the RNA viruses are independent of such enzymes and can replicate their genome in the cytoplasm. HIV-1 replicates in the nucleus after it reverse transcribes its RNA in the cytoplasm.

Replication of different types of virus can be exemplified using the following viruses: adenovirus, a dsDNA virus; adeno-associated virus, an ssDNA virus; reovirus, a dsRNA virus; poliovirus, a positive-sense ssRNA viruses; influenza A virus, a negative-sense ssRNA virus; HIV-1, a positive-sense ssRNA-RT virus; and hepatitis B virus, a dsDNA-RT virus.

Adenovirus transcription is typical for that of some of the larger DNA viruses as it proceeds in stages. Initially, the immediate early gene is transcribed. The resulting gene products alter the host cell to provide a more favorable environment for viral replication and initiate transcription of early viral genes, which have regulatory functions and serve to modify host cell functions

or subvert immune responses. Thereafter, the viral genome replicates concomitantly with transcription of the late viral genes that encode

structural proteins. Specifically, the replication cycle of adenovirus starts with expression of E1A, which encodes two polypeptides that bind to cellular proteins, including cellular transcription factors, which in turn changes the cell's gene expression profile and allows for transcription of the other early viral genes E1B, E2, E3, and E4. E1A promotes apoptosis, while E1B proteins are antiapoptotic. E1B polypeptides turn off host cell protein synthesis and help to stabilize, transport, and selectively translate viral RNA. E2 encodes DNA-binding proteins and a polymerase. E3 gene products are nonessential for virus replication but serve to evade immune responses. E4 encodes seven polypeptides, which collaborate with E1 gene products in promoting viral transcription and modulating host cell functions. E4 gene products are also essential for nuclear export of viral RNA. Adenoviruses also encode one or two virus-associated (VA)-RNA species, which form short hairpin loop structure of approximately 200 bases, are transcribed by polymerase III and stimulate translation of viral genes. VA-RNA can be processed into shorter RNAs and act as micro RNA,[38] inhibiting activation of protein kinase R, which inhibits further messenger RNA (mRNA) synthesis through phosphorylation of the translation initiation factor EIF2A. Transcription and translation of early gene products is followed by DNA replication, which is initiated by a terminal protein that is covalently bound to the 5′ ends of the long terminal repeats. Once DNA replication is initiated, the late gene products, which form the viral capsid, are produced from the L1-L4 domains. Viral assembly begins in the cytoplasm and is completed in the nucleus.

Adeno-associated viruses are ssDNA viruses that cause no known disease in humans. They are dependoviruses and require coinfection with another virus, most commonly an adenovirus, to complete their lifecycle. The approximately 4.7 bp genome is flanked by terminal repeats that contain a multipalindromic terminus that forms a loop and thereby promotes priming for DNA replication. The genome contains only two genes; one, the *rep* gene, encodes four regulatory proteins needed for DNA replication and conversion of the dsDNA intermediate into the final ssDNA. The viral capsid is composed of three virus proteins derived from the *cap* gene by transcript splicing. Initiation of transcription of the rep gene requires proteins from a helper virus such as gene products from E1, E2, E4, as well as VA-RNA from adenovirus. Final assembly of the adeno-associated virus takes place in the nucleolus.

Reovirus infections are asymptomatic in humans but cause disease in newborn mice. This virus, which contains 10 to 12 segments of dsRNA, replicates in the cytoplasm of infected cells without completely uncoating. RNA is transcribed from the negative strand of the genomic RNA and leaves the capsid to be translated. Secondary transcription occurs later followed by assembly within the cytoplasm.

The viral genome of positive-sense ssRNA viruses, such as poliovirus, a picornavirus, can directly serve as mRNA. Poliovirus RNA lacks the methylated cap structure that is typical for mammalian mRNA but rather has an internal ribosomal entry site. To avoid competition with translation of mammalian mRNA, poliovirus interferes with recognition of the host's methylated cap, thus inhibiting host cell protein synthesis.[39] The poliovirus RNA is translated into a single polypeptide that is cleaved into a replicase, proteases, and structural proteins. The polymerase transcribes the positive-stranded RNA into a minus-sense RNA to serve as template for new positive-stranded RNA. The latter can either be translated, serve as template for minus stranded RNA, or be packaged into new virions. Replication as well as assembly occurs in the cytoplasm.

Influenza viruses are segmented negative-sense ssRNA viruses, which replicate in the nucleus. The RNA-dependent RNA polymerase transcribes positive-stranded RNA segments that are either transported to the cytoplasm for translation or remain in the nucleus to serve as templates for negative-stranded RNA synthesis. Newly produced internal proteins are

transported into the nucleus where they, together with RNA segments, form new virus particles. The two viral surface proteins, the HA and the neuraminidase are secreted through the Golgi apparatus to the cell surface where they are then picked up by the envelope once the virus leaves the cell.

HIV-1 is initially reversed transcribed in the cytoplasm by the viral reverse transcriptase into an RNA/negativestranded DNA hybrid. This process is error prone and contributes to the high mutation rate of HIV-1. The RNA is degraded, and a positive-stranded DNA is synthesized allowing for the formation of a dsDNA, which, together with some enzymes, enters the nucleus; there the viral genomes integrates with the help of the viral integrase and serves as a template for synthesis of viral transcripts. Two newly produced viral proteins, Tat and Rev, are essential for efficient protein production: Tat by enhancing transcription and Rev by supporting export of unspliced mRNA from the nucleus, which allows for production of the structural proteins Gag and Env. The full-length viral RNA binds initially to Gag and is then packaged into new virus particles. Env is transported to the cell surface after it is cleaved into two subunits and, with the help of cellular chaperone proteins, folded into a trimer. Assembly of mature virions takes place at the plasma membrane.

Hepatitis B virus (HBV) carries a circular partially dsDNA genome that encodes four structural and two nonstructural proteins through overlapping open reading frames (ORFs). Within the nucleus of an infected cell, the genome is converted into a full dsDNA, which serves as a template for the viral transcripts. The largest mRNA, which is longer than the viral genome, is called the RNA pregenome and is packaged into core particles within the cytoplasm. Within these particles, the pregenomic RNA is reverse transcribed into viral DNA genomes. Upon synthesis, the viral surface protein is transported to the cell membrane and complete assembly of the virion takes place during budding of the virus.

Once replication is completed and full virions have been assembled, viruses need to leave the cells. This again can occur through several pathways. Some viruses, such as HIV-1 or influenza virus, assemble their newly synthesized viral surface proteins on the cell surface and then bud through this part of the cell membrane, picking up not only their own surface proteins but also membrane proteins belonging to

the host cell. Budding eventually destroys the cell membrane and leads to cell death. Other viruses, especially those that are nonenveloped, instruct the infected cell to undergo apoptosis and virus released from dying cells is encapsidated into apoptotic bodies, which are taken up by neighboring cells, thus facilitating infection of new cells. Some viruses are released by exocytosis, a process that resembles reversed pinocytosis in which virus particles are encapsidated into small vesicles that enter the secretory pathways. This form of exit does not kill the cells and is used by so-called nonlytic viruses.

Viral Persistence

Some viruses such as poxviruses or influenza viruses are lytic, which means they inevitably kill the cells they infect. Such viruses cause acute infections in immunocompetent hosts. Other viruses can replicate within a cell without causing its demise, or they can switch between a lytic and a nonlytic infection. These viruses can persist and cause chronic or latent infections, which pose unique challenges to the immune system. In chronic infections, some viruses, such as HIV-1 or hepatitis C virus (HCV), replicate constantly, dodging destruction by the immune system. Other viruses replicate and then persist by turning off synthesis of most of their viral proteins, causing so-called latent infections. Herpesviruses can switch to a latent phase from which they are periodically reactivated to undergo renewed lytic cycles of replication. Adenoviruses persist at low levels in activated T cells, presumably as episomes that remain transcriptionally active.[40] Yet other viruses, such as HIV-1 or HPVs, integrate into the host cell genome and thus become an integral part of the cell. In general, DNA viruses with a nuclear replication cycle are able to persist, which may be favored due to the complete lack of DNA degrading enzymes within the nucleus. Rabies virus, a negative-

sense ssRNA virus, does not cause chronic infections but kills within days after causing symptoms. Nevertheless, in some individuals years pass between viral transmission and onset of symptoms,[41] and it is unknown where and how the virus persists during this long incubation time. Measles virus, another negative-sense ssRNA virus of the paramyxovirus family can cause subacute sclerosing panencephalitis in about 1 out of 100,000 infected individuals within 5 to 15 years after primary infection. Subacute sclerosing panencephalitis is most common in children who are infected early in life, and it has been speculated that the relative immaturity of their immune system allows for the development of a chronic central nervous system infection.[42]

INNATE ANTIVIRAL IMMUNE RESPONSES

Both innate and adaptive immune responses are essential to wards off pathogens, and individuals with inherited or acquired immunodeficiencies rapidly succumb to virus infections. Even individuals with weakened immunity, such as the very young whose immune system is still immature, the elderly undergoing immunosenescence, or pregnant women whose immune system is transiently suppressed, show markedly increased susceptibility to many viruses.

Immune responses to viruses can roughly be divided into four stages. At first, the immune system has to recognize the threat, then an immediate early response is mounted by cells of the innate immune system, which is followed a few days later by a response from the adaptive immune system. Once the virus is eliminated, the immune response contracts and adaptive immunity enters a stage of immunologic memory. Memory T and B cells, upon reexposure to the same pathogen, mount a response that is more potent and comes up faster than a primary response. In cases where virus persists, the acute phase of the immune response is followed by a chronic immune response.

Early Recognition of a Virus

Viruses like other microbes carry so-called pathogen-associated molecular patterns (PAMPs) that are recognized by pattern recognition receptors (PRRs) expressed on many cell types including cells of the innate and adaptive immune system.[43] This recognition system is not as specific as the antigen-recognition receptors of T and B cells, but rather it responds to motifs that are commonly found on pathogens but not within mammals or it identifies molecules present in the wrong compartment within the cell. PRRs can be subdivided into four main types (ie, toll-like receptors [TLRs], retinoic acid inducible gene [RIG]-I-like receptors, nucleotide oligomerization domain [NOD]-like receptors [NLRs], and the interferon-inducible p200 family member absent in melanoma 2).

Ten TLRs (TLR1-10) have been defined in humans and 9 in mice.[44] Some TLRs are widely expressed on many different cell types such as TLR1 or 4, while others are expressed mainly on cells of the immune system such as TLR5, antigen-presenting cells (TLR8), or subsets of antigen-presenting cells, such as TLR7 and TLR9, which are primarily expressed in plasmacytoid DCs. Expression patterns of TLRs in humans do not always mirror those in mice. Expression levels of most of the virus-sensing TLRs are upregulated by inflammatory cytokines mainly interferon (IFN)-γ but for TLR3 that is modulated upon cell differentiation. Viruses are sensed by five TLRs. TLR4, which is best known for its response to lipopolysaccharide, also reacts to the fusion protein of RSV[45] and to a surface glycoprotein of Ebola virus.[46] TLR3 senses double-stranded RNA, TLR9 senses viral and bacterial CpG sequences, and TLR7 (in humans only) and TLR8 (in both humans and mice) reacts to ssRNA. It was initially debated if indeed TLRs directly recognized their PAMP or became instead activated by an intermediate host cell protein. More recent evidence has shown direct binding between TRLs and their ligands. TLR4, which can recognize viral surface proteins, is expressed on the cell membrane where an encounter with such an antigen is most likely. TLR3, 7/8, and 9 are within endosomes where many viruses uncoat, which in turn leads to

exposure of their genomes.

Viruses such as herpesviruses,[47] West Nile virus,[48] or influenza virus[49] signal through TLR3; RSV[50] and Ebola virus[46] can signal through TLR4; influenza virus,[51] HIV-1,[52]

and herpesviruses[53] can signal through TLR7 or 8; DNA viruses such as herpesviruses signal through TLR9.[54]

All TLRs carry an intracellular toll-IL-1 receptor-resistance (TIR) domain, which interacts with TIR domains on intracellular adaptor molecules. TLRs, with the exception of TLR3, signal through myeloid differentiation primary response gene (MyD)88, which in turn interacts with interleukin-1 receptor associated kinases (IRAKs)1, 2, and 4, leading to activation of tumor necrosis factor receptor -associated factor (TRAF)6 and upon additional steps to activation of NF-κB, mitogen-activated protein (MAP) kinases, and Jun-terminal kinases (JNKs). TLR3 signals through TIR-domain-containing adapter-inducing interferon-β (TRIF), which binds to TANK-binding kinase 1 (TBK1), thus activating interferon regulatory factor (IRF)3. In addition, TRIF interacts with receptor-interacting protein 1, which can activate NF-κB. TLR4, in addition to signaling through MyD88, can also bind the TRIF-related adaptor molecule, which recruits TRIF, allowing for signaling to IRF3. Activation of IRF3 results in production of type I IFN, whereas activation of NF-κB induces production of a number of proinflammatory cytokines, such as interleukin (IL)-6, tumor necrosis factor (TNF)-α, and IL-12 (Fig. 39.1).

Deficiencies in TLRs can change an individual's susceptibility to viral infections. For example, TLR3 deficiency in humans is associated with increased susceptibility to HSV-1 infections,[47] whereas mice that lack TLR3 are more resistant to West Nile virus.[55] West Nile virus triggers TLR3, and the resulting cytokine response opens the blood-brain barrier, which allows the virus to establish an infection within the central nervous system; in absence of TLR3, the virus remains excluded from the brain.

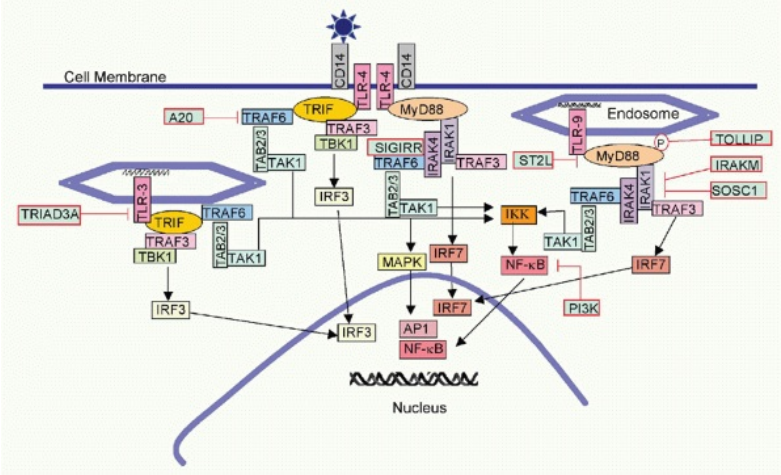

FIG. 39.1. Toll-like Receptor Signaling Pathways.

TLR signaling and the resulting production of cytokines can be extremely toxic. TLR signaling is therefore tightly regulated.[56] Some negative regulators target specific TLRs while others affect common downstream adaptor molecules. Regulators that affect TLRs, which react to viruses, include IRAKM, an IRAK homolog that inhibits IRAK1 and blocks TLR4 and 9, suppressor of cytokine signaling 1, which also suppresses IRAK. Others include phosphoinositide 3-kinase (PI3K), a key regulator of T-cell differentiation, which inhibits JNK and NF-κB functions, toll-interacting protein, which phosphorylates IRAK1, A20 which deubiquitylates TRAF6 and thus affects TLR3, 4, and 9, ST2L which sequesters MyD88,

single immunoglobulin (Ig) IL-1R-related molecule, which binds to TRAF6 and IRAK and TRIAD3A, and E3 ubiquitin-protein ligase, which initiates degradation of TLRs (see Fig. 39.1).

Some viruses neither carry PAMPs on their surface for recognition by membrane-bound TLRs nor enter cells through endosomes, and their genomes thus fail to become accessible for recognition by TLRs. Such viruses can be recognized by RIG-I-like receptors, which are located in the cytoplasm.[57,58] RIG-I-like receptors are RNA helicases, which respond to ss or dsRNA. Three RIG-I-like receptors

have been identified to data (ie, RIG-I, melanoma differentiation-associated gene 5 [Mda5], and LGP2). RIG-I and Mda5 carry N-terminal caspase activation and recruitment domain (CARD)-like regions, which are involved in downstream signaling and C-terminal RNA helicase domains, which bind RNA and can distinguish between viral and cellular RNA species. LPG2 lacks the CARD domain and is assumed to negatively regulate RNA virus-induced inflammatory responses by blocking binding of RNA to RIG-I. RIG-I recognizes a number of ssRNA viruses such as para- and orthomyxoviruses,[59] rotavirus,[60] filoviruses,[61] and flaviviruses,[62] while Mda5 recognizes picornaviruses.[63] RIG-I and Mda5 signaling involves binding of their C-terminal CARD domains to the CARD domain on IPS-1, which then through kinases receptor interacting protein 1 or Fasassociated protein with death domain activates NF-κB; they also activate IRF3 and IRF7 through TRAF3/TBK1, which results in production of IFNs and other proinflammatory cytokines (Fig. 39.2).

NLRs are a very large family of PRRs that respond to viral RNA in the cytoplasm.[64,65] They contain N-terminal domains for protein-protein interactions such as CARD, pyrin or inhibitor of apoptosis domains, NOD domains for nucleotide binding, and C-terminal leucin-rich repeat domains. NLRs are subdivided according to their N-termini into CARD (CIITA, NOD1, 2, NLRC3-5), pyrin domain (PYD, NLRO1-14), or pyrin or inhibitor of apoptosis domain (NAIP) members. Most NLRs activate cytokine responses, although some are inhibitory and dampen innate immune responses. To give some examples of the specificity of NLRs, NOD-2 senses ssRNA and interacts with paramyxoviruses and myxoviruses.[66] NLRC5 interacts with Poly(I:C) and responds to some paramyxoviruses and herpesviruses.[67,68]NLRX1, an inhibitory NLR, signals upon recognition of Sendai or Sindbis virus and blocks activating signals through RIG-1 like helicases.[69] Signaling pathways have not yet been fully characterized for NLRs. NOD-1 and -2, the best known NLRs, bind receptor-interacting serine-threonine kinase 2 resulting in NF-κB and MAP kinase signaling. They also induce autophagy and activate the mitochondrial antiviral signaling protein for induction of type I IFN. Several NLR members containing CARD or PYD domains can assemble into inflammasomes.

Inflammasomes are multiprotein complexes that recruit and activate inflammatory caspases.[70] Inflammasomes include PRRs and, as such, are divided into NLRP3 inflammasomes, RIG-I inflammasomes, and absent in melanoma 2 inflammasomes. In these complexes, the PRR activates caspase I through an adaptor, which cleaves the immature forms of IL-1β and IL-18 resulting in biologically active cytokines. NLRP3 inflammasomes were shown to react with influenza virus, rhabdoviruses, and picornaviruses.[71,72] Viral RNA can directly activate the caspase activities. The M2 protein of influenza virus, which has ion channel activity, localizes to the trans-Golgi network and reduces the H+ content; the acidity of the Golgi then results in NLRP3 activation.[73] Absent in melanoma 2 inflammasomes recognize DNA within the cytoplasm and, as such, play a role in responses to DNA viruses (eg, poxviruses and herpesviruses).[74]

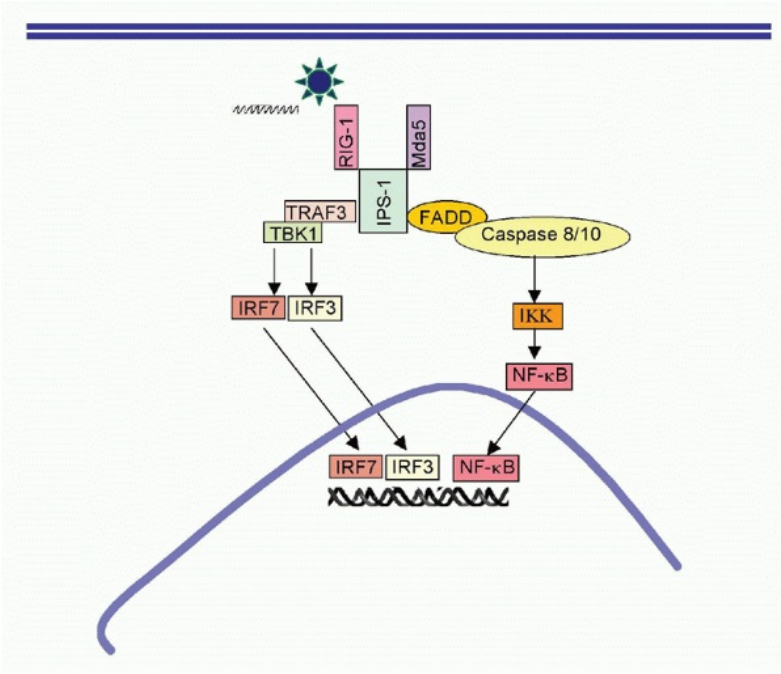

FIG. 39.2. Signaling through Retinoic Acid-Inducible Gene I Receptors.

The Early Inflammatory Response: Cytokines and Chemokines

Interaction of a PRR with a PAMP initiates a cellular response. Signaling through most of the PRRs results in activation of NF-κB. In resting cells, NF-κB is retained in the cytoplasm through binding to IκB. Upon activation of the IκB kinase (IKK), IκB becomes phosphorylated, then ubiquinated and finally degraded. This in turn releases NF-κB and allows for its entry into the nucleus where it initiates gene expression. NF-κB thus does not require de novo synthesis, which accelerates its activity. A very large number of genes have NF-κB binding sites including genes involved in antigen processing and presentation, lymphocyte effector functions and motility, and cell metabolism. Cytokine genes induced by NF-κB include those for type I IFN, IL-1A and B, IL-2, IL-6, IL-9, IL-11, IL-15, TNF-α, colony stimulating factor (CSF)1 to 3, lymphotoxin B, and the chemokine genes IL-8, CCL2, 5, 11, 15, and CXCL5. In addition, several cytokine-inducing transcription factors, such as IRF1, 2, and 4, are produced in response to NF-κB. IRF3 activated by TLR3, TLR4, or cytosolic PRR signaling is a transcription factor that promotes production of type I IFN and the chemokine RANTES. The MAP kinase activated AP-1 transcription factors also have binding sites specific for regulatory sequences of multiple genes. Most pertinent for early immune responses is probably induction of signal transducers and activators of transcription (Stat)1 and 3, which upon formation of homo- or heterodimers bind to the IFN-gamma activated sequences. Thousands of such motifs can be found in the human genome, and their products affect most cell functions.

Most cells can produce cytokines and chemokines, although, during the initial phase of an immune response, many are synthesized by cells of the innate immune system. The early cytokines have a multitude of functions, which are in part antiviral and in part designed to promote further activation of immune responses. Type I IFNs, which can be produced at capacious amounts by plasmacytoid DCs, bind to the IFN-α receptor. This causes activation of tyrosine kinase (Tyk)2 and Janus kinase (Jak)1, which in turn causes tyrosine phosphorylation and then nuclear translocation of Stat1 and Stat2 proteins. In addition, type I IFN has strong antiviral activity[75] and has been licensed for treatment of chronic infections with HBV[76] and HCV[77] and for treatment of HPV-associated genital warts (*Condyloma*

acuminata).[78]

IFN-1s downregulate viral promoters. They dampen expression of viral receptors and thus reduce viral entry. They induce expression of the dsRNA-activated protein kinase PKR, which phosphorylates translation initiation factor 2α (eIF2α) causing inhibition of translation of both viral and cellular transcripts. IFN-1s also trigger expression of 2′5′-oligoadenylsynthases that upon binding dsRNA generate AMP-oligomers, which activate RNAseL to cleave both cellular and viral RNAs. IFN-1s induce dsRNA kinase, which inhibits production of viral progeny. IFN-1s lead to synthesis of MxA.[79] This protein binds to the nuclear membrane and inhibits trafficking of viral nuclear capsids. In addition, MxA can bind and inhibit the RNA polymerase of influenza virus. APO-Bec3G and F are IFN-induced deoxycytidine deaminases that interfere with the replication of retroviruses.[80]

In addition to their antiviral activity, IFNs and other early cytokines play a dominant role in initiating both innate and adaptive immunity by causing activation of macrophages, natural killer cells, and DCs. The early cytokines promote proliferation and differentiation of lymphocytes, granulocytes, and antigen-presenting cells, whereas chemokines recruit such cells. IL-6 should be noted, as this cytokine, due to its immunostimulatory effects on B cells, has been implicated in the pathobiology of EBV-associated lymphoproliferative disorders and HHV-8-associated lymphomas in patients with acquired immunodeficiency syndrome.[81,82]

The apparent redundancy of some of the molecules that contribute to the initial inflammatory response is remarkable. Viruses commonly trigger multiple PRRs, some of which are expressed on or in the same cells, while other are carried by different subsets of cells. For example, influenza viruses thus far are known to signal through TLR3, 7/8, NOD-2, RIG-1, and NLPR3 inflammasomes. Most of the PRRs in the end initiate transcription through NF-κB or through members of the IRF family. Nevertheless, the immune response that is very much guided by the initial inflammatory reaction is unique for each virus, suggesting a finely orchestrated series of events during which the type, strength, and location of PRR signaling elicits for each virus a special mixture of cytokines and chemokines that results in signature immune responses. This is exemplified by recent studies with a vaccine, in which antigen-containing nanoparticles were mixed with ligands for TLR4 and 7.[83] This vaccine did not induce a strong effector cell response but drove differentiation of T cells toward memory and B cells toward long-lived plasma or memory cells. Although the slow release of antigens from the nanoparticles may have contributed to this, both TLR ligands were needed to maximize the vaccine's immunogenicty.

Cells of the Innate Immune System

Cells of the innate immune system, which include DCs, neutrophils, eosinophils, basophils, mast cells, γ/δ T cells, macrophages, and natural killer cells, provide a first layer of defense against virus infections and promote activation of adaptive immunity. Unlike T and B cells, which carry antigen-specific receptors, cells of the innate immune system are, as described previously, activated by PRRs. They act rapidly without undergoing the massive proliferation of T and B cells and then, in general, with the potential exception of natural killer cells,[84] fail to establish long-lasting memory.

Granulocytes: Neutrophils, Basophils, Eosinophils, and Mast Cells

Granulocytes play major roles in controlling bacterial and parasitic infections but also influence viral infections. Neutrophils, which are abundant and contribute to more than 50% of circulating leukocytes, release hydrogen peroxide, free oxygen radicals, and hypochlorite, and have been described to limit replication of HSV-1.[85] They may also

contribute to the immunopathology, such as of pulmonary RSV infections.[86]

Basophils release histamine, which increases blood vessel permeability and thus allows for

lymphocyte trafficking into inflamed tissues. Basophils are recruited and activated by a number of viruses, such as influenza viruses or RSV.[87]

Eosinophils, which accumulate in lungs during RSV infection,[86] release enzymes, such as ribonuclease, deoxyribonucleases, lipase, as well as plasminogen and peroxidase.

Mast cells release heparin, histamine, and chemokines, and have been reported to respond to Dengue virus infections.[88]

Gamma/delta T cells

T cells that carry the γ/δ T-cell receptor (TCR) exhibit characteristics of both innate and adaptive immune cells. They are mainly located in the gut and skin but can also be found at low frequencies in blood and lymphatic tissues. Although they are educated in the thymus, their receptor recognizes pathogen patterns or cellular stress molecules independent of major histocompatibility complex (MHC) molecules, and they can expand without the intricate antigen presentation pathways that dictate differentiation of α/β T cells. γ/δ T cells, which evolutionary predate α/β T cells, can secrete cytokines such as IFN-γ, IL-4, or IL-17,[89] chemokines such as macrophage inflammatory protein (MIP)-1α; MIP-1β; regulated upon activation, normal T cell expressed and secreted; lymphotoxin (LT)[90]; and lytic enzymes (ie, perforin and serine esterases for target cell lysis). These T cells play diverse roles in virus infections. To name a few, they promote Th1 responses following infection with coxsackievirus B3[91]; they can kill cells infected with HSV-1[92]; they have been described to lyse cells infected with influenza virus[93]; and they provide resistance to humans against HIV-1 infections[94] and to mice against infections with West Nile virus[95] or vaccinia virus.[96]

Macrophages

Monocytes upon activation by proinflammatory cytokines, specifically IL-6 and macrophage-CSF (M-CSF), differentiate into macrophages. These cells, as their name “large eaters” implies, are phagocytic. Phagocytosis is a specialized form of endocytosis during which the engulfed particles are transported to lysosomes where they are degraded by a toxic and acidic soup composed of oxygen radicals, nitric oxide, proteases, and defensins. Macrophages, in addition, release cytokines, such as IL-1, 6, 10, and 12, type I IFN, and TNF-α, as well as chemokines, such as MIP-2, IL-8, and cytokine-induced neutrophil chemoattractant-1. Some viruses replicate in macrophages (eg, HIV-1, influenza viruses, rhinoviruses, and Ebola viruses).

Dendritic Cells

A crucial role of DCs is their ability to present antigen to naïve T cells. A few years ago, DCs were divided into myeloid DCs, plasmacytoid DCs, and lymphoid DCs, although it is now accepted that lymphoid DCs do not belong to a separate lineage.

Viral antigens are mainly presented by myeloid DCs. Myeloid DCs, which differentiate from Lin-CD115+Flt3+ $CD117^{lo}$ precursors, can further be divided into subsets according to phenotypic markers, functions, and anatomic site of origin.[97]

Three subsets of myeloid DCs have been identified in human skin. Langerhans cells, which are $CD1^{hi}$ CD14- CD207+, are located in the epidermis. They look and act like DCs, and they are originally derived from bone marrow precursors but unlike other DC subsets, numbers of Langerhans cells are maintained by local proliferation. They only express discreet amounts of TLRs, induce CD8+ T cell responses in vitro and trigger proliferation of naïve CD4+ T cells. Interestingly, CD4+ T cells induced by Langerhans cells do not produce the typical Th1, Th2, or Th17 cytokines but rather produce IL-22,[98] which causes skin inflammation as well as wound healing through induction of keratinocyte proliferation.

The dermal layer of skin contains CD14+ CD11b^{hi} DCs, which differentiate from CD34+ precursors and express TLR 1, 2, 4, 5, 6, 8, and 10. They produce a multitude of proinflammatory cytokines including IL-6 and IL-12, which allows them to induce differentiation of naïve B cells into plasma cells. They also prime CD4+ T cells that can promote B-cell differentiation. The other DC subset in the dermis is CD103+CD11b^{low}, which can cross-present antigen and drive proliferation and differentiation of CD4+ T cells into Th1 cells.

Mouse spleen contains two subsets: CD8+CD205+ DCs and CD8+33D1+CD11b+ DCs; whereas the former can cross-present antigen in association with MHC class I and thus drive activation of CD8+ T cells, the latter is more efficient at processing antigen for MHC class II presentation for CD4+ T cell activation.

Lymph nodes also contain these two subsets and in addition migratory DCs such as Langerhans cells, which transport antigen from other locations to lymph nodes. Lymphatic tissues in addition contain follicular DCs.[99] These cells are not derived from hematopoietic progenitors but are of mesenchymal origin. They are an integral part of B-cell follicles, where they present antigen to naïve B cells and maintain long-lived plasma cell responses by initially capturing and then slowly release antigen-antibody complexes.

The intestine has three populations of DCs. CD103+ CD1b^{low} DCs can be found in Peyer patches and CD103+ CD11b^{hi} and CD103-CD11b^{hi} DCs in the lamina propria. The latter subset is known to transport antigen from the intestine to draining lymph nodes. Other tissues such as lung, kidney, and spleen contain similar subsets.

It was initially thought the DCs are terminally differentiated, nondividing cells. Recent studies have shown that DCs can divide and that this division is driven by fms-related tyrosine kinase (Flt)-3, which is also a key factor for DCs differentiation from bone marrow precursors.[97]

Plasmacytoid DCs were originally though to originate from lymphoid progenitors as they share many of the characteristics of lymphocytes: they lack the typical dendrites of other DC subsets, but look like lymphocytes; they express B-cell markers, such as B220 and T cell markers (eg, CD4), as well as transcription factors involved in lymphocyte development, such as terminal deoxynucleotidyltransferase, recombination activating genes 1 and 2, Ig supergene family members, and the pre-T-cell antigen receptor alpha chain. But plasmacytoid DCs also have characteristics of myeloid

DCs and can even differentiate into myeloid DCs.[100] It is assumed that plasmacytoid DCs can arise from both lymphoid and myeloid bone marrow precursors, although the latter probably provide the dominant source. Plasmacytoid DCs, which can be distinguished from myeloid DCs by expression of plasmacytoid DC antigen-1 (CD317) in mouse or blood DC antigen-2 (CD303) or -4 (CD304) in human, circulate in blood and are present in lymphatic tissues. Unlike myeloid DCs, they express CD62L and CCR7, which allows them to cross high-endothelial venules to enter T-cell-rich areas in lymphatic tissues. While myeloid DCs take up antigen to present it to cells of the adaptive immune system, plasmacytoid DCs do not phagocytose antigen. Their primary role might be regulatory by producing cytokines most notably type I IFNs, which assist maturation of myeloid DCs.

DCs present in tissues are immature. They take up antigen, but they do not produce cytokines, nor are they able to present antigen efficiently to naïve lymphocytes. Their maturation starts either through interactions of a PRR with a PAMP, through cytokines, ligation of CD40, receptor activator of NF-κB (RANK) or even, as has been observed in vitro, vigorous shaking.[101] DC maturation is associated with marked changes in their gene expression profiles[102] and their biological functions. Maturing DCs stop phagocytosis and endocytosis. They start secreting chemokines and thus initiate an inflammatory response at the site of infection. They upregulate expression of CCR7 and migrate from tissue to the T-

cell-rich zones of draining lymph nodes. They increase synthesis of molecules that are involved in antigen processing and presentation, and translocate MHC class II molecules that are preformed and stored within intracellular vesicles to the cell surface. They also, in a presumably orchestrated but yet ill-defined pattern, start to increase expression of cell surface molecules that regulate immune responses (Fig. 39.3). Such molecules include CD80, CD86, CD40, inducible T-cell costimulator (ICOS) ligand, ligands 1 and 2 for programmed death 1 (PDL1, PDL2), HVEM, and others that are less well defined thus far. Interactions of T and B cells not just with their cognate antigen, but also with these ligands, is crucial for the induction of an adaptive immune response that is of sufficient magnitude to combat the threat without being overwhelming and thus causing undue damage. These interactions are also important to determine the ultimate differentiation fate of responding T and B cells.

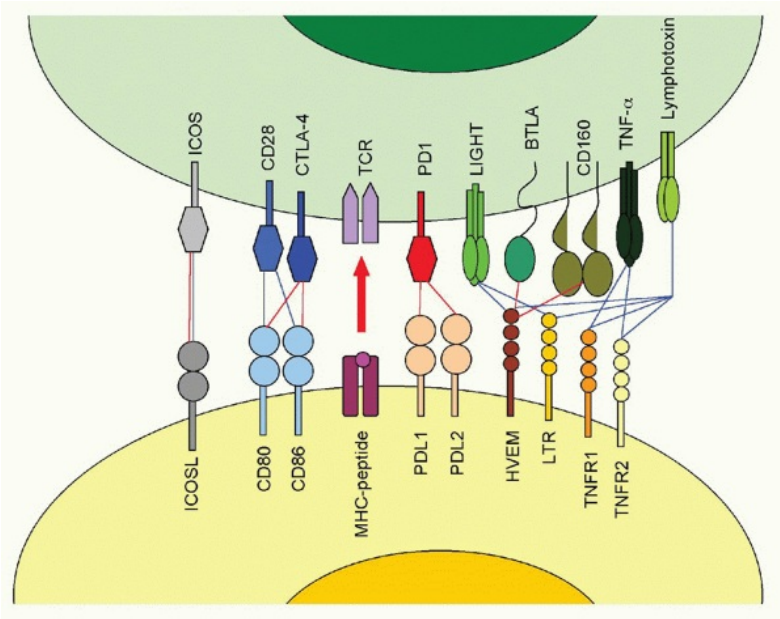

FIG. 39.3. Costimulatory (*blue lines*) and coinhibitory (*red lines*) T cell (*green*)-dendritic cell (*yellow*) interactions.

Signaling through CD40, which is expressed at low levels on immature DCs, facilitates full maturation of DCs; its expression increases upon activation of TLR pathways. CD40 is upregulated on myeloid DCs upon interactions with TLR4 agonists[103] and on both plasmacytoid and myeloid DCs upon TLR7 and 9 signaling.[104] The CD40 ligand (CD40L) is induced upon CD40 stimulation.[105] Ligation of CD40 causes signaling through TRAF6, which results in activation of MAP and Jun kinases and in production of CD86 and cytokines, such as IL-6 and IL-12. CD40 ligation also results in activation of NF-κB and in many aspects seems to complement signaling through TLRs.[106]

Ligation of CD40L upregulates expression of RANK (also called TNF-related activation-induced cytokine [TRANCE]

receptor), which is a member of the TNF-receptor family. RANK interacts with RANK ligand (also called TRANCE), which is induced on T cells upon their TCR ligation. Signaling through TRANCE induces B-cell lymphoma-extra large expression, which in turn promotes DC survival.[107]

Signaling between DCs and cells of the adaptive immune system involves a number of B7

family members of costimulatory molecules that are expressed by mature DCs.[108] CD80 and CD86 on DCs interact with the activating CD28 and inhibitory cytotoxic T-lymphocyte antigen (CTLA)-4 molecules on T cells. Ligation of CD28 activates Akt/PI3K and thus mammalian target of rapamycin (mTOR) while CTLA-4 inhibits this pathway. Activation of these pathways is needed to adjust the increased bioenergetic needs of differentiating lymphocytes by augmenting glucose uptake and glycolysis through the Krebs cycle and inhibiting forkhead box O, thus allowing for cell cycle entry. Another means by which CD80 and CD86 may influence immune responses is through reverse signaling into B7-expressing DCs.[109]

The ICOS ligand pathway has some overlapping functions with CD28. Ligation of ICOS on T and B cells upregulates PI3K and thereby influences cellular metabolism.[110] ICOS through PI3k/Akt and Rho family members also affects lymphocyte polarization and migration.[111] ICOS also plays a role in controlling T-helper-cell development and function.[112] ICOS also plays a critical role in the development of both Th17 cells and follicular T-helper cells by inducing the transcription factor c-Maf and the cytokine IL-21.[113,114] Patients with a defect in ICOS expression exhibit a profound defect in B-cell maturation and Ig isotype switching.[115]

PDL1 and PDL2 are coinhibitors expressed on DCs and some other cells that interact with PD1 expressed on T cells, B cells, macrophages, and some types of DCs. PD1 ligation induces cell cycle arrest.[116] PDL1 regulates development, maintenance, and function of regulatory T cells (T_{reg}s) through downregulation of Akt and mTOR, and upregulation of phosphatase and tensin homolog.[117] PD1 expressed on CD4+ T cells regulates selection and survival of PDL2+ B cells in germinal centers, and affects the magnitude and the quality of the plasma cell response.[118]

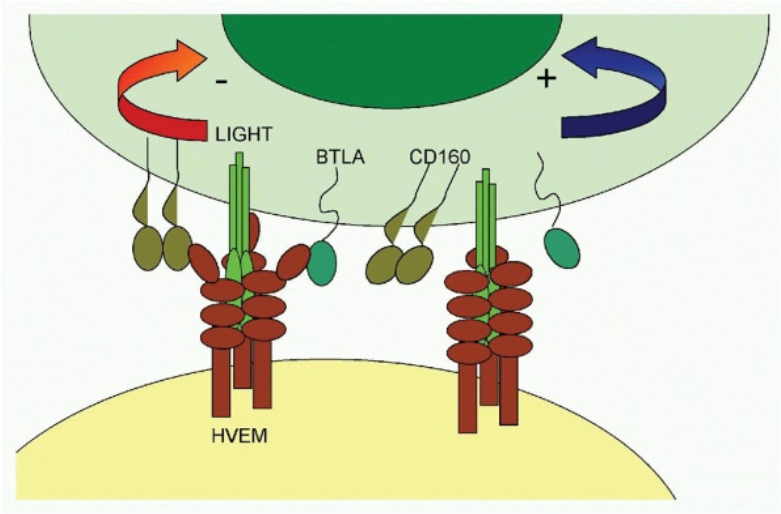

FIG. 39.4. Stimulatory (+) and Inhibitory (−) Signals through Herpes Virus Mediator Interactions.

Another inhibitory pathway involves the BTLA[13] expressed by B and T cells. BTLA provides inhibitory signals upon binding to HVEM expressed on DCs. HVEM also interacts with glycoprotein gD of herpes virus and with the immunoinhibitory receptor CD160.[13,119] Distinct regions of HVEM interact with two immunoactivators of the TNF family members (ie, LIGHT and lymphotoxin-A) (Fig. 39.4). BTLA, unlike other immunoinhibitory molecules, is expressed on naïve T cells, whereas CD160 is induced upon their activation. Blockade of the HVEM-BTLA/CD160 pathways during T-cell stimulation results in enhanced primary T-cell

responses both in young and aged mice.[120,121,122] Signaling pathways initiated by BTLA ligation remain poorly understood. It is known thus far that the cytoplasmic tail of BTLA binds growth factor receptor-bound protein (Grb)-2, which in turn recruits p85 of PI3K.[123] HVEM is also expressed on T_{reg}s, which through ligation of BTLA suppress effector T cells.[124] Another inhibitory molecule on DCs is CD48, which interacts with 2B4 on T and natural killer cells.[125] A number of additional inhibitory molecules have been identified on T and B cells and include LAG3, PIR-B, GP49, KLRG1, NKG2A, and NKG2D,[125,126,127,128] but their matching ligands remain elusive.

Through the expression of costimulatory and coinhibitory receptors, DCs not only activate but also terminate adaptive immune responses. DCs thus play a dominant role in maintaining tolerance through a number of pathways. Thymic DCs negatively select for T cells with receptors that have high reactivity to self-proteins, and they promote thymic T_{reg} selection. Presentation of antigen by immature DCs induces T-cell anergy and promotes the activity of T_{reg}. Immature as well as mature CD123+ DCs can express indoleamine dioxygenase (IDO),[129] which catalyzes the degradation of the L-tryptophan, an amino acid that is

essential for T cells, into N-formylkynurenine. Production of IDO is initiated by CD80/CTLA-4 interactions, TGF-β, or IL-10. IDO inhibits generation of effector T cells but instead promotes activation of T_{reg}s.

DCs influence the homing behavior of T cells. DCs within the intestine activate T cells that preferentially home to gut-associated lymphoid tissues. Such homing is mediated by expression of CCR9 and α4β7 on T cells. Skin or lamina propria-derived DCs, unlike DCs in the spleen or in central lymph nodes, express the integrin chain of CD103, which induces T cells with gut or skin homing preference.[130]

Natural Killer Cells

Although it was initially assumed that natural killer cells originate from bone-marrow precursors, it is now understood that most of them develop in lymph nodes and tonsils. Natural killer cells express TLR2, 3, 4, and 9, but not 7 or 8, and can be activated by PAMPs. They can also be activated by proinflammatory cytokines and chemokines such as IFNs, IL-12, IL-15, IL-18, IL-2, and CCL5.

Numerous activating and inhibiting receptors, some of which are constitutively expressed, while others are induced, regulate effector functions of natural killer cells. Natural killer cell receptors belong to the family of killer cell Iglike receptors in humans or C-type lectin receptors, such as CD94/NKGD2 and Ly49, in mice.[127,128,129] CD244, also known as 2B4, can also serve as a natural killer receptor. Receptors encoded by the same gene families can be activating or inhibitory (Table 39.4).

TABLE 39.4 Natural Killer Cell Receptors

Gene	Protein	Superfamily	Ligand	Function
KIR2DL1	CD158a	Ig superfamily	HLA-A, -Bw, Cw, G	Inhibitory

SLAMF4	CD244		CD48

CD, cluster of differentiation; HLA, human leukocyte antigen; Ig, immunoglobulin; MHC, major histocompatibility complex; MIC, monolayer immune complex; NTBA, NK-T-B antigen; SLAM, signaling lymphocytic activation molecule.

All of the inhibitory natural killer cell receptors carry an immunoreceptor tyrosine-based inhibitory motif in the cytoplasm, which upon phosphorylation recruits the lipid phosphatase SHIP-1 or the tyrosine phosphatases SHP-1 or SHP-2. This in turn results in dephosphorylation of proteins bound to activating natural killer cell receptors. Activating receptors thus largely function through lack of signaling through inhibitory receptors. Activating receptors belong to the same families. The cytoplasmic tails of activating receptors are shorter than those of inhibitory receptors, and they do not carry an immunoreceptor tyrosine-based inhibitory motif. Signaling through combinations of activating receptors is needed to elicit natural killer cell functions. The inhibitory natural killer cell receptors respond to a variety of ligands, including classical MHC class I molecules, nonclassical MHC molecules (Qa-1 in mouse and HLA-E in human), adhesion molecules, cadherins, lectins, CD markers (CD44, 99, and 66), and sugars such as a-2,8-linked disialic acid. Activating receptors respond to some of the same ligands as inhibitory receptors, such as classical and nonclassical MHC determinants. Some also respond to Igs, CD112, CD155, themselves (ie, NTB-A and CD319 encoded by Slam6/7),[130] or C-type lectins, such as AICL. They also recognize viral proteins or stress proteins released by cells in response to an infection. Ly49H, an activating receptor encoded by Kira8,

recognizes the m157 gene product of mouse CMV, while NKp46 recognizes influenza virus HA in humans.[131] NKG2D recognizes the stress-induced MHC class I-related MICA and MICB proteins released in response to CMV infection.[132]

Some activating receptors contain immunoreceptor tyrosine-based activation motifs, which through Syk result in activation of the Ras/Raf/Erk and PI3K/Akt pathways leading to cytokine production and degranulation.[133] Others, such as NKG2D, signal through DAP10, a PI3K adaptor protein that contains a small Tyr-Ile-Asn-Met (YINM) motif, which binds either PI3K or Grb2.[134] Ligation of both is needed for cytolysis of NKG2D targets. Interestingly, IL-15 also promotes NKG2D-dependent lysis by causing Jak3-mediated phosphorylation of DAP10.[135] Signaling through CD244, a signaling lymphocyte activation molecule (SLAM) family member, which depending on circumstances can be activating or inhibitory, involves an immunoreceptor tyrosine-based switch motif, which upon recruitment of SLAM-associated protein causes activation through PI3K, while recruitment of EAT2 or ERT may cause inhibition.[136]

Natural killer cells contribute to early viral control through direct lysis of virus-infected cells and through the production of cytokines such as IFN-γ, IL-10, IL-18, TNF-α, MIP-1α, and MIP-β. Interestingly, activated natural killer cells can not only lyse virus-infected cells, but they can also kill immature DCs.[137] It is assumes that this type of natural killer cell-mediated DC editing prevents presentation of viral antigens by not yet fully matured and hence tolerogenic DCs to T cell. Natural killer cells are clearly crucial for the early defense again viral infections and their lack has been shown to result in enhanced susceptibility to infections with a number of different viruses, such as Sendai virus, influenza virus, or CMV, a finding that was confirmed in human patients with natural killer cell deficiency.[138,139]

Recent publications have shown that natural killer cells upon stimulation with antigens such a murine CMV undergo expansion, persist for months, and mount a recall response upon reexposure with the same antigen, suggesting that they cells can differentiate into memory cells, a function that thus far had been reserved for cells of the adaptive immune system.[140,141]

Natural Killer T Cells

Natural killer T (NKT) cells are a subset of natural killer cells that share characteristics of T and natural killer cells. NKT cells referred to as type 1 or iNKT cells express an invariant TCR that recognizes glycolipids presented by CD1d.[142] Other NKT cells, referred to as type 2 NKT cells express a more variant TCR that does not recognize CD1d-associated ligands. NKT cells express T-cell lineage markers and, for example, in humans, iNKT cells can be CD4+, CD8αβ+, or CD8αα+, but they also express natural killer cell receptors. NKT cells release cytokines, mainly IL-4 and IFN-γ, that affect the differentiation fate of CD4+ T cells, and they can be lytic through secretion of perforin and granzyme or through the Fas/FasL pathway. Upon activation, NKT cells upregulate CD40L and can thus contribute to DC maturation through CD40. In turn, IL-12 secreted by DCs can drive activation of NKT cells. NKT cells are involved in resistance to a number of viruses including HSV-1 and -2, CMV, HIV-1, HBV, HCV, lymphocytic choriomeningitis virus (LCMV), and encephalomyocarditis virus,[142] but they may also contribute to virus-associated immunopathology, such as upon infections with RSV.[143]

ANTIGEN-SPECIFIC IMMUNE RESPONSES

The innate immune system, which can cause extensive symptoms or even death through massive release of cytokines, is our main defense system during the early phase of a viral infection until cells of the adaptive immune system (ie, T and B cells) differentiate into effector cells. This takes time and in a primary infection requires at least 4 to 5 days. Antigen-driven activation of T and B cells depends on signals from the innate immune system and is very much shaped in its flavor by characteristics of the initial inflammatory reaction and the antigen-presenting cells. Although cells of the adaptive immune system can express PRRs, their activation is driven by recognition of antigens with exquisitely specific, clonally expressed receptors, which in the case of B cells have a virtually unlimited repertoire. Prior to an infection, cells with a specific receptor for a given pathogen are only present at very low numbers. Therefore, upon activation, B and T cells first proliferate extensively with an approximate doubling time of 4 to 6 hours to accumulate to numbers suited to eliminate viruses that, if unchecked, can replicate by far more efficiently than lymphocytes.

T Cells

T cells based on surface markers are divided into CD4+ T cells, which have primarily regulatory functions, and CD8+ T cells, which have mainly effector functions. T cells express an antigen-specific receptor that unlike B-cell receptors (BCRs) does not recognize soluble antigen, but rather peptides derived from degraded viral proteins that associate with MHC molecules. This ensures that T cells only respond to cell-associated antigens, which makes them uniquely suited to respond to intracellular parasites such as viruses.

Cluster of Differentiation 4+ T Cells

CD4+ T cells can be divided into Th cells, which promote activation of immune responses, and T_{reg} cells, which have inhibitory functions.

Cluster of Differentation 4 + T-Helper Cells: Subsets. CD4+ Th cells are divided into Th1, Th2, Th17, and follicular Th (Tfh) cells[144,145,146] (Fig. 39.5). Th cells originate from a common precursor in the periphery, the naïve CD4 T cell. The inflammatory cytokine milieu during antigen-driven activation dictates its differentiation into any of these subsets. Th1 cells

are induced when antigen activation occurs in presence of IL-12 or IL-18. Naive cells differentiate into Th2 cells in a milieu that contains IL-4. Th17 cells were discovered more recently. Naive cells develop into Th17 cells in presence of transforming growth factor (TGF)-β and IL-6. IL-1β and IL-23 enhance/stabilize their differentiation. Once activated, Th subsets block differentiation of uncommitted naïve cells into other subsets. Th1 cells

prevent Th2 differentiation through IL-12, Th2 cells block Th1 development through IL-4, and Th1 derived IFN-γ and Th2 derived IL-4 both inhibit Th17 formation. Tfh cells are only found in B-cell follicles in spleens, lymph nodes, and Peyer patches, where they are instrumental in germinal center formation by secretion of IL-21 and IL-4.

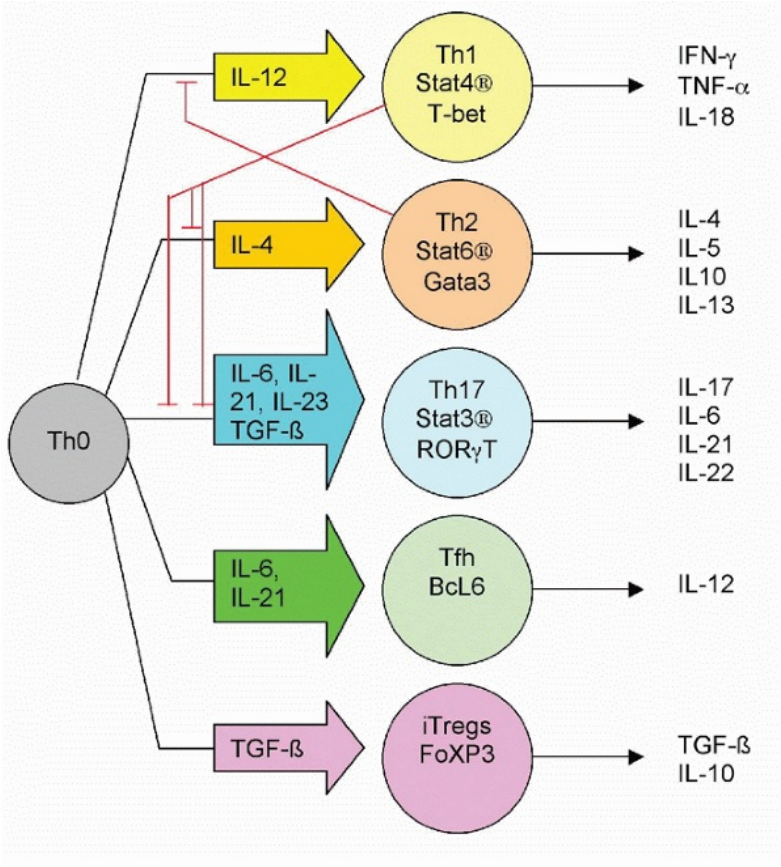

FIG. 39.5. Cluster of differenation 4+ T-helper cells subsets: cytokines driving their induction. Lineage defining transcription factors and effector functions.

Th cell subsets are characterized by lineage defining transcription factors.[147] Th1 cells express T-bet, a T-box transcription factor that controls expression of IFN-γ. Th2 cells express trans-acting T-cell-specific transcription factor (GATA3), which promotes production of IL-4, IL-5, and IL-13. The transcription factors Stat3, the orphan nuclear receptors (ROR) gamma-t, and RORalpha are involved in Th17 differentiation. B-cell lymphoma (Bcl)-6 is required for differentiation of Tfh cells, which are distinguished from other subsets by the expression of CXCR5 that enforces their homing to lymph node follicles. Other Th cell subsets have been suggested, such as Th3 and Th9 cells, but as unique transcription factor signatures have not yet been defined for these proposed subsets, it remains unclear if they indeed represent distinct lineages. It should also be noted that there is a certain degree of plasticity between defined Th subsets; Th1 cells can differentiate into Th2 cells and vice versa, Th17 cells can differentiate into Th1 or Th2 cells and Th1, and Th2 and Th17 cells can turn into T_{reg}s.

Most crucial for control of viral infections are Th1 cells, which are induced by antigen-presenting DCs that upon virus-driven maturation typically produce IL-12. Some viruses produce IL-10 homologs[148] or induce cellular IL-10 mimetics,[149] which support the development of Th2 cells, while suppressing Th1 cell differentiation. Induction of Th17 cells together with Th1 cells was reported in severe influenza A virus infections.[150] Th17 cells are also generated during viral infections and have been reported to promote coxsackie virus-associated myocarditis[151] and persistent infections with Theiler murine encephalomyelitis virus.[152] They have been implicated in promoting liver injury in chronic HBV infections in humans.[153] Tfh cells are presumably crucial for effective antiviral antibody responses, but, thus far rather little is known about their fate during viral infections. It is known that exceptionally strong TCR signaling through high-avidity interaction with MHC class II peptide complexes supports differentiation of naive cells into Thf cells.[154]

Cluster of Differentiation 4 + T-Helper Cells: Antigen Processing and Presentation. CD4+ T cells recognize MHC class II-bound peptides, which originate from pathogens that are broken down by proteolysis in the endosomes.[155] Expression of MHC class II molecules is restricted to macrophages, B cells, and DCs in mice, and in humans is also expressed on CD4+ T cells. Expression of MHC class II on the cell surface increases upon cell activation, in part through translocation of preformed molecules from intracellular compartments to the cell surface, and in part through increased synthesis. MHC class II molecules are heterodimers composed of α and β chains. A number of chaperone proteins ensure transport of MHC class II molecules

to the endosomes. First upon their synthesis, the two MHC class II chains assemble in the endoplasmic reticulum (ER) into a nonameric complex composed of three chains of the α and β molecules and three invariant molecules. The invariant molecules contain a peptide sequence, termed class II linked invariant peptide, that promiscuously binds to the groove of MHC class II α/β chain dimers, thus preventing binding of other peptides. It also contains an ectodomain, which mediates trimerization and interferes with DM/MHC class II binding. The MHC class II-invariant chain complexes are translocated to endosomes/lysosomes, where the invariant chain is degraded by cathepsin S and dissociates from MHC class II molecules, which then bind the DM accessory protein. DM binds close to the peptide groove inducing conformational changes that allow for loading of antigenic polypeptides. Polypeptides that fit poorly are forced to disconnect again through DM-mediated conformational changes, while peptides that fit well are insensitive to DM-mediated dissociation. Long peptides that bind the MHC class II groove are clipped at this stage; the portions of the polypeptide that overhangs the groove are cleaved off by peptidases. The MHC class II-peptide complexes are then transported to the cell surface, where they can be recognized by the TCR of CD4+ T cells.

Cluster of Differentiation 4 + T-Helper Cells: Activation. Naïve CD4+ T cells circulate between blood and secondary lymphoid tissues. Their activation requires presentation of antigen by MHC class II molecules carried by professional antigen-presenting cells, such as mature DCs. Once a CD4+ T cell recognizes its specific antigen, the DC-CD4+ T cell interaction is stabilized through integrins such as ICAM-1 or DC-SIGN on DCs, which bind lymphocyte function-associated antigen (LFA)-1 or ICAM-3 on CD4+ T cells, respectively.[156] Full activation of CD4+ T cells requires then a second signal in form of interactions with costimulatory molecules.[157] In the initial activation of CD4+ T cells, CD80 and CD86, which are both expressed on mature DCs and signal through CD28, provide costimulation. Although costimulation through CD28 is dominant, other molecules, such as CD2, Ox40, ICOS, CD40, or SLAM (CD150) can provide or complement this function. CD2 upon interaction with LFA-3 induces Jun kinases, which in turn results in IL-2 production.[158] Ligation of Ox40, which is expressed 2 to 3 days after T-cell activation, with Ox40L recruits TRAF2 and causes activation of NF-κB, PI3K, and Erk pathways and augments CD4+ T-cell functions, such as

cytokine production, proliferation, and survival at a later stage than CD28-mediated activation and may involve cells other than antigen-presenting DCs.[159] Ox40 has also been implicated to be essential for Tfh development.[160] ICOS has overlapping functions with CD28 and signals through PI3K.[161] It has been reported that myeloid DCs mainly induce CD4+ T cell activation through CD28, while plasmacytoid DCs, which express high levels of ICOS-L, may costimulate through ICOS. CD40L is induced upon CD4+ T-cell activation and upon interaction with CD40 on DCs or B cells promotes CD4+ T-cell proliferation. SLAM, which is also induced upon CD4+ T-cell activation, results in a SLAM-associated protein/proto-oncogene tyrosine-protein kinase (Fyn) signaling cascade, which in turn enhances CD4+ T-cell proliferation and cytokine production.[162]

Upon activation, CD4+ T cells start to produce IL-2. They also increase cell surface expression of CD25, the receptor for IL-2, which promotes their own proliferation. CD4+ T cells do not expand as extensively as CD8+ T cells but they do undergo approximately 8 to 10 cycles following activation.

Cluster of Differentiation 4 + T-Helper Cells: Effector Functions. CD4+ effector cells provide helper functions mainly through the secretion of cytokines and chemokines.[163] All Th cells can produce IL-2, which promotes their own proliferation as well as proliferation of CD8+ T cells and T_{reg}s. The Th1-derived cytokines TNF-α and IFN-γ activate natural killer cells, macrophages, and B cells. They are also essential for activation of CD8+ T cells, although some viruses, such as LCMV, sendai virus, influenza virus, or ectromelia virus (a mouse poxvirus) can induce CD8+ effector T cells without CD4+ T help. Nevertheless, T helper-independent CD8+ T cells are fundamentally defective and fail to differentiate efficiently into memory CD8+ T cells.[164] Th cells can lyse virus-infected target cells that express MHC class II molecules, such as EBV-infected B cells[165] or HSV-1-infected macrophages.[166] Th2 cell secrete cytokines, such as IL-3, IL-4, IL-5, and IL-10, that drive B-cell proliferation and differentiation and activate mast cells and eosinophils. Th17 cells produce IL-17, IL-21, and IL-22 and induce strong inflammatory responses mainly through IL-17-mediated recruitment and activation of neutrophils. Tfh cells, upon initial stimulation through the TCR and CD28 followed by interactions with Ox40, upregulate CXCR5 and home to B-cell follicles, where they assist in B-cell proliferation and differentiation through CD40L interactions and production of cytokines, such as CD21 and IL-4, which promote germinal center formation, class switching, and plasma cell differentiation.

Cluster of Differentiation 4 + T-Helper Cells: Memory Differentiation. Upon removal of antigen, effector CD4+ Th-cell numbers contract over a period of weeks and the remaining antigen-experienced CD4+ T cells differentiate intro long-lived memory cells, which preferentially home to the bone marrow. The overall size of the CD4+ T-cell memory pool depends on signals present during activation such as antigenic load, duration of antigen presentation, and presence and type of costimulators. Transition of CD4+ effector T cells into long-lived CD4+ memory Th cells depends on HVEM-LIGHT interactions.[167] Such interactions do not require classical antigen-presenting cells but can happen between adjacent T cells, which express both HVEM and LIGHT. Memory CD4+ T cells, upon reencounter of their antigen, differentiate into effector Th cells and they assume effector functions more rapidly than naïve T cells, in part through storage of RNA for key cytokines and chemokines, which are available for immediate translation once the TCR has been engaged. Although this reactivation is less dependent on costimulation compared to activation of naive CD4+

T cells, it is nevertheless optimized by interactions between CD28-CD80/86, OX40-OX40L, or ICOS-ICOSL.[168] As a rule, the Th cell's fate decision during primary activation remains unchallenged during recall responses (ie, memory Th1 cells will become effector Th1 cells, memory Th2 cells will become effector Th2 cells, etc.).

Regulatory Cluster of Differentiation 4 + T Cells. Two subsets of CD4+ T cells have immunoinhibitory functions[169]; one subset is constitutively present and is termed natural T_{reg}s (nT_{reg}s) while the other is induced by antigen (iT_{reg}s). CD4+ T_{reg} subsets are characterized by expression of the lineage defining transcription factor forkhead box P (FoxP)3 in mice, although in humans other T-cell subsets can transiently become positive for FoxP3. T_{reg}s constitutively carry surface markers, such as CD25, CTLA-4, GITR, and Lag-3, that are also transiently expressed by recently activated CD4+ Th cells. T_{reg}s suppress immune responses and are essential to maintain tolerance and limit immunopathology following infections. Lack of T_{reg}s, such as in scurfy mice, which have a mutation in the *foxP3* gene, rapidly succumb to a fatal lymphoproliferative disease.[170]

nT_{reg}s, which comprise approximately 5% to 10% of the circulating pool of CD4+ T cells, are educated in the thymus and recognize self-peptides, while iT_{reg}s develop in the periphery from FoxP3-CD4+ T cells. This conversion seems to by driven by DCs that provide a metabolic microenvironment that does not meet the high energetic demands of activating effector T cells. Specifically, DCs that produce enzymes that cannibalize essential amino acids such as IDO, which targets tryptophane; IL-4il, which converts aromatic amino acids; arginase, which depletes arginine; or histidine ammonia lyase, which destroys histidine and promotes iT_{reg} development.[171] Central to this conversion is the mTOR pathway, which is activated by signals from nutrient receptors, growth factor receptors, and presumably branched amino acids, and then initiates translation and mitochondrial energy production. TCR signaling in absence of mTOR activation or under conditions of artificial mTOR inhibition, such as through rapamycin, induces FoxP3 and conversion of CD4+ T cells into iT_{reg}s.[172]

T_{reg}s suppress effector immune responses through several mechanisms. They inhibit IL-2 production and through expression of high levels of CD25 consume large amounts of IL-2, thus causing depletion of this cytokine, which is essential for T-cell proliferation. They produce IL-10, which downregulates the expression of Th1 cytokines, MHC class II, and costimulatory molecule expression by inhibiting NF-κB and Jak/Stat signaling pathways. T_{reg}s produce TGF-β, which upon signaling through similar to mothers against decapentaplegic 2 and 3 modulates gene expression. They also produce IL-35, a heterodimeric protein composed of IL-12α and IL-27β chains, which promotes proliferation of T_{reg}s and inhibits Th17 development.[173] T_{reg}s can form very stable clusters with DCs, and it is assumed that this limits access of other T-cell subsets. Through CTLA-4 or PDL1, T_{reg}s downregulate expression of CD80 and CD86 on DCs, thus reducing their ability to provide costimulatory signals.[174] T_{reg}s can directly bind B and T cells, such as through interactions between HVEM on T_{reg}s and BTLA on T and B cells,[175] and cause lysis of cells through the release of granzyme and perforin.[176]

T_{reg}s play a role in infectious diseases by reducing the magnitude of primary immune responses, by limiting effector T-cell functions, and by reducing secondary immune responses. Mice that lack T_{reg}s are better able to control viral infections, but they are also prone to more damaging immune responses.[169] This is exemplified by ocular infections of mice with HSV, which causes severe blinding infections upon depletion of T_{reg}s. Dampening of potentially pathologic immune responses upon viral infections not only benefits the host but also the virus by allowing for its persistence. For example, in chronic HCV infections, the severity of liver damage as well as viral loads are inversely correlated with numbers of T_{reg}s in liver and blood.[177] CD8+ T-cell responses to HIV-1/simian immunodeficiency virus (SIV) are dampened by T_{reg}s.[178] The chronic phase of such infections is associated with a loss of T_{reg}s, which may contribute to T-cell hyperactivation in response to microbial translocation

from the gut.[179] Chronic infection of mice with Friend leukemia virus is associated with an increase in T_{reg}s and a suppression of CD8+ T-cell function.[180] Depletion of T_{reg}s in this model rescues cytokine production and lysis by CD8+ T cells resulting in sustained lowering of viral loads.

Cluster of Differentiation 8+ T Cells

CD8+ T cells are crucial to resolve virus infections through direct lysis of virus-producing cells and through the release of antiviral cytokines.

Cluster of Differentiation 8 + T Cells: Antigen Processing and Presentation. CD8+ T cells respond to peptides displayed by MHC class I determinants.[181] The pathway for peptide-MHC class I loading differs from that of MHC class II loading. While MHC class II molecules associate with peptides derived from degraded proteins in endosomes, MHC class I peptides largely originate from misfolded newly synthesized proteins. MHC class I molecules, which are expressed on nearly all cells are thus uniquely suited to detect cells that upon infection are producing new viral progeny. Proteins that are not faithfully translated or that are incorrectly folded are degraded in the cytoplasm into peptides by proteolytic enzymes that form the proteasome complex.[182] The resulting peptides are then transported into the ER though the transporter associated with antigen presentation (TAP).[183] Newly synthesized MHC class I heavy chains are also transported into the ER, where they bind to calnexin, which promotes appropriate folding of the protein. The correct folding of the MHC class I heavy chain is further facilitated by calreticulin and the oxidoreductase ERp57, which breaks up incorrectly folded MHC molecules. Once the heavy chains are folded, calnexin is released and the heavy chains bind β2 microglobulin. The resulting complex is linked to TAP by interactions with tapasin. Peptides, once they reach the ER, may be digested further by peptidases, until they get to a size that permits their association with the MHC class I groove, which can accommodate peptides of 8 to 10 amino acids in length. Binding of peptides to MHC

class I molecules causes release of calreticulin and tapasin, and is followed by transport of the MHC-peptide complex through the Golgi apparatus to the cell surface (Fig. 39.6). Synthesis of molecules needed for MHC class I-mediated antigen presentation is upregulated by proinflammatory cytokines, such as IFNs.

Naïve CD8+ T cells generally require antigen presentation by DCs in presence of costimulatory molecules. Proteins from viruses that directly infect DCs readily provide peptides that enter the MHC class I presentation pathways. Antigens from viruses that do not infect DCs are processed and presented by alternative mechanisms, called cross-presentation or cross-priming.[184] In cross-priming, DCs can gather antigen from the outside by a number of pathways (see Fig. 39.6). DCs can pinocytose or phagocytose antigen released by other cells. They can actively chop off parts of viral surface proteins displayed on membranes of infected cells, or they can acquire preformed MHC class I antigen by trogocytosis, which involves conjugation of DCs with antigen-carrying cells through immunologic synapses, followed by ingestion of membrane fragments of one cell by the other. DCs that express connexin-34 can form gap junctions with other connexin-34+ cells, which allows for influx of small molecules, such as peptides, from the cytoplasm. A number of receptors facilitate antigen uptake by DCs, such as mannose receptors, DC-SIGN, DEC205, and Fc receptors, and contribute to cross-presentation. MHC class I molecules are normally formed in the ER, but they can be recycled from the cell surface into early endosomes. TLR signaling increases MHC class I recycling and recruits TAP to endosomes. Proteins that are internalized into endosomes initially exit into the cytoplasm, where, still in close proximity to endosomes, they are degraded by proteasomes. The resulting peptides then reenter the endosomes through TAP and now can bind to empty, recycled MHC class I molecules.

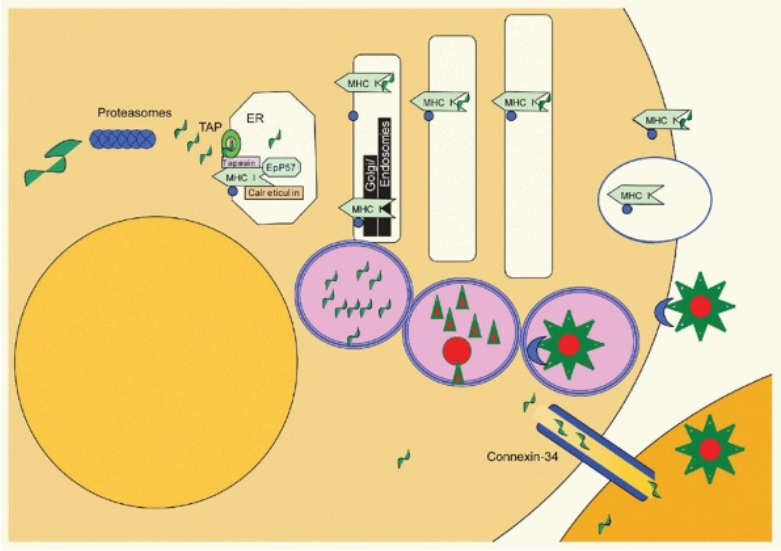

FIG. 39.6. Major histocompatibility complex class I processing and presentation pathways: endogenous pathway (*green*) and cross-presentation (*pink*).

Although MHC class I molecules can, in theory, bind thousands of different peptides that have fitting anchoring residues and, vice versa, viruses, especially those that are large, carry proteins with hundreds of putative MHC class I-binding motifs, antiviral immune responses are commonly dominated by CD8+ T-cell responses to one or two epitopes, with rapidly mutating viruses allowing for their escape.[185] Immunodominance of some peptides and immunosubdominance of others is dictated mainly by affinity between peptide and the MHC class I molecules, and most of the defined immunodominant peptides have an

affinity constant of 500 nm or higher. It is also affected by processing as epitopes can be lost through proteolytic cleavage or they are not generated by lack of flanking sequences that permit such cleavage. Immunodominance is further affected by location of the peptide within the viral protein. Translation is initiated at the 5′ end of an mRNA, which for surface proteins encodes the signal sequence. Incomplete protein synthesis is common, especially for larger proteins or mRNAs with mutations that incorporate a stop codon. Truncated proteins do not fold correctly and are degraded in the cytoplasm. Peptides encoded by the 5′ part of gene and thus located toward the N-terminus of a protein are more likely to be present in incomplete proteins, and as such more likely to be immunodominant compared to epitopic peptides within the C-terminus.

The timing of viral protein synthesis affects which epitopes are predominantly recognized. CD8+ T cells often respond preferentially to early viral proteins, which is highly advantageous for the host, as such proteins are produced well ahead of viral replication, so that destruction of cells expressing early viral protein proceeds assembly of infectious viral progeny.[186] As viruses commonly interfere with cellular protein synthesis, the favored recognition of early viral proteins may in part be a default pathway, as such proteins are produced at a time when the cell is still relatively intact and thus able to process and present the antigen efficiently. Viral antigens are not produced in equal quantities. The most abundant structural protein of HIV-1 is gag, which is also the major target antigen for CD8+ T cells. Enzymes such as the polymerase of rhabdoviruses are produced at minute quantities that are unlikely to be immunogenic. Some viral proteins are extremely stable. For example, EBNA1, which is produced in cells latently infected with EBV, carries a glycine-alanine repeat sequence that is resistant to proteolytic degradation.[187] Last but not least, the TCR repertoire, which has holes to ensure tolerance, influences immunodominance; epitopes that can bind with very high affinity to MHC class I molecules will not elicit a response if they

resemble self peptides.

The TCR of CD8+ T cells only needs a few MHC class I peptide complexes to mount an immune response. Although some viral infection can result in the display of hundreds of peptide-MHC class I molecules on the surface of infected cells, others only express a dozen or so, which still suffices for CD8+ T-cell activation and effector functions.

Cluster of Differentiation 8 + T Cells: Activation. Naive CD8+ T cells are activated within the T-cell-rich zones of lymphatic tissue, which provide a sufficient density of antigen-presenting DCs and Th cells. During activation, T cells interact repeatedly with DCs until they form stable connections, which are sustained by adhesion molecules, such as LFA-1 and CD2 on T cells and ICAM-1 and CD48/CD59 on DCs, respectively, and by costimulatory molecules that can function as adhesion molecules. Binding between T cells and DCs leads to the formation of an immunologic synapse,[188] in which the TCR-MHC-peptide complexes are central, surrounded by interacting costimulators and their ligands. Interacting adhesion molecules form the next ring and the outer ring contains CD43, CD44, and CD45 molecules.[189] Formation of synapses presumably allows for activation of a CD8+ T cell by low density of its cognate antigen. Costimulation is essential for CD8+ T-cell activation and the predominant pathway signals through the constitutively expressed CD28 upon its interaction with CD80 or CD86. Ligation of CD28 initiates a number of signaling cascades that result in activation of NF-κB and Jun/Fos transcription factors. It also activates the PI3K/Akt/mTor pathway, which augments energy production and protein synthesis by increasing amino acid transport, ribosome functions, and translation.[190] In addition, mTOR affects expression of the transcription factors T-bet and eomesodermin, which are crucial for lineage decisions in T cells.[191] Later during CD8+ T effector cell differentiation, CTLA-4 expression is induced, which binds to the same molecules that CD28 recognizes, but serves as a coinhibitor, by for example blocking CD28-induced Akt activation.[192] As CTLA-4 has higher affinity than CD28 to CD80 and CD86, coinhibition prevails if both are expressed. Other costimulators and conihibitors play a role in initiating, sustaining, or dampening CD8+ T-cell activation. Interactions between HVEM-lymphotoxin/LIGHT, Ox40-Ox40L, or 4-1BB-4-1BBL provide costimulatory signals by activation of NF-κB, Jun kinase, and Ap1. Costimulation through different pathways is functionally, spatially, and temporarily segregated. T cells during or shortly after activation also receive inhibitory signals through PD1, BTLA, CD160, or LAG-3, which are either induced or upregulated during T-cell activation. While such inhibitory signals dampen primary immune responses, they may be crucial to allow for fate-decisions of antigen-experienced CD8+ T cells.[193]

As a third signal, CD8+ T-cell activation requires cytokines such as type I IFN or IL-12. Activating CD8+ T cells requires T help in form of IL-2 for sustained proliferation.

Upon activation, CD8+ T cells proliferate extensively in a 4- to 6-hour cycle. Naïve cells, which are present at frequencies below 0.00001% of all CD8+ T cells prior to the infection, can reach frequencies of 10% or more within 5 to 7 days. Early after activation, CD8+ T cells transiently express CD25 and CD69. In addition, they start to express CD44, an adhesion molecule, and CD27, a TNF-receptor family member. T cells destined to become central memory cells increase expression of CD127. Upon activation and proliferation, CD8+ T cells downregulate expression of CCR7, the receptor for CCL19, which is primarily produced in lymphatic tissues and CD62L, an adhesion molecule, which facilitates entry into lymph nodes and then they can enter the bloodstream to migrate to sites of infection following gradients of chemokines, such as CXCL9 or 10. Proinflammatory cytokines produced in response to a virus increase expression of the adhesion molecules P- and E-selectins on adjacent blood vessels, which slows down the flow of CD8+ T cells; they first attach loosely to the blood vessel wall and then assume a rolling motion, which is replace by tight adhesions of T cells allowing them to transmigrate between the endothelial cells to the infected tissue,[194] where, upon encounter of their antigen, they commence effector function.

Cluster of Differentiation 8 + T Cells: Effector Functions. CD8+ T cells can release a number of cytokines and chemokines. Antiviral CD8+ T cells predominantly produce IFN-γ, IL-2, TNF-α, MIP-1-α and MIP-1-β, or regulated upon activation, normal T cell expressed and secreted. CD8+ T cells can secrete single or several cytokines/chemokines, and in infected individuals multiple subsets, defined by their cytokine/chemokine production profile, arise.[195] Although the profile of cytokine/chemokine may be predictive for effectiveness of the CD8+ T cells in limiting viral spread, the highly dynamic patterns that evolve during the course of an infection suggest that they may readily assume new functions or let go of others. IFN-γ upregulates the antigen processing machinery and MHC class I expression, thus facilitating interactions between infected cells and activated CD8+ T cells. IFN-γ also activates natural killer cells and macrophages, and blocks viral spread, similar to IFN-1s. TNF-α can inhibit replication of the viral genome or assembly of viral capsids.[196,197] Another important function of activated CD8+ T cells is their ability to kill infected target cells. CD8+ T cells predominantly lyse through the release of two lytic enzymes, granzyme, and perforin.[198] These two enzymes are present in granules that, once CD8+ T cells encounter their target, are released by exocytosis. Perforin molecules insert themselves into the plasma membrane of target cells and form a pore. Granzyme molecules enter through the pore into the cells where granzyme A activates DNase and inhibits the DNA repair machinery. Granzyme B activates caspase 3, which in turn activates caspase 7, while cleaving the proapoptotic molecule BID, thus causing cells to apoptose. Alternatively, CD8+ T cells can lyse target cells through interactions between CD95 expressed by all activated T cells and Fas expressed by some target cells. Interactions between CD95 and Fas trigger activation of caspase 8 and apoptotic cell death. CD8 + T-cell-mediated lysis is rather inefficient, as each CD8+ T cells can only lyse a limited number of targets; nevertheless, it is crucial for rapid viral clearance as mice lacking lytic enzymes showed increased susceptibility to a number of viruses.[199,200]

Cluster of Differentiation 8 + T Cells: Memory Differentiation. Four transcription factors play a role in determining the fate of an activating CD8+ T cell: T-bet and eomesodermin (Eomes), which are both required for effector and memory formation, the transcriptional repressor B-lymphocyte-induced maturation protein (Blimp)-1 which dampens and Bcl-6 which sponsors differentiation into memory.[201] The differentiation fate of CD8+ T cells is at least in part dictated by the conditions of their stimulation. CD8+ T cells can develop into short-lived effector cells, and this is supported by expression of the transcriptional repressor Blimp-1.[202] Alternatively, CD8+ T cells can transition into the memory T cells' pool. Strong TCR signaling in presence of excessive amounts of antigen seems to favor effector cell differentiation, while limited amounts of antigen promote development of memory T cells.[203] IL-2 through binding to CD25 similar to CD28 activates PI3K, which in turn initiates downstream phosphorylation of Akt/PKB. Activated Akt/PKB inhibits forkhead box O and thus expression of the IL7 receptor CD127, which favors memory formation.[204] Signaling through CD25 downregulates CD127 expression,[205] inhibits expression of Bcl-6, a memory marker,[206] and induces T-bet, which, if present at high levels, induces generation of CD8+ effector T cells. Memory CD8+ T-cell development is promoted by low levels of T-bet and by proinflammatory cytokines such as IFN-1s, IL-12, and IL-15.[207]

In acute viral infections, the immune system eliminates the infected cells within 1 or 2 weeks. Once their cognate antigen is gone, most of the activated CD8+ effector T cells undergo apoptotic cell death and only 5% to 10% survive and differentiate into memory cells, leaving the organism with a 10- to 1000-fold increase in numbers of CD8+ T cells able to react against a given virus. Two major types of memory cells have been identified: effector memory T cells, which remain comparatively active and circulate in the periphery, where upon reencounter of their antigen then can assume immediate effector functions; and central

memory T cells, which express increased levels of CD62L and CCR7 and return to lymphatic tissues, where they become reactivated upon reinfection.[208,209] Effector memory T cells, although longer lived than effector T cells, decline in numbers over time, while numbers of central memory T cells remain at constant levels through homeostatic antigen-independent proliferation driven by IL-7, which provides survival signals, and IL-15, which promotes proliferation.[210] There is ample evidence to suggest that during activation T-cell differentiation is rapidly imprinted, potentially already during the first division of activating T cells.[211] Within a week after the initial activation, T cells that are terminally differentiated can be distinguished from those that will evolve into memory T cells; those that express low levels of CD127 and high levels of KLRG1 die once the effector phase is terminated, while those that are $CD127^{high}$ and $KLRG1^{low}$ become central memory T cells.[212] Lineage relationships between effector, effector memory, and central memory CD8+ T cells remain debated; some studies suggest a linear relationship, in which effector T cells differentiate into effector memory CD8+ T cells and then central memory CD8+ T cells,[213] while others argue for independent development of these populations.[214]

The importance of effector/effector memory CD8+ T cells versus central memory CD8+ T cells in providing protection to viral infections remains debated as well. While some argue that the more activated effector-like CD8+ T cells, which are present at the port of viral entry, are crucial,[215,216] others provide evidence that central memory CD8+ T cells with their higher proliferative potential are essential.[213] For example, in a low-dose SIV infection model of rhesus macaques, effector memory CD8+ T cells were shown to correlate with protection.[217] Similarly, in an influenza virus challenge model of mice, activated CD8+ T cells present in the lung at the time of challenge were required for protection.[218] In contrast, central memory CD8+ T cells were shown to provide superior protection to LCMV.[213] One could argue that mode of infection dictates which T-cell subset is indeed more suited to eliminate virus-infected cells before extensive viral replication takes place. Viruses such as HIV-1 and SIV invade through mucosal surfaces

and a productive infection is established by very small numbers of founder viruses. Activated effector memory CD8+ T cells present within the mucosa might be superior to eliminate the few cells that initially become infected compared to central memory CD8+ T cells, which reside in far away lymph nodes, where they most likely remain ignorant of the incoming few viral particles. In an infection where substantial amounts of virus are implanted directly into a body cavity, central memory CD8+ T cells with their higher proliferative capacity may be better suited to eliminate the virus.

Cluster of Differentiation 8+ T Cells: The Effect of Persistent or Repeated Infections on Cluster of Differentiation 8+ T Cells. Many viruses, especially DNA viruses, are not completely cleared from an organism, but rather establish long-lasting infections. Such infections can be chronic when the virus continues to replicate extensively, such as HIV-1 or HCV in humans or some strains of LCMV in mice. Herpesviruses establish latent infections by shutting off most viral protein synthesis; they periodically become reactivated and resume replication. Other viruses, such as adenoviruses, persist at very low levels and apparently remain transcriptionally active. In this case, the immune system is continuously stimulated by low amounts of antigen, which maintain high frequencies of activated effector-like CD8+ T cells. T cells may encounter the same viral antigen repeatedly due to repeated infections. Although neutralizing antibodies induced by a viral infection may prevent a subsequent infection with this particular virus, they are not effective against other viruses from the same family, which may not share neutralizing antibody binding sites, but, nevertheless, carry conserved T cell epitopes, such as different serotypes of adenoviruses. T cells may thus encounter the same epitope presented by related viruses over and over again. Repeated stimulation in turn affects the quality of memory CD8+ T-cell responses.

Chronic infections overwhelm the immune system. The continued high presence of antigen prevents differentiation of effector CD8+ T cells into central memory CD8+ T cells and instead induces, in a hierarchical fashion, loss of effector cell functions[217]; first, T cells lose the ability to proliferate and then they cease to produce cytokines or lyse target cells. Loss of function is accompanied by upregulation of coinhibitory receptors such as PD1, LAG-3, CD160, 2B4, CTLA-4, PIR-B, and Gp49 in a process that is controlled by Blimp-1.[218] Signaling through coinhibitors such as PD1 inhibits the PI3K/Akt/mTor pathway and thus the T cell's ability to meet its demand for energy. The degree of exhaustion is correlated with the numbers of coinhibitory receptors on the CD8+ T cell's surface, as numbers of upregulated coinhibitors correlate with the severity of the T cell's impairment.[219] Partially, but not fully, exhausted CD8+ T cells can be rescued by treatment with antagonists to immunoinhibitory pathways.[220]

Reactivation of latent viruses causes expansion of specific memory CD8+ T cells, which once activated rapidly control the infection. The profile of memory CD8+ T cell changes upon repeated recall; they become more activated and their numbers increase.[221] This can become rather extreme, and in elderly humans up to 30% of peripheral CD8+ T cells show specificity to antigens of herpesviruses, most notably (HCMV).[222] High frequencies of Hhuman CMV CMV-specific CD8+ T cells are inversely correlated with life expectancy,[223] presumably as a consequence of increased disease susceptibility due to irreversible loss of immunologic space and repertoire.

Frequencies of circulating activated CD8+ T cells to adenoviruses can also be high.[224] It is unknown if this relates to the ability of the virus to persist at low levels causing continuous activation of CD8+ T cells or if it rather reflects repeated infections with serologically distinct adenoviruses. The former pathways seems more likely as other viruses, such as influenza A viruses, which also infect repeatedly, fail to establish high frequencies of specific CD8+ T cells.

Regulatory Cluster of Differentiation 8 + T cells. CD8+ T cells that express FoxP3 and exert immunosuppression through the release of IL-10 or TGF-β have been identified in acute SIV infection of nonhuman primates, where they correlate with viral load and inversely correlate with effector CD8+ T-cell responses.[225] They also may play a role in limiting liver damage during chronic HCV infection.[226]

B Cells

The primary task of B cells is to produce antibodies that can limit viral spread. In addition, they serve as antigen-presenting cells and produce cytokines.

B Cells: Subsets

In mice, B cells are divided into three distinct subsets: marginal zone (MZ) B cells, follicular B cells, and B1-B cells, which are further divided into B1a- and B1b-B cells.[227] B1-B cells, which have not yet been identified in humans, reside mainly in the pleural and peritoneal cavities, although, upon activation, they can migrate to lymph nodes. B1-B cells are activated by PAMPs and can mount early IgM or IgA responses without requiring T-cell help. MZ B cells, which, as their name indicates, reside mainly in the MZ of the spleen, can also rapidly, without T-cell help, differentiate into shortlived plasma cells that produce IgM. MZ B cells, which express high levels of MHC class II antigens and costimulatory molecules, can also present antigen to Th cells. Unlike MZ or B1-B cells, follicular B cells, which circulate between blood and B-cell follicles in lymphatic tissues, are not directly activated by antigen ligation of the BCR and concomitant PRR stimulation, but, in addition, require T-cell help through CD40-CD40L interactions.

B Cells: Activation and Differentiation. Mature naïve B cells derive from bone marrow

precursors. They express IgD and IgM molecules as antigen receptors. B cells with high affinity to self are deleted or edited first in the bone marrow and then again in the periphery. B cells that pass these checkpoints then circulate from blood through lymphatic tissues where they are guided toward follicles by a network of reticular fibers and follicular DC dendrites. Small antigens, such as peptides, reach lymph nodes rapidly by passive diffusion;

once there, they are taken up by macrophages that line the lymph node sinuses or complexed onto follicular DCs through complement and Ig Fc receptors. Larger antigens, such as virions, are engulfed by peripheral DCs, which then migrate to lymph nodes, a process that takes about 12 to 18 hours. B cells through their Ig receptors can acquire antigen from the surface of follicular DCs or macrophages.[228] Once the BCRs are cross-linked by complex antigens, which carry repeat sequences of the same antigen, or are oligomerized by soluble antigen, a conformational change occurs in the cytoplasmic domain of the BCR. This first activates Lyn. Lyn in turn phosphorylates the Ig chains leading to the attachment of Syk and recruitment of CD19.[229] These initial signals promote the formation of larger clusters, which form an immunologic synapse with the BCRs in the center surrounded by LFA-1. Formation of BCR clusters, which are needed to initiate a signaling cascade, is favored by high-affinity BCR-antigen interactions and may thus serve as an early selection process for the best fitting antibodies. Full BCR-CD19 signaling activates a number of cascades that result in activation of the NF-κB, Pi3K/Akt, Erk, and JNK/p38 pathways. This in turn initiates proliferation and maturation of B cells, which at this stage can differentiate into short-lived plasma cells or enter follicles to form germinal centers and differentiate into long-lived plasma cells and memory B cells. Shortlived plasma cells produce antibodies rapidly, although such antibodies are of low affinity compared to those produced by long-lived plasma cells. The fate decision between shortlived versus long-lived plasma cells or memory cells is in part governed by cytokines such as IL-12, which favors the development of short-lived plasma cells, as well as by the affinity between antigen and the BCR with very-high-affinity interactions apparently also favoring the development of shortlived plasma cells. It may also be influenced by local PAMPs and the resulting PRR signaling cascades.[230] For example, vaccines providing antigen together with TLR4 and TLR7 ligands favor the development of long-lived plasma cells and memory B cells.[83]

Germinal center formation requires Tfh cells, which promote B-cell responses through cytokines, such as IL-4, IL-6, IL-10, and IL-21, through direct cell-to-cell interactions and through costimulatory signals, such as CD40, ICOS, or lymphotoxin.[230] Coinhibitory signals also shape the fate of activated B cells. For example, upon activation, B cells rapidly adjust their metabolic needs by increasing glucose uptake and glycolysis in an Akt/PI3K dependant fashion. This in turn is inhibited by signaling through FcγRIIB.[231] PD1 on Tfh cells through interactions with PDL2 and to a lesser extend PDL1 reduce rates of cell death and thus increases numbers of surviving cells with lower-affinity BCR.[118]

During proliferation, B cells undergo hypermutation leading to the development of plasma cells producing antibodies with increased affinity. They also undergo isotype switching through recombination, and this process is influenced by the surrounding cytokine milieu; in mice, IL-4 favors switching to IgG1 and IgE, IL-5 promotes switching to IgA, and IFN-γ supports switching to IgG2a. Competition for T-cell help and T-cell-derived cytokines favors continued proliferation of B cells with the highest affinity receptors.

Differentiation of naïve or memory B cells into plasma cells causes changes in key transcription factors with a reduction of paired box protein-5 and Bcl-6 and an induction of Blimp-1, which turns off germinal cell functions and allows for a switch to antibody secretion.[232] It is not yet fully understood what drives B cells within the germinal center to differentiate into resting memory B cells or longlived plasma cells. B cells with lower-affinity receptors may be outcompeted by those that have higher-affinity receptors and thus be forced to differentiate into memory cells, whereas B cells with the highest-affinity receptors

continue to proliferate and eventually form the pool of long-lived plasma cells. The finding that the memory B-cell pool forms earlier than the pool of long-lived plasma cells supports this idea.[230] Plasma cells home preferentially to bone marrow, while memory B cells home to spleen or bone marrow. Upon reexposure to antigen, memory B cells differentiate into antibody-secreting plasma cells, which requires proliferation accompanied by another round of hypermutations and affinity maturation.

Chronic viral infections can lead to B-cell exhaustion.[233] During this process, B cells express increasing levels of the inhibitory Fc-receptor-like-4 molecule, which is accompanied by a loss of their proliferative capacity. Chronic infection can also cause a pathologic accumulation on antigen-antibody complexes causing vasculitis or glomerulonephritis.

B Cells: Effector Functions. B cells protect against pathogens primarily through the secretion of antibodies. The rapid production of low-affinity antibodies by B1-B cells and MZ B cells can reduce the spread of viral pathogens by forming complexes that are retained within lymphatic tissues, where they may aid activation of other adaptive immune responses. Plasma cells derived from B2-B cells can produce IgM, IgD, IgG, IgA, and IgE. Of those, IgA, IgG, and IgM are important to control viral infections. IgM is produced first and is then over time replaced by IgG or IgA upon isotype switching. IgGs, which are further divided into IgG1 to 4 circulate in blood and tissues. IgA can be transported actively across epithelial surfaces, allowing for its secretion at mucosal surfaces. IgA is thus crucial for protection against pathogens that invade through the mucosal epithelium.

All antibody isotypes can block viral infections by neutralization. Virus-neutralizing antibodies are directed against parts of viral surface proteins that are exposed and commonly nonessential for viral fitness. For example, humans can be infected with more than 40 different serotypes of adenoviruses that belong to six different families; chimpanzees are infected with viruses that are phylogenetically related. The hexon of adenoviruses, which is the main target of neutralizing antibodies, forms trimers on the surface of virions. The stalk of the trimers, which is poorly accessible by antibodies, is highly conserved. The tower region contains a number of flexible loops that are highly variable. Neutralizing antibodies bind to these loops.[234] As these loops do not contribute to the structural integrity of the protein, they can readily be mutated, thus allowing the virus to escape neutralization.

Antibodies of the IgG or IgM isotypes can lyse viruses or virus-infected cells through activation of complement.

They can complex viruses, thus facilitating phagocytosis by macrophages. They can lyse virus-infected cells through antibody-dependent cell-mediated cytotoxicity, during which natural killer cells through Fc-receptors bind to an IgG molecule on an infected cell and then release perforin and granzyme.

Although preexisting natural antibodies provide an immediate layer of defense, which is rapidly joined by antibodies secreted by B1 and MZ B cells, production of affinity-matured antibodies takes up to 2 weeks and, by then, an acute viral infection has been resolved, while in chronic infections the virus, such as HIV-1 or HCV, has mutated extensively, rendering antibodies directed against the incoming virus rather useless. Affinity-matured antibodies are thus unlikely to play a dominant role in limiting a primary infection, but they are crucial to ward off secondary infections. Neutralizing antibodies can completely prevent a secondary infection or they can reduce the amount of incoming virus to levels that can rapidly be controlled. Protection by neutralizing antibodies against reinfection has been documented for numerous viruses such as rabies virus, influenza A virus, poliovirus, HPV, HIV-1, and many others, and is the main correlate of protection for most antiviral vaccines. Nonneutralizing antibodies can also dampen infections without necessarily providing sterilizing immunity. For examples, antibodies to the ectodomain of the matrix protein of influenza A virus lack neutralizing activity, but nevertheless can prevent fatal infections with influenza A viruses in animal models.[235]

In some infections, preexisting antibodies can exacerbate disease as exemplified by Dengue virus. Dengue virus replicates preferentially in macrophages, monocytes, and DCs. A first infection causes relatively mild symptoms and induces antibodies that cross-react between any of the four strains of Dengue virus. Following a second infection with a serologically distinct virus, circulating nonneutralizing antibodies form complexes with the virus. Such complexes facilitate uptake by macrophages, which in response produce IL-10 rather than IFN-γ. This allows for more vigorous replication of the virus, a skewing toward a Th2 immune response leading to hemorrhagic fever, which is characterized by impaired clotting and vascular leakage.[236]

Antibodies play an additional altruistic role. Children are born with an immature immune system and are thus potentially hypersusceptible to viral infections. Antibodies of the IgG isotype are transferred from mothers to their offspring across the placenta and through breast milk. Maternal antibodies are crucial to protect an infant against the onslaught of pathogens that will attack as soon as it has left its mother's womb. Maternal antibodies do not necessarily provide sterilizing immunity, but may attenuate inflections and thus allow for active immunization under conditions that do not threaten the life of the infant. The argument has been made that vaccination reduces transfer of maternal antibodies as natural infections of the mother as a rule elicit higher and more sustained levels of antibodies than most vaccines. This, combined with improved hygienic standards, which delays exposure to common pathogens, may in the end harm the offspring by delaying their first exposure to pathogens until such a time when maternal antibodies have declined from their circulation, which may happen before their own immune system is fully developed. Exposure to viruses at this susceptible stage, in turn, may favor the induction of pathological or self-reactive immune responses.[237] Although there is no direct proof for this ominous side effect of mass vaccination, it might be supported by recent increases in the incidence of allergies and autoimmune diseases.

THE MUCOSAL IMMUNE SYSTEM

The mucosa of the airways, the intestines, and the urogenital tract, which in adult humans covers a total surface area of approximately 400 m^2 are the most common ports of viral entry. Mucosal surfaces are also bathed in antigens that are harmless or useful such as the 10^{14} commensal bacteria that live in the intestine, where they are essential to outcompete pathogenic bacteria and promote normal intestinal functions. The immune system that controls mucosal surfaces, the so-called mucosal immune system, must be able to distinguish between dangerous and nondangerous antigens and has thus unique characteristics.

The mucosal immune system consists anatomically of local inductive sites, called organized mucosa associated lymphoid tissue, such as tonsils in the oral cavity, Peyer patches along the wall of the small intestine, the appendix close to the junction between small and large interesting, and bronchus associated-lymphoid tissues in the respiratory tract. Although these sites resemble lymph nodes, they are not encapsidated nor are they connected by lymphatic vessels.[238,239]

The mucosa of the intestine is covered by the lamina propria (LP) and a single layer glanular epithelium. Both activated and resting B- and T-lymphocytes can be found within the LP, while the mucosal intestine is densely seeded with highly activated T cells. The vaginal surface is covered by a multilayered squamous epithelium that contains both B and T cells originating from iliac lymph nodes. T and B cells can also be found in the epithelium of the airways. B cells in the intestine and airways are skewed toward those that produce IgA. Most T cells in the mucosa of the genital tract and the airways carry the α/β TCR, unlike T cells in the intestinal part, many of which carry a γ/δ TCR. In newborn mice, nearly all if the intraepithelial lymphocytes that initially populate the intestine express the γ/δ receptor, which has a less diverse repertoire than the α/β receptor. T cells with a γδ receptor develop independently of the thymus and do not recognize MHC class I peptide complexes but rather

respond to self-antigens and microbial phosphorylated metabolites. Their response does not involve extensive proliferation and differentiation; upon encounter of antigen, they commence production of cytokines within a few hours.[240] T cells expressing the α/β TCR appear later in the intestine under the influence of antigenic stimulation. T cells within the intestine can also be double positive for CD4 and CD8, or they can carry two CD8α chains rather than heterodimers of CD8α and CD8β.

DCs acquire antigen in the intestine with the help of M cells, which sample luminal antigen and then pass it on to

the underlying DCs.[241] DCs in the mucosa predominantly secrete IL-6, IL-21, and TGF-β, thus favoring induction of Th17 cells, the latter in turn produce IL-17 and IL-22.[242] IL-17 increases tight junction formation in the gut thus reducing permeability, while IL-17 and IL-22 induce granulopoiesis through granulocyte-CSF and recruit neutrophils through CXC chemokines. Infections with HIV-1 or SIV cause rapid depletion of mucosal Th17 cells, which in turn increases gut permeability and causes microbial dissemination and chronic immune activation.[243]

Viral infections induce CD8+ T cells that can be isolated from the LP and the gut epithelium. These CD8+ T cells can produce IFN-γ and kill infected target cells. Antigeninduced CD8+ T cells in the epithelium and the LP were found to contract more rapidly than antigen-specific CD8+ T cell in spleen. Interestingly, antigen-specific CD8+ T cells from the LP and the overlaying mucosa were shown to be distinct in their TCR usage; T cells from epithelium were more oligoclonal and had lower affinity to their antigen, suggesting limited exchange of T cells between these two adjacent compartments.[244] Effector T cells of the central immune system can migrate to the intestinal mucosa, and this process requires expression of α4β7. Strength of the initial activation seems to control expression of α4β7. For example, CD8+ T cells induced by LCMV, which proliferates extensively in mice, express α4β7,[245] while those induce by an E1-deleted adenoviral vector only express this homing marker very transiently and consequently fail to migrate to the intestinal mucosa.[246] Homing of activated T cells is also influenced by characteristics of the antigenpresenting cells; CD103+ DCs derived from skin, lung, and intestine drive T cells to increase expression of $\alpha_4\beta_7$ integrin.[247]

Within the female genital tract, primary immune responses are induced in draining lymph nodes. Upon clearance of a virus, as was shown in mice and humans infected with HSV-2 or HIV-1, respectively, clusters of memory T cells, B cells, and DCs remain underneath the epithelium of the vagina and the cervix, potentially providing an immediate barrier against infection.[248,249] Systemically induced effector CD8+ T cell can readily migrate to the mucosa of the genital tract[250]; it remains unknown if this requires a specialized homing receptor.

Within the airways, an infection, such as with influenza virus, can result in organized lymphoid structures within the lungs composed of B-cell follicles and surrounded by T cells. These structures called inducible bronchus associated-lymphoid tissue can recruit naïve lymphocytes and provide a first-line defense against subsequent pulmonary infections.[251]

THE AGED IMMUNE SYSTEM

Immune responses become impaired during aging, resulting in an increased susceptibility to infectious agents, as exemplified by influenza virus that mainly kills the very young or the aged. Immunosenescence affects multiple aspects of the immune system. DCs derived from blood or bone marrow from the elderly develop defects in their responses to inflammatory cytokines and their ability to present antigen and activate adaptive immune responses.[252] B-cell lymphopoiesis is reduced with aging, leading to a decline of naïve B cells and an increase of antigen-experienced B cells with an extended lifespan. Primary B-cell responses

in the elderly are commonly both low and short-lived, resulting in antibodies with low affinity.[253] Formation of germinal centers decreases, antigen transport is impaired, and follicular DCs have reduced capacity to form antigen depots.[254,255] Autoantibodies are more common, and the B-cell repertoire becomes more restricted. The E2A-encoded transcription factor E47 is downregulated in old splenic B cells, which causes a reduction in the activation-induced cytidine deaminase, needed for class switch recombination and Ig somatic hypermutation.[256] Some of the defects of B-cell responses are secondary to an age-related decline of helper functions from CD4+ T cells, which show reduced expression of critical costimulatory receptors that are essential for activation of B cells, germinal center formation and rearrangement, and hypermutation of Ig genes.[257,258,259] T cells show clonal senescence, their potential for expansion decreases, and their ability to produce certain cytokines or to respond to cytokines may become impaired. The proportion of T cells with a memory cell phenotype increases, while numbers of naïve T cells decrease, in part reflecting loss of thymic output following thymic involution, and in part resulting from chronic stimulation. Expression of activating molecules, such as CD40L and CD28 decreases,[260,261] while that of inhibitory pathways increase.[262,263] Stimulations with new antigens or previously encountered antigens result in CD8+ T-cell responses that are delayed and show defects in transition into memory. The delay in T-cell expansion reflects an intrinsic defect of aged T cells and may well be one of the reasons for increased susceptibility of the aged to rapidly replicating pathogens. Upon aging, the T-cell repertoire loses diversity.[264,265] Chronic antigenic stimulation leads to continued clonal expansion of some T cells. The effect of aging on cytokine production remains controversial.[264,265,266,267] The number of T_{reg} cells appears to increase with age,[268] while autoimmunity is more common, suggesting that inhibitory pathways may become dysregulated during aging.

AUTOIMMUNITY AND DEGENERATIVE DISEASE

Viral infection can lead to the development of autoimmunity. Some viruses carry antigens with superantigen activity, such as the nucleoprotein of rabies virus or nef of HIV-1.[269,270] Superantigens trigger polyclonal activation of T cells and can thus lead to stimulation of self-reactive T cells.

Some viruses carry sequences that resemble those of their host. For example, a sequence in coxsackie B virus is homologous to one in glutamic acid decarboxylase, a protein expressed by insulin-producing pancreatic islet cells. Coxsackie B virus infections can trigger in animals antibodies to glutamic acid decarboxylase, which can cause diabetes.[271] The polymerase of HBV mimics myelin basic protein,[272] and may thus, in theory, stimulate an immune response that could cause multiple sclerosis.

Nevertheless, thus far antigenic mimicry of a self-protein has not been confirmed to be causative for human autoimmune diseases.

Strong inflammatory responses elicited by a virus can cause concomitant activation of immune responses to selfproteins. For example, infections of mice with Theiler virus can elicit T cells recognizing myelin basic protein or proteolipid protein causing neurologic damage.[273] Coxsackievirus B3 can infect the heart muscle and inflict initial damage; this can induce autoreactive lymphocytes against cardiac myosin,[274] which cause chronic myocarditis resulting in permanent heart damage and even death.

Herpesviruses have been implicated as etiologic factors in the pathogenesis of human arteriosclerosis by accumulating saturated cholesteryl esters and triacylglycerols to the endothelial walls of blood vessels.[275] This can be prevented by cytokines such as TNF-α or IL-1.[275]

CANCER

Viruses can cause cancer. Oncogenic types of HPV such as HPV-16 or -18 are causative for cervical[276] and head and neck cancer through the activity of two oncoproteins, E7 and E6, which disrupt the retinoblastoma (Rb) and p53 pathways, respectively. Chronic infections with HCV and HBV can lead to hepatocellular carcinoma, primate T-lymphotropic virus 1 can cause T-cell leukemia, EBV can result in lymphoma and nasopharyngeal carcinoma, Merkel cell polyoma virus is associated with Merkel cell carcinoma, and HHV-8 is associated with with Kaposi sarcoma.[277] Some types of viral cancers are common in the general population, while others arise primarily in immunocompromised individuals. The immune system, although able to prevent the establishment of some types of viral cancers, is in general ill suited to halt progression of an already established advanced cancer even if its cells express viral antigen, as tumors establish an immunosuppressive microenvironment that is effective at suppressing immune responses.[278]

Virus-specific T cells have found utility in treatment of cancer. EBV-specific T cells isolated from children with neuroblastoma were expanded in vitro and transduced with an artificial TCR composed of an antibody variable region with specificity to a surface antigen on the cancer linked to the intracellular signaling domain of the TCR. Upon transfer of these modified T cells back into the children, remission of some of the advanced cancers was achieved.[279]

IMMUNOEVASION BY VIRUSES

While cellular organisms evolved over the millennia to combat virus infections, first with a primitive innate immune system and then, about 410 million years ago, once jawed vertebrates developed with the more sophisticated adaptive immune system, viruses evolved in tandem to subvert their hosts' defense mechanisms. While small RNA viruses, which replicate and spread rapidly and, as a rule, do not establish chronic infections, attack mainly the early defense mechanisms, the more complex DNA viruses, especially those with large genomes, also subvert adaptive immune responses.

Escape by Hiding

The central nervous system is an immunologically privileged site hidden behind the blood-brain barrier that cannot be penetrated by antibodies or resting lymphocytes. It also contains cells such as neurons that lack MHC class I expression and can thus not be attacked by CD8+ T cells. Viruses, exemplified by rabies virus, take advantage of this safe haven. Herpesviruses after an acute lytic infection assume a stage of latency where most viral synthesis is shut off. HSV-1 establishes latent infections in neurons, where it is sheltered from attack by CD8+ T cells, while EBV remains more exposed in B cells. The only protein of EBV that is expressed during deep latency is EBNA-1, which contains a glycine-alanine repeat domain that appears to protect the antigen from proteasomal breakdown and thus from the display of antigenic peptides on MHC molecules.[280]

Escape through Mutation

Viruses can evade by rapid mutations caused by the infidelity of their replication machinery that lacks the proofreading capacity of mammalian polymerases. Although lack of faithful genome replication is costly and many of the resulting viruses lack the fitness of the parent virus, it serves the virus population as a whole, which produces thousands of new infectious viruses from each original virus and can thus afford to lose some due to defective genomes. Mutations are primarily driven by neutralizing antibodies through selection of variants with mutations of their surface molecules. Most binding sites for neutralizing antibodies are on exposed areas on the very top of viral surface proteins, which do not contribute to the assembly of the virus and as such are not essential for the virus. Nevertheless, such mutations can affect viral fitness. Mutations of the HA of influenza virus can increase the

affinity to its receptor, which makes it difficult for the virus to gain release from the cell where it replicated. Influenza viruses compensate by additional mutations that readjust the affinity between HA and its receptor.[281] Some neutralization sites are located in domains that are essential for the virus and that cannot be mutated without devastating consequences. Neutralizing antibodies can bind to the stalk of the HA of influenza virus.[282] This antibody-binding site is highly conserved in several strains, indicating that it is crucial for some aspect of the life cycle of the virus. Nevertheless, this site is so well hidden that most humans fail to produce antibodies against it. HIV-1 is a master in escaping neutralizing antibodies. HIV-1 originated from SIVcpz, which is endemic in common chimpanzees, *Pan troglodytes troglodytes*, although it can spill over into gorillas. It has been calculated that humans acquired this virus sometimes at the beginning of the last century around 1908 on three occasions from chimpanzees and in one event potentially from a gorilla, resulting in infections with three groups of HIV-1 (ie, M, N, and O).[283] Group M was the most

successful and within a mere hundred years evolved into several clades and multiple subspecies. Even in a new host, where a few founder viruses establish an infection, viral variants evolve so rapidly that the humeral immune system is hard pressed to keep up.

T cells can select for mutations in the generally more conserved internal proteins. This is typically found during choric infections such as with HIV-1 or HCV,[283,284] but can also happen in acute infection, as exemplified by influenza virus.[285]

Antiviral cytokines, such as IFNs, can select for mutants. The only approved treatment for chronic infections of HCV is IFN-α, which results in complete viral clearance in only a fraction of patients. In many patients, the virus escapes through mutations that increase its resistance to IFN-α.[286]

Escape by Destruction of Immune Cells

An efficient way to stage a hostile takeover is to eliminate a crucial component of the opponent's armor. HIV-1 infects and eventually kills CD4+ T cells, which are essential to drive B and CD8+ T cell responses. HIV-1 preferentially replicates in activated CD4+ T cells as resting CD4+ T cells express the antiretroviral deoxycytidine deaminase APOBEC3G,[287] which through editing C to U nucleotide base exchanges inhibits elongation of the HIV-1 genome. To ensure an ample supply of activated CD4+ T cells, HIV-1 rapidly depletes gut-residing CD4+ T cells, causing intestinal hyperpermeability and leakage of bacterial products into the organism, which in turn nonspecifically activates more CD4+ T cells.

Escape from Early Innate Immune Responses

Inhibition of Pattern Recognition Receptor Signaling

The invention of stealth technology should be credited to viruses, which long ago figured out that flying under the radar (ie, dodging initial recognition by PRRs) promotes their own ability to propagate. Many viruses antagonize recognition by PRRs either by sheltering products that can be sensed or by directly interfering with components of PRR signaling cascades.

An example of sheltering recognizable patterns is the Ebola virus vp35. It binds viral dsRNA in a rather peculiar manner; one molecule binds the backbone of the RNA, whereas the other caps the terminus, thus effectively blocking dsRNA binding to TLR3, MDA5, RIG-I, or PKR.[288] Similar dsRNA hiding mechanisms are employed by vaccinia virus E3L, influenza virus NS1, reovirus σ protein, and HSV-1 US11.[289]

Several viruses interfere with TLR signaling. Vaccinia virus A46R and HCV NS5A bind to the TIR domain of MyD88, thus preventing activation of most TLRs. Vaccinia virus A46R, HCV NS4A, and ORFI329L of African swine fever virus[290] bind TRIF thus blocking stimulation through the alternative TLR4 pathway. Hantavirus G1 and MC159 from molluscum contagiosum virus (MCV) block TRAF3.[291] Vaccinia virus A52R binds IRAK2 thereby inhibiting signaling to TRAF6. Of note, IRAK2 operates redundantly with IRAK1 (see Fig. 39.1) in the initial response but continues to function after IRAK1 disappears (Fig. 39.7).

A number of viral proteins target sensors in the cytoplasm (Fig. 39.8). Influenza virus NS1 binds and blocks RIG-I.

Protein V of paramyxoviruses binds MDA5 and inhibits access of ssRNA. Picornaviruses, such as poliovirus, cause proteasome-mediated degradation of MDA5. IPS1, which is downstream of RIG-I or MDA5, is cleaved by HCV NS3-4A or hepatitis A virus 3ABC. The ATP-dependent DEAD box RNA helicase, DDX3, is part of the RIG-I signaling complex. By binding to RIG-I-associated IPS-1, DDX3 can bind viral RNA and as such enhance its recognition by RIG-I. Vaccinia virus K7, HCV core protein, or HBV polymerase can bind DDX3 and inhibit its association with cellular proteins.[289] Kaposi sarcoma-associated herpesvirus (KSHV) Orf63 is an inhibitory homolog of NLRP1.[291]

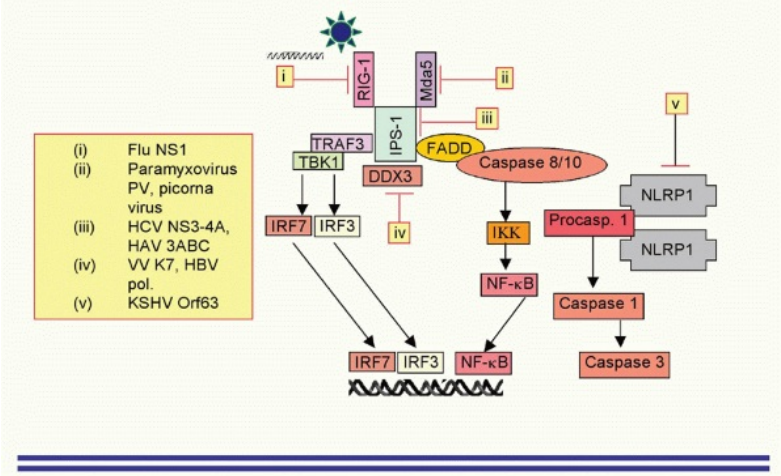

FIG. 39.8. Inhibition of retinoic acid-inducible gene I signaling by viral antigens: (*i*) to (*v*) indicate points of interactions between viral antigens and components of the pathways.

Multiple proteins of vaccinia virus interfere with NF-κB or IRF3 activation. Vaccinia virus N1L

associates with several components of the multisubunit IKK-B kinase complex, including the TBK1 and thus inhibits activation of both NF-κB and IRF3 pathways.[292] B14R of vaccinia virus binds the IKK complex and prevents phosphorylation of Iκκβ,[293] K1L inhibits NF-κB activation by blocking degradation of IκBα,[294] and M2L downregulates ERK-mediated NF-κB induction.[295] Another poxvirus, MCV, encodes MC160, which induces IKK1 degradation[296] and M159L, which inhibits PKR signaling.[297] Measles virus V protein can bind Iκκα and thus prevent phosphorylation of IRF7. It can also prevent phosphorylation of IRF3 by acting as an IRF3 mimetic[298] (see Fig. 39.7).

KSHV encodes an immediate-early nuclear transcription factor that promotes the ubiquitination and degradation of IRF7[299] and another protein K-bZIP, which binds DNA and competes with IRF3 binding.[300] ICP10 from bovine herpesvirus, protease N from flaviviruses, E6 of HPV-16, HIV-1 Vpr, and Vif cause degradation of IRF3. NSP1 of rotavirus causes destruction of IRF5 and 7.[289] Rabies virus protein P prevents phosphorylation of IRF3.[301] Papain-like protease of SARS-CoV blocks the nuclear transport of IRF3.[302]

PKR, once activated by dsRNA, inhibits viral protein synthesis and as such is another favorite target for viruses in their zest to optimize their chance for replication. The VA-RNA of adenoviruses can serve as a decoy; it binds PKR but does not trigger signaling.[303] Similarly, the TAR RNA of HIV-1's long terminal repeat, which initiates tat-mediated activation of transcription, can block PKR activation.[304] Tat is phosphorylated by PKR and outcompetes phosphorylation of eIF2α. HCV NS5A prevents dimerization of PKR.[305] Vaccinia virus K3L[306] and HCV E2[307] prevent interactions between PKR and eIF2α. Poliovirus activates a protease that destroys PKR,[308] while influenza virus NS-1 activates the cellular PKR inhibitor p38 to prevent PKR dimerization.[309] HSV-1 protein IPC34.5 activates a cellular phosphatase that dephosphorylates PKR and eIF2α.[310]

Some viruses manipulate PRR signaling pathway to create a more favorable environment. Vaccinia virus A52R blocks IRAK2 but allows signaling through TRAF6, which activates MAPKp38 and JNK leading to the induction of IL-10, which in turn suppresses Th1-type immune

responses.[311] The ATP-dependent DEAD box RNA helicase DDX3 interacts with rev of HIV-1 and enhances nuclear export of viral RNA. HCV utilizes DDX3 for its replication possibly by taking advantage of DDX3's ability to unwind dsRNA.[312]

Inhibition of Apoptosis

Inhibition of NF-κB, activation of PKR, or signaling through TNF receptors can induce apoptotic pathways. Apoptosis can also be initiated in response to cell damage. Although many viruses eventually cause death of the infected cells, premature apoptosis before the virus replication has been completed would be counterproductive and viruses therefore devised mechanisms to block apoptosis pathways (Fig. 39.9).

Apoptosis can be triggered through members of the TNF-receptor family. TNF receptors carry an intracellular receptor domain that contains a death effector domain (DED), which binds to corresponding DEDs on adaptor proteins such as Fas-associated protein with death domain. Upon ligation of the extracellular part of the receptor, the cytoplasmic tail binds to the death inducing signal complex containing procaspase 8, which is then cleaved into caspase 8. Caspase 8 activates caspase 3, which induce cells death. Cellular FLICE-like inhibitors can inhibit caspase 8 activation by competitive binding to the death inducing signal complex. Inhibition of the AKT/PI3K pathways or p53 can lead to dephosphorylation of the Bcl-2-associated death promoter, which forms a heterodimer with Bcl-2-associated X protein. This

complex can increase the permeability of mitochondrial walls. Consequently, cytochrome C is released from mitochondria, which forms a complex with apoptotic protease activating factor 1 (APAF1) and procaspase 9. Procaspase 9 is cleaved into an active form and then activates caspase 3. This apoptosis pathway can be blocked by Bcl-2.

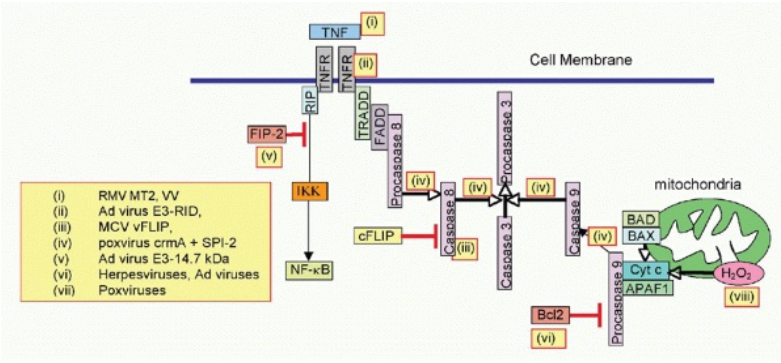

FIG. 39.9. Viral interference with apoptotic pathways: (*i*) to (*vii*) indicate points of interactions between viral antigens and components of the pathways. *Cyt c*, cytochrome C.

Poxviruses encode proteins that subvert TNF-receptor signaling. MT2 of rabbit myxomavirus sequesters TNF-α, and vaccinia virus encodes a number of TNF-receptor homologs, which can be secreted or expressed on cell surfaces.[313] The adenovirus E3 gene product RID induces internalization and degradation of TNF-receptor family members.[314]

Several herpesviruses and MCV prevent caspase 8 activation through a viral FLICE inhibitory protein.[315,316] Some poxviruses produce serine protease inhibitor-like molecules called crmA (cowpox) or SPI-2 (ectromelia virus), which contain DED domains and inhibit activation of caspases.[316,317] The adenovirus E3 14.7 kDa protein inhibits caspase 8 through a yet-to-be-identified pathway upon binding to the host protein FIP-2.[318] A number of herpesviruses and adenoviruses increase antiapoptotic pathways by encoding a Bcl-2 homolog.[319]

Cells infected with viruses can undergo a stress response with accumulation of reactive oxygen species, which in turn increase mitochondrial permeability and induce apoptotic cell death. Cellular enzymes, such as glutathione peroxidase, a selenocysteine containing protein, can reduce H_2O_2. Poxviruses encode a homologous protein.[320] The p28 of ectromelia virus (mousepox) and the N1R of Shope fibroma virus have a RING finger motif that inhibits apoptosis induced by UV light.[321]

Inhibition of Cytokines/Chemokines

Manipulation of PRR signaling reduces production of proinflammatory cytokines. Viruses have developed additional strategies to inhibit production and effector activities of cytokines and chemokines, which may interfere with their replication.

Interferons. IFNs and IFN-induced proteins have potent antiviral activity and are thus targeted by numerous viruses. IFN-1, upon binding to its receptor, activates Jak1 and Tyk2. This causes phosphorylation of Stat1 and Stat2, which form heterodimers, translocate to the nucleus, and associate with IRF9 to form the transcription factor complex ISGF3. This complex initiates transcription of IFN-stimulated genes (ISGs). The binding of IFN-γ to its receptor causes complex-formation between Jak1 and Jak2. This causes phosphorylation of Stat1, which forms homodimers, which then translocates to the nucleus to interact with

gamma activated sequence elements in promoters.

Poxviruses encode proteins that are secreted from infected cells and bind with high-affinity type I or II IFN receptors, thus preventing those neighboring, not-yet-infected cells from becoming resistant. They also produce molecules that mimic the receptors for IFNs and thus soak up IFN molecules to prevent their binding to cellular receptors.[322]

Rabies virus P protein blocks translocation of phosphorylated Stat1 to the nucleus, and in the nucleus binds to Stat1/2-IRF9 complexes thus preventing activation of transcription.[323] SARS-CoV ORF6 binds to nuclear transport proteins thus blocking transport of Stat1.[324] Stat2 is targeted for destruction by Dengue virus NS5[325] or RSV NS1.[326] Stat1 can be degraded by a cellular ubiquinase induced by paramyxoviruses.[327]

IFN induces synthesis of over 300 proteins, many of which have antiviral or immunomodulatory functions. One of those is tetherin, which can prevent the cellular egress of viruses such as lyssaviruses, KSHV, HIV-1, or Ebola virus. KSHV K5 or HIV-2 Vpu ubiquinate tetherin and thereby initiate its degradation.[328] ISG15 is an IFN-induced ubiquitin-like protein, which upon binding to proteins causes their degradation through an ubiquitin-independent pathway in a process called ISGylation. As ISG15 has broad antiviral activity and increases resistance to numerous viruses, many have devised avenues to subvert its activity (341). Influenza B virus NS1 sequesters ISG15,[329] Crimean Congo hemorrhagic fever virus, a member of the *Bunyaviridae* family, encodes proteins with de-ISGylating activity, which removes ISG15 from its target.[330]

MX-1 is another IFN-induced protein that in mice is critical for recovery from influenza A virus infection. A human homolog MxA has broad antiviral activity against RNA viruses and DNA viruses with an RNA intermediate.[331] The functions of Mx1 or MxA are not yet fully understood, but the proteins seem to bind capsid or nucleoproteins early after infection, thus somehow blocking virus replication. A rather old-fashioned mechanism allows some influenza A viruses to escape control by Mx1; they grow so fast that they can outrun the IFN-induced production of Mx1.

Other Cytokines. Parapoxvirus, which infects sheep and goats, as well as EBV, encodes an IL-10-like protein that inhibits synthesis of IL-12 and thus generation of Th1 immune responses.[332,333] Similarly, the UL111A ORF of HCMV has sequence homology with IL-10.[334] IL-18-binding proteins are encoded by poxviruses, such as MCV, ectromelia virus, cowpox, or vaccinia viruses.[335] KSHV encodes an IL-6-like protein.[336] The poxvirus-encoded GIF binds to both granulocyte M-CSF and IL-2.[337] EBV encodes BARF1, a M-CSF-binding protein.[338] Vaccinia virus encodes two proteins (ie, B15R and B18R), which bind and inhibit IL-1β.[339] The C10L protein of vaccinia virus encodes a protein that blocks the IL-1 receptor.[340] IL-1β is synthesized as a precursor that only gains functional activity upon cleavage by caspase 1. The same caspase also cleaves the precursor molecule of IL-18. Cowpoxvirus encodes a serine protease inhibitor called crmA that inhibits the function of caspase 1.[341]

Several viruses encode molecules that resemble those of the mammalian TNF-receptor family. HCMV encodes UL144, which is related to HVEM.[342] Shope fibroma virus and myxoma virus encode a single TNF-receptor homolog called T2,[343,344] whereas orthopoxviruses encode one to three different TNF-receptor homologues called crmB, crmC, crmD, and CrmE.[345] T2, crmB, and cmrD bind TNF-α and lymphotoxin A, while crmC binds only TNF-α. T2, crmC, and crmD TNF-α-mediated cell lysis. The E13 of ectromelia virus resembles CD30, another TNF-receptor family member, and can bind and inhibit CD30L signaling, which under physiologic conditions can support DC maturation.[346]

Chemokines Chemokines direct trafficking of leukocytes and are essential to initiate an inflammatory response by attracting a cellular infiltrate. Chemokines are divided into four classes depending on the spacing of their first two cysteine residues (ie, C CC, CXC, and CX3C). Chemokines are referred to as ligands (L), which bind to correspondingly named receptors (R). There are a total of 27 CC chemokines, 17 CXC chemokines, 2 C chemokines, and 1 CX3C chemokine. Viruses manipulate chemokine functions by producing decoy chemokines or chemokine receptors or by secreting chemokine-binding proteins.

Viral chemokines can be agonistic or antagonistic. Examples of agonists are tat of retroviruses, which binds CCR2/3,[347] herpesvirus UL146, a CXCR2 binder,[348] and murine CMV m131. MC148R of molluscipox virus and K4 of HHV8 are CCR antagonists.[349,350] Marek disease virus produces a viral IL-8, which recruits granulocytes.[351] UL146 and 147 of HCMV also encode an IL-8 like molecule.[352]

Herpes and poxviruses encode numerous members of the chemokine receptor family that serve as decoys for chemokines. UL33, UL78, US27, and US28 of HCMV,[353] U12 and U51 of HHV6/7,[354] and M78 and M33 of murine CMV show homology with CCR receptors.[355] ORF74 of several herpesvirus strains mimics CXCR2.[356] K2R of is a homolog of a CXCR[357] whereas MC148 protein of molluscipox virus shows similarity with CCR8.[358]

Poxviruses and herpesviruses produce secreted viral chemokine proteins, which prevent binding of chemokines to their receptors. MT-1 of myxoma, B29R of vaccinia virus, and a 35 kDa protein of Shope fibroma virus inhibit CC chemokines.[359,360,361] M3 of murine gamma-herpesvirus 68 inhibits all four classes of chemokines.[362]

Viruses, by enhancing the effects of some chemokines while inhibiting others, presumably create a microenvironment that is best suited for their propagation. They bias the immune response so that it is only marginally harmful to

virus-producing cells, by, for example, recruiting eosinophiles and Th2 cells and excluding Th1 cells, or by secreting IL-8, which can block the activity of type I IFN. They may also selectively recruit cells that are permissive for viral replication, such as CMV, which through production of viral IL-8 recruits neutrophils so that they can then become infected.[363]

Inhibition of Complement Activation

The complement system is composed of more than 25 proteins that are sequentially activated through three distinct pathways called the classical, alternative, and lectin pathways. The classical pathway is activated once a pathogen or an antigen-antibody complex binds to C1q, which forms the C1 complex with C1r and C1s. Conformational changes of C1q activate C1r, which cleaves C1s into a protease, which in turn cleaves C2 and C4 into a and b subunits. C4b and C2a bind and form C3 convertase, which cleaves C3 into a and b. C3b binds the C3 convertase forming C5 convertase, which cleaves C5. C5b, C6, C7, C8, and C9 form the membrane attack complex, which initiates cell lysis. In the alternative complement pathway, C3 is spontaneously split into C3a and C3b. C3b can bind to a cell surface-expressed antigen from a pathogen and then also to factor B, which, in presence of factor D, is cleaved into Ba and Bb. The C3bBb complex can act as a C3 convertase. In the lectin pathway, mannan-binding lectin on the cell surface binds mannose on the surface of pathogens. This activates mannan-binding lectin-associated serine protease-1 and -2, which can cleave C4 and C2 thus allowing formation of C3 convertase. The complement pathways, which can be very damaging once fully activated, are tightly controlled by regulators of complement activation, which acts at three key points. C1 inhibitors block spontaneous activation of C1 and bind C1 in serum. Decay accelerating factor (CD55) and CR1 destroy C3 convertase. C4 binding protein and factor H promote dissociation of C4 or C3 subunits from complement complexes. They can also activate factor I, which together with its cofactor CD46 cleaves

C3b and C4b. Polymerization of C9 into the final membrane attack complex is blocked CD59 and homologous restriction factor.

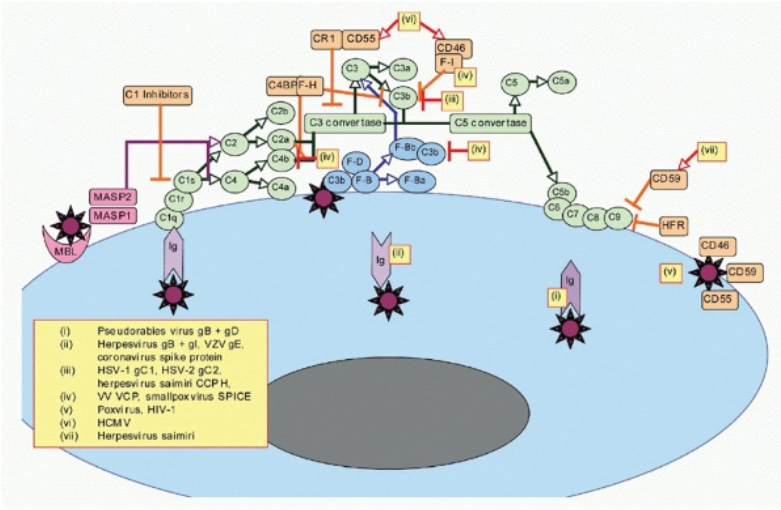

FIG. 39.10. Virus-Mediated Inhibition of Complement Pathways. The classical complement pathway is shown in *green*, the alternative complement pathway is shown in *blue*, and the lectin pathway is shown in *pink*; physiological inhibitors are shown in *orange*; *Ig*, virus-specific antibody. (*i*) to (*vii*) indicate compenents of the pathway that are inhibited or enhanced by viral antigens.

Complement can alter the structure of viruses, together with antibodies lyse viruses or virus-infected cells, and promote phagocytosis. Viruses have evolved three strategies to avoid destruction by complement: 1) they can interfere with activation of the classical pathway by shedding antigenantibody complexes from the surface of infected cells or by expressing Fc-receptor-like structures that complex antibodies that are bound to viral surface proteins; 2) they can encode complement inhibitors; and 3) they can incorporate host-derived complement inhibitors into their envelope (Fig. 39.10).

Herpesviruses and coronaviruses avoid recognition of antigen-antibody complexes by shedding such complexes from the surface of infected cells, by internalizing them, or by expressing Fc-receptor-like molecules. More specifically, gB and gD of pseudorabies virus are internalized once they bind antibodies.[364] The gE and gI of a number of herpesviruses,[365] the gE of varicella zoster virrs,[366] and the spike protein of some coronaviruses[367] resemble mammalian Fc receptors that nonspecifically bind Igs, thus sterically hindering binding of antibodies to their antigen on infected cells. Fc receptors present on an infected cell force antibodies bound with their variable region to an antigen to loop over and bind with their constant region to the Fc receptors, which prevents complement activation.

Viral complement inhibitors interfere with complement activation. HSV-1, HSV-2,[368] and herpesvirus saimiri[369] encode gC1, gC2, or CCPH, respectively, which bind C3b and inhibits formation or accelerates decay of C3 convertases. VCP of vaccinia virus[370] and SPICE of smallpoxvirus[371] bind C4b and C3b and serve as cofactors for factor I.

Enveloped viruses bud through the cell membrane at lipid rafts that are rich in cholesterol and other lipids and also contain glycosyl phosphatidyl inositol-anchored complement control proteins such as CD46, CD55, and CD59, which are incorporated into the membrane of the extracellular enveloped form of poxviruses[372] and HIV-1.[373] Furthermore, some viruses

directly increase numbers of complement regulatory proteins; HCMV augments cellular expression of CD55 and CD46,[374] while herpesvirus saimiri encodes a CD59 homolog.[375]

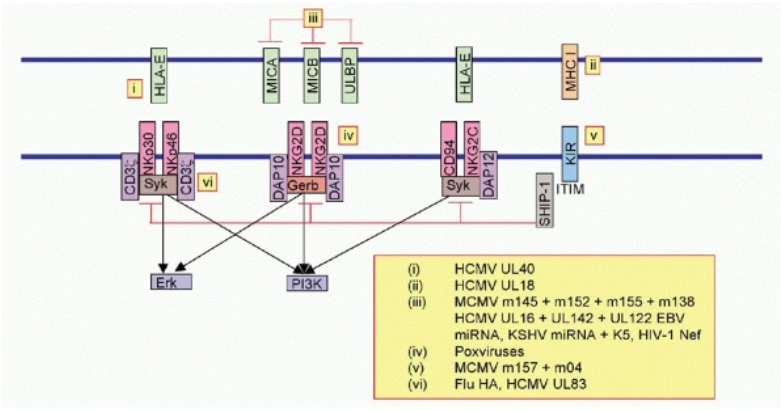

FIG. 39.11. Subversion of Natural Killer Cell Responses by Viruses. Activating receptors are shown in *pink*, inhibitory receptors in *blue*, and ligands in *green* and *orange*, respectively. (*i*) to (*vi*) indicate interactions with viral antigens and components of natural killer cells or their ligands.

Modulation of Natural Killer Cell Activity

Natural killer cells have antiviral functions through secretion IFN, which also promotes adaptive immune responses, and they can lyse virus-infected cells directly, especially if these cells downregulate MHC class I expression or if they bind antibody-dependent cellular cytotoxicity-inducing antibodies. Viruses thus evolved to kill natural killer cells, strengthen signals through the natural killer cell's inhibitory receptors, or weaken those through activating receptors (Fig. 39.11).

Influenza virus can infect natural killer cells and induce their apoptosis.[376] HCV E2 uses CD81, which is expressed on natural killer cells, as a receptor and attenuates its signaling.[377]

Herpesviruses reduce MHC class I expression, which would allow for activation of natural killer cells through loss of inhibitory signals. Herpesviruses solve this problem by ensuring expression of HLA-E, an MHC class I-like molecule that only presents the leader sequence of other MHC class I molecules and as such is not recognized by traditional CD8+ T cells, but by inhibitory receptors on natural killer cells. The signal sequence of UL40, an HCMV-encoded protein, carries a sequence that associates with HLA-E, thus allowing its translocation to the cell surface.[378] In addition, UL18 of HCMV is an MHC class I analog and binds inhibitory ILT2 (LIR1), but not the TCR of CD8+ T cells.[379] Flaviviruses take the opposite approach and augment MHC class I expression.[380]

Cellular stress responses can lead to expression of MHC class I chain-related genes, such as MICA/MICB and ULBP proteins in humans, and Rae-1, a likely RNA export protein,

H60, a minor histocompatibility antigen, and mouse UL16-binding protein-like transcript 1, an MHC class I-like molecule, which can be spotted by activating natural killer cell receptors, especially NKG2D.[381,382] Both HCMV and murine CMV encode proteins that downregulate the cellular ligands for NKG2D. Murine CMV proteins m145, m152, and m155 interfere with the expression of all known NKG2D ligands, whereas m138 affects the expression of mouse UL16-binding protein-like transcript 1 and H60. HCMV UL16 causes intracellular retention of MICB and ULBP, UL142 downregulates MICA, micro-RNA UL122 interferes with the

translation of MICB, as does the EBV encoded micro-RNA BART2-5b, and the KSHV encoded micro-RNA K12-7. KSHV also produces K5, which causes ubiquitination of MICA and MICB. HIV-1 nef down-regulates expression of MICA and ULBP.[383] Orthopoxviruses produce a secreted NKG2D ligand thus saturating the receptor.[384]

Ly49s are inhibitory receptors that recognize MHC class I molecules. MCMV encodes two proteins, m157 and m04, that can serve as ligands for inhibitory Ly49 receptors, specifically in murine CMV-resistant strains of mice; m157 is a ligand for the natural killer-activating Ly49H receptor; in susceptible strains of mice it binds the inhibitory Ly49A receptor.[385] NCR1-encoded NKp46 recognizes the HA of influenza virus. NKp46 and NKp30 receptors associate with the CD3 ζ-chain for signaling. Free HA can induce lysosomal ζ chain degradation thus blocking signaling.[386] HCMV UL83 uses a similar pathway and dissociates the ζ chain to block its recognition by NKp30.[387]

Viruses not only increase the strength of inhibitory signals to natural killer cells, but also interfere with activating receptors. K5 of KSHV downregulates AICL, a target for NKp80.[388] UL141 of HCMV sequesters CD155, the poliovirus receptor that is a target for DNAM-1.[389] UL16 of HCMV reduces expression of LFA-3, an adhesion molecule that binds to CD2 on natural killer cells and by unknown mechanisms increases the infected cells's resistance to natural killer cell-mediated lysis.[390]

Escape from Adaptive Immune Responses

Subversion of Antigen Presentation by Major Histocompatibility Complex Class II

Stimulation of CD4+ T cells, which requires presentation of epitopes on MHC class II, can be reduced by limiting the amount of antigen available for processing and presentation of by decreasing expression of MHC class II molecules on the cell surface.

Autophagy serves the cells to eliminate unwanted proteins from the cytoplasm by delivering them to lysosomes for degradation. This pathway is also used to destroy viruses and deliver viral peptides to compartments, where they associate with MHC class II molecules. The importance of autophagy in antiviral defense is underscored by its induction through signals from viral sensors, such as TLR4. Viruses, as described previously, interfere with such signals. Alpha- and gamma-herpesviruses through ICP34.5 and viral BcL-2, respectively, can directly block Beclin-1, a molecule needed for formation of autophagosomes.[391,392]

Herpesviruses, poxviruses, and HCV interfere with MHC class II expression. For example, gB of HSV-1 binds HLA-DR complexes in a post-Golgi department and then shuttles them into exosomes rather than allowing for their transfer to the cell surface.[393] A mutation of the precore protein of HBV has been linked to decreased levels of MHC class II on antigen-presenting cells, suggesting a potential evasion pathway,[394] and a variant in the HCV NS3 proteins has been shown to serve as an epitope antagonist by binding MHC class II molecules and blocking binding of the CD4+ T-cell epitope.[395] HCMV can impair MHC class II expression through two pathways. MHC class II transcription is tightly regulated, mainly through the class II transactivator (CIITA), a non-DNA-binding protein that interacts with transcription factors, which then associate with the MHC class II promoter. CIITA is rate-limiting factor for MHC class II production and thus determines the expression pattern of these molecules. Four promoters, two of which sponsor constitutive expression of CIITA in antigen-presenting cells, regulate CIITA production. One is activated by IFN-γ through the Jak/Stat1 pathway. Proteins of HCMV inhibit induction of CIITA by disrupting this pathway.[396]

Subversion of Antigen Presentation by Major Histocompatibility Complex Class I

Many viruses subvert presentation of their antigens by the MHC class I pathway, thus

reducing activation and effector functions of antigen-specific CD8+ T cells, again stressing the importance of this cell subset for antiviral defense. Nearly every step of the MHC class I presentation pathway can be affected, and some viruses encode multiple proteins that act at different levels of the MHC class I processing/presentation pathway (see Fig. 39.12).

Major Histocompatibility Complex Class I Synthesis. Viral gene products such as tat of HIV-1 can suppress transcription of MHC class I genes.[397]

Protein Degradation. EBNA-1 of EBV and LANA1 of KSHV carry leucine-alanine repeats that appear to block their degradation by proteasomes.[398] Once proteins are degraded, the aminopeptidases CD10 and CD13 trim them to a size that allows their binding to the groove of MHC class I molecules. HCMV blocks synthesis of CD10 and retains CD13 within the ER.[399]

Peptide Transport. Loading of MHC class I molecules depends of active transport of peptides from the cytoplasm to the ER with the help of TAP. The E7 of HPV-18 and the E1A protein of adenovirus human serotype 12 inhibit the promoter controlling TAP production. EBV encodes a viral IL-10 receptor homolog that reduces expression of TAP. The mK3 protein of mouse gamma-herpesviruses binds to TAP and tapasin resulting in their ubiquination and degradation. The 19K polypeptide encoded by the E3 domain of adenoviruses binds to TAP and prevents association between TAP and tapasin. US6, a protein encoded by HCMV, binds to TAP and prevents binding of ATP, which is needed for peptide transport. The ICP47 polypeptide from HSV inhibits TAP by blocking its peptide binding. EBV encodes

a protein that weakly binds the IL-10 receptor. Similar to cellular IL-10, the EBV protein reduces expression of TAP.[400] BNLF2a, a lytic phase protein of EBV is anchored by its C-terminal tail to the ER membrane, while its cytosolic N terminus inhibits TAP.[401]

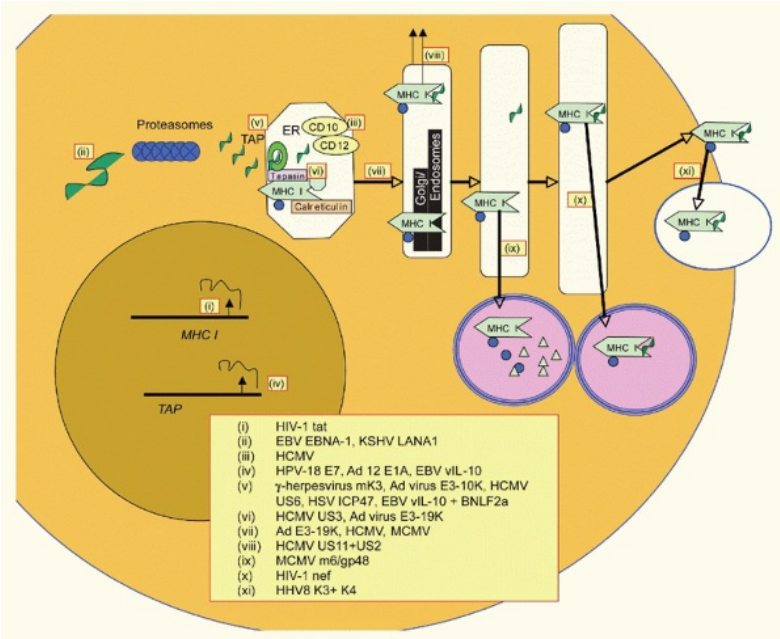

FIG. 39.12. Inhibition of Major Histocompatibility Complex Class I Processing and Presentation of Endogenously Produced Proteins by Viral Antigens. (*i*) to (*xi*) indicate at what points the pathway is attacked by viral antigens.

Major Histocompatibility Complex Class I Peptide Loading. Loading of peptides to MHC class I is supported by tapasin, which stabilizes the molecule and prevents binding of self-

peptides. US3 of HCMV binds and inhibits tapasin.[401] E3-19K of adenovirus blocks the formation of the TAP-tapasin complex.[402]

Major Histocompatibility Complex Class I Transport. Once MHC class I molecules have bound peptides, they are transported to the cell surface. A number of viral products interfere with this transport by either retaining MHC class I molecules within the ER, by inducing their export into the cytoplasm, or by interfering with passage through the Golgi apparatus. The E3-19K protein of adenovirus[402] and proteins of HCMV and murine CMV prevent the exit of MHC class I from the ER and from pre-Golgi compartments.[403] US11 and US2 of HCMV dislocate the MHC class I molecules from the ER to the cytoplasm, where they are rapidly degraded. The m6/gp48 protein of MCMV binds to MHC class I-β2-microglobulin in the ER and during transport to the cell surface, targets the MHC class I complexes to lysosomes, where they are proteolytically digested.[404] Nef of HIV-1 reduces cell-surface expression of MHC class I by redirecting the molecules from the trans-Golgi network to the endosomes.[405] The K3 and K4 proteins of HHV8 lower expression of cell surface MHC class I molecules by enhancing their endocytosis into clathrin-coated pits.[406]

Escape from Antibodies

To summarize, viruses escape antibody-mediated neutralization mainly by mutations; they evade destruction by antibody and complement by interfering with activation of complement, and they dodge antibody-dependent cellular cytotoxicity by masking antigen display on cell surfaces and by inhibiting natural killer cell functions. All of these pathways have been described previously. EBV directly subverts B cells, where it resides during latency and where it can be transformed through the viral oncoprotein LMP1, a molecule that has functional homology with CD40 and can activate the NF-κB pathway. Unlike CD40 signaling, which requires ligation with CD40L, LMP1 is constitutively active, although one would assume that it is negatively regulated by yet unknown pathways as it would otherwise inevitably lead to B-cell transformation.

CONCLUSION

Viruses continue to raise havoc. Each year, millions of humans die prematurely due to viral infections and many more become temporarily incapacitated. Vaccines licensed for a handful of viruses and antiviral drugs available for even fewer have lessened the impact of some viral infections, but for most the immune system remains our only defense. Our knowledge in basic immunology has exploded over that last century. Although early vaccines were developed without knowing anything about immunology, but as it is stated in the “Míshlê Shlomoh,” the Book of Proverbs: *‘scientia potentia est*,” knowledge is power. A better understanding of the intricate pathways that regulate the interactions between viruses and their hosts' immune system should empower us to eventually win this eternal battle and lessen human suffering caused by something as small but as deadly as a bit of invasive genome with a few proteins around it.

Chapter 40

Immunity to Intracellular Bacteria

Anca Dorhoi

Stephen T. Reece

Stefan H. E. Kaufmann

INTRODUCTION

This chapter focuses on infections by intracellular bacteria with emphasis on both pathogenicity and general immune mechanisms underlying protection. Intracellular bacteria comprise numerous pathogens, some of which are of utmost medical importance. Ancient (but still existent), as well as newly emerging, diseases are caused by intracellular bacteria, with tuberculosis (TB), typhoid, leprosy, and trachoma as the most relevant etiologically associated infections.

Intracellular bacteria live inside host cells for most of their lives. This coexistence must allow survival of the infected cell; therefore, intracellular bacteria generally lack toxicity. Instead, they have evolved multiple strategies to interfere with key host cell biologic processes to promote replication or persistence. This has direct consequences for the immune response evoked by the host attempting to resolve intracellular infection. In fact, acquired resistance against intracellular bacterial infections depends on activation of multiple arms of the immune system. In this chapter, we start by examining the complex molecular crosstalk between pathogen and host. We then consider how these molecular events translate into the development of adaptive immunity. Finally, we examine effects of both adaptive and innate immune mechanisms on long-term effects of intracellular bacterial infection. Such long-term effects include tissue remodelling, nonresolved inflammation, and chronic immune responses, which for the most part are tolerated by the host. We hope this chapter will stimulate an interest in intracellular infection and the unique immunologic insights it can provide.

FEATURES OF INFECTIONS WITH INTRACELLULAR BACTERIA

Intracellular Bacteria/Public Health Relevance

Bacterial pathogens are prokaryotic microorganisms that cause disease in a given host species. They are single cells, typically micrometers in length, and present a specific spectrum of interactions with their human host. Infectious disease is the direct and invariable consequence of an encounter between host and pathogen. Often, it is the eventual outcome of complex interactions between them. There is a marked degree of diversity among bacterial species that are able to induce intracellular infections. This encompasses structural organization of the cell wall (ie, gram-negative versus -positive, salmonellae versus listeriae), presence of motility organelles (eg, fimbriae and flagella, of salmonellae and listeriae[1,2]) or secretion apparatus (type III secretion system [T3SS], type IV secretion system (T4SS), type VII secretion system [T7SS] in *Salmonella*,[3] *Legionella*,[4] and *Mycobacteria*,[5] respectively), and metabolic characteristics that dictate replication time (fast- versus slow-growing,

Salmonella versus *Mycobacterium*). This diversity is reflected most often in differences related to cell biology of the pathogen. However, major patterns of the immune response are shared, as detailed in the following.

Of paramount significance for humans are *Mycobacterium tuberculosis*, *Mycobacterium leprae, Salmonella enterica* serovar Typhi, *Chlamydia trachomatis*, and the etiologic agents of TB, leprosy, typhoid, and trachoma, respectively, which together afflict more than 200 million people globally. Some opportunistic pathogens such as *Mycobacterium avium/Mycobacterium intracellulare* are gaining increasing significance particularly for immunodeficient patients, such as acquired immunodeficiency syndrome (AIDS) sufferers. Many zoonotic agents are intracellular bacteria and include *Chlamydia psittaci* (psittacosis), *Brucella* (brucellosis, Malta fever/Bang disease), *Coxiella burnetii* (Q fever), *Rickettsia* (Rocky Mountain/Mediterranean spotted fever), *Francisella tularensis* (tularemia), *Burkholderia mallei* (glanders), *Yersinia pseudotuberculosis* (yersiniosis), *Yersinia pestis* (plague), *Bartonella* (cat scratch disease), and *Listeria monocytogenes* (listeriosis). Other opportunistic pathogens with an intracellular lifestyle that are relevant for human health include *Legionella pneumophila* (Legionnaires disease) and *Ehrlichia* (ehrlichiosis).

Epidemiology and Pathogenesis

Some intracellular bacteria, in particular *Rickettsia*, are introduced directly into the bloodstream by insect bites from where they have ready access to internal tissues. Most intracellular bacteria, however, enter the host through the mucosa.[6] Major ports of entry are the lung for airborne pathogens, such as *M. tuberculosis* and *L. pneumophila*, and the intestine for foodborne pathogens, such as *S. enterica* and *L. monocytogenes.* Subsequently, intracellular bacteria pass through the epithelial layers. Either they actively induce transcytosis (ie, endo- and exocytosis) through the epithelial cells or they are passively translocated within phagocytes. Bacteria may be removed by nonspecific defense mechanisms such as mucociliary movements and gut peristalsis, or they may be destroyed by professional phagocytes without necessitating the specific attention of the immune system. Cells that survive these nonspecific defense reactions

colonize deeper tissue sites and stably infect a suitable niche. At this stage, the host generally develops a specific acquired immune response.

BOX 40.1. CENTRAL FEATURES OF INFECTIONS WITH INTRACELLULAR BACTERIA

- Infection is separated from disease, and the immune response is already induced at the stage of infection.
- Infection persists latently in the face of dynamic interactions between pathogen and immune mechanisms.
- The host-pathogen relationship represents a highly sophisticated form of parasitism that does not necessarily lead to disease but rather allows for long-lasting coexistence.
- Infection includes the potential to harm the host severely at a later stage, and pathogenesis is strongly influenced by the immune response.

Infection is unsuccessful when the immune system succeeds in eliminating the pathogen before overt clinical disease develops. Alternatively, tissue damage increases to a significant level before the immune system succeeds in controlling the pathogen effectively and clinical disease develops. This is the case with many extracellular bacteria and is due to their cell lytic strategies (toxins) that cause diseases of acute type, but is less common for intracellular bacteria. Finally, it is possible that the immune response restrains the infectious agent but fails to completely eradicate it. Under these conditions, a long-lasting equilibrium between

microbial persistence and the immune response unfolds. This balance, however, remains unstable and can be tipped in favor of the pathogen at a later time, converting infection into disease.

The time lapse between host entry and expression of clinical disease is termed incubation time and from what has been said previously, it follows that in many intracellular bacterial infections the incubation times are long-lasting to lifelong. By improving the immune response or by impairing bacterial growth (typically accomplished by chemotherapy), or both, disease can be overcome. Ideally, bacterial eradication is achieved; alternatively, some dormant bacteria continue to persist in niches poorly accessible to the immune response (Box 40.1).

There is a close correlation between the cell biology and cell tropism of the pathogen and disease signs and pathology in, for instance, enteric versus lung conditions. However, even bacteria that use the same niches as habitat show major clinical differences. This is due to pathogenintrinsic biology (ie, metabolism) and peculiarities of each species to subvert host elimination. For instance, *M. tuberculosis*, *L. pneumophila*, *F. tularensis*, and *C. burnetii* cause aerogenic infections with *Coxiella* being the most successful in establishing infection (one bacterium is sufficient to induce disease, probably the most infectious bacterium). These pathogens successfully infect lung macrophages and parenchymal cells to establish infection. However, TB has a protracted course and insidious clinical signs while francisellae and coxiellae induce acute and subacute pneumonias with tissue changes substantially different from TB. Disease pathogenesis is principally the outcome of the crosstalk between host and pathogen at the cellular level with strong influences from bacteria-specific behavior, while clinical signs and pathology are often induced by host responses.

"Idealized" Intracellular Bacterium

Although this chapter focuses on general mechanisms underlying immunity to intracellular bacteria, it is important to emphasize that this group is extremely heterogeneous. Therefore, the major hallmarks of intracellular bacterial infections will first be described for a nonexistent "idealized" intracellular bacterium (Table 40.1). Subsequently, characteristics of selected intracellular bacteria will be specified.

Facultative and Obligate Intracellular Bacteria

With respect to preferred habitat, intracellular bacteria can be divided into two groups: First, those pathogens that do not essentially depend on the intracellular habitat, including *M. tuberculosis*, *Mycobacterium bovis*, *M. leprae*, *S. enterica*, *Brucella*, *L. pneumophila*, *L. monocytogenes*, and *F. tularensis* (Table 40.2).[7,8,9,10,11,12,13,14,15] Although these pathogens

favor mononuclear phagocytes (MPs) as their habitat, other types of host cells are infected as well. *M. leprae*, for example, lives in numerous host cell types, notably in Schwann cells and hepatocytes serve as an important reservoir for *L. monocytogenes.* Although *M. tuberculosis* can infect a variety of mammalian cells in vitro, in vivo it seems to restrict itself to phagocytes and perhaps epithelial cells.

TABLE 40.1 Hallmarks of Intracellular Bacterial Infections

Hallmark 1	The intracellular lifestyle represents the distinguishing feature of intracellular bacteria.

Hallmark 2	T cells are the central mediators of protection against intracellular bacterial infections. In contrast, antibodies play a facilitating role.
Hallmark 3	Infections with intracellular bacteria are accompanied by delayed-type hypersensitivity, which expresses itself after local administration of soluble antigens as a delayed tissue reaction mediated by T cells and effected by macrophages.
Hallmark 4	Tissue reactions against intracellular bacteria are granulomatous. Protection against, as well as pathology caused by, intracellular bacteria are centered on these lesions. Rupture of a granuloma promotes bacterial dissemination.
Hallmark 5	Intracellular bacteria express little or no toxicity for host cells by themselves, and pathology is primarily a result of immune reactions, particularly those mediated by T-lymphocytes.
Hallmark 6	Intracellular bacteria coexist with their cellular habitat for long periods of time. A labile balance develops between persistent infection and protective immunity, resulting in long incubation time and in chronic disease. Accordingly, infection is dissociated from disease.

Hallmarks 1 to 4 should be considered essential, and Hallmarks 5 and 6 conditional, criteria for defining intracellular bacteria.

TABLE 40.2 Major Infections of Humans Caused by Facultative Intracellular Bacteria

Pathogen	Disease	Preferred Target Cell	Preferred Location in Host Cell	Preferred Port of Entry
Mycobacterium tuberculosis	Tuberculosis	Macrophages	Early phagosome	Lung
Mycobacterium leprae	Leprosy	Macrophages, Schwann cells, other cells	Phagolysosome, cytosol	Nasopharyngeal mucosa
Yersinia pestis	Plague	Macrophages	Autophagosome	Gut, skin
Salmonella enterica serovar Typhi	Typhoid fever	Macrophages	Late phagosome, spacious phagosome	Gut

Shigella spp.	Shigellosis	Macrophages	Cytosol	Gut
Brucella spp.	Brucellosis	Macrophages	Early phagosome	Mucosa
Legionella spp.	Legionnaires' disease	Macrophages	Endoplasmic reticulum-derived phagosome	Lung
Listeria monocytogenes	Listeriosis	Macrophages, hepatocytes	Cytosol	Gut
Francisella tularensis	Tularemia	Macrophages	Late endosome, cytosol	Skin, lung, mucosa

The second group includes so-called obligate intracellular bacteria, which fail to survive outside host cells. Most of these bacteria prefer nonprofessional phagocytes as their habitat —for example, endothelial and epithelial cells. Rickettsiae, chlamydiae, and ehrlichiae are representatives of this group. They include *Rickettsia prowazekii*, *Rickettsia rickettsii*, *Rickettsia typhi*, and *Orientia tsutsugamushi* (*Rickettsia tsutsugamushi* until 1995), the etiologic agents of louse-borne typhus, Rocky Mountain spotted fever, typhus, and scrub typhus, respectively.[16,17,18,19] Various biovars of *Chlamydia trachomatis*, which are responsible for trachoma,[20] conjunctivitis, urogenital infections, and lymphogranuloma venerum,[21] as well as *C. psittaci* and *Chlamydia pneumoniae*, causative agents of psittacosis or rare types of pneumonia,[22] respectively, also belong to this group (Table 40.3). Certain obligate intracellular bacteria, such as *Ehrlichia* and *Anaplasma phagocytophilum*, parasitize blood cells.[23,24] *C. burnetii*, the causative agent of Q fever, resides in macrophages and lung parenchymal cells.[25,26]

TABLE 40.3 Major Infections of Humans Caused by Obligate Intracellular Bacteria

Pathogen	Disease	Preferred Target Cell	Preferred Location in Host Cell	Preferred Port of Entry
Rickettsia rickettsii	Rocky Mountain spotted fever	Endothelial cells, smooth muscle cells	Cytosol	Blood vessel (tick bite)
Rickettsia prowazekii	Endemic typhus	Endothelial cells	Cytosol	Broken skin, mucosa
Rickettsia typhi	Typhus	Endothelial cells	Cytosol	Blood vessel

				(flea bite)
Rickettsia tsutsugamushi	Scrub typhus	Endothelial cells	Cytosol	Blood vessel (mite bite)
Coxiella burnetii	Q fever	Macrophages, lung parenchymal cells	Late phagosome	Lung
Chlamydia trachomatis	Urogenital infection, conjunctivitis, trachoma, lymphogranuloma, venereum (different serovars)	Endothelial cells	Phagosome/nonacidified inclusion	Eye, urogenital mucosa
Chlamydia psittaci	Psittacosis	Macrophages, lung parenchymal cells	Phagosome/nonacidified inclusion	Lung
Chlamydia pneumoniae	Pneumonia	Lung parenchymal cells	Phagosome	Lung
Ehrlichia ewigii	Ehrlichiosis	Granulocytes	Cytosol	Blood vessel (tick bite)
Ehrlichia chaffeensis	Ehrlichiosis	Monocytes, macrophages	Cytosol	Blood vessel (tick bite)
Anaplasma phygocytophilum	Anaplasmosis	Granulocytes	Cytosol	Blood vessel (tick bite)

Preferential living in macrophages does not depend on specific invasion mechanisms but rather on highly sophisticated intracellular survival strategies. Yet, most facultative intracellular bacteria express unique invasion factors, if only to cross epithelial layers. Selection of nonprofessional phagocytes as habitat essentially depends on invasion molecules whereas survival inside these cells is generally less hazardous.

CELL BIOLOGY

For intracellular bacteria, entry into host cells represents the central requirement for survival in, as well as elimination by, the host. Host cell-directed uptake, called phagocytosis, is a feature of the so-called professional phagocytes that comprise polymorphonuclear granulocytes (PNGs) and MPs. Examples of bacteria that are engulfed by phagocytosis include *M. tuberculosis*, *L. pneumophila*, and *C. burnetii.* Entry induced by the pathogen is termed invasion, which allows entry into nonphagocytic cells (nonprofessional phagocytes). Salmonellae, shigellae, and listeriae are paradigms of enteroinvasive pathogens.[27] Contact between host cells and pathogens proceeds either directly via receptor-ligand interactions or indirectly via deposition on the surface of the pathogen of host molecules for which physiologic receptors exist on the target cell.

Depending on the cellular target, the final outcome of host cell entry varies markedly.

1. Nonprofessional phagocytes are nonphagocytic, and hence entry depends on expression of surface receptors that can be exploited for invasion. Because of their low antibacterial activities, they primarily serve as a habitat.
2. PNGs are short-lived. Because they are highly phagocytic and express potent antibacterial activities constitutively, uptake by PNGs is often fatal for the pathogen.
3. MPs are phagocytic and express medium to high antibacterial activities depending on their activation status. Accordingly, they serve both as habitat and as effector cell.

Following entry, bacterial pathogens begin intravacuolar life.[28] Two main strategies are followed to avoid killing: 1) avoidance of delivery to degradative lysosomes, either by blocking phagosome maturation, divergence from the endocytic pathway to establish a vacuole with unique features, or by escape into the cytosol; and 2) development of strategies to survive within acidic degradative organelles. Certain bacteria have developed mechanisms that allow them to impede nutrient flow inside the infected cell for their own benefit, to modulate generation of antimicrobial molecules, or to alter cell death pathways.[29,30] In the following, the major steps from uptake to bacterial elimination by, or survival in, host cells will be described (Fig. 40.1).

Adhesion and Invasion

Adhesion to mammalian cells is a prerequisite for extracellular colonization and for host cell invasion. Bacterial adhesins that solely expedite adhesion to host cells are expressed by numerous extracellular bacteria. In contrast, invasion-inducing molecules are a feature of bacteria that permanently or transiently enter host cells. Adherence to the cell membrane is based on protein-protein interactions mediated by adhesins, such as internalins (bind E-cadherin) of *L. monocytogens* or invasins (bind β1 integrins) from *Yersinia.* Adhesins may be located on the bacterial surface or on pili. In addition, adhesion may be induced by bacterial virulence factors, which recruit fibronectin to attach to host cells by binding to integrins.[29,31]

Although induced by the bacterium, invasion is ultimately a function of the host cell. Following adhesion, invasion can be induced in two ways. First, cell signaling by host cell receptors that serve as targets of adhesion induces uptake; second, uptake is induced independently from the molecules that mediate adhesion.[31,32] The term “zipper mechanism” refers to the first process. Bacterial proteins interact with host cell surface proteins to mediate internalization. This term has been suggested for the highly selective receptor-mediated bacterial entry, whereas the term “trigger mechanism” has been proposed for indiscriminate, apparently adhesion-independent uptake. Bacterial effectors are delivered to the host cytosol via a secretion system to induce bacterial entry.[27]

Entry by Zipper Mechanisms

Host cell invasion by *Yersinia* and *L. monocytogenes* are examples of invasion via the "zipper mechanism." Receptor binding induces phagocytic mechanisms in nonprofessional phagocytes similar to those that are constitutively operative in MPs. The eukaryotic cell membrane tightly enwraps the bacterium and a cascade of events, including protein phosphorylation, ubiquitination, and phospholipid modifications then contribute to vacuole genesis.[28] Host entry of *L. monocytogenes* through the intestinal epithelia is mediated by internalin on the surface of this pathogen and E-cadherin on human epithelial cells.[33] Murine E-cadherin does not serve as a receptor for internalin due to an amino acid substitution in position 16.[34] Schwann cells, a major target of *M. leprae*, are shielded by a basal lamina composed of laminin, collagen, and proteoglycans. The unique tropism of *M. leprae* for peripheral nerves appears to be due to bacterial binding to laminin. This molecule, which serves as natural ligand for integrins, thus provides a link between pathogen and Schwann cell.[35] Caveolin and lipid rafts serve as entry portals for *Brucella* and certain strains of *Chlamydia.* More recently, evidence was provided that clathrin-mediated endocytosis contributes to entry of *L. monocytogenes* and *Rickettsia* in a similar zipper mechanism.[36,37] Septins, which are small guanine triphosphatases (GTPases), are able to form filaments and interact with actin to facilitate bacterial entry as well.[38]

Entry by Trigger Mechanisms

Different molecules and mechanisms participate in host cell entry by *S. enterica.* Interactions between *S. enterica* and host cells causes large "membrane ruffling" at the site of attachment followed by bacterial entry. Ruffling induces indiscriminate uptake even of other particles in the vicinity of *S. enterica*. This process has been termed macropinocytosis. *S. enterica* triggers its uptake by exploiting the signaling machinery of

the host cell, thus inducing cytoskeletal rearrangements. In certain mouse cells, *S. enterica* induces phosphorylation of the receptor for the epidermal growth factor.[39] Yet, *S. enterica* can also enter cells that do not express the epidermal growth factor receptor. This pathogen possesses two T3SS that allow it to directly manipulate intracellular molecules within host cells.[40] *Salmonella* outer proteins are secreted into the host cells rapidly after contact. *Salmonella* outer proteins activate the small GTP-binding protein cell division control (CDC)42 of the Ras superfamily, which, in turn, induces the reorganization of the actin cytoskeleton, thus promoting bacterial invasion through membrane ruffling. A homolog of *Salmonella* outer protein (termed *Salmonella* outer protein 2) performs similar functions, and hence the two molecules may partly compensate each other's functions. The transiently intracellular pathogen *Shigella* utilizes similar mechanisms for uptake via membrane ruffling.[41,42] More recently, filopodia were shown to trap and direct shigellae to target cells in a process that involves bacterial T3SS.[43] Generally, modulators of the eukaryotic cell cytoskeleton are T3SS or T4SS products, which modulate GTPase cycling of proteins of the Rho, Rab, and Arf families.[44]

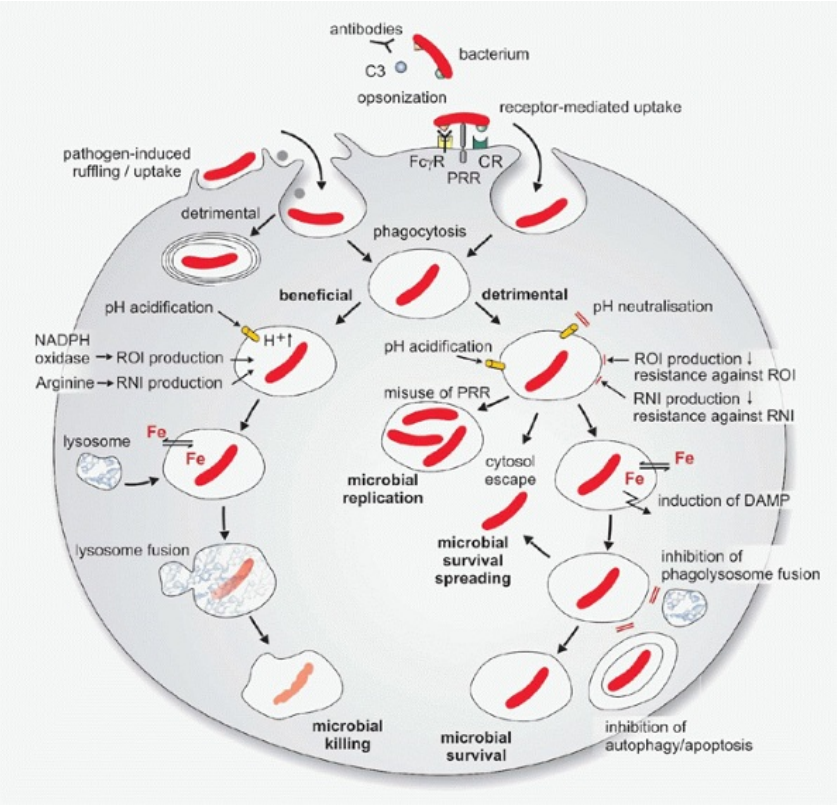

FIG. 40.1. The Multiple Encounters Between Phagocytes and Intracellular Bacteria. Bacterial uptake is both pathogen-induced and receptormediated. Multiple opsonic receptors, including complement receptor (CR) and receptors for immunoglobulins (FcγR), facilitate phagocytosis. In addition, certain pattern recognition receptors (PRRs) may contribute to bacterial internalization. Macrophages and neutrophils direct their bacterial cargo to the endosomal pathway, endosomes become acidic and progressively accumulate reactive oxygen intermediates (ROIs) and reactive nitrogen intermediates (RNIs). The phagosome maturation process culminates in fusion between late endosomes and lysosomes, which leads to bacterial killing but intracellular bacteria can interfere with phagosomal killing. Certain bacteria modulate early uptake events to prevent endosomal maturation. Other species prevent acidification of the phagosome or nullify ROIs and RNIs. Escape from the phagosome into the host cytosol is a strategy used by pathogenic bacteria and can occur at multiple stages of phagosome maturation. Certain bacteria exploit PRRs to enable self-replication in modified endosomes or modulate iron (Fe) abundance. Inhibition of phagolysosome formation, apoptosis, and autophagy also contribute to establishment of infection with intracellular bacteria. DAMP, danger-associated molecular pattern; NADPH, nicotinamide adenine dinucleotide phosphate-oxidase.

Invasion of Nonprofessional Phagocytes

Microbe-directed uptake allows entry into nonphagocytic cells and hence can be seen as an evasion mechanism of phagocytosis by professional phagocytes. The target spectrum of intracellular bacteria ranges from very broad to

highly specific. *M. leprae* is found in a large variety of host cells and hence shows a broad target cell spectrum. *L. monocytogenes* enters the host through the gut epithelium and its major target besides MPs is the hepatocyte; *M. tuberculosis* is almost, if not exclusively,

restricted to MPs, although pneumocytes have been proposed as a safe niche in the lung. It is noteworthy that intracellular bacteria are often capable of entering a variety of cell lines in vitro. These in vitro experiments do not necessarily reflect an in vivo situation, and care should be taken in extrapolating conclusions from them. For obligate intracellular bacteria, nonprofessional phagocytes rather than MPs represent the preferred habitat. These bacteria are primarily found in endothelial and epithelial cells.[17,21]

Recognition and Downstream Events

Microbes are composed of various molecules that are structurally different from host cell/tissue composition (ie, lipopolysaccharide [LPS], peptidoglycan [PGN], cytosinphosphatidyl-guanosin [CpG] deoxyribonucleic acid [DNA]). These microbe-specific molecules encompass various biochemical entities and have been named pathogenassociated molecular patterns (PAMPs).[45] Once pathogens assault host tissues, PAMPs are recognized by pattern recognition receptors (PRRs). PRRs are nonclonally distributed on various cell types; they are germline encoded and their activation, following PAMP ligation, is an essential event for initiation of the immune response and disposal of the intruder.[46,47,48,49] Microbial ligand diversity parallels the receptor repertoire, and currently there are several classes of PRRs known (Fig. 40.2), which may be classified based on chemical structure as detailed in the following:

- Toll-like receptors (TLRs) are type-I transmembrane proteins. Currently, 10 TLR members in humans and 12 in mice have been described.[50] TLRs 1, 2, 4, 5, and 6 are cell surface-associated, and TLRs 3, 7, 8, and 9 are associated with vesicles of the endoplasmic reticulum (ER), endosomes, and lysosomes (see Fig. 40.2).[51] TLRs are signaling receptors and recruit single or a combination of toll-interleukin (IL)-1 receptor-resistance (TIR)-containing adaptors, including myeloid differentiation primary response gene 88 (MyD88), TIR domain-conining adaptor protein, TIR domain-containing adaptor-inducing interferon-beta (IFN-β, and TIR domain-containing adaptor-inducing IFN-β-related adaptor molecules.[46] Timing (sequential versus simultaneously) and space (vacuole characteristics, early versus late phagosome) are essential for TLR downstream effects. TLR-4 senses LPS and thus detects extracellular gram-negative bacteria. TLR-4 first initiates nuclear factor kappa-beta (NF-κB) and secondly IFN I pathway activation via MyD88 and TIR domain-containing adaptor-inducing IFN-β, respectively. Once bacteria are phagocytosed, TLR-9 senses CpG DNA and signals via MyD88 to NF-κB in early endosomes while in lysosomes Traf3/IRF3 is assembled to enable IFN I responses.[50] TLR activation may impact the microbicidal capacity of the infected cell.[52]
- C-type lectin receptors (CLRs) belong to a large superfamily of membrane or soluble proteins, which have one or more calcium-dependent carbohydrate-binding lectin domains (see Fig. 40.2).[53,54] CLRs have high avidity for carbohydrates/glycans. CLRs mediate endocytic uptake, a feature distinct from that of TLRs. Signaling is mediated by immune-receptor tyrosine-based activation motif/spleen tyrosine kinase (Dectins; macrophage-inducible C-type lectin, Mincle), hemITAM (Dectin-1), immune-receptor tyrosine-based inhibition motif, and the kinase Raf1 (Dectin-1, dendritic cell [DC]-specific intercellular adhesion molecule-3-grabbing nonintegrin [SIGN]) to activate mitogenactivated protein kinase (MAPK) and NF-κB. CLRs are involved in generation of reactive oxygen species via the syk pathway in myeloid cells, modulate adaptive immune responses, and seem to be indispensable elements for T helper (Th)17 responses. Other CLR, notably DC-SIGN, induce inhibitory signals.

- Nucleotide oligomerization domain (NOD)-like receptors (NLRs) are cytosolic proteins (see Fig. 40.2). This family comprises more than 20 members, which are structurally diverse and are involved in pathogen sensing (NOD1, NOD2) and initiation of the inflammatory response (nucleotide-binding domain and leucine-rich repeat with pyrin domain-containing [NLRP]1, NLRP3, nucleotide-binding domain with leucine rich repeat and caspase recruitment domain [NLRC]4; NLRC5).[55,56,57] NOD1 and 2 use the receptorinteracting protein 2 adaptor to signal and are involved in PGN recognition. Thus, they are essential for sensing cytosolic bacteria in professional and nonprofessional phagocytes. NRLP and NLRC members, as well as NOD2, are essential components of inflammasomes, which are cytosolic platforms responsible for secretion of IL-1β, as detailed later.
- Retinoic acid-inducible gene I (RIG-I)-like receptors (RLRs) are cytosolic ribonucleic acid helicases (RIG-I, MDA5, and LGP2) involved in antiviral immunity.[58]
- Scavenger receptors (SRs) are cell membrane proteins that recognize modified host molecules, as well as microbial structures.[59] These receptors are mainly involved in uptake of particles including intracellular bacteria (eg, macrophage receptor with collagenous structure, MARCO; SR-A, cluster of differentiation [CD]36) (see Fig. 40.2).
- Pyrin- and HIN-containing proteins (PYHINs) have been recently associated with pathogen sensing (see Fig. 40.2). Absent in melanoma 2 (AIM2) and gamma-IFN-inducible protein 16 are the most prominent receptors involved in DNA sensing and consequently modulation of IFN secretion and inflammation.[60] AIM2 is associated with inflammasome activation and senses host and bacterial cytosolic DNA.

A key issue for host defense is the receptor profile at particular time and tissue site of infection. PRR expression in phagocytes is influenced by cell type (resident tissue macrophage versus inflammatory monocytes), tissue (lung versus

gut), milieu, and activation status (certain cytokines up- or downregulate receptors).[61] Importantly, multiple PAMPs engage multiple PRRs simultaneously or sequentially and therefore, a given pathogen by means of specific combinations of PAMPs can tailor the host response in a highly specific way. TLRs can form dimers (eg, TRL-1/2 or TLR-2/6), and may collaborate with distinct CLRs (TLR-2/Dectin-1; TLR-2/MARCO; TLR-4/CD14). On the other hand, a given PAMP may be sensed by multiple PRRs (glucans sensed by Dectin-1; complement receptor [CR]; CD36). Thus, PRRs orchestrate pathogen- and cell type-specific host immune responses. Pathogens able to alter molecules or modulate host cell death add an additional layer to this recognition process by inducing activation of PRRs via recognition of pathogens in combination with sensing of danger signals. Certain PRRs are involved in sensing both microbial components and danger signals. For instance, Mincle recognizes mycobacterial trehalose dimycolate (TDM) and the ribonucleoprotein spliceosome-associated protein 130, a protein associated with eukaryotic cell death. Despite their name, PAMPs are not restricted to pathogens but are also expressed by nonpathogenic microbes. Hence, the host probably needs to sense pathogen-specific signals in addition. In the case of intracellular bacteria, such signals could emanate from bacterial persistence, that is, from duration of PAMP expression. More recently, bacterial messenger ribonucleic acid was suggested as a signal from viable bacteria (vitaPAMP), which alerts the immune system.[62]

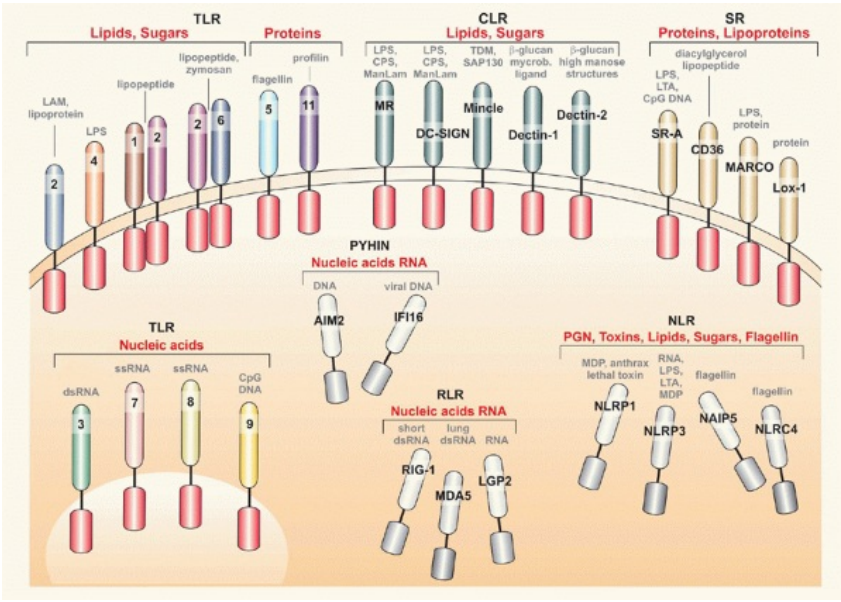

FIG. 40.2. The Pattern Recognition Receptors. Bacterial recognition is paramount in the crosstalk between host and pathogen. Several classes of receptors contribute to this process. Toll-like receptors are present at the surface membrane or within ensodomal compartments and recognize lipids, carbohydrates or proteins. C-type lectin receptors and scavenger receptors are expressed at the cell surface and sense glycolipids and lipoproteins, respectively. Surveillance of the cytosol is mainly performed by nucleotide oligomerization domain-like receptors (NLRs), RIG I-helicase receptors (RLRs), and pyrin- and HIN-containing proteins (PYHINs). RLRs are exclusively involved in viral detection, whereas NLRs recognize a wide range of structures. PYHIN detect deoxyribonucleic acid from various sources. AIM2, absent in melanoma 2; CpG, cytosinphosphatidyl-guanosin; CPS, capsular polysaccharide; DC-SIGN, dendritic cell-specific intercellular adhesion molecule-3-grabbing nonintegrin; ds, double stranded; FI16, gamma-interferon-inducible protein 16; LAM, lipoarabinomannan; LGP2, laboratory of genetics and physiology 2; Lox-1, lectin-type oxidized LDL receptor 1; LPS, lipopolysaccharide; LTA, lipoteichoic acid; ManLAM, mannosylated lipoarabinomannan; MARCO, macrophage receptor with collagenous structure; MDA5, melanoma differentiation-associated gene 5; MDP, muramyl dipeptide; Mincle, macrophage-inducible C-type lectin; MR, mannose receptor; NAIP, baculoviral IAP repeat-containing protein; NLRP, NACHT, LRR and PYD domaincontaining protein; NLRC, NLR family CARD domain-containing protein 4; PGN, peptidoglycan; RIG-I, retinoic acid-inducible gene I; ss, singlestranded; TDM, trehalosedimycolate; SAP130, spliceosome-associated protein 130.

PRRs may be classified according to pathogen-binding propensity and impact on uptake as:

- Opsonic receptors: Fc receptors (FcRs), CRs, pentraxins, surfactant proteins, ficollins
- Nonopsonic receptors: TLRs, NLRs, RLRs

Based on their effects on pathogen internalization, PRRs may be classified as:

- Phagocytic receptors: CRs, FcRs, mannose receptors (MRs), and DC-SIGN (CLRs), CD36, MARCO, and SR-A (SRs)
- Signaling receptors: TLRs, NLRs, RLRs, CLRs

Bacterial cell wall composition, secretion products, as well as intracellular location are fundamental aspects for recognition of intracellular bacteria. *M. tuberculosis* is rich in several classes of PAMPs. This pathogen interferes with the endocytic pathway and resides in an early phagosome. Phagocytosis is mediated by CLRs (MRs, DC-SIGN) and SRs (CD36), which primarily recognize mannosylated cell wall mannans and by opsonic receptors, FcRs, and CRs. Another CLR, namely Langerin, seems to have a role in *M. leprae* recognition. Lung surfactant proteins mediate the recognition of tubercle bacilli in the alveolar space. Sensing of the lipopeptides and phosphatidylinositol mannans is performed by TLR-2, while TLR-4 involvement is still debated. Multiple CLRs sense mycobacterial glycans or lipoglycans. TDM, a specific component of mycobacteria, is recognized by Mincle, while DC-SIGN senses mannosylated lipoarabinomannan. SIGNR3 and Dectin-1 and -2 are also involved in recognition. However, to date no specific structure from mycobacteria has been identified as a ligand for these lectins. Once in the phagosome, bacteria may be sensed by TLR-9. Bacterial PGN, which accesses the cytosol, is recognized by NOD2. Notably, there is a degree of redundancy between receptors belonging to different classes, as revealed by studies with mice with single or multiple deficiencies in TLRs, NLRs, and SRs.[63] It appears that adaptors able to gather signals from various PRRs, such as MyD88[64] and caspase recruitment domain-containing protein 9 (Card9)[65] are key in controlling susceptibility to TB.

Recognition of *Salmonella*, which lives in a late phagosome, is dominated by TLR members. LPS and the lipopeptides from the cell wall are sensed by TLR-2 and -4 before internalization. Ablation of these TLR renders mice highly susceptible to disease.[66] Vacuolar bacteria are recognized by TLR-9 via CpG DNA. Interestingly, triple-deficient (TLR- 2, -4, -9) animals are resistant as simultaneous TLR activation is necessary for acidification of the vacuole, which in turn induces *Salmonella* pathogenicity island 2 (SPI2) genes. Virulence effectors are translocated into the cytosol transforming the phagosome into a replicative niche for *Salmonella.*[67] Flagella are sensed by TLR-5 and NLRC4.

Recognition of *L. monocytogenes*, which escapes from phagosome into cytosol, is complex. Cell wall lipopeptides are sensed by TLR-2, while PGN is recognized by NOD1 and NOD2. MyD88 seems to be essential for defense against listeriae.[68] Bacterial DNA is monitored by multiple sensors in the cytosol, including AIM2[69,70,71,72,73] and leucine-rich repeat flightless-interacting protein 1.[74] *Francisella*, which also egresses into the cytosol, is recognized in a similar way by multiple receptors, including AIM2[70,75] and NLRC4.

By sensing the broad molecular spectrum of pathogens, PRRs induce cellular programs as the first line of defense, including antimicrobial effector functions and maturation of DCs for instruction of the adaptive immune response. However, PRRs and their adaptors may be exploited by intracellular pathogens to escape killing and establish stable infection. Mycobacteria use CRs to ensure a safe entry into macrophages and limit maturation of the phagosome. They also use the TLR/MyD88 pathway to induce cytokines (IL-6 and IL-10), which through signal transducer and activator of transcription (STAT)3 signalling bias arginine metabolism to arginase-1 over nitric oxide production by inducible nitric oxide synthase (iNOS).[76,77] In addition, polymorphonuclear leukocyte encounters with mycobacteria results in MyD88/Card9-dependent IL-10 release to dampen immune responses.[65,78] Similarly *Yersinia* uses TLR-2 to induce IL-10.[79]

Phagocytosis and Phagosome Dynamics

Phagocytosis of inert particles initiates a series of events that ultimately lead to the formation

of a phagolysosome (see Fig. 40.1).[80,81] Phagosome maturation is a strictly coordinated sequence of fusion and fission events, which involves defined compartments of the endocytic pathway.[81,82] Immediately after or even during phagosome sealing, phagosome maturation proceeds.

- The early phagosome is characterized by a slightly acidic to neutral pH (6.0 to 6.5) and membrane markers, such as MR, the tryptophane aspartate-containing coat protein, and the transferrin receptor (TfR) with its ligand transferrin, small GTPase (Rab5), early endosomal antigen 1, phosphatidylinositol 3-phosphate, and Syntaxin13.
- The late phagosome is characterized by a pH between 5.0 and 6.0 and the acquisition of the vacuolar adenosine triphosphatase (ATPase) proton pump (V-H+ATPase), mannose-6 phosphate receptor, Rab-interacting lysosomal protein, and Rab7.
- The phagolysosome results from the fusion between phagosomes and lysosomes, characterized by a pH between 4.0 and 5.5, high density of lysosome-associated membrane proteins, and typical lysosomal enzymes (such as cathepsins).

The three stages form a continuum involving the sorting of membrane proteins, as well as budding of, and fusion with, other vesicles. During this dynamic process, the phagosomes successively interact with the corresponding endosomes and subsequently with lysosomes.[81] Characterization of the Rab family of GTPases on vacuoles harboring pathogens facilitates identification of the host membrane transport pathways, which are turned on during infection.[83] *M. tuberculosis* and *S. enterica* interfere with the endocytic pathway by retaining Rab5 and Rab7, respectively, on their vacuoles.[84] *L. pneumophila*, *Brucella abortus*, and *C. trachomatis* interact with the secretory pathway as revealed

by the presence of Rab1, Rab2, and Rab6, respectively, on their phagosomes.[85,86]

Acquisition of a vacuolar ATPase proton pump plays a central role in acidification of the phagosome.[81,87] Immediately after phagocytosis, the phagosome becomes alkaline for a short time before acidification is initiated. The basic milieu is optimal for the activity of defensins and basic proteins, whereas the acidic pH is optimal for lysosomal enzymes. Defensins are small (3.5 to 4.0 kD) peptides rich in arginine and cysteine.[88,89] They are abundant in PNG and present in some, though not all, MPs (depending on species and tissue location). Purified defensins are microbicidal for certain intracellular bacteria, such as *S. enterica* and *L. monocytogenes.* The contribution of lysosomal enzymes to bacterial killing is likely minor. Their major task is the degradation of already killed bacteria. These enzymes reside in the lysosome and are delivered into the phagosome during maturation through several independent waves, and they reach their optimum activity during later stages, that is, in the phagolysosome.

Most intracellular bacteria interfere with phagosome maturation and alter the phagosome in order to facilitate their own survival (see Fig. 40.1).[80,90,91] These include *L. pneumophila*, *M. tuberculosis*, *S. enterica*, *C. burnetii*, and *Chlamydia.* Although the specific mechanisms are incompletely understood, mycobacterial sulfatides and some mycobacterial glycolipids, most notably mannosylated lipoarabinomannans, impede phagolysosome fusion. Mycobacterial products, such as SapM and MptpB, contribute as well to the arrest of maturation of the early endosome. Antibody-coated *M. tuberculosis* organisms lose their capacity to block discharge of lysosomal enzymes, suggesting an auxiliary function of antibodies in cell-mediated protection against TB.[92] Finally, the robust, lipid-rich cell wall of mycobacteria renders them highly resistant against enzymatic attack. *M. tuberculosis*, as well

as *M. avium*, arrest phagosome maturation at an early stage. They restrict phagosome acidification via the exclusion of the V-H+ATPase proton pump from the phagosome. Additional mechanisms may contribute to this event, such as NH_4+ production by *M. tuberculosis.* Consistent with intraphagosomal NH_4+ production, the urease of *M. tuberculosis* is active at low pH. It has been known for some time that NH_4+ also interferes with phagosome-lysosome fusion. Exogenous adenosine triphosphate (ATP) has been shown to promote phagolysosome fusion resulting in concomitant death of macrophages and killing of *M. bovis* bacillus Calmette-Guérin (BCG).[93,94]

Phagosome maturation is arrested somewhere between the early and late stages by *M. tuberculosis*, *M. bovis* BCG, *L. pneumophila*, *S. enterica*, and *C. trachomatis*, all of which replicate in nonacidified vacuoles. Phagosomes containing *S. enterica*, *M. bovis* BCG, or *C. trachomatis* appear uncoupled from the maturation process through which phagosomes containing inert particles proceed.[80,90] *S. enterica* remains in the spacious membrane-bound phagosome, which is formed after uptake by the trigger mechanism. Moreover, the bacteria manipulate the cytoskeleton via kinesin and tether the vacuole to membranes of the Golgi apparatus.[95] The vacuole containing *C. trachomatis*, which lacks any specific phagosome markers, is loaded with ATP, which is required by the pathogen, by an unknown mechanism. In addition, elements of the cytoskeleton (actin and filamin) are used to stabilize the vacuole.[96] *L. pneumophila* prevents fusion of the vacuole with the endosomal compartment and recruits vesicles derived from Golgi and ER[97] by use of the T4SS. Moreover, *Chlamydia* employ mimics of soluble NSF attachment protein receptor to modulate membrane transport. *Legionella* uses an array of proteins to control Rab1 activity in the vacuole.[98,99] Bacterial DrrA (SidM protein) is a highly efficient guanine nucleotide exchange factor for Rab1A.[44] *C. burnetii* have evolved to live in the acidic late phagosome.[82,100] Recent in vitro studies confirmed *Coxiella*'s requirement for low pH and oxygen tension. The fusogenic properties of the vacuole are tightly regulated by the T4SS apparatus, through ankirin proteins.[101]

Egression into the Cytoplasm

Egress from the phagosomal into the cytoplasmic compartment represents a highly successful microbial survival strategy because bacterial killing is focused on the phagolysosome to limit self-damage of MPs. This egression has been extensively studied in *L. monocytogenes*, but is known to be utilized by other intracellular pathogens, including shigellae, rickettsiae, francisellae, and mycobacteria (see Fig. 40.1).[102]

Cytoplasmic invasion by *L. monocytogenes* depends on listeriolysin (LLO), an SH-activated cholesterol-dependent cytolysin. LLO requires activation by a host factor (gamma-IFN-inducible lysosomal thiol reductase), a thiol reductase.[103] In the cytosol, LLO is degraded, thus avoiding killing of host cells.[104] Deletion of the LLO gene (*hly*) renders *L. monocytogenes* avirulent. LLO is also required for replication of *L. monocytogenes* in spacious listeria-containing phagosomes. These compartments are nonacidic and allow slow replication of the pathogen.[105] Other molecules, such as phospholipase and lecithinase, are likely involved in membrane transition but are insufficient on their own. Invasion of *L. monocytogenes* into the cytoplasmic compartment is markedly reduced in IFNγ-activated macrophages in which the microbe, entrapped in the phagosome, rapidly succumbs to attack by toxic oxygen and nitrogen species and/or defensins. Cytosol evasion of shigellae is mediated by factors, which are also involved in bacterial entry (eg, IpaB, product of T3SS).

Listeria simultaneously activates caspase-1 and consequently modulates death of infected cells via danger signals represented by remnant vacuolar membranes.[106] *M. tuberculosis* uses proteins encoded by the T7SS, located in the region of difference 1 gene region, to successfully translocate to the cytosol.[5,107]

Cell-to-Cell Spreading

L. monocytogenes is cleared from the blood by Kupffer cells and then spreads to adjacent hepatocytes without reentering the extracellular milieu. This mechanism of cell-to-cell spreading has been carefully studied in vitro.[108] Having entered the cytoplasm, *L. monocytogenes* induces a tail of host

actin filaments, which push the bacterium forward to the outer region of the cell, where it induces pseudopod formation. Intracellular movement is achieved by coordinated actin polymerization at, and polarized release from, the bacterial surface. The ActA gene encodes a 90-kDa protein located on the bacterial surface, which is responsible for these actin-based movements.[109] A host cytosolic complex composed of eight polypeptides has been identified which, on binding Act A, induces actin polymerization.[110] The pseudopod-containing *L. monocytogenes* is engulfed by the adjacent cell, and the microbe reaches the phagosome of the recipient cell, which is still enclosed by cytoskeletal material from the donor cell. The two plasma membranes of the host and recipient cells apparently fuse, thereby allowing the introduction of *L. monocytogenes* into the cytoplasm of the recipient cell. Thus, *L. monocytogenes* can infect numerous cells without contacting extracellular defense mechanisms. *Shigella* use similar mechanisms for evasion and intracellular movement, and a similar spreading mechanism seems to be employed by *S. enterica* and by *R. rickettsii*, but not by *R. prowazekii* and *R. typhi*. A role for motility and manipulation of host actin-based structures was recently demonstrated for virulent mycobacteria.[111] Bacterial T7SS mediates ejection from the infected host cell and facilitates spreading through actin structures coined “ejectosomes.”

Cell Death Patterns

Death of mammalian cells occurs by accidental or programmed cell death, which were once thought to be associated exclusively with necrosis or apoptosis, respectively.[112] Increasing evidence, however, suggests that necrosis can progress in a programmed sequence. Moreover, in addition to necrosis and apoptosis, additional modes of cell death have been described recently, namely autophagic cell death, pyroptosis, pyronecrosis, necroptosis, mitotic catastrophe, NETosis, and lysosomal membrane permeability.[113,114,115] Although autophagy is a complex process aimed at preventing cell death, it has emerged as relevant mechanism to control infection and hence will be described in this section. Generally, intracellular pathogens often counteract host cell death in order to maintain their habitat. Thus, ability of microbes to modulate eukaryotic cell survival evolved as an essential pathogenicity feature.

Apoptosis and Necrosis

Apoptosis is a tightly controlled process that is initiated by intrinsic mechanisms within the dying cell. It involves a series of tightly controlled enzymatic events, notably intracellular caspases. Necrosis is the result of cell destruction caused by various exogenous effector mechanisms, including those mediated by complement and cytolytic T-lymphocytes. In contrast to necrosis, apoptosis is generally noninflammatory and thus associated with tissue

repair rather than destruction. However, cell death associated with bacterial infection frequently results in release of microbial PAMPs, which serve as inflammatory signals. Intracellular bacteria interfere with apoptosis in various ways to delay or even block this process and thus sustain their preferred habitat. *C. burnetii* antagonizes the intrinsic apoptotic death of macrophages by means of ankirin proteins related to T4SS.[116,117] *A. phagocytophilum* blocks PNG apoptosis by secreting the Ats1 protein via T4SS across the phagosomal membrane. Ats1 enters the mitochondria and subverts apoptotic signaling.[118] *Chlamydia* prevents immature cell death and uses autophagy in addition.[113] *L. pneumophila* induces rapid apoptosis in DCs,[119] but prevents programmed cell death in other cell types.[120] Moreover, this pathogen limits multiple pathways leading to cell death, including necrosis in macrophages.[121] Mycobacteria offer a good example of how virulence is associated with modulation of death of infected cells. Avirulent mycobacteria induce apoptosis, while *M. tuberculosis* preferentially causes necrosis.[122] Tubercle bacilli interfere with eicosanoid-regulated cell death to facilitate necrosis. Generally, death of infected cells impacts on the acquired immune responses, pathology, and ultimately disease manifestation.

Autophagy

Autophagy is a catabolic process that controls the integrity of eukaryotic cells.[123] This mode of "self-digestion" is paramount for the disposal of protein complexes that cannot be degraded via the proteasomal route and for the elimination of damaged organelles. Three different autophagic processes have been described: chaperone-mediated autophagy, microautophagy, and macroautophagy (canonical autophagy).[115] A unique feature of autophagy is the direct sequestration of the cargo into autophagosomes, which are surrounded by a double membrane and delivered to the lysosomal compartment. Autophagy is tightly orchestrated by over 30 autophagic components. This cell-autonomous housekeeping process is also an efficient system for the elimination of intracellular pathogens. Direct autophagy of intracellular pathogens occurs in any cell type and has been named xenophagy.[124] As a process of cytosol surveillance, autophagy is directed primarily against pathogens that egress into the cytosol. However, most bacteria, which successfully adapted to the intracellular milieu, have developed mechanisms to protect themselves against autophagy. Some species even harness the autophagic machinery to their advantage.

Autophagosome-like structures were first described in PNG infected with *Rickettsia*,[125] and a role for autophagy in control of intracellular bacteria was first demonstrated for *M. tuberculosis.*[126] Subsequently, the protective functions of autophagy were established in infections with *M. tuberculosis*,[127,128] *S. enterica*,[129] and *L. monocytogenes.*[130,131,132] Microbe-derived PAMPs stimulate autophagy[131,133] as do cytokines like IFNγ, most likely through induction of GTP/guanylate-binding protein (GBP) molecules.[134,135] Lipids were also found critical for autophagy in intracellular bacterial infections. Thus, the signaling lipid diacylglycerol is required for autophagy induced by *S. typhimurium.*[136] Recently the term sequestosome-like receptors was coined to define cytosolic innate receptors (p62, NBR1, NDP52), which target intracellular pathogens to the autophagic machinery[115] including salmonellae,[137,138] shigellae,[106] listeriae,[139] and mycobacteria.[140]

Pathogens interfere with autophagy through multiple strategies: by blocking induction or maturation of autophagosomes into autolysosomes, by evading recognition by the autophagic

machinery, and by misusing autophagy for their own benefit. Microarray studies revealed that *F. tularensis* downregulates autophagy-related genes.[141] Similarly, whole genome-wide profiling of macrophages infected with *M. tuberculosis* suggests that host factors that regulate bacterial replication are regulators of autophagy.[142] *S. enterica* blocks autophagy by interference with the ubiquitination machinery,[137,138] and *L. pneumophila* induces autophagy, but delays fusion with lysosomes.[143] A similar scenario was reported for *C. burnetii*[144] and *A. phagocytophilum.*[145] A different strategy is employed by bacteria that egress into the cytosol. The shigella protein VirG targets bacteria to the autophagic pathway by binding to the autophagic protein Atg5. However, once in the cytosol, the pathogen uses the T3SS IcsB to competitively bind to Atg5 and thus renders it unavailable for VirG.[146] Similarly, ActA impedes autophagic targeting of listeriae by recruiting actin and protecting it.[139,147] Some intracellular bacteria not only affect autophagy but may also exploit it. Thus, chlamydiae gain access to nutrients by stimulating autophagy,[148] and listeriae exploit this process for establishing chronic infection.[105] *F. tularensis* reenters the endocytic pathway following its egression into the cytosol through autophagosomes.[149] Autophagy is implicated in the biogenesis of vacuoles and persistence of *C. burnetii* therein.[150]

Pyroptosis

Pyroptosis is a form of programmed cell death that is controlled by caspase-1. It is an inflammatory process that results in rapid lysis of infected cells, mostly macrophages.[114] This process was first described for shigellae[151] and subsequently for salmonellae,[152,153] legionellae, and burkholderiae.[154] Mouse studies showed that pyroptosis is an innate immune effector mechanism during infection with *S. typhimurium*.[154] It still needs to be clarified how intracellular bacteria escape or modulate pyroptosis.

Intracellular Iron

Iron is required by most organisms and is a cofactor for enzymes involved in many essential biologic processes. The same divalent cation is toxic at high concentration and therefore is tightly controlled by multiple elements.[155] As both host and intracellular pathogens require iron, microbes have evolved ways to interfere with iron homeostasis. Generally, the strategy of the mammalian host is to deprive the pathogen of iron. However, depending on microbial habitat (extracellular versus intracellular bacteria), a given mechanism may be beneficial or detrimental. While systemic iron withdrawal and hypoferremia contribute to the control of extracellular bacteria, these strategies are counterproductive for intracellular microbes. Rather, down regulation of iron uptake and augmentation of iron export are advantageous for the host in defense against intracellular pathogens.[156,157]

Intracellular bacteria require iron, and production of reactive oxygen intermediates (ROIs) and reactive nitrogen intermediates (RNIs) also depends on iron. Thus, competition for the intracellular iron pool between the intracellular pathogen and the host cell markedly influences the outcome of their relationship.[158] To improve their iron supply, mammalian cells utilize specific molecules. In the extracellular host milieu, iron is tightly bound to transferrin and lactoferrin, and the transferrin-iron complex is taken up by host cells via TfRs. The lactoferrin-iron complex does not enter the cell. Iron is released from the transferrin-TfR complex under the reducing conditions of the early phagosome. This event is controlled by Hfe (the product of the hereditary hemachromatosis gene).[155] Hfe reduces iron uptake either

by inhibiting TfR internalization or by blocking iron release from transferrin in the early phagosome. Macrophages can also acquire iron via the divalent metal transporter-1. Iron may also bind to haptoglobin, haemopexin, and lipocalin-1 and -2 in the extracellular space. Within the endocytic pathway, the Nramp system is involved in iron transport from the phagosome to the cytosol, where iron is bound to ferritin. Ferroportin (FPN) is one of the best-characterized iron export molecules in eukaryotic cells. Hepcidin, a product not only of liver cells but also macrophages, regulates FPN activity by inducing FPN internalization and proteasomal degradation. Accordingly, iron availability is controlled in multiple ways, including lactoferrin concentration in the extracellular space, intracytosolic ferritin concentration, hepcidin levels and abundance of TfRs, divalent metal transporter-1, and FPN on the cell surface. Many intracellular bacteria, including *M. tuberculosis*, *L. pneumophila*, and *S. enterica*, accommodate themselves in the early phagosome, where the abundance of iron-loaded transferrin guarantees a high availability of iron. Moreover, these bacteria, as well as *Chlamydia* and *F. tularensis*, induce divalent metal transporter-1 expression to support their replication.[159] Hepcidin is induced in mycobacterial phagosomes[160] and limits iron export by degrading FPN. Hepcidin also promotes *Salmonella*'s growth.[161] Similar observations, suggesting that iron efflux is detrimental for intracellular pathogens, were reported for *C. psittaci* and *L. pneumophila*.[162] To successfully compete for iron, bacteria possess a variety of iron-binding proteins. These include iron chelators (siderophores), transferrin-binding proteins, hemelike proteins, and ATP-binding cassette transporters.[163,164,165] Expression of genes involved in iron uptake is controlled by a conserved mechanism involving the Fur protein. However, lipocalins, which are host proteins produced by professional phagocytes and epithelial cells, bind siderophores from mycobacteria and salmonellae and thus minimize iron usage by microbes. Moreover, deletion of lipocalin-2 impacts on invasion of epithelial cells by tubercle bacilli.[161,166]

Importantly, there are many crossregulatory interactions linking iron homeostasis and immune responses. Th1 immunity and iron availability are interconnected. IFNγ-activated MPs downmodulate TfR expression and intracellular ferritin, resulting in reduced iron availability within the phagosome. Overall, IFNγ induces iron sequestration by downregulating FPN, while IL-4 favors iron release.[156,167] IFNγ, on the other hand, induces Nramp1, whose relevance for protection against salmonellae and mycobacteria has

been established.[168] The iron content of the phagosome in the resting MP seems to be sufficient for *L. pneumophila.* However, available iron is markedly reduced in IFNγ-activated MPs and, as a consequence, *L. pneumophila*, which lacks efficient iron uptake mechanisms, starves from iron deprivation in activated macrophages. In contrast, *M. tuberculosis* possesses a potent iron acquisition system comprising exochelins and mycobactins. The exochelins successfully compete for iron under limiting conditions and transfer it to mycobactins in the cell wall.[169,170] Similarly, SPI2 are upregulated as a response to Nramp-1-induced iron starvation and modify the vacuole to ensure bacterial replication.

Toxic Effector Molecules

Killing of intracellular bacteria by MPs and/or PNGs is primarily accomplished by highly reactive toxic molecules, notably ROIs and RNIs.[171,172,173,174] Within infected cells, these molecules are bactericidal. However, both ROIs and RNIs have a broader functional spectrum. They are also involved in signaling, regulation of vascular tone, tissue injury, and control of inflammation. Thus, ROIs and RNIs can both alleviate and promote tissue damage.[171]

Most if not all bacteria are susceptible to ROIs in vitro. Yet, contribution of ROIs to killing of intracellular bacteria by MPs is less clear; in murine macrophages, RNIs are more important. On the contrary, in PNGs, the role of ROIs seems to prevail.[175] In the mouse, ROIs and RNIs act consecutively in defence against *S. enterica* infection.[176,177] Production of RNIs by human MPs at concentrations sufficiently high for bacterial killing remains controversial.[178,179,180] However, evidence is accumulating that human MPs from sites of intracellular bacterial infection produce adequate concentrations of RNIs. Thus, using antibodies with exquisite specificity for human iNOS, this enzyme could be detected in a large proportion of lung macrophages from patients with TB.[181,182,183,184] iNOS can be induced by different mechanisms in different species as suggested, for example, by divergence of the iNOS promoter in mouse and human.[171,185,186]

ROI production is initiated by a membrane-bound nicotinamide adenine dinucleotide phosphate-oxidase (NADPH oxidase) complex composed of six enzyme units (Rho guanosine triphosphatase, gp91PHOX also named NOX2, p22phox, p40phox, p47phox, and p67phox). NADPH oxidase is activated by IFNγ and by immunoglobulin (Ig)G-FcR binding:

$$O_2 + NADPH \xrightarrow{\text{NADPH oxidase}} NADP + O_2^- H^+$$

O_2^- is further metabolized by superoxide dismutase:

$$2O_2^- + 2H^+ \xrightarrow{SOD} O_2 + H_2O_2$$

In the presence of appropriate iron catalysts, the Haber-Weiss reaction takes place:

$$O_2^- + Fe^{3+} \longrightarrow O_2 + Fe^{2+}$$

$$H_2O_2 + Fe^{2+} \longrightarrow {}^{\bullet}OH + OH^- + Fe^{3+} \text{ (Fenton reaction)}$$

$$\text{Net reaction: } O_2^- + H_2O_2 \longrightarrow {}^{\bullet}OH + OH^- + O_2$$

In addition, O_2^- is transformed into $^1O_2$. The $^1O_2$ and $^{\bullet}OH$ radicals are short-lived powerful oxidants with high bactericidal activity causing damage to DNA, membrane lipids, and proteins. (Note: O_2^-, hyperoxide anion; $^{*}OH$, hydroxyl radical containing a free electron; $^1O_2$, singlet oxygen, a highly reactive form of O_2.)

Granulocytes, blood monocytes, and certain populations of tissue macrophages possess myeloperoxidase, thus allowing halogenation of microbial proteins[172]:

$$H_2O_2 + Cl^- \xrightarrow{MPO} OCl^- + H_2O$$

In addition to hypochlorous acid, chloramines are formed and both agents further increase the bactericidal power of the ROI system by destroying biologically important proteins through chlorination.

Nitric oxide is exclusively derived from the terminal guanidino nitrogen atom of L-arginine (Fig. 40.3). This reaction is catalyzed by the iNOS, which leads to the formation of L-citrulline and $NO^{\bullet}$.

$NO^{\bullet}$ can act as oxidizing agent alone or interact with O_2^- to form the unstable peroxynitrite ($ONOO^-$). This may then be transformed to the more stable anions, NO_2^- and NO_3^-, or

decomposed to $NO^{\bullet}$:

$$O_2^- + NO^{\bullet} \longrightarrow ONOO^-$$

$$ONOO^- + H^+ \longrightarrow NO_2^- + {}^{\bullet}OH$$

$$NO_2^- + {}^{\bullet}OH \longrightarrow NO_3^- + H^+$$

$$ONOO^- + H^+ \longrightarrow {}^{\bullet}OH + NO^{\bullet}$$

$NO^{\bullet}$ and $ONOO^-$ are highly reactive antimicrobial agents. $NO^{\bullet}$ may be transformed to nitrosothiol, which expresses the most potent antimicrobial activity. In contrast, NO_2^- and NO_3^- are without notable effects on microorganisms.

Three distinct nitric oxide synthase isoenzymes are known. The two constitutive nitric oxide synthases (neuronal nitric oxide synthase and endothelial nitric oxide synthase) exist in various host cells and account for basal nitric oxide synthesis, whereas iNOS is primarily found in professional phagocytes and is responsible for microbial killing. Its induction is controlled by exogenous stimuli such as IFNγ, agonist of PRRs, and inflammatory cytokines. This iNOS stimulation results in a burst of high RNI concentrations required for microbial killing, whereas the low nitric oxide levels produced by neuronal nitric oxide synthase

and endothelial nitric oxide synthase perform physiologic functions. The RNIs exert their bactericidal activities by directly inactivating iron-sulfur-containing enzymes, by S-nitrosylating proteins, by damaging DNA, or by synergizing with ROIs. Both ROIs and RNIs are relevant for killing of *Salmonella*, while most other intracellular pathogens are primarily controlled by iNOS products. In chlamydial infections, insufficient as well as excessive production of nitric oxide can be immunosuppressive.[187] RNIs prevail as antimicrobial molecules against *L. monocytogenes*,[188] *C. burnetii*,[189] *C. trachomatis*, *F. tularensis*, *Brucella*, and *L. pneumophila.*[190] The pivotal role of iNOS in control of *M. tuberculosis* infection has been demonstrated in the mouse system.[191] Despite resistance of NOX2-ablated mice against TB, recent data supporting a role of macrophage ROIs in humans have been reported.[192] Thus, nitrosative and oxidative processes under the control of iNOS and NADPH oxidase together are paramount for protection against intracellular bacteria.

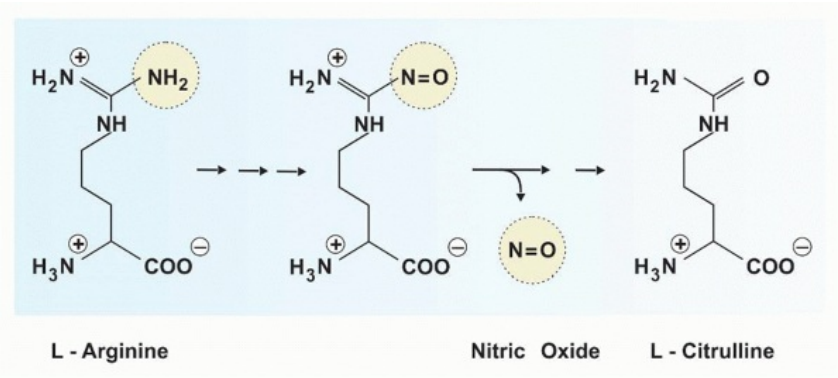

FIG. 40.3. Generation of Nitric Oxide from L-Arginine. L-Arginine is metabolized to the toxic molecules nitric oxide and L-citrulline by inducible nitric oxide synthase.

Evasion of Killing by Reactive Oxygen Intermediates and Reactive Nitrogen Intermediates

Microbes use multiple strategies to nullify ROI and RNI attack: evasion, inhibition, enzymatic inactivation, generation of scavenger molecules, as well as stress and repair mechanisms (see Fig. 40.1).[171] SPI2 enables *S. enterica* to exclude NADPH oxidase from the phagosomal membrane, thus interfering with ROI release into the *Salmonella* phagosome. *S. enterica* mutants deficient in SPI2 are susceptible to ROIs.[193] Similarly, proteins translocated into the cytosol interfere with iNOS activity.[194] *F. tularensis* undergoes phase variation to switch to a phenotype that is less stimulatory for iNOS.[195] *A. phagocytophilum* inhibits ROI production in PNGs after an initial ROI induction process.[196] Many intracellular bacteria produce superoxide dismutase and superoxide catalase that detoxify O_2 and H_2O_2, respectively.[171,197] Production of ROI-detoxifying molecules by intracellular bacteria is not constitutive; rather, expression of these enzymes is controlled by regulators such as soxR or oxyR that sense for concentrations of O_2 or H_2O_2, respectively. Accordingly, transposon mutants of *S. enterica* that fail to survive inside murine MPs are highly sensitive to ROI in vitro. Although less is known about specific mechanisms by which intracellular bacteria interfere with killing by RNIs, catalase and other antioxidative enzymes may indirectly inhibit RNI functions. ROI- and RNI-detoxifying gene products have been identified in *M. tuberculosis.*[198] KatG,[199] SodA, and SodC are involved in these processes. Recently, mycobacterial nicotinamide adenine dinucleotide dehydrogenase and enhanced intracellular survival (*eis*) gene products were reported to be relevant for inflammatory responses by controlling infected cell death as a consequence of ROI generation.[200,201] These mechanisms are separated from the direct antimicrobial effects of toxic radicals and will be discussed in the following. Intracellular pathogens may generate scavenger molecules to dispose of toxic radicals. Low molecular mass thiols, such as mycothiols from *M. tuberculosis*[197] or homocysteine in *Salmonella*,[202] are examples of ROI/RNI scavengers. In addition, both oxidative and nitrosative stresses are reflected in transcriptional changes in bacteria and initiation of DNA repair processes. Proteasome involvement in RNI resistance was reported for *M. tuberculosis.*[203] Further, certain macrophage receptors interfere with NADPH oxidase function. Binding to CR1/CR3 does not induce respiratory burst and ROI production.[204] The CRs, therefore, provide a relatively safe way of entry for intracellular bacteria.

Antimicrobial Peptides

Antimicrobial peptides (AMPs) encompass diverse groups of molecules that can be divided in subgroups based on their amino acid composition and structure. They are present systemically, at mucosal sites, or packed in granules of phagocytes.[205] AMPs active against intracellular microbes belong to different classes. Cathelicidin (LL-37) is a cationic peptide with bactericidal functions against *M. tuberculosis.*[206] Cationic and anionic peptides, including human neutrophilic peptides and defensins, kill microbes inside PNGs. PR-39 promotes filamentation of *S. typhymurium.* Most AMPs need to attach to the bacterial cell wall. Next, the peptides are inserted into the bacterial membrane rendering it permeable. AMPs are also generated upon infection-induced autophagy. During mycobacterial infection, ubiquitin generates peptides with lytic activity within autophagosomes.[207] Importantly, microbes develop mechanisms of resistance against AMPs.

Cell Autonomous Defense: Guanine Triphosphatases

The dominant role of IFNγ in defense against intracellular pathogens is beyond doubt. Besides ROI and RNI generation (detailed previously), a role for small GTPase family cognates was recently established. Three families of GT Pases are regulated by IFN: 65kDa GBPs, Mx family, and p47 kDa GTPases or immune-related GTPases.[208] Mx proteins are critical for antiviral responses and are mostly induced by type I IFN. In their promoters, GBPs and immune-related GTPases possess both gamma-activated site and IFN-stimulated response element binding sites. Accordingly, although the main inducer is IFNγ, type I IFN may also initiate their transcription.[209] Studies with mice ablated of proteins from these GTPases revealed that distinct members are paramount for protection against a range of intracellular bacteria, while other GTPases are redundant. Irgm1 (formerly Lrg-47) is essential for resistance against infection with *M. tuberculosis*, *M. avium*, *L. monocytogenes*, *S. typhymurium*, and *C. psittaci.*[210,211,212,213,214,215] Irga6 (formerly Iigp1), on the other hand, restricts *C. thrachomatis* replication only. More recently, GBP7 and GBP1 were found to be involved in control of infection with *L. monocytogenes* and *M. bovis* BCG.[134,135] Interestingly, GBPs and immune-related GTPases seem to trigger multiple pathways, as members of both families are essential for defense against intracellular bacteria residing in different cellular compartments. Members of these GTPase families localize to the ER, Golgi, plasma membrane, or intracellular vesicles. They may be recruited to the bacterial phagosome early upon infection, as demonstrated for Irgm1 in infections with mycobacteria or listeriae. However, the antimicrobial mechanisms are

diverse and encompass enhancement of phagosome fusion with lysosomes, interference with the autophagy machinery, regulation of oxidative responses, or induction of bacteriolytic peptides. Irgm-1 regulates T-cell dynamics and macrophage motility, suggesting cellular responses rather than effector functions are controlled by this and perhaps other GTPases.[216] In contrast to the multitude of p65 and p47 kDa GTPases in mice, only few cognates exist in humans. Accordingly, the relevance of these molecules in human diseases remains to be clarified.

INNATE IMMUNITY: PROFESSIONAL PHAGOCYTES

The innate immune system comprises various cell types of different hematopoietic lineages. Besides phagocytes (macrophages, monocytes, DCs, PNGs) and other cells of myeloid origin (eosinophils, basophils, mast cells), certain lymphoid cells (natural killer [NK], NKT, γδT lymphocytes, B1 lymphocytes), as well as platelets and the nuocytes act in concert to limit replication of the pathogens. Many intracellular bacteria infect professional phagocytes, and this strategy contributes to their evolutionary success. The professional phagocytes are represented by mononuclear cells, including monocytes, macrophages, and DCs, and by polymorphonuclear cells, namely the PNGs.

Mononuclear Phagocytes

Metchnikoff[217] was the first to realize the importance of professional phagocytes in resistance against bacterial infections. He observed that leukocytes accumulated at the site of inflammation and bacterial growth, and were heavily engaged in microbial engulfment and destruction. Metchnikoff distinguished two types of phagocytes: 1) the early appearing and short-lived microphages now referred to as PNGs, and 2) the late-appearing long-lived macrophages still known under the same name. The preferential localization of tubercle bacilli inside macrophages discovered at the time of Koch[218] and Metchnikoff[217] pointed to

the central role of these MPs in defense against intracellular bacteria. Metchnikoff also observed that during infection, macrophages are nonspecifically activated. Macrophage activation as an important factor of acquired resistance against bacterial infections was further substantiated by Lurie[219] and shown to be under the control of lymphocytes by Mackaness.[220] Later, cytokines were identified as the mediator of macrophage activation.[221,222]

Ontology studies and careful characterization of MP populations revealed that they show a tremendous degree of diversity and plasticity.[223] Tissue cues modulate the MP mode of response to bacterial insult (eg, lung versus liver, alveolar macrophages in the lung are mostly antiinflammatory, whereas liver Kupffer cells are mostly proinflammatory). Moreover, developmental branching of the mononuclear progenitor enables differential responses to pathogens. Thus, monocytes are specialized in their response to pathogens: certain populations ($CD14^{dim}$) primarily react to viral infections while others (CD14+) respond to a broad range of microbes.[224]

Many of the antibacterial activities of the MPs are not constitutively expressed. Rather, expression of full antibacterial activities by MPs depends on appropriate stimulation by cytokines, with IFNγ being of paramount importance.[225] Furthermore, significant differences exist among MPs of different maturation states or from different species. For example, higher RNI levels are produced by murine MPs as compared to human MPs. IFNγ activation of MPs coincides with increased phagocytosis, elevated CRs, reduced FcR expression, and a higher overall metabolic rate. Most importantly, during macrophage activation, iNOS and NADPH oxidase, which initiate RNI or ROI production, respectively, are stimulated. Moreover, this type of activation augments autophagy, which in turn contributes to microbial destruction. In other words, activation by cytokines results in transition of MPs from habitat-supporting microbial replication into an effector cell capable of terminating, or at least restricting, microbial survival.[185,226,227,228]

Polymorphonuclear Granulocytes

Although the role of PNGs in intracellular bacterial infections has often been neglected, their high antibacterial potential allows them to kill many intracellular bacteria. Pathogen disposal is the synergistic outcome of toxic molecules (mainly ROIs), PNG granular enzymes, and antimicrobial peptides.[229] PNGs are short-lived, however longer than previously appreciated, and thus may interact not only directly with bacteria, but modulate the function of other immune cells.[230] Generally, intracellular bacteria are sequestered in intracellular niches; hence, the overall contribution of PNGs to defense against chronic infections seems to be hindered to a certain extent due to the location of the pathogen. Nevertheless, PNGs may exclusively harbor certain intracellular bacteria (*A. phagocytophilum*) despite their broad arsenal of antimicrobial factors. *M. tuberculosis*, although it infects primarily MPs, has been found in PNGs in sputum from patients with TB.[231] It is likely that during the early acute inflammatory response, PNGs can help to reduce initial bacterial load. During experimental listeriosis, which is an acute disease, the first day of infection is characterized by extensive PNG infiltration at sites of listerial growth.[232] Elimination of PNGs and inflammatory monocytes/macrophages by monoclonal antibody treatment remarkably exacerbates listeriosis.[233,234] However, recent studies using specific depletion of PNGs have questioned the central role of these cells during systemic listeriosis.[235] Depletion of PNG apparently does not affect experimental TB in resistant mice, despite modulation of T-cell

responsiveness.[236,237] However, susceptible mouse strains can be rendered resistant following PNG depletion.[63,238] The detrimental effect of PNGs is largely due to their tissue-damaging propensity. PNGs are potent secretors of hypochlorous acid as well as of proteolytic enzymes, such as elastase (a serine proteinase), collagenase, and gelatinase.[172,239,240] Such proteases express potent microbicidal activity but can also be deleterious and induce tissue damage. These secretion products of PNGs act as mediators of tissue destruction. At the same time, neutrophil elastase has been shown to specifically destroy the virulence

proteins of *Salmonella* organisms.[239,240] In the extracellular milieu, protease inhibitors are normally present, preventing tissue damage by these proteases. However, the concomitant secretion of hypochlorous acid inactivates these proteinase inhibitors, thus promoting cell lysis. Accordingly, PNGs have been shown to cause inflammatory liver damage by destroying infected hepatocytes during early listeriosis.[232] MPs are less potent secretors of proteinases and fail to produce the major inactivator of proteinase inhibitors, hypochlorous acid. Thus, solid granulomas in chronic TB are dominated by MPs and are characterized by necrosis and fibrosis and lack signs of tissue liquefaction. During reactivation, however, PNGs may eventually be recruited to tuberculous granulomas and then contribute to granuloma caseation and liquefaction.

In PNGs, pathogen sensing or exposure to cytokines or chemokines rapidly causes transcriptional events that result in release of soluble mediators. PNGs are important mediators and regulators of the Th17 pathway. They release proinflammatory cytokines (eg, IL-1α, IL-1β, tumor necrosis factor-α [TNF]-α) and chemokines,[230] thus amplifying inflammation. Recent studies suggest that PNGs may participate in the resolution of inflammatory processes and thus may have a role in nonresolving inflammation. Mycobacteria stimulate production of IL-10 from PNGs via MyD88[78] and Card9[65] pathways. The capacity to manifest diverse and probably context-dependent functions suggests that PNGs can polarize into distinct phenotypes.[230] This concept has been developed for certain cancers and awaits clarification for infectious diseases.

PNGs are able to kill microbes via a unique process coined neutrophil extracellular trap formation.[241] This mechanism is characterized by entrapment of pathogens in fibrillar structures composed of chromatin and specific proteins from PNG granules, NADPH and myeloperoxidase dependence, and by tight coordination.[242,243] Neutrophil extracellular trap killing has thus far been reported for shigellae and salmonellae, and may be relevant for other intracellular microbes.

ACQUIRED IMMUNITY

Acquisition of immunity against intracellular bacteria crucially depends on T-lymphocytes that, ideally, accomplish sterile bacterial eradication. Bacterial clearance is rapidly achieved in the case of bacteria such as *L. monocytogenes.* In the case of persistent pathogens such as *M. tuberculosis*, clearance frequently remains incomplete and is arrested at the stage of bacterial containment. Bacterial containment and eradication occur in granulomatous lesions. The longer the struggle between host and microbial pathogen continues, the more essential the granuloma becomes.

The T-cell requisite is probably best exemplified by the high incidence of TB and other intracellular bacterial infections in patients suffering from T-cell deficiencies, particularly AIDS.[244,245,246,247] At the same time, T-lymphocytes are an unavoidable element of the

pathogenesis of intracellular bacterial infections. First, granulomas impair tissue functions by occupying space and affecting surrounding cells. Second, the physiologic functioning of host cells may be affected by specific T-lymphocytes and their cytokines.

Dendritic Cells

MPs not only serve as major habitat for intracellular bacteria, they are also potent antigen-presenting cells (APCs). However, MPs are not the most efficacious APCs, and their capacity may even be reduced during infection. DCs are the most proficient APCs.[248,249,250] DCs, like MPs, are present in all tissues (resident DCs), and they rapidly accumulate at sites of pathogen entry. PRR composition in DC populations is variable, according to origin and location. The "maturation" status of DCs, which relates to their propensity to stimulate naïve T cells, anticorrelates with their phagocytic potential. Immature DCs, exposed to pathogens for the first time, are phagocytic, while upon microbial encounter they augment their T-cell stimulatory capacities and minimize their phagocytic propensities. Following pathogen encounter in peripheral tissues, DCs migrate to draining lymph nodes (dLNs), where stimulation of T cells and antigen presentation takes places. Microbial killing is limited in DCs. Thus, DCs are specialized in linking innate immunity to adaptive immunity rather than in pathogen elimination.[251] Antigen presentation requires controlled proteolytic processing of microbial antigens. In DCs, phagosomal degradation[252] and acidification[253] is limited compared to MPs, thus conserving antigenic peptides for presentation via major histocompatibility complex (MHC)-class I and -II molecules. In addition, the superior antigen-presenting capacity of DCs is promoted by their copious expression of 1) MHC and CD1 molecules for antigen presentation; 2) PRRs to rapidly sense infection[47]; and 3) costimulatory molecules to regulate T-cell stimulation. Moreover, they produce cytokines that influence T-cell activation and differentiation.

DCs have critical roles in infections with intracellular bacteria. First, DCs can be infected by these bacteria, and can thus readily present accessible antigens from microbes they harbor. For instance, tubercle bacilli infect lung-resident and -recruited DCs.[254] Second, the transfer of microbial antigens from infected MPs to bystander DCs can combine the high phagocytic and degradative capacity of MPs with the high antigen-presenting capacity of DCs ("cross presentation," see following discussion).

Induction and Modulation of T-Cell Responses

The peripheral T-cell system comprises several phenotypically distinct and stable populations. T-lymphocytes expressing the αβ T-cell receptor (TCR) make up >90% of all T cells in secondary lymphoid organs and peripheral blood of humans and experimental mice. They are further subdivided into CD4 αβ T cells that recognize antigenic peptides presented by gene products of the MHC class II, and CD8 αβ T cells that interact with antigenic peptides in the context of MHC class I molecules. Undoubtedly, these conventional αβ T cells are of primary importance for antibacterial resistance, although evidence exists that unconventional T cells also participate in the control of intracellular bacteria.[226,255,256,257]

Generally, antigen presentation and activation of distinct T-cell populations is highly dependent on the route of antigen acquisition. Most intracellular bacteria reside in the phagosomal compartment of APCs and hence pathogenderived peptides have ready access to the MHC-II presentation pathway to stimulate CD4 T cells (Fig. 40.4). Cytosolic antigens, potentially derived from microbes, which access the cytosol, are processed by the proteasomes and loaded to MHC-I to stimulate CD8 T cells. Certain intracellular bacteria are

capable of egressing into the cytosol (eg, listeriae, shigellae, and mycobacteria). Obviously, antigens from cytosolic pathogens can be readily introduced into the MHC-I processing pathway, thus promoting activation of CD8 T cells. Yet, CD8 T cells have also been isolated from mice infected with phagosomal pathogens, such as *S. enterica.* Thus, bacteria unable to egress into cytosol may induce potent CD8 T-cell immunity. This is achieved by a process coined cross presentation, namely presentation of exogenous antigens by MHC-I molecules. Antigen cross presentation may occur directly and multiple pathways likely lead to this phenomenon. Another way of accomplishing cross presentation is indirect and is a consequence of engulfment of vesicles derived from infected cells undergoing infection-induced apoptosis, by bystander APCs (see Fig. 40.4). During mycobacterial infection, the direct and indirect modes of cross presentation coexist. *M. tuberculosis* can access the cytosol[107] and induce death of infected cells.[258,259]

Intracellular bacteria also invade nonprofessional phagocytes, some of which do not express MHC-II molecules constitutively. Consequently, such cells remain unrecognized by CD4 T-lymphocytes and provide a niche for persistent bacteria—a situation that has consequences for the course of disease. Because MHC-I molecules are expressed by almost every cell, CD8 T-lymphocytes have the potential to survey the whole body. This is particularly important for intracellular bacteria that hide in MHC-II-deficient host cells. Obviously, recognition of these cells depends on CD8 T-lymphocytes (and perhaps unconventional T cells). *L. monocytogenes*, on the one hand, resides in nonprofessional phagocytes with low antibacterial potential and, on the other hand, promotes MHC-I presentation of its antigens. This may explain the predominance of MHC-I-restricted CD8 T-lymphocytes in defense against experimental listeriosis both by number and by biologic relevance. In contrast, *S. enterica* is primarily restricted to MPs and remains in the phagosome. This is compatible with its preferential control by MHC-II-restricted CD4 T-lymphocytes.

Intracellular bacteria interfere at various levels with antigen presentation. Tubercle bacilli affect activation of CD4 T cells by interfering with MHC-II expression.[260] Autophagy can contribute to T-cell activation[261] and numerous intracellular bacteria impair autophagy thus reducing adaptive immune responses.

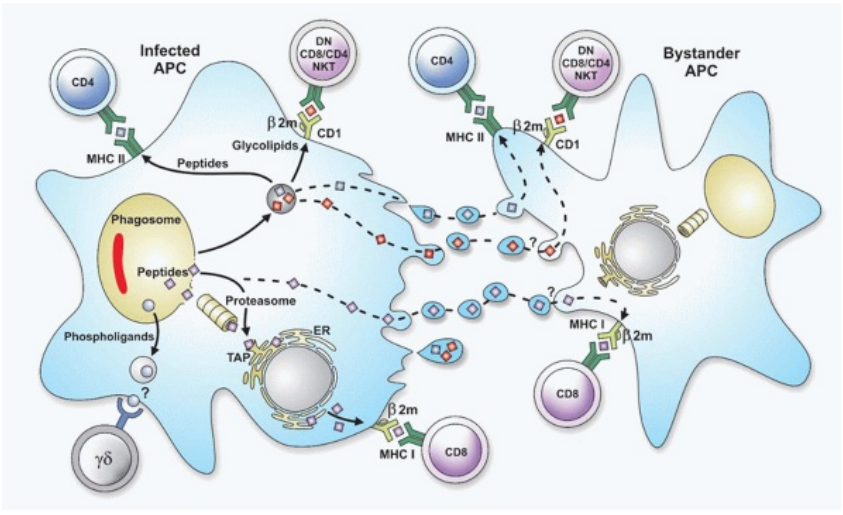

FIG. 40.4. Multiple Antigen-Processing Pathways for Stimulation of T Cells during Bacterial Infections. Infected antigen-presenting cells (APCs) directly present phagocytosed bacterial antigens to naïve cluster of differentiation (CD)4 T cells through the major histocompatibility complex (MHC)-II pathway. In addition, bacterial glycolipids

are processed for presentation by CD1 molecules to stimulate double negative CD4/CD8 lymphocytes or natural killer T (NKT) cells. Antigen cross presentation occurs either following the direct way, as a consequence of cytosolic access of the bacterial antigens in infected APCs, or following a detour pathway. In the latter case, apoptotic bodies from infected cells carry antigens to bystander APCs, which activate MHC-I-restricted CD8 T cells. Recognition of infected cell death also stimulates CD4 and NKT cells. β2m, β2 microglobulin; DN, double negative; ER, endoplasmic reticulum; TAP, transporter associated with antigen processing.

T cells may be polarized to various phenotypes, as discussed in the following, and this has a tremendous impact on the ensuing immune response. Certain factors are pivotal for this process. For instance, microbes rich in CLR ligands (eg, mycobacterial TDM) polarize T cells toward a Th17 phenotype.[262] Abundance and composition of PRRs in various APC populations contribute to this process by modulating cytokine production. Susceptibility of resident tissue (eg, epithelia) to infection and their capacity to release cytokines/chemokines influences T-cell differentiation. Finally, death of infected cells and subsequent recognition of pathogens in context of inflammatory signals from APCs impacts on T-cell polarization.[263]

Cluster of Differentiation 4 T Cells

Overwhelming evidence, including experimental animal studies, and their abundance in "protective" granulomas of patients suffering from bacterial infections clearly demonstrate a critical role of CD4 T cells in immune defense against intracellular bacteria. Further evidence for this is high prevalence of disease caused by intracellular bacteria in patients with AIDS suffering low CD4 T-cell counts.[264] CD4 T cells recognize peptide epitopes in the context of MHC-II molecules, which gain access to peptides present within the endosomal system. Thus, antigens from all intracellular bacteria, even those that evade the phagosome at later stages, are accessible to processing and presentation through the MHC-II pathway. However, cells that do not express the MHC-II machinery consistently, namely endothelial cells, epithelial cells, hepatocytes, and Schwann cells, are invisible for CD4 T cells and thus potential targets of *Rickettsia*, *C. trachomatis*, *L. monocytogenes*, and *M. leprae*, respectively.

The CD4 T-cell population has been subdivided into distinct subsets, according to the pattern of cytokine production. Th1 cells that overwhelmingly produce IFNγ, TNF-α, and IL-2, and Th2 cells which produce IL-4, IL-5, and IL-13 were the first subsets to be defined in both mice and humans. More recently, these subsets have been categorized based on expression of transcription factors, which mediate characteristic patterns of gene expression. The Th1 subset typically expresses the T-bet transcription factor, while the Th2 subset is consistent with expression of the transcription factor GATA-3.[265] More recently, a further distinct Th-cell population, termed Th17, was identified that produces the cytokines IL-17, IL-22, and granulocyte macrophage-colony stimulating factor. In addition, Th17 cells are also characterized by expression of the transcription factor RORγt.[266] Cytokines of the IL-17 family strongly induce mobilization of granulocytes during infection. This occurs by abundant production of proinflammatory mediators such as IL-6, and more specifically by increased secretion of the chemokines CXCL1, CXCL8, and CXCL6. These chemokines both attract neutrophils and eosinophils into infected tissue but also act as prosurvival factors to prolong the activity of these cells.[267] Th17 cells appear to have limited importance for protection in murine models of primary infection with mycobacteria, salmonellae, and listeriae. Despite this,

Th17 cells are instrumental in driving more rapid Th1 responses against pulmonary TB in mice resulting in enhanced protection.[268] Therefore, induction of the Th17 subset could be important in vaccination strategies against TB. Recent work has also demonstrated that IL-17 is required for optimally protective Th1 responses during primary infection of mice with *F. tularensis*.[269] In this model, IL-17A produced by Th17 cells directly induced DCs to produce IL-12, which in turn enhanced Th1 subset differentiation. IL-17A also acted directly on *F. tularensis*-infected MPs to produce both IL-12 and IFNγ, which enhanced killing of intracellular bacteria indicating a prominent role for this T-cell subset in control of intracellular bacterial infection.

Cluster of Differentiation 8 T Cells

In humans, the major function of CD8 T cells is believed to be via cell contact-mediated target cell lysis. CD8 T cells recognize peptide epitopes in the context of MHC-I gene products, which acquire peptides for presentation from the cell cytosol. Intracellular bacteria are under some circumstances able to enter the cytoplasm, where antigen becomes available to MHC-I processing and presentation in a manner similar to newly synthesized host or viral proteins.[107,270] Upon target cell recognition by CD8 T cells, perforin, granzymes, and granulysin are transferred to the infected host cell to allow direct killing of intracellular bacteria in addition to host cell lysis.[271] Perforin oligomerizes to form a pore in the target cell, through which granules containing granzymes and granulysin are conveyed. Granzymes are a family of serine proteases that include granzymes A and B.[272] Granzyme B induces apoptosis of target cells by both caspase-dependent and -independent mechanisms, while granzyme A induces apoptosis by a caspase-independent mechanism. In addition, CD8 T cells also function by producing T_H1 cytokines including IFNγ and TNF-α, and directly activating infected macrophages to control intracellular bacteria in mice, which lack granulysin. Perforin- or granzyme B-deficient mice are able to control *M. tuberculosis* equivalently to wild-type mice.[273,274] Moreover, protection against primary infection in mouse models of *C. pneumonia* and *C. trachomatis* is perforin-independent.[275,276] Despite this, perforin is critical for protection of mice against secondary *L. monocytogenes* infection.[277] Granulysin is a saponin-like protein that has been shown to directly kill intracellular *S. typhimurium*, *M. tuberculosis*, and *L. monocytogenes.*[278]

Conventional CD8 T cells recognize peptide in the context of polymorhphic MHC-I. A group of CD8 T cells also recognize MHC-I of limited polymorphism and present short formylated peptides, which are often characteristic of intracellular bacterial infection in mice.[279] In humans, this group includes human leukocyte antigen (HLA)-E-restricted T cells, which respond to *M. tuberculosis* antigens, and lung mucosal-associated invariant T cells, which recognize antigen in the context of MHC-related protein 1.[280] Protection conferred by CD8 T cells is likely to be complementary to that conferred by CD4 T cells as unlike MHC-II expression, which is restricted to professional phagocytes, virtually all nucleated cells express MHC-I molecules.

Unconventional T Cells

Unconventional T cells express nonpolymorphic receptors for antigen recognition and make an important contribution to protection during the early stages of infection, shaping the response mediated by conventional αβ T cells. These comprise T cells that express the gamma-delta γδ TCRs, named γδ T cells and T cells that express a low-varient form of the αβ

TCRs.[281] Similar to CD8 T cells, γδ T cells both produce inflammatory cytokines and are cytolytic. In mice, γδ T cells recognize heat shock protein-derived peptides presented by nonpolymorphic MHC-I-like molecules.[281] Human γδ T cells can respond to nonpeptidic phosphorylated metabolites, for example, of the isoprenoid pathway of bacterial and host origin.[281] In experimental murine listeriosis, γδ T cells participate in granuloma development in the liver with liver abcesses developing in their absence.[282] Recently, it was also shown that in the early stages of *M. tuberculosis* infection of mice, γδ T cells constitute a major source of IL-17, perhaps until canonical Th17 αβ T cells can take over production of this cytokine during the ensuing adaptive response.[283]

Unconventional T cells that express the αβ TCR also respond to CD1, a group of nonpolymorphic MHC-related molecules. In humans, T cells that respond to CD1a, b, and c (group I CD1) are either CD4-/CD8- or CD8+. These T cells recognize a variety of microbial glycolipids, including lipoarabinomannan, phosphatidylinositol mannans, mycolic acids, sulfatides, sulfoglycolipids, and lipopeptides.[257] Their TCR repertoire shows broad variability, and these group I CD1-restricted T cells appear to perform similar biologic functions as canonical αβ T cells. In contrast, CD1d (group II CD1) is expressed by both humans and mice, and controls development of invariant NKT (iNKT) cells that express both the NK cell marker NK1.1 and an evolutionarily conserved TCR with restricted variability.[284] iNKT cells can recognize phosphatidylinositol mannans from mycobacteria and glycosphingolipids from *Ehrlichia* and *Sphingomonas.*[285] Recent findings suggest that iNKT-cell activation may also be mediated by altered host cell metabolic activity. TLR engagement by bacterial ligands results in a temporary downregulation of the enzyme α-galactosidase A, which in turn leads to accumulation of lipid metabolites as α-galactosidase A processes these lipids during homeostatic metabolism. iNKT cells can respond to these lipids loaded onto CD1d.[286] In addition, an abundant host glycolipid, β-D-glucopyranosylceramide can act as a potent iNKT stimulator, with activity dependent on composition of the N-acyl chain.[287] Upon antigen activation, iNKT cells rapidly produce cytokines and are capable of secreting both IL-4 and IFNγ, and could be critical in early responses that drive later differentiation of canonical antigen-specific T cells during development of adaptive immune responses. iNKT cells can also provide cognate antigen-specific help to B cells that express CD1d, driving primary B-cell responses, but not B-cell memory.[288] Therefore, iNKT not only rapidly produce cytokines to drive T-cell responses, they also stimulate rapid antibody production by both noncognate and antigen-cognate mechanisms. As a result, iNKT cells might play central roles in development of protective immunity against intracellular bacteria.

B Cells

B cells and antibodies clearly play a role in infections with intracellular bacteria. Accumulating evidence suggests that IgG and IgA are important in preventing intracellular bacteria from gaining entry via mucosal surfaces.[289] Furthermore, salmonellae are often present outside cells during infection where antibody is important in neutralizing them. B cells are also potent APCs for soluble antigens including lipids presented by CD1c[257] and secrete many cytokines otherwise associated with T cells, DCs, and MPs. Recently, B cells have been shown to perform regulatory functions during development of host immunity, which may benefit intracellular bacteria. B cell signalling via MyD88 during *S. typhimurium* infection has been associated with B-cell production of IL-10 and mice with B cell-specific MyD88 deficiency were found to be more resistant to infection.[290]

Regulatory T Cells

Th1 responses that are required to control intracellular bacteria ultimately contribute to exacerbated tissue pathology requiring host counter measures. This is achieved largely by production of IL-10 and TGF-β, which limit inflammation and control IFNγ production. Although other cells such as macrophages and DCs can produce these cytokines as well, regulatory T (T_{reg}) cells are the main producers of these cytokines. Natural T_{reg} cells are responsive to IL-2 due to constitutive CD25 expression and are characterized by expression of the transcription factor FOXP3.[291] The inducible T_{reg} are antigen-specific and hence can develop during infection to specifically deaccelerate ongoing immune responses and thus avoid excessive damage.[292] Hence, expansion of T_{reg} cells appears to be both antigen-dependent and -independent. T_{reg} cells also selectively express TLRs and can be activated by TLR ligands. Therefore, T_{reg} cells could act both during innate and adaptive immune responses. Although T_{reg} act by controlling T-cell responses and immunopathology, they can also prevent the complete elimination of bacteria, and benefit intracellular bacteria by promoting the persistent chronic state of infection.

Memory T Cells

Protective immunity against intracellular bacteria is believed to last for decades due to generation of immune memory. This notion remains a touchstone in efforts to develop effacious vaccines against intracellular bacteria, which aim at efficiently driving development of T- and B-cell memory.[293] It is thought that during an ongoing immune response, most T cells and B cells become effector cells and eventually die of exhaustion during a primary immune response.[294] A small proportion of these cells that receive stimulatory signals of intermediate strength change their phenotype and become long-lived memory T or B cells. The memory T cells respond to the homeostatic cytokines IL-7 and IL-15 via expression of the respective cytokine receptors.[295] Central memory T cells and effector memory T cells are defined by differential surface molecules and functions.[295] Effector memory T cells are not able to home to LNs and instead traffic to peripheral

tissues where they secrete cytokines and express cytotoxic functions. Central memory T cells persist in LNs and are able to quickly propagate upon IL-2 stimulation due to IL-2 receptor expression. It is believed that memory T cells survive in the absence of MHC peptide recognition. Little is known about the induction and maintenance of long-lasting T cell immunity during chronic infections where antigen is everpresent.[296] In experimental listeriosis of mice, induction of memory T cells is dependent on duration of infection.[297] A clearer understanding of the requirements for memory T-cell development is essential if novel vaccines are to achieve longlasting T-cell immunity against intracellular bacteria.

BACTERIAL-TRIGGERED INFLAMMATION

Inflammation during infection with intracellular bacteria is initiated by sensing of bacterial components with PRRs. Immune cells are attracted to the site of infection in an attempt to combat the invader. Although direct toxicity of intracellular bacteria is generally low, their propensity to induce release of alarmins as a consequence of necrotic host cell death exacerbates inflammation.[298] Inability to dispose of the intruders and to accomplish tissue healing can result in unresolved inflammation.[299] As a consequence, host factors rather than microbial virulence factors drive pathology. Most of the factors involved in inflammation (ie, cytokines [TNF-α, IFNγ], ROIs/RNIs, and eicosanoids [prostaglandins, leukotrienes]) can act

in both a pro- and anti-inflammatory direction, depending on the context. Thus, a fine-tuned balance of these factors is essential as recently demonstrated for infection with mycobacteria.[300]

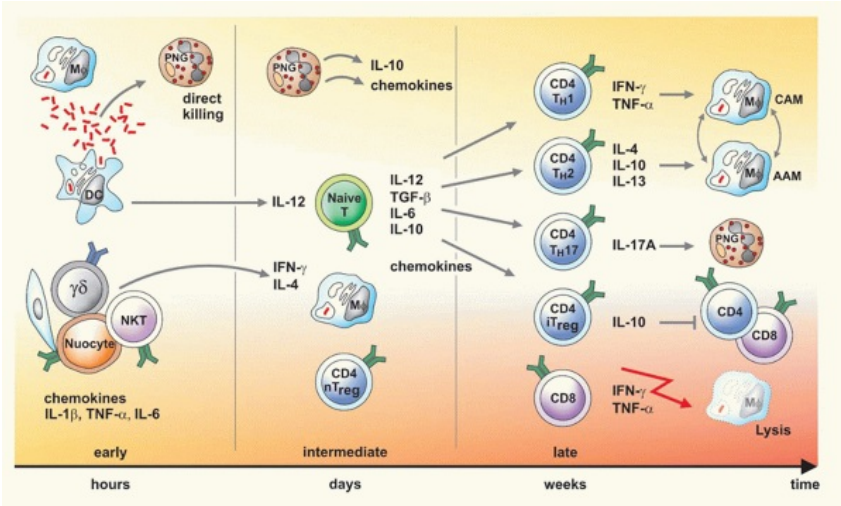

FIG. 40.5. Kinetics of the Immune Response during Infection with Intracellular Bacteria. This figure depicts critical events in the development of immunity to intracellular bacterial infection over a temporal scale. *Early innate responses (hours):* Polymorphonuclear granulocytes (PNGs) phagocytose extracellular bacteria and kill them. Macrophages (MΦ) and dendritic cells (DCs) become infected. DCs secrete interleukin (IL)-12 and present antigen to naïve T cells. Natural killer T cells, nuocytes, and gammadelta (γδ) T cells respond to presented bacterial products, become activated and produce cytokines such as IL-4 and interferon (IFN)γ. The host cell epithelium also responds to infection by producing chemokines and cytokines. These molecules act in concert to trigger inflammation and help shape naïve T-cell differentiation. *Intermediate innate/adaptive responses (days):* Naïve T cells activated by antigen presentation and costimulation respond to a milieu of cytokines including IL-12, IL-6, IL-10, and transforming growth factor-beta (TGF-β). This results in programs of gene transcription causing T cells to embark on distinct pathways of differentiation. PNGs respond to inflammatory signals and produce IL-10. Natural Tregulatory cells also produce IL-10 to dampen inflammation. *Late adaptive responses (weeks):* Cluster of differentiation (CD)4 T-cell differentiation gives rise to T-cell subsets that are able to produce different patterns of cytokines. These cytokines then act in concert to drive different MΦ activation states, such as classically activated macrophages (T helper 1 via IFNγ) and alternatively activated macrophages (T helper 2 via IL-4, IL-10, and IL-13) activation, control unregulated host immunity (inducible regulatory T cell via IL-10). T helper 17 drive inflammation, potentiate T helper 1 and mobilizes PNGs. CD8 T-cell activation and expansion result in cells able to directly lyse infected cells. These combined effects are critical in defining whether infection is completely cleared or remains persistent. TNFα, tumor necrosis factor-alpha.

Kinetics of Infection

The course of infection with intracellular bacteria can be conveniently separated into three stages (Fig. 40.5). At each stage, cytokines are produced that perform two functions.

First, they execute effector functions directed at reducing the microbial burden, and second, they express regulatory functions that influence the subsequent course of infection. The *early stage* is initiated within minutes after microbial entry and dominated by cells of the innate immune system, in particular PNGs and MPs, which are attracted to the site of bacterial replication by chemokines and proinflammatory cytokines. Phagocytosis and intracellular killing of bacterial pathogens by PNGs and MPs probably represents the predominant effector function at this early stage. At the same time, DCs mature and migrate to dLNs, where they produce proinflammatory and immunoregulatory cytokines, notably IL-12 for Th1 priming and IL-6 and IL-23 for Th17 cell stimulation,[301,302,303] and thus influence the subsequent stages by promoting induction of the protective acquired immune response. In addition, during early infection, NK cells, NKT cells, and γδ T cells can produce IFNγ and IL-17. Because NKT cells express a lowvariant TCR, they recognize a limited set of antigens and hence lack the diversity of conventional T cells governing the late stage. Moreover, cells operative at the intermediate stage can be activated via nonclonally distributed receptors such as TLRs.[304,305,306] The intermediate stage links the early (innate) with the late (acquired) immune response. This stage is essential for priming and polarization of conventional T cells. APCs, depending on the context and pathogen, tailor CD4 T-cell responses. Moreover, innate cells harboring the pathogen are activated by cytokines in an autocrine manner or by cytokines produced by innate lymphocytes, nuocytes, and tissue-resident cells. At the late stage, conventional αβ T cells with unique specificity become operative, which mobilize and sustain host defense that results in effective control and ideally sterile eradication of the pathogen. These include both MHC-I/peptide and group I CD1/lipid-specific αβ T cells. Subsequently, reparatory processes are initiated resulting in tissue repair and remodeling and return to homeostasis. In this last stage, the trophic functions of MPs surmount their antimicrobial capacities.[185,307]

The length and importance of each stage are markedly influenced by the type of intracellular pathogen. In experimental listeriosis of mice, the complete sequence of the host response lasts for less than 2 weeks, whereas in human TB it may endure for decades. The early stage is particularly important for control of *L. monocytogenes* organisms that divide rapidly and, at the same time, are highly susceptible to intracellular killing. The more robust and slowly dividing *M. tuberculosis* organisms are less vulnerable to this early stage of response. The relevance of the intermediate stage to microbial control is significantly influenced by the strength of the innate and the acquired immune response. The broader the window between these two stages, the more important the intermediate stage becomes. Upon secondary infection, the conventional T cells are activated more rapidly from the pool of memory T cells. The early and intermediate stages become largely dispensable because invading pathogens are rapidly confronted with the late-stage immune response. Suffice it to say that this is the major principle of vaccination. Deciphering the innate immune factors activated promptly after infection or vaccination, which determine the later ensuing protective immune response, has become a highly active topic of research, termed systems immunology or systems vaccinology.[293]

Some bacteria persist in the host lifelong. This is frequently the case for *M. tuberculosis*, which persists during latent *M. tuberculosis* infection without overt clinical signs. Control of latent TB, however, is T cell-dependent and hence, these T cells need to be fine-tuned to avoid deviation from protective immunity by confounding coinfections, for example, with helminths.[308,309,310] Protective immunity, however, breaks down after coinfection with human immunodeficiency virus frequently causing active TB within months after coinfection.[246]

Cytokines and Chemokines

Cytokines are central to resistance against intracellular bacteria. At all stages, cytokines are produced that perform regulatory and/or effector functions. Although cytokines are essential for control of infection, they can also cause harm to the host. To avoid such harmful consequences, downregulation of the immune response is required at later stages of infection. Neutralization of cytokines with specific antibodies and application of knockout mice lacking defined cytokines or cytokine receptor genes have provided deep insights into the role of single cytokines. The highly intertwined steps of the anti-infectious host response, which are controlled by cytokines, are listed in the following.

- Leukocyte recruitment to the site of bacterial deposition
- Formation of granulomatous lesions
- Activation of antibacterial functions in MPs
- Induction and maintenance of a protective T-cell response
- Downregulation of the antibacterial host response to avoid harmful sequelae of exaggerated immunity

Inflammation is usually a life-preserving process that needs to be tightly controlled. Certain steps are essential for recruitment of leukocytes, including PNGs and MPs, which phagocytose and—following activation—destroy the microbe. The essentiality of these processes is underlined by the high risks of lethal bacterial infection in humans with genetic defects affecting leukocyte motility/adhesion.[311] Accumulation of leukocytes at sites of microbial assault is guided by cytokine/chemokine gradients, and the process has been coined leukocyte recruitment. Tissue influx of leukocytes is a consequence of their extravasation and is mediated by close interactions between circulating leukocytes and the blood vessel endothelia, in close proximity to the area of infection.

Leukocyte Recruitment

Influx of inflammatory phagocytes occurs prior to the appearance of specific T-lymphocytes, and accordingly the relevant cytokines are primarily produced by MPs, as well as by epithelial and endothelial cells in response

to microbial invasion. Early produced cytokines with effector functions include the proinflammatory cytokines, TNF-α, IL-1, IL-6, as well as chemokines.[312,313,314] Four subgroups of chemokines can be distinguished on the basis of a conserved cysteine motif: the CC chemokines with two unseparated terminal cysteine residues, the CXC chemokines with nonconserved amino acids separating the two terminal cysteine residues, the CX3C chemokines with several amino acids separating the cysteine residues, and the C chemokine with only one terminal cysteine (C chemokine). Grouping of the large chemokine family can be further extended on the basis of different chemokine receptors.[315] The CC chemokines preferentially act on MPs, whereas PNGs are primarily activated by CXC chemokines. Other leukocytes, including lymphocytes, eosinophils, and basophils, may also be stimulated by these chemokines. The C and CX3C chemokines primarily recruit NK cells and lymphocytes.

Chemokines as a group play an important role in early mobilization of host defense. Knockout mice lacking the receptor for the CC chemokine MCP-1 are more susceptible to listeriosis than controls.[316] Knockout mice deficient in CC chemokine receptor 2 (CCR2) succumb to TB. In these mutants, the recruitment of macrophages, DCs, and T cells to the lung is impaired.[317] On the other hand, MCP-1-deficient knockout mice control *M. tuberculosis*

infection similarly to wild-type animals. MCP-1 acts via the CCR2 receptor. It therefore appears that these chemokines are essential for antibacterial protection but are mutually compensatory.[318] Experiments in other systems have revealed a central role of chemokines in early inflammation, in particular PNGs and monocyte extravasation. Chemokines, particularly those able to bind CCR2 receptor, are essential for bone marrow emigration of MPs and are therefore essential for infection with intracellular pathogens, as demonstrated for listeriae.[319] In addition, some chemokines activate professional phagocytes and in this way probably promote early reduction of bacterial load. Abundant levels of CC chemokines are on the other hand deleterious, as mice lacking a chemokine decoy receptor (D6) have been shown to be impaired in controlling tissue inflammation during TB.[320] The proinflammatory cytokines, IL-1, IL-6, TNF-α, and migration inhibitory factor are also involved in the early accumulation of inflammatory phagocytes at the site of bacterial growth. The essential role of IL-6 and TNF-α in antibacterial immunity is demonstrated by the exacerbated susceptibility to listeriosis and TB of knockout mice with a deficient IL-6 or TNF-type 1 receptor gene.[321] Similarly knockout mice deficient in migration inhibitory factor suffer from exacerbated *S. enterica* infection.[322] The proinflammatory cytokines, when produced in high amounts, cause acute-phase responses by inducing release of various plasma proteins from hepatocytes. They also serve as endogenous pyrogens that stimulate fever, and TNF-α is responsible for cachexia, the characteristic feature of wasting in infections with many intracellular bacteria, notably TB. Clinical trials showing that detrimental effects of excessive TNF-α production in patients with TB and leprosy can be ameliorated by treatment with thalidomide emphasize the double-sided role of TNF-α in chronic infections.[323,324]

Leukocyte Extravasation

In the early phase of inflammation, extravasation of (and invasion by) PNGs and, subsequently, blood monocytes is induced by proinflammatory signals mediated by bacterial components (N-f-met-containing peptides, such as f-Met-Leu-Phe or ligands for PRRs), complement components (C5a), arachidonic acid metabolites (PGE2), and cytokines. Infected MPs produce numerous proinflammatory cytokines, as well as various chemokines that stimulate local endothelial cells and blood phagocytes. The inflamed endothelium around the primary lesion expresses elevated levels of adhesion molecules, thus promoting extravasation of inflammatory phagocytes.[325] Extravasation is mediated by interactions between leukocytes and endothelial cells by means of adhesion molecules. These include selectins, integrins, and members of the Ig superfamily.

The L-selectins are found on leukocytes, whereas the P- and E-selectins are expressed by endothelial cells. Selectins bind to carbohydrate ligands on the corresponding cell type. The integrins are expressed on many cell types, including leukocytes and endothelial cells. Contact between leukocytes and endothelial cells is initiated when the blood vessel is suddenly broadened in diameter at inflammatory foci.[326] This fast process is controlled by histamines, eicosanoids, and tryptases derived from tissue mast cells and recruited PNGs. Release of platelet activation factor following PRR stimulation in MPs and the subsequent coagulation cascade augment blood vessel permeability changes as well. Activated endothelial cells and leukocytes upregulate surface expression of adhesion molecules and thus promote leukocyte binding to the endothelium. This sets into motion the cascade of adhesion events. Selectin-mediated interactions result in leukocyte tethering and rolling. Subsequently, integrin interactions with Ig superfamily molecules cause tight leukocyte adhesion to endothelial cells. Once leukocytes firmly adhere to the endothelium, transmigration to the inflammatory focus occurs. Upregulation of P- and E-selectin expression

primarily promotes PNG extravasation. In contrast, the L-selectins are constitutively expressed on virtually all leukocytes. Activated and memory T cells, as well as inflammatory phagocytes, however, express higher levels of integrins such as lymphocyte function-associated antigen-1 and very late antigen-4 and activated endothelial cells show elevated expression of Ig superfamily molecules. Intercellular adhesion molecule-1 and vascular cell adhesion molecule-1 upregulation is primarily important for monocyte and T-cell transmigration to inflammatory foci. Chemokine receptors are decisive factors for selective T-cell migration.[314,327] Differential expression of chemokine receptors on human Th1 and Th2 cells, effector versus memory T cells, as well as central memory T cells versus effector memory T cells, direct preferential migration of selected T cells to the site of inflammation.[328,329] Chemokines can bind to glycosaminoglycans bound to the endothelial surface without loss of biologic activity. Interactions between

chemokine receptors on lymphocytes and chemokines bound to endothelial cells further promote selective T-cell migration. The lack of CCR7 (receptor type 7 for CC chemokines) combined with the low expression of CD62L and the high expression of lymphocyte function-associated antigen and of α4β1 integrin seems characteristic for effector memory T cells of Th1 type that migrate to sites of inflammation. In summary, tethering and rolling, which is then succeeded by tight adhesion and subsequent extravasation of leukocytes, results in leukocyte accumulation at the site of microbial colonization. This forms the basis for antimicrobial defense at site of microbial residence.

The Inflammasome

IL-1β is a key inflammatory cytokine in host defense,[330] and the generation of biologically active IL-1β is controlled by the inflammasome. Transcriptional regulation of this cytokine is primarily induced by PRR agonists and distinct cytokines, while cleavage of the proform is executed in the inflammasome. The inflammasome is a multiprotein cytosolic platform consisting of an NLR or PYHIN member, the ASC protein, and the procaspase-1.[331] Depending on the NLR/PYHIN cognate that is recruited to the cytosolic complex, four major inflammasomes have been described: NLRP1, NLRP3, NLRC4, and the AIM2 inflammasome. These inflammasomes detect intracellular cues from microbes, which provide the basis for optimal responses against infections with intracellular bacteria. Certain microbes induce activation of single or multiple inflammasomes.[332,333,334] Thus, *L. monocytogenes* activates NLRP3 by virtue of its virulence factor LLO. Bacterial DNA is recognized through the AIM2 inflammasome and bacteria may also interfere with NLRC4 inflammasome assembly. AIM2 is relevant for recognition of other cytosolic bacteria, particularly for francisellae.[70,75] Mycobacteria stimulate the NLRP3 inflammasome in macrophages, although evidence for inhibitory activity of tubercle bacilli has also been reported.[334] Salmonellae induce activation of NLRC4 inflammasome via T3SS and flagella, and also trigger the NLRP3 inflammasome.[335] Thus, most pathogens are sensed by multiple inflammasomes, suggesting that during coevolution, diverse pathways converge to ensure release of bioactive IL-1β upon infection. In addition, inflammasomes sense danger signals released by dying cells.[332,334] Accordingly, inflammasome activation by intracellular microbes, which induce extensive tissue destruction, represents a double-edged sword: the benefit of IL-1β in the early phase of infection bears risk for the host in the case of prolonged release during chronic infection.

Interferons

Both classes of interferons, IFN-I (comprising multiple members, with IFNα and IFNβ being of

highest relevance) and IFN-II (IFNγ), are closely associated with host defense. IFN-I and IFN-II show partition in defence against viral and bacterial infections, respectively. However, this classification is oversimplified, and it is becoming increasingly clear that both IFN classes participate in infections with intracellular bacteria. IFN-II can be viewed as primarily beneficial, whereas type I IFN often seem to be detrimental.

Activation of antibacterial macrophage properties by IFNγ represents a central step in acquired resistance against intracellular bacteria. IFNγ-activated macrophages rapidly kill susceptible intracellular bacteria, such as *L. monocytogenes*. Although the question as to whether IFNγ-stimulated MPs actually kill *M. tuberculosis* remains a matter of controversy, it is certain that they markedly inhibit growth of this pathogen. Consistent with such a central role of IFNγ in antibacterial immunity, IFNγ- or IFNγR-deficient knockout mice rapidly succumb to infections with *L. monocytogenes*, *M. tuberculosis*, *S. enterica*, and other intracellular pathogens.[336,337,338] Support for the central role of IFNγ in control of intracellular bacterial infections in humans stems from the identification of hereditary IFNγR deficiency in children who suffer from frequent infections with various intracellular bacteria or even from *M. bovis* BCG vaccination.[339,340] Conversely, IFNγ treatment in adjunct to chemotherapy has been used successfully in the treatment of leprosy, TB, and atypical mycobacteriosis.[341]

IFN-I cognates on the contrary are deleterious during infection with listeriae,[342,343,344] mycobacteria,[345,346,347] chlamydiae,[348] and francisellae.[349] These notions emerged from studies with mice lacking the receptor for the cytokine (IFNAR knockout mice), revealing impact of IFN-I on both innate and adaptive immune responses. Recently, crosstalk between type I and II IFN was described during infection with *L. monocytogenes*.[350] The role of IFN-I during infections with other intracellular pathogens as well as detailed mechanistic explanations as to how these cytokines negatively impact on disease control awaits clarification.

Macrophage Heterogeneity and Polarization

The myelomonocytic pathway, which comprises mature and immature cells, is characterized by a tremendous diversity and plasticity.[351] The most prominent member of this pathway, the macrophage, performs a dual role in infections with intracellular bacteria. It may harbor, and at the same time dispose of, the intruder. These binary effects are correlated with the functional plasticity of the MP. From sensing of pathogens and initiation of inflammation to the resolution of infection and tissue repair/remodelling, MPs play diverse functions of critical importance. Similar to the dichotomy of Th1/Th2 cells and closely related to the cytokines produced by these lymphocyte subsets, macrophages may develop into classically activated macrophages (CAMs) or alternatively activated macrophages (AAMs).[352] These two forms should be viewed as extreme poles of a continuum, with intermediate forms occurring in between. In stark contrast to T cells, chromatin reorganization in activated macrophages is not fixed. As a corollary, macrophage activation mirrors functionality of these cells in a particular spatiotemporal context. More recently, epigenetic modifications (Jmjd3-Irf4 axis) were associated with preferential AAM development.[353,354]

CAMs or M1 macrophages are polarized by IFNγ or TLR agonists, such as LPS. Thus, Th1 cells and NK/NKT cells

promote CAM genesis. The polarized CAMs secrete copious amounts of inflammatory cytokines (TNF-α, IL-12/23) and antimicrobial molecules (RNIs, ROIs), modulate iron homeostasis by repressing ferroportin and inducing ferritin, and upregulate costimulatory and

MHC-II molecules on their cell surface. Production of CXCL9 and CXCL10 by CAMs boosts Th1-cell recruitment. Concomitantly, the beneficial antimicrobial effects may cause collateral tissue damage.[355]

AAM or M2 macrophages are polarized by the canonical cytokines IL-4 and IL-13 as well as by the more recently described mediators IL-21,[356] IL-33,[357] and IL-25.[358] Accordingly, Th2 lymphocytes and nuocytes[358,359,360] may induce AAM polarization. AAMs seem to exclusively derive from resident tissue macrophages.[361] Functionally, AAMs are characterized by increased endocytic activity, release of IL-10, upregulation of IL-1RA and IL-1R2, and secretion of chemokines (CCL17, CCL22, CCL24) involved in recruitment of Th2 cells, T_{reg} cells, eosinophils, and basophils. AAMs upregulate ferroportin and express folate receptors. A hallmark of these macrophages is the expression of arginase-1, which not only enables AAMs to perform tissue remodeling, but also induces expression of E-cadherin,[362] involved in homotypic fusion. IL-4 and IL-13 induce homokaryon formation, a cell pathologic event particularly relevant for infections with intracellular bacteria. The metabolic and secretory properties of AAMs favor trophic functions and tissue tolerance.[363] The precise role of AAMs and their cytokines in giant cell formation during chronic bacterial infection awaits further clarification.

Although CAMs and AAMs are phenotypically and functionally different, both undergo a vivid crosstalk with adaptive lymphocytes (αβ T cells) and innate lymphocytes (γδ, NK, and NKT cells). The tremendous plasticity of polarized macrophages has been elucidated in malignancy,[351,364] and should similarly hold true in bacterial infections. During *L. monocytogenes* infection, CAMs ($Gr1^{low}$ patrolling monocytes) remodel to AAMs.[365] *F. tularensis* induces similar transition in macrophage polarization, to the advantage of the bacterium,[366] and *M. tuberculosis* seems to hijack this polarization pattern toward AAMs.[367,368] Blood cell gene transcripts from patients with TB show a combined IFN-I and IFN-II response accompanied by classical CAM gene expression.[369,370] Patients suffering from typhoid fever present enrichment for genes encoding IFNγ-mediated immune responses. However, patients in which a CAM signature has been replaced by an AAM signature and have maintained it are prone to becoming carriers or to manifesting disease relapse.[371] A clear scenario related to CAM/AAM balance has been reported for leprosy.[372]

Remodeling of recruited macrophages from alternative to classical phenotype occurs in patients who have converted from a lepromatous to a tuberculoid form of this disease.

GRANULOMA FORMATION: A PATHOLOGIC HALLMARK OF INTRACELLULAR BACTERIAL INFECTION

A characteristic feature of many infections caused by intracellular bacteria is the need for tissue remodeling by the host at the site of infection when the ensuing inflammatory response is not successfully resolved. This process leads to formation of structures called granulomas[373] (Fig. 40.6). The granuloma is primarily composed of T-lymphocytes and MPs, some of which contain indigestible antigen. In addition, granulomas also contain B-lymphocytes and DCs. MPs in granulomas demonstrate a degree of morphologic plasticity. Major macrophage phenotypes seen in granulomas include epitheloid-like and multinucleated giant cells. Macrophage plasticity may also be reflected in presence of both CAMs and AAMs, although the contribution of different states of macrophage maturation and activation is unclear at present.

Granulomatous lesions are generally initiated by innate inflammatory signals mediated by

microbial products, chemokines, and proinflammatory cytokines that are produced by endothelial cells and MPs at the site of infection. The best-studied granulomatous disease is TB where development of granulomas in the lung eventually leads to transmission of bacteria via cough. During TB, the granuloma is encapsulated by a fibrotic wall and its center becomes necrotic.[374] The combined effects of prolonged macrophage activation, persistence of intracellular bacteria, and tissue hypoxia likely lead to enhanced cell death in the center of granulomas resulting in the formation of caseum. This caseum may favor the local replication of facultative intracellular bacteria in the cellular detritus, as well as microbial dissemination to distant tissue sites and to the environment to transmit infection. T cells are the critical driving forces of granuloma formation and maintenance in most granulomatous diseases, and T cell production of IFNγ and TNF-α is crucial. Experiments utilizing the respective knockout mice emphasize a role of IFNγ, TNF-α, and lymphotoxin-α3 in granuloma formation and maintenance during TB.[337,375,376] Hereditary IFNγR deficiency has been described in humans, and these immunodeficient patients severely suffer and ultimately die of infections with intracellular bacteria.[339,340] That this high susceptibility was accompanied by impaired granuloma formation is suggestive of the central role of granuloma formation in control of bacterial growth. The critical role of TNF-α in the containment of *M. tuberculosis* in humans has been impressively demonstrated by the increased risk of the reactivation of TB in patients with rheumatoid arthritis undergoing treatment with anti-TNF-α monoclonal antibody.[377] Noncontagious diseases also characterized by granuloma formation include berylliosis caused by the undegradable irritant beryllium[378] and sarcoidosis of unclear etiology.[379]

Early Immunologic Events in Granuloma Development

The laboratory mouse model provides a plethora of genetic and immunologic tools to dissect the granulomatous response to infection. Although the classically used mouse model of TB fails to fully reproduce human-like granulomas, it represents a useful model for the generalized early stages of granuloma development during chronic infection. Orchestration of granuloma formation requires induction of *M. tuberculosis*-specific T-cell responses. In this section, we highlight recent findings using the murine model of TB to

give insight into events governing how granulomas develop during the early stages of infection. These responses can be enhanced by early production of the cytokine IL-17 by activated γδ T cells.[283] IL-17 enhances influx of Th1 cells producing IFNγ and TNF-α into the infected lung that are in turn able to control bacterial replication.[380] Excessive IL-17 may also enhance host pathology due to enhanced Th1 responses and require counter measures of control.[381] Such control could be provided by IL-10 as Th1 cell influx into the lung during murine TB is enhanced in its absence.[382] Furthermore, enhanced IL-17 production in the lung of mice after repeated application of *M. bovis* BCG during TB results in exacerbated disease, demonstrating the need to regulate inflammation to maintain a protective immune balance.[383]

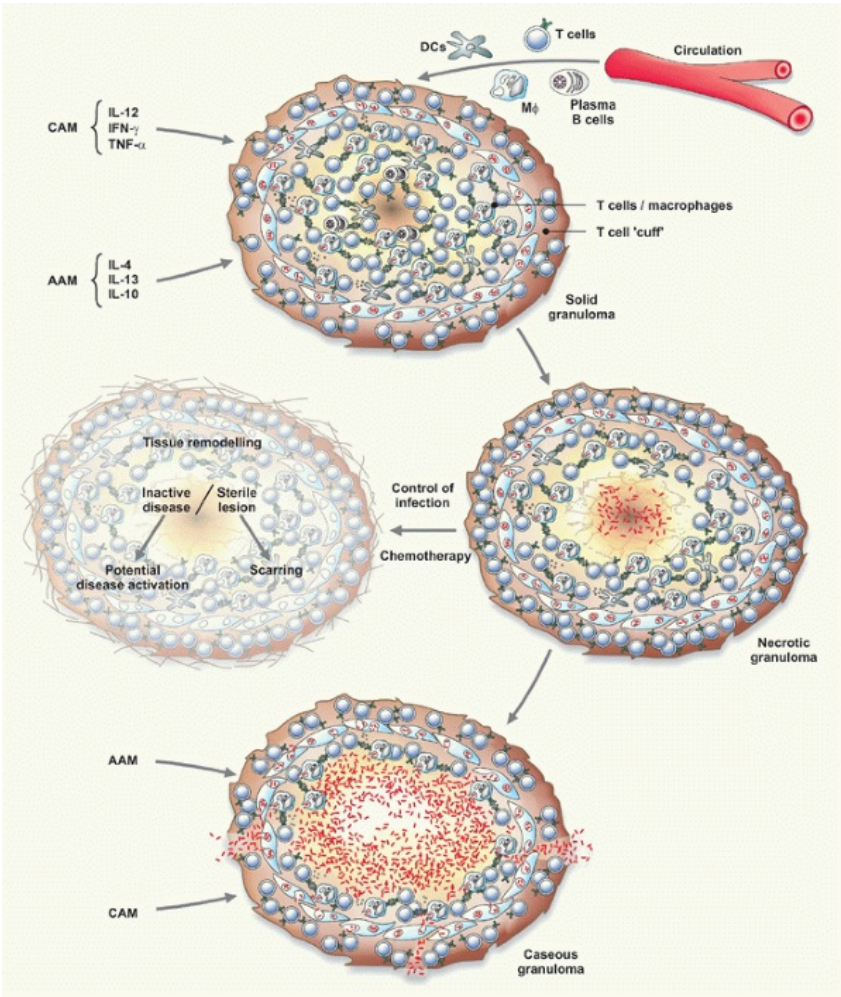

FIG. 40.6. Stages of Granuloma Development during Intracellular Infection. This figure describes a generalized scheme of granuloma development during intracellular infection, using tuberculosis (TB) as a paradigm. The *upper panel* depicts formation of a solid granuloma from bloodborne macrophages (MΦ), T cells, B cells, and dendritic cells (DCs) in response to infection. The center of the solid granuloma is composed of T cells as well as infected and uninfected MΦ which are, in turn, orchestrated by T-cell cytokines. Such signaling leads to classically activated macrophages and alternatively activated macrophages within granulomas. Eventually, the center of the granuloma shows extensive necrosis of MΦ to produce a necrotic granuloma. The necrotic granuloma may spontaneously heal or become sterilized by chemotherapy. Complete inactivation and scarring then ensues or in the event of incomplete clearance of persistent bacteria, reactivation of disease may occur later. In the case of TB, the necrotic granuloma may also further develop to produce a large central caseous mass that eventually liquefies to give rise to a caseous granuloma. Absorption of bronchi by this structure allows egression of bacteria into the airway mediating transmission. IFNγ, interferon gamma; IL, interleukin; TNF-α, tumor necrosis factor-alpha.

In addition, IL-12 signalling of DCs represents a key event initiating Th1 responses, and this IL-12 signaling shows multifunctionality during the early granulomatous response to infection. Signaling of immature DCs via engagement of IL-12 receptor β1 chain by the IL-12p40 homodimer, IL-12p80, mediates DC migration to dLNs, a prerequisite for driving rapid T-cell responses in the lung.[384] DCs can also produce an IL-12 receptor splice variant that not only

drives naïve T-cell proliferation in lymph nodes but also enhances migratory activity of T cells.[385] Chemokines, which play multiple roles in early immune responses, are also involved in granuloma formation. CCR7 is required for murine granuloma formation[386]; CCL19 and CCL21 participate in development of the Th1 responses while another homeostatic chemokine, CXCL13, is involved in the spatial construction of granulomatous lesions.[387] CCL19 and CCL21 are ligands of CCR7 on DCs and also signal their trafficking to dLNs to prime T-cell responses.[254] Therefore, homeostatic chemokine function demonstrates an intimate relationship between the need to drive T-cell responses in dLNs and the orchestration of granuloma formation in the lung during early stages of TB. During later stages of this disease, when granuloma formation has been fully established, T-cell activation can occur in the lung via ectopic or tertiary lymph node structures, such as inducible bronchus-associated lymphoid tissue.[388] This ability to prime T cells directly in the lung may become more relevant in later stages of human disease when cavity formation and extracellular growth of *M. tuberculosis* results in the need to provide protective immunity in the face of increased bacterial loads in the lung.[388,389] In addition, IL-17 produced by T cells enhances CXCL13 expression, which is required for inducible bronchus-associated lymphoid tissue formation, indicating an additional role for this cytokine in protective immunity.[388,390]

Contribution of Granuloma to Disease

In addition to its central role in TB, granuloma formation and development represents a central feature of disease resulting from intracellular infection with brucellae.[391] Brucellosis is a multiorgan disease in which granulomas contain largely epithelioid macrophages occurring in lymphatics, brain, lung, and bone. Hepatic granulomas can develop central necrosis. The structural similarity of these granulomas to those seen in other infections makes a definitive diagnosis of brucellosis complicated.[392]

Melioidosis represents another systemic disease with an important granulomatous component in bone, brain, and lung.[393] The disease in humans is caused by *B. pseudomallei*. Granulomas often show layers of epithelioid macrophages and presence of giant cells. These granulomas are often unable to contain bacteria because systemic spread of bacteria and septicemia can occur.

Lymphogranuloma venereum, a sexually transmitted disease where granuloma formation is central, is caused by the L1, L2, and L3 serotypes of *C. trachomatis.* Trachoma, which results from a granulomatous response of the upper eyelid due to *C. trachomatis* infection, is a leading cause of infectious blindness worldwide.[20] In human infection with *S. enterica* serovars, *Typhi* and *Paratyphi*, bacteria are disseminated within MPs to the liver, spleen, and lymph nodes where granuloma are formed.[394]

The definitive role of granuloma formation in development of active TB has been difficult to establish. A century ago, Anton Ghon defined latent subclinical TB in humans as the Ghon complex, which is composed of single subpleural caseous granulomas accompanied by caseation in the corresponding dLNs.[395] Animal models currently in use are biased toward accelerated disease, where granuloma development consistently accompanies pathology, making understanding the role of the granuloma in protection difficult to discern. Key to initial control of *M. tuberculosis* very early in infection is how the infected cell dies. Should the cell die by apoptosis, bacterial growth is primarily prevented. Should the cell die to necrosis, where the host cell membrane is breached, *M. tuberculosis* can proliferate and

disseminate.[396,397] Central necrosis and caseation in granulomas could in some way reflect the balance between these mechanisms of cell death. Infected macrophages also employ antibacterial mechanisms to control intracellular bacterial growth, such as autophagy[126,142] and production of antimicrobial peptides.[398,399] IFNγ enhances these mechanisms, but intracellular bacteria are often incompletely eradicated requiring consecutive waves of specific T cells and monocytes to arrive in the lung or dLNs, which then arrange into the classic stratified granuloma structure.[374,400,401]

The murine model of mycobacterial disease has addressed the contribution of T-cell immunity to granuloma development using intravital imaging. These studies have shown that antigen presentation to T cells within granulomas leads to production of TNF-α, which is critical to maintenance of granuloma structural integrity.[402] Furthermore, the T-cell compartment within granulomas was shown to be highly dynamic with T cells entering and exiting lesions. T-cell effector function in this model could be potentiated by exogenously introduced antigen, and this strategy might be explored using therapeutic strategies to augment the protective properties of granulomas.[403]

The understanding of granuloma development has benefited remarkably from use of zebrafish infected with *Mycobacterium marinum* to simplify study of the early events of granuloma formation in vivo. In particular, intravital imaging of zebra fish embryos to model early events in granuloma formation in the absence of adaptive T-cell responses showed that infected macrophages traffic readily

between multiple nascent granulomas.[404] This suggests that granuloma formation before the onset of adaptive immunity may in fact assist stable establishment of infection at an early stage. Later, T cells may be required to imprint on the granuloma the ability to contain mycobacterial growth. The zebrafish has been exploited for forward genetic screening revealing a critical function of *lta4h*, whose gene product catalyses leukotriene B4 synthesis. Leukotrienes are eicosanoids derived from essential fatty acid metabolism that demonstrate chemotactic and anti-inflammatory activity. Increased leukotriene B4 synthesis was found to suppress TNF-α production, which in turn abrogated protection in nascent granulomas.[300] This finding highlights the utility of using diverse models to address fundamental issues in granuloma biology.

Other animal models of TB, namely nonhuman primates (NHPs), rabbits, and guinea pigs show some ability to model granuloma formation. In contrast to the murine model, granulomas formed in rabbits and guinea pigs demonstrate central caseation and hypoxia.[405,406]

The NHP represents the closest model to human granuloma formation. Infection of NHPs results in a portion of animals with latent *M. tuberculosis* infection. Unlike other animal models of TB, disease in NHPs transitions through formation of a Ghon complex, suggesting that this initial event may represent the very early response in all cases.[407] The lymphatic lesion then undergoes necrosis and caseation as early as 3 to 4 weeks postinfection. These data and those seen in humans suggest that the Ghon complex indeed represents the site at which disease is either contained or progresses. Data from NHPs indicate that granuloma cellular composition and T-cell function can vary greatly in the same host and even in the same organ, for example, the lung. Additional studies in NHPs have established that early granuloma formation is accompanied by potent inflammatory responses, which are characterized by transcriptional networks controlled by the cytokines IFNγ and TNF-α as well as the intracellular JAK and STAT signaling pathways, while later granulomas show transcriptional networks reflective of tight control of inflammation and chemokine

production.[408] This inhibitory property of the late-stage granuloma could reflect the necessity to limit host tissue damage resulting from a nonresolved inflammatory response.

Cellular Mechanisms Active within Granulomas

In terms of understanding of cellular mechanisms operative in granulomas and how these impact granuloma biology, TB is the most widely studied granulomatous disease. Macrophages within granulomas demonstrate remarkable morphologic plasticity. Different macrophage morphologies in granulomas include epithelioid and foamy cells. In addition, macrophages can fuse to produce multinucleated giant cells.[374] On the tissue scale, one of the most characteristic gross morphologic features of granulomas in TB is their propensity to form a region of central necrosis, which softens in end stages to become caseous or cheese-like. This white mass results from extensive MP cell death.[409] Central necrosis appears at the onset of vigorous T-cell immunity, suggesting that it could represent a sacrifice of tissue to allow efficient killing of intracellular bacteria. At this stage, granulomas can become inert and eventually calcify. However, if intracellular bacteria continue to grow to up to hundreds of billions of microorganisms, granulomas in the lung become enlarged and can erupt into a bronchus with the central caseous mass liquefying. Coughing up the liquefied caseous mass containing bacteria allows transmission of TB. The molecular and cellular events that define these processes enable understanding of how TB is transmitted and offer important targets for therapy. In a model of granuloma caseation in the lung after dermal infection of knockout mice unable to produce RNIs, central granuloma caseation is accompanied by a local increase in serine protease activity. The serine proteases cathepsin G and neutrophil elastase are both active at neutral pH. Although both serine proteases show antibacterial activity,[398,410] cathepsin G enhances necrosis of IFNγ-activated macrophages infected with *M. tuberculosis.*[410] Therefore, deployment of serine protease activity in the lung may represent a double-edged sword, reflecting at a molecular level the need to balance mycobacterial killing with macrophage cell death in the granuloma. Recent studies suggest that products of the *sst1* genetic locus in mice prevent development of necrotic lung lesions during murine TB. A protein product encoded at this locus termed intracellular pathogen resistance 1 shows ability to direct infected macrophages to undergo apoptosis rather than necrosis.[411]

For disease transmission to occur, the lung extracellular matrix must be remodeled. Fibrillar collagens, highly resistant to enzymatic degradation, lend the lung extracellular matrix its extraordinarily tensile strength. In matrix remodelling, matrix metalloproteinases (MMPs), which cleave collagen at neutral pH, appear to be critical players. Patients with TB demonstrate increased levels of MMP-1 activity in sputum, and a transgenic mouse expressing human MMP-1 suffered increased lung tissue destruction during TB, suggesting MMP-1 is a key proponent of lung remodeling.[412]

Tissue containing caseous granulomas shows an increase in host cell lipid metabolism.[413] Foamy macrophages, containing multiple lipid droplets, are also found in regions surrounding central necrosis in granulomas.[413] In addition, human macrophages infected in vitro with *M. tuberculosis* demonstrate upregulated lipid metabolism.[414] *M. tuberculosis* in sputum from patients with TB are contained in lipid droplets and show reduced antibiotic susceptibility.[415] It is therefore possible that persistence of mycobacteria in foamy macrophages my represent a survival strategy in the face of drug therapy.

GENETIC CONTROL OF RESISTANCE AGAINST INTRACELLULAR BACTERIA

Resistance against intracellular bacteria is genetically controlled, and inherited factors are of particular importance in chronic infections with broad clinical spectrum, such as TB and leprosy. Although the impact of host genetic mechanisms on the outcome of infectious disease has been recognized for a long time, our understanding of the underlying

factors remains fragmented.[416,417] First, resistance to infection is highly polygenic. Second, a marked heterogeneity exists within populations. Third, variability in the genome of the pathogen, as well as environmental factors such as the availability of nutrients, further affect the outcome of the host-pathogen relationship. However, technologic advances in recent years have markedly facilitated the progress of immunogenetic studies. Single nucleotide polymorphism arrays and DNA sequencing are frequently applied in such investigations and genome-wide association studies have allowed identification of distinct loci associated with susceptibility to infection.[418,419,420]

The significance of genetic factors is perhaps most dramatically illustrated by the Lübeck disaster in 1927, when 251 babies were accidentally vaccinated with viable *M. tuberculosis* instead of BCG. At the end of the 6-year observation period, six children (2%) still suffered from TB, 129 (51%) had become ill but recovered, 77 (31%) had died, and in 39 children (16%) clinical signs of TB had never developed.[421] The marked influence of ethnic differences on the prevalence of TB further supports the role of genetic factors.[422]

In the 1940s, Lurie studied native resistance to TB in rabbits, and by selective inbreeding he succeeded in establishing strains of rabbits that differed remarkably in their susceptibility to infection with *M. tuberculosis.*[219] Similarly, congenic mouse strains that differ in their susceptibility to experimental infection with several intracellular bacteria have been developed.[423]

At least three levels of the host-pathogen relationship serve as potential targets for genetic control, which are briefly described in the following.

1. Genetic factors decide whether infection becomes abortive or establishes itself in a stable form. Convincing evidence for genetic control mechanisms at this level does not exist.
2. Genetic factors control transition from infection to disease. This control step distinguishes susceptible from resistant individuals. Such inherited influences are well proven in mice and begin to unfold in the human population.
3. Severity and/or form of disease are controlled by genetic factors.

Primary Immunodeficiencies

Numerous single-gene (Mendelian) disorders that perturb immune functions (ie, currently >300 primary immunodeficiencies) have been reported.[424] These monogenic diseases are rare, arise from major functional aberrations at single genes, and confer predisposition to a certain type of infection. The most thoroughly characterized of these syndromes in context of infection with intracellular pathogens is the Mendelian susceptibility to mycobacterial diseases.[423] The IFNγR1 deficiency was described first.[339,425,426,427] Subsequently, deficiencies in other Th1-associated molecules, namely IFNγR2,[428,429] STAT1,[430,431] IL-12B,[432] and IL-12B1[433] were reported. More recently, IRF8 mutations, which affect development of monocytes and DCs, have been associated with susceptibility to mycobacterial diseases.[434] Patients with Mendelian susceptibility to mycobacterial diseases also develop infections with typhoidal and especially nontyphoidal salmonellae with high

frequencies.[435]

Multigenic Predispositions/Major Genes

Linkage studies, and more recently genome-wide association studies, suggest polygenic characteristics of most infectious diseases. Studies in the mouse system have revealed a single dominant autosomal gene on chromosome 1, which is responsible for resistance against *M. bovis* BCG, *M. lepraemurium*, *M. avium/M. intracellulare*, *S. enterica*, and the protozoan pathogen *Leishmania donovani*. In contrast, murine resistance against other intracellular bacteria, most remarkably *M. tuberculosis*, is apparently not controlled by this gene.[436] The responsible gene has been named Nramp1 for natural resistance-associated macrophage protein.[437] The role of Nramp1 in controlling infectious diseases in humans remains controversial.[438,439] Other mouse gene loci affecting susceptibility to mycobacterial disease are Icbp,[440] Trl-1,[441] Trl-4,[442] Tbs1,[443,444] and Ipr1.[411,445] Certain loci impact on resistance against multiple intracellular bacteria. Ipr1 affects susceptibility to listeriae,[411] whereas Icbp affects responses against salmonellae.[446] The contribution of human homologues of the previously mentioned loci to antibacterial resistance needs further in-depth investigations. Genomewide association studies have described susceptibility loci for TB on chromosome 18q11.2[447] and chromosome 8q12.[448] Susceptibility to leprosy is associated with multiple innate immune-relevant genes.[449,450] Legionnaires' disease seems to be differently associated with polymorphisms in TLR-4 and TLR-5.[451,452,453] Single nucleotide polymorphism arrays, to analyze the association between clinical TB and certain PRRs (TLR-1, 2, 4, 6, 8, 9; DC-SIGN; NOD2; mannan-binding lectin) and adaptor molecules (TIR domain-containing adaptor protein), came to divergent results indicating a need for further studies.[423,454] Polygenic predispositions and immune defects in innate elements are currently being investigated and seem to bear an unanticipated role in resistance against infectious diseases.[455]

Major Histocompatibility Complex Control of Severity and Form of Disease

Segregation analyses in various human populations also indicate linkage of HLA types with severity of TB and leprosy. Strong evidence exists suggesting an influence of HLA on the development toward the tuberculoid or the lepromatous pole of leprosy. Although some linkage with MHC-I molecules has been observed in certain populations, MHC-II control appears to be more important.[456] Originally, it was found that HLA-DR2 subtypes are linked with increased incidences of lepromatous leprosy and that HLA-DR3 represents a linkage marker for tuberculoid leprosy. Recent population-based association studies, however, have provided evidence for an association between distinct HLA-DR2 alleles and susceptibility to tuberculoid leprosy. In TB, evidence for association of HLA-DR2 subtypes with pulmonary TB has been found. With more data from various population groups

becoming available, it is increasingly clear that HLA-DR associations with distinct disease forms differ among population groups, thus making it impossible to extrapolate from one population to another. These discrepancies underline the polygenic nature of resistance to infectious diseases.

CONCLUSION AND OUTLOOK

It is hoped that the reader of this chapter has not only become familiar with the principal mechanisms underlying immunity against intracellular bacteria, but also realizes the great

complexity at the interface between prokaryotic and mammalian eukaryotic systems. Understanding intracellular bacterial infections requires knowledge not only of immunology, but also of molecular biology of the infectious agent and biology of the target cell. In vitro analyses can only provide incomplete answers to the questions relevant to antibacterial immunity and must be complemented by in vivo experiments. Despite the high degree of complexity, such interdisciplinary research efforts certainly provide rewards.

First, understanding the performance of the immune system in bacterial infections can provide clues to questions pertinent to basic immunology. Knowledge of the rules underlying the extraordinary plasticity and adaptability of the immune system required for coping with transmutable “viable antigens” that developed during millennia of coexistence will provide deeper insights into the immunoregulation and evolution of the immune system. Second, applied questions will benefit equally well from these approaches. With the increasing inadequacy of chemotherapy in the control of bacterial infections, the need for adjunctive immune measures is gaining importance. Rational strategies toward vaccination and immunotherapy will benefit from the deeper understanding of the immune mechanisms operative in intracellular bacterial infections. With the elucidation of the genomes of major intracellular pathogens, as well as of the human and murine genomes, this type of interdisciplinary research has, in fact, entered a new phase and novel next-generation deep-sequencing technologies promise more rapid and less costly progress. Global analyses of the transcriptome and proteome down to the single-cell level will undoubtedly provide a comprehensive view of this dynamic interplay in the near future. The reader may find it ironic that the spirit of these investigations remains the same as it was at the early beginnings of immunology, which started as an approach to the intervention of bacterial infections.

ACKNOWLEDGMENTS

The authors acknowledge financial support from the German Ministry of Science and Technology (Bundesministerium für Bildung und Forschung; BMBF grant nos. 01KA1010, 01KI1007C and 01KI0781, 01GS0814, 0313801K), The Bill & Melinda Gates foundation (BMGF GC6-74 37772), the European Union Framework Programme 7 (EU FP7 NEWTBVAC, PHAGOSYS, SysteMTB, TRANSVAC), the European and Developing Countries Clinical Trials Partnership (EDCTP projects AE-TBC and TB-TEA) and the National Institutes of Health (NIH grant no. 745090-HHSN272200800059C). We are grateful to M.L. Grossman for help preparing the chapter and to D. Schad for preparing graphics.

Chapter 41

Immunity to Extracellular Bacteria

Moon H. Nahm

Jannet Katz

INTRODUCTION

Human interactions with bacteria are complex, with a consortial relationship having been developed between humans and microbes. Each human being is composed of 10^{12} human cells and is inhabited by 10^{14} bacteria composed of innumerable species.[1] More than 500 distinct bacterial species are estimated to reside in the human oropharynx alone.[2] Recent studies of gut microbiota have begun to reveal both the extensive diversity of microbes in the gut as well as their complex relationship with the host.[3] Relatively few of these bacteria are harmful to us in any way. We know little about the innate or acquired immune mechanisms that maintain this equilibrium. In large part, many diseases caused by bacteria are mistakes in which this consortial relationship breaks down and the lines that define the relationship are crossed. The innate and adaptive responses to these transgressions can in themselves lead to dire consequences. In *Lives of the Cell* , Lewis Thomas points out:

The microorganisms that seem to have it in for us in the worst way—the ones that really appear to wish us ill—turn out on close examination to be rather more like bystanders, strays, strangers in from the cold. They will invade and replicate if they get the chance, and some of them will get into our deepest tissues and set forth in the blood, but it is our response to their presence that makes the disease. Our arsenals for fighting off bacteria are so powerful, and involve so many different defense mechanisms, that we are in more danger from them than from the invaders. We live in the midst of explosive devices; we are mined.[4]

While certain bacterial species are classified as pathogens, they can live in harmony on our surfaces for long periods and never cause disease. The bacteria that can cause human disease are quite diverse. Based on the pathogenesis of infection and the resulting immune response, these bacteria can be categorized into two general types: those causing intracellular infections and those causing extracellular infections. Most bacteria causing intracellular infections avoid being killed after phagocytosis by either interfering with phagosome-lysosome fusion or by escaping from the phagosome and into the cytoplasm. Cellular immunity is critical against bacteria that reside mainly within an intracellular milieu. In contrast, the bacteria causing extracellular infections survive in the host by avoiding engulfment by professional phagocytic cells such as neutrophils and macrophages. They do this by presenting a surface that minimizes the opsonic and lytic effects of antibody, complement, and other opsonins. Although extracellular bacteria have the ability to enter and

pass through cells as a means of moving from one in vivo environment to another, they are readily killed once captured by phagocytes. Accordingly, the host defense against extracellular bacteria is critically dependent on humoral immunity: complement and the production of specific antibody. Table 41.1 lists many of the important bacteria that can cause extracellular infections in humans, together with the diseases they cause and some of their major virulence factors. In this chapter, we describe the surface structures of many of these bacteria and provide examples of how they are able to infect their hosts and cause disease. We also describe the salient aspects of the innate immunity and antigen-induced immunity important in the host's defense against these bacteria.

SURFACE STRUCTURE OF GRAM-POSITIVE AND GRAM-NEGATIVE BACTERIA

Differences among bacteria contribute to their specific adaptation to either a particular host species or to microenvironments within their host. In general, we currently have only a limited understanding of the limitations in nutrients and the specificity of enzymes and bacterial adhesins, or host receptors, that account for these highly specific microbial tropisms. The diversity of bacterial structures encountered by the host offers a major challenge to immune detection of potential pathogens. There are no structural features that reliably differentiate pathogens from nonpathogens. Moreover, many important extracellular pathogens exist mainly as commensals, only causing damage when the balance between host and microbe is perturbed (opportunistic pathogens). Thus, their diversity requires that initial recognition through innate immunity be focused on the more conserved structural features or “molecular patterns” of bacteria. These molecular patterns are, in general, structures such as peptidoglycan, lipoteichoic acid (LTA), and lipopolysaccharide (LPS) that are also essential for bacterial viability and are, thus, unlikely to be modified so as to evade innate immunity. A further consideration is that these structural differences between types of bacteria may dictate differences in host responses and contribute to distinct patterns of disease. That said, different types of bacteria may also give rise to remarkably similar host responses. The syndrome of sepsis, for instance, looks very similar regardless whether it is caused by a gram-positive or gram-negative organism, although there may be little overlap in the specific bacterial mediators involved.

TABLE 41.1 Extracellular Bacteria Commonly Associated With Diseases

Species	Disease	Important Virulence Structures/Molecules	Special Adaptations Critical to Host Infection
Neisseria gonorrhoeae	Urethritis, cervicitis, salpingitis, endometritis, prostatitis, arthritis, proctitis, pharyngitis	Lipopolysaccharide, fimbria, peptidoglycan, Opa protein adhesin, IgA1 protease	Phase and antigenic variation, molecular mimicry of human antigens

Neisseria meningitidis	Bacteremia, meningitis, septic arthritis	Capsule, lipopolysaccharide, fimbria, IgA1 protease	Phase and antigenic variation, molecular mimicry of human antigens, asymptomatic carriage common
Haemophilus influenzae	Otitis media, bronchitis, pneumonia, sepsis, meningitis (encapsulated strains)	Lipopolysaccharide with phosphorylcholine, fimbria, high-molecular-weight adhesions, IgA1 protease	Phase and antigenic variation, molecular mimicry of human antigens
Bordetella pertussis	Whooping cough in children, chronic cough syndrome in adults	Pertussis toxin, pertactin, filamentous hemagglutinin, fimbria	Coordinate regulation of multiple virulence factors upon exposure to the host environment
Pseudomonas aeruginosa	Infections in compromised hosts, pneumonia, sepsis	Lipopolysaccharide, proteases, lipases, lecithinases, exotoxin A, elastase, flagella	Relatively large genomic size (approximately six megabases) allows considerable adaptability to changes in environmental conditions, biofilms
Escherichia coli	Urinary tract infection, sepsis, traveler's diarrhea, dysentery, neonatal meningitis, hemolytic-uremic syndrome	Capsular polysaccharide, lipopolysaccharide, fimbria, toxins, siderophores	Antigenic heterogeneity of capsule and lipopolysaccharide
Vibrio cholerae	Diarrhea	Cholera toxin, fimbria	Bacterial dispersal via cholera toxin, which induces

			copious watery diarrhea
Helicobacter pylori	Peptic ulcer disease	Urease, flagella, CagA	Ability to survive at low pH provides a niche lacking bacterial competition or efficient immune surveillance
Streptococcus pneumoniae	Pneumonia, otitis media, meningitis, sinusitis	Capsule, PspA and C, pneumolysin, neuraminidase, hyaluronidase, teichoic acids with phosphorylcholine, IgA1 protease	Asymptomatic colonization, genetic transformation permitting continual generation of new genotypes
Streptococcus pyogenes (group A *Streptococcus*)	Acute pharyngitis, scarlet fever, necrotizing fasciitis, streptococcal toxic shock syndrome, rheumatic fever, and glomerulonephritis	Hyaluronic acid capsule, M-protein, streptococcal pyrogenic exotoxins, streptolysin O, streptolysin S, NAD-glycohydrolase, C5a peptidase	Molecular mimicry of human antigens, high diversity of M-proteins
Streptococcus agalactiae (Group B *Streptococcus*)	Bacteremia, neonatal pneumonia and meningitis	Capsule, beta hemolysin, hyaluronidase, C5a peptidase	Asymptomatic colonization, acquisition by infants during parturition
Staphylococcus aureus	Impetigo, folliculitis, boils, cellulitis, wound infections, toxic shock, osteomyelitis, endocarditis, bacteremia, pneumonia, food poisoning	Tissue-degrading enzymes, alpha toxin and other membranedamaging toxins, epidermolytic toxins, enterotoxins, capsule, protein A, TSST1, pigment	Resistant to dehydration, asymptomatic colonization
Bacillus	Cutaneous infection,	Capsule, lethal and	Opportunistic

anthracis	inhalation anthrax	edema factors	infection by a spore-forming soil organism
Corynebacterium diphtheria	Diphtheria (pharyngitis/tonsillitis)	Diphtheria toxin	Toxin gene contained intemperate phage and expression regulated by iron concentration
Clostridium tetani	Tetanus (spastic paralysis)	Tetanus toxin (blocks inhibitory neurotransmitters)	Opportunistic infection by a spore-forming soil anaerobe
Clostridium perfringens	Gas gangrene, anaerobic cellulitis, endometritis, food poisoning	More than 10 exotoxins	Opportunistic infection of wounds
Clostridium botulinum	Flaccid paralysis: cutaneous, infant, and ingestion forms	Botulism toxin blocks acetylcholine release at synapses	Opportunistic infection by a spore-forming anaerobe

CagA, cytotoxin-associated gene A, Ig, immunoglobulin; Psp, pneumococcal surface protein; TSST1, toxic shock syndrome toxin 1.

Most extracellular, as well as intracellular, pathogenic bacteria can be divided into two major groups (gram-negative and gram-positive) based on their response to staining with Gram stain. To illustrate the surface of the bacteria in the two groups, the surface structures of *Streptococcus pneumoniae* (Panel A) and *Neisseria meningitidis* (Panel B) are shown in Figure 41.1. Three layers are commonly recognized: cytoplasmic membrane, cell wall, and outer layer. Although these layers are described in detail in the following, it is important to note that these definitions are operational and that, in reality, the layers are not entirely distinct. For instance, molecules anchored in the cytoplasmic membrane or cell wall may extend into or through other layers. It is also important to note that the capsule, O antigens, and cell wall are not contiguous shields; rather they are permeable enough to allow through secreted products and nutrients as well as some immunologic factors (eg, antibodies and complement).

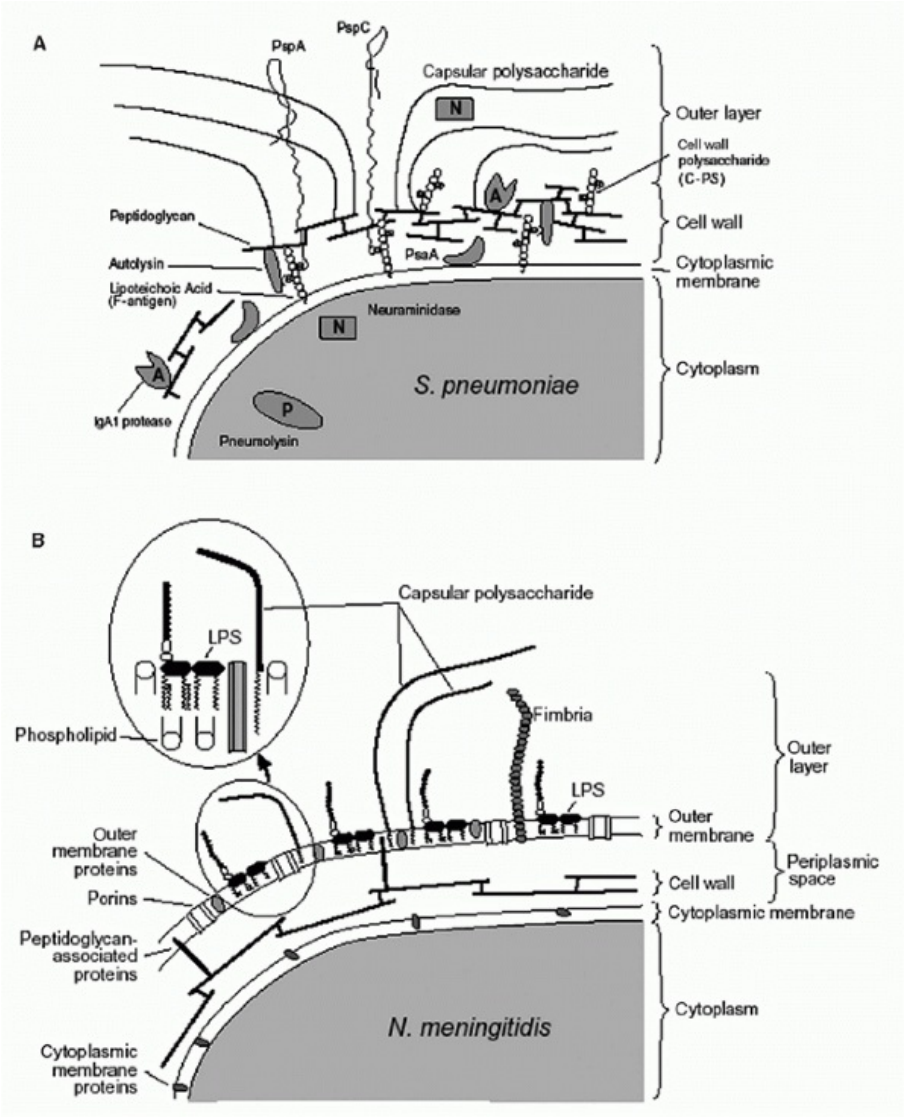

FIG. 41.1. Schematic representation of the surfaces of *Streptococcus pneumoniae* **(A)** and *Neisseria meningitidis* **(B)** as examples of gram-positive and gram-negative bacteria, respectively. The cell wall polysaccharide of *S. pneumoniae* is often called C-polysaccharide. The inset in *B* shows lipopolysaccharide anchored to the outer leaflet of the outer membrane.

All bacteria have a cytoplasmic membrane, a non-sterol-containing phospholipid bilayer. This membrane is an osmotic barrier and also forms a barrier for most molecules. The cytoplasmic membrane has various proteins, many of which function in transport. Some of these proteins, referred to as lipoproteins (eg, pneumococcal surface adhesion A, which is a manganese permease in *S. pneumoniae*), are noncovalently anchored to the membrane through

lipid modifications and are especially common among some bacteria (eg, *Borrelia burgdorferi* and *Mycobacterium tuberculosis*). Proteins not exposed on the surface generally display a greater degree of structural and functional conservation compared with those exposed to the selective pressure of host immunity.

A cell wall is found in all of the pathogenic bacteria of both groups, with the exception of

mollicutes (which include the genus *Mycoplasma*). The cell wall surrounds the cytoplasmic membrane and is made of peptidoglycan, which is a polymer of alternating sugars N-acetylglucosamine and N-acetylmuramic acid, the latter being connected to a stem peptide. The stem peptides include four to five D- and L-amino acids that are extensively cross-linked by bridges that provide rigidity to the cell wall and protect it from environmental extremes (especially differences in osmolarity). These cell wall peptides include atypical amino acids such as diamino pimelic acids, which are the anchoring site for Braun lipoprotein of gram-negative bacteria and are found in most gram-negative bacteria but in few gram-positive bacterial species. Peptidoglycan polymerization is carried out by enzymes, many of which are the target of β-lactam antibiotics and are referred to as penicillinbinding proteins. Compared with gram-negative bacteria, gram-positive organisms may have different stem peptides and cross-linking as well as a thicker (20 to 30 nm compared with 2 to 4 nm) cell wall layer that can retain the Gram stain better. The thick cell wall of the gram-positive bacteria may be responsible for their greater resistance to complementmediated lysis. Other features of the cell wall such as the O-acetylation of N-acetylmuramic acid or the deacetylation of N-acetylglucosamine[5,6] found in some species mediate resistance to lysozyme, an enzyme that lyses bacteria by cleaving the peptidoglycan backbone.[6]

In addition to peptidoglycan, many gram-positive bacteria have polysaccharide (PS) associated with their cell walls, with this cell wall PS often extending into the outer layer. The structure of the cell wall PS of gram-positive bacteria varies between species but is relatively invariant within a species. Differences in the antigenicity of the cell wall PS have been used to distinguish species (eg, separate streptococci into groups A, B, C, etc.).[7,8] Cell wall PS often has phosphate group(s) in repeating units of glycerol or ribitol in a structure known as teichoic acid. Teichoic acid may also be linked to lipid molecules and is then called LTA, which is anchored to the cytoplasmic membrane and extends out through the cell wall.[9] In pneumococci, the overall PS structures of LTA and cell wall teichoic acid (also referred to as C-polysaccharide) are very similar, with the difference being their mode of attachment to the bacterial surface.[10,11]

Another major difference between the surface structures of gram-negative and gram-positive bacteria is the presence of an outer membrane on gram-negative bacteria. The outer membrane contains many proteins, including channel-forming porins. The outer membrane is an asymmetrical lipid bilayer. The inner leaflet is comprised primarily of phospholipids while the outer leaflet contains lipid A, the hydrophobic component of LPS. LPS, also called endotoxin, is an amphipathic glycolipid with four distinct regions: lipid A, the inner core, the outer core, and, in some species, the O antigen. Lipid A is composed of a dihexosamine backbone to which between five and seven saturated (12- to 16-carbon) fatty acids are attached through amide and ester linkages. Lipid A is the principal “toxin” associated with most gramnegative bacteria, although it is now clear that lipid A is not a true toxin. Rather, its ability to induce cytokines accounts for its potentially detrimental effects. The carbohydrate portion of the LPS, which makes a minimal contribution to its endotoxin activity, is attached to lipid A through a molecule unique to gram-negative bacteria called ketodeoxyoctanoate. Together with heptose moieties, this molecule forms the inner core of the LPS.

The outer core is composed of 7 to 10 monosaccharide units whose arrangement is relatively conserved among gram-negative species.[12] In many gram-negative bacteria, the outer core of LPS is connected to a repeating series of carbohydrates called the O antigen. The O

antigen forms a hydrophilic shield around the bacterium that provides a barrier to complement deposition on the bacterial cell surface. The O antigen is variable in length, is antigenically diverse, and confers serotypic specificity. The O antigens of *Escherichia coli*, *Klebsiella*, and *Salmonella* have as many as 30 repeating units composed of four to six sugars each.[12] Members of the genera *Neisseria* and *Haemophilus*, on the other hand, lack LPS with O antigens but instead have lipooligosaccharides, which have short oligosaccharides that do not exceed 7000 daltons.

For many pathogenic extracellular bacteria, PS components dominate the outer layer. In addition to the PS on LPS (gram-negative) and teichoic acid (gram-positive), there is often another thick layer of carbohydrate referred to as "capsule" that may account for more than half of the bacterial mass. An exception to this general rule is *Bacillus anthracis*, whose capsule is made of poly-D-glutamic acid rather than a polysaccharide.[13] *S. pneumoniae* has capsular PS that is covalently attached to the cell wall in most (but not all) serotypes.[14] In contrast, the capsule PS is anchored to the outer membrane by acyl chains in *N. meningitidis*[15] and *Haemophilus influenzae* type b.[16] Capsular PSs may be highly diverse both within and between species. In the case of *S. pneumoniae*, each strain expresses a single type of capsular PS, with members of this species being capable of synthesizing more than 90 structurally distinct types.[17,18] This diversity limits immune recognition until antibody is generated to the capsular PS of the infecting strain (antigenic variation).

The outer layer is well developed in bacteria that cause extracellular infections and has many features that help the bacteria circumvent the host immune system. First, the outer layer has properties that reduce the attachment of extracellular bacteria to eukaryotic surfaces, including those of phagocytes. Generally, the PS capsules render the bacteria hydrophilic and negatively charged like eukaryotic cell surfaces, which are rich in sialic acid. By enhancing the degradation of C3b, the negatively charged surface makes the bacteria partly resistant to the deposition of complement by the alternative pathway.[19] Second, in some cases, elicitation of antibody is minimized because the capsular PS or

LPS mimics host antigens, as is more fully described in the section on Antigen-Specific Host Defense Response of this chapter. Third, by physically masking most of the other bacterial surface components, the outer layer minimizes the number of exposed epitopes that can be recognized by the antibody and complement. Although the capsule is porous to antibodies and complement, the binding of antibodies and fixing of complement beneath the capsule surface are relatively ineffective in promoting opsonophagocytosis and clearance.[20]

BACTERIAL VIRULENCE FACTORS

Extracellular bacteria often elaborate molecules called "virulence factors" that are useful to their survival and proliferation in the host. For example, the shielding function of the outer layer is further augmented by the presence of surface proteins that can interfere with host clearance mechanisms. Proteins inhibiting effective complement deposition include M-protein in *Streptococcus pyogenes*,[21] pneumococcal surface protein A (PspA), and pneumococcal surface protein C, which is alternatively called choline binding protein A or the C3-binding protein in *S. pneumonia.*[22,23] An example of a protein that interferes with antibody is protein A, which is expressed on the surface of *Staphylococcus aureus* and binds immunoglobulin

(Ig) in a manner that precludes recognition of its target antigen.[24] In addition, many successful mucosal pathogens, including members of the *Neisseria*, *Haemophilus*, and *Streptococcus* genera, express proteases with specificity for the hinge region of human IgA1.[25] These IgA1 proteases remove the Fc_{α} component required to promote the inflammatory process, leaving the organisms' antigens obscured by the binding of inert Fab_{α} fragments. By inhibiting the deposition of complement or antibody, many of these proteins act to diminish phagocytosis.

The best-known virulence factors are toxins, which interrupt specific host functions. These proteinaceous molecules (also referred to as exotoxins to differentiate them from endotoxin) can be grouped on the basis of their molecular structure and their mechanism of action.[26] The largest group are called A-B toxins, which are comprised of two subunits, each with a different function. The A subunit has enzymatic activity, and the B subunit targets the A subunit to the host cells. This group includes diphtheria toxin, cholera toxin, pertussis toxin, and two anthrax toxins (lethal factor and edema factor). For instance, the lethal factor of *B. anthracis* behaves as the A subunit and requires a B subunit protein named “protective antigen” to enter into target cells. In some cases, the toxin alone is sufficient to account for the detrimental symptoms of its respective infection. Cholera toxin causes ADP ribosylation of G proteins, which stimulates adenylate cyclase and increases cyclic adenosine monophosphate in cells lining the gut. This results in the secretion of electrolytes and is responsible for a severe diarrhea, which promotes transmission of *Vibrio cholerae* but often also causes dehydration that, if not treated, may be fatal. Uptake of botulism toxin by nerve endings leads to retrograde transport that interrupts synaptic transmission and causes a flaccid paralysis.[27] Staphylococcal enterotoxin A (a toxin that acts from the gut lumen), which is one of five membrane-damaging toxins produced by staphylococci, is the primary cause of staphylococcal food poisoning and plays a major role in invasive infections.[28] Some strains of *E. coli* produce a protein synthesis-inhibiting verotoxin, which may damage the microvasculature of the kidney and cause hemolytic uremic syndrome.[29] Another group of proteins secreted by *S. aureus* and *S. pyogenes* have toxin-like effects but lack any enzymatic activity. These “superantigens” cause a nonclonal stimulation of T cells by bridging major histocompatibility complex (MHC) class II molecules (outside the antigen-binding site) on antigen-presenting cells with the Vβ region of the T-cell receptor on T cells. The ensuing massive release of cytokines by localized release of a superantigen, such as the toxic shock syndrome toxin 1 expressed by some strains of *S. aureus*, results in systemic symptoms that are collectively known as “toxic shock syndrome.”[30]

Another class of virulence factors neutralizes host defenses. As stated previously, many virulence factors interfere with complement deposition on bacteria. *S. pyogenes* and group B streptococci produce a C5a peptidase that inhibits the chemotaxic effects (recruitment of host phagocytes to the sites of infections) of C5a, a product of complement activation.[31] Pneumolysin produced by *S. pneumoniae* is a member of a large class of cholesterol-dependent cytotoxins that oligomerize to form large pores, which interfere with a number of host cell functions or induce cell death when present in higher concentrations.[32] Pneumolysin also depletes complement at a distance from the pneumococci and interferes with both the function of phagocytes and the development of protective immunity.[33] *Helicobacter pylori* produces urease, which can generate ammonia that can neutralize acid

in the stomach and thereby promotes the survival or the organism. *S. aureus* produces a pigment that makes the bacterium more resistant to oxidative stress and killing by neutrophils.[34]

While evasion of professional phagocytes is critical for extracellular pathogens, the ability to attach to other cell types, including both mucosal and nonmucosal surfaces, is important for their persistence. Many bacterial surface proteins have an adhesive function that confers a high affinity for binding to specific host cell receptors. Nasopharyngeal carriage of pneumococci is mediated largely by adherence to the host molecules N-acetylglucosamine β1→3 galactose or N-acetylglucosamine β1→4 galactose.[35] Bacteria often mimic host ligands in order to coopt host receptors for their own purposes. Many pathogens of the airway express phosphorylcholine (phosphocholine [PC]) on their surfaces.[36] This molecule, which is otherwise unusual in bacteria, is found on platelet-activating factor (PAF) and allows bacterial binding to its receptor (rPAF).[37] To facilitate their attachment to host cells, many bacteria use pili (fimbriae), long filamentous structures extending from the organism. The Pap pilus of *E. coli* binds the galactose α1→4 galactose unit of cell surface globoside in urethral epithelial cells.[38] The *V. cholerae* pilus allows that bacterium to attach to the enterocyte for more efficient toxin delivery.[39,40] *Bordetella pertussis* has three adherence factors—a filamentous hemagglutinin,

pertactin, and a pilus—that allow it to attach to ciliated respiratory epithelial cells in the trachea and bronchi and thus resist the cleansing action of mucus flow.[41,42]

Another group of virulence factors helps bacteria acquire essential nutrients. Motile bacteria (eg, *Pseudomonas aeruginosa*) express flagellin, a complex motor apparatus that allows the bacterial cell to transit along a concentration gradient of nutrients.[43] While in some cases the host and microbe provide nutrients for one another, for other nutrients there is fierce competition. Mucosal fluid and blood are low in free ferric iron due to the presence of iron-binding proteins such as lactoferrin and transferrin. To successfully compete with the host for this vital metabolite, *N. meningitidis*, *Neisseria gonorrhoeae*, and *H. influenzae* have complex surface transport systems that can obtain iron from human transferrin, lactoferrin, and hemoglobin.[44] Other bacteria such as *E. coli* and salmonella use a different mechanism to acquire iron; they secrete small, high-affinity iron chelators, called siderophores, that remove iron from human proteins in the environment surrounding the bacteria. The iron-siderophore complex is then taken up by the bacterium, which then degrades the siderophore so that the iron can be freed for its use.[45]

Production of virulence factors is often highly regulated by bacteria in order to adapt to different environments, such as the natural environment outside of a host, the mucosa of a host, or more invasive sites within a host. For staphylococci, it has been shown that the amount of capsule is regulated in response to environmental stimuli.[46] One of the best studied of such regulatory systems is the BvgAS, a two-component regulatory system in *B. pertussis*.[47] This system, which regulates the expression of adhesins, toxins, and other virulence factors, is controlled by external signals including Mg^{2+}, temperature, and nicotinic acid. Two proteins are involved in this regulatory system: BvgS and BvgA. BvgS, the sensor, is a kinase and is able to autophosphorylate itself in response to the environmental signal.

BvgA, the response regulator, is in turn phosphorylated by BvgS. Phosphorylated BvgA is able to activate transcription of virulence genes through a change in its interaction with a 70-bp consensus sequence repeated in bvg-regulated promoters.[47] Analogous two-component regulatory systems in other pathogens are frequently used to regulate the expression of genes associated with virulence.[48]

Another strategy used by extracellular pathogens depends on selection among a heterogeneous population for those members with permissive characteristics. This heterogeneity in a population is commonly generated through genomic rearrangements, such as recombinational events or slipstranded mispairing in highly repetitive deoxyribonucleic acid (DNA) sequences.[49] This latter mechanism allows for reversible on-off switching (phase variation) and is especially prevalent in genes encoding cell surface structures subject to immune pressure. For instance, the capsular PS on *N. meningitidis* is needed to protect the organism during invasive infection but inhibits adherence on the mucosal surface where complement is less abundant. Phase variation of a gene required for capsule synthesis allows for selection of organisms without capsule (phase-off).[50] This change facilitates the bacterial adhesion to the epithelial cells, perhaps by exposing the bacterial adhesins. Alternatively, by decreasing capsule production, the bacteria become less hydrophilic and less negatively charged. This change facilitates their entry into the epithelial cells and their subsequent invasion into deeper tissues. Upon the emergence of the bacteria from the epithelial cells into the submucosa, capsule synthesis is restored (phase-on) because of the selective pressure of complementmediated clearance and the requirement for the capsule to survive where the concentration of complement is higher. The flexibility to express different surface properties helps bacteria successfully evade the host immune system and survive in many niches within the host.

Bacteria-to-bacteria signaling is another important mechanism for the control of virulence factors. This phenomenon, called “quorum sensing,”[51] has been shown to be operative in a large number of gram-negative and grampositive species. The signal transmitted between the bacteria can be an acylated lipid (eg, homoserine lactone) in gramnegative bacteria (eg, vibrios) or a peptide in gram-positive bacteria (eg, *S. aureus*). Quorum sensing has been shown to be important in biofilm formation in a number of bacterial species, in the expression of “competence” for the uptake and incorporation of exogenous DNA (transformation), and in the regulation of a number of virulence factors.[52] Biofilms are communities of one or multiple bacterial species that adhere both to each other and to a target surface. Bacteria in biofims are particularly resistant to many host clearance mechanisms and to antibiotics that are effective against free-living (planktonic) bacteria. Biofilms, therefore, are often a contributing factor in more chronic bacterial infections such as those involving foreign bodies or chronic otitis media.[53]

An important characteristic of virulence factors is their structural polymorphism. For instance, there are at least 100 different serologic types of M proteins of *S. pyogenes*.[54] Similarly, pneumococci have more than 90 serologically distinct capsular PSs.[17,18] The polymorphism in the structure of many virulence factors allows the bacteria making them to avoid antigen-specific host immunity. For example, antibodies to the immunodominant region on one serotype of M protein do not cross-react with M proteins of other serotypes and thus do not provide protection against strains expressing other serotypes. Similarly, newly acquired

pneumococci can escape recognition by anticapsular antibodies produced in response to previous pneumococcal infections with other serotypes.

The polymorphism in virulence factors is achieved by various genetic mechanisms. Variation in M proteins is the result of sequence differences in the N-terminal (but not C-terminal) half of M proteins.[55] *S. pneumoniae* has the genes for synthesizing capsular PS as a "genetic cassette" that can be exchanged among different strains[56] and may result in the shift in the serotype distribution following the use of vaccines designed to elicit serotype-specific protection.[57,58] *Neisseria* has genetic machinery for rapid gene rearrangement[59] through gene conversion using the multiple "silent" pili genes with different sequences. This process, similar to gene rearrangements that generate specific Ig, permits an individual bacterium to quickly produce progeny expressing pili with different characteristics. The number of potential

pilus-antigen variants within the progeny of a single organism is estimated to be greater than 100,000.[60] In addition, *Neisseria* contain large numbers of genes with tandem repeats that undergo phase variation through slip-stranded mispairing of these sequences. Based on predictions from whole genome sequencing, through this mechanism alone the organism may be able to generate more than 2^{65} different phenotypic variants.[61]

Sequencing of the entire genomes of bacteria has shown that the genes for virulence factors have generally originated from other organisms and exist as a part of large blocks of DNA containing multiple genes. These DNA blocks are called "pathogenicity islands" (PAIs). For instance, strains of "enteropathogenic" *E. coli* contain a PAI encompassing about 41 genes encoding a surface ligand required for intimate association of the bacterial and host cells and for a bacterial secretion apparatus.[62] This system (type IV secretion system) allows for delivery of the receptor for its own adhesin, encoded on the same PAI, into host cells. Elaborate secretion mechanisms (types III and IV) and pore-forming toxins are now known to be mechanisms whereby extracellular organisms gain access to the host cell cytoplasm to modify its activity to suit their needs. Another example is *H. pylori*, which injects cytotoxin-associated gene A (CagA) molecules directly into host cells using a syringe-like type IV secretory apparatus. CagA is then phosphorylated by the host cells, and the phosphorylated CagA alters host cell function, with the *H. pylori* strains producing the CagA molecules being more likely to cause ulcers.[63] In the case of *S. pyogenes*, its pore-forming toxin, streptolysin O, allows for translocation of an enzyme (NAD-glycohydrolase) that is capable of producing the potent cytoplasmic second messenger, cyclic ADP-ribose.[64]

BACTERIAL INVASION OF THE HOST

Both keratinized skin and mucosal surfaces have inherent nonimmune defense mechanisms that modulate bacterial growth and minimize the risk of invasion. Healthy human skin is an effective physical barrier to infection by most human extracellular and intracellular pathogens. The keratinization of fully differentiated skin epithelium results in a relatively impermeable surface. In addition, lysozymes, toxic lipids, and hydrogen ions secreted by cutaneous glands offer bacteriostatic protection for cutaneous pores and hair follicles. Occasionally, this defense can be breached by extracellular bacteria such as *S. pyogenes* or *S. aureus*, causing cellulitis and abscess. More commonly, bacterial invasion through intact skin requires physical damage, such as abrasions, burns, or other trauma. For instance, cutaneous anthrax

develops when *B. anthracis* enters the body through a break in the skin. *Staphylococcus epidermidis*, a member of the commensal skin flora, can infect indwelling catheters by invading through the puncture site in the skin and may lead to bacteremia or colonization of prosthetic devices, including artificial heart valves and shunts. A major factor allowing these bacteria to cause disease is their ability to form a biofilm, which facilitates their adhesion, is antiphagocytic, and acts as a barrier to antibiotic penetration.[65]

Unlike the skin, the mucosal epithelium is not keratinized. Instead, mucosal areas, such as the gastrointestinal tract, nasopharynx, upper airway, and vagina, are moist and nutritionally rich. Thus, it is not surprising that mucosal areas contain a large number of bacteria. In oral secretions and gastrointestinal products, 10^8 and 10^{11} bacteria/mL may be found, respectively. To ensure their survival in the mucosal environment, extracellular bacteria elaborate many virulence factors required for the acquisition of essential nutrients or for their adherence to the host cells. In some cases, bacteria may subvert the host inflammatory response. Salmonella species can block the activation of NF-κB and the subsequent activation of the inflammatory response. They achieve this by preventing the degradation of IκB, which is essential for the translocation of NF-κB from the cytoplasm to the nucleus.[66] In some cases, pathogens locate in a less well-protected microenvironment within the mucosal areas. *H. pylori* survives in the very acidic stomach by burying itself in the mucus, which protects it from direct exposure to the acid and from phagocytes. There are also few other species for *H. pylori* to compete with in this more hostile environment.

Mucosal sites play host to an especially diverse array of bacterial species. Most of the bacteria species found at mucosal sites are harmless. In addition, polymerase chain reaction analysis of 16S ribosomal ribonucleic acid sequences suggests the presence of many additional unidentified (and so far unculturable) bacterial species on the mucosal surface.[67] Many potentially pathogenic bacterial strains are also often found in the mucosal areas of healthy individuals without causing symptoms. *S. pneumoniae*, *N. meningitidis*, *H. influenzae*, and *S. aureus* are examples of pathogenic extracellular bacteria that are frequently carried in the nasopharynx of healthy individuals. The carriage rate of pathogenic bacteria can be relatively high; for example, 50% to 60% of healthy young children may carry *S. pneumoniae* in their throats.[68]

Maintenance of species diversity in mucosa is dynamic. In some situations, collaboration among bacteria is essential for their successful colonization, as seen among the complex hierarchical communities adhering to tooth surfaces. In other situations, bacterial species compete and regulate diversity among themselves.[36] Many bacterial species produce molecules that suppress the growth of other bacterial species. These molecules may include bacteriocins, small molecules that target members of the same or different species that do not express the same bacteriocins.[69] Some species can take advantage of host responses to which they are resistant to outcompete another member of the same niche that is less resistant.[36] The host may also control the diversity of colonizing bacteria by modifying the pH or other environmental conditions in the mucosal area. Interference with these homeostatic mechanisms, as occurs with antibiotic therapy, may alter the flora and predispose the host to disease. As noted previously, stomach acid is an effective barrier to reaching the nutrient-rich environment of the gut. When stomach acid is pharmacologically reduced, the inoculum of organisms like *V. cholerae* required to infect the intestines is greatly diminished.

Several explanations have been advanced to explain why many pathogens that colonize mucosal sites do not cause disease. One explanation is that the maintenance of diverse bacterial population is responsible for the prevention of the disease. For instance, the destruction of the normal gastrointestinal bacterial flora with some antibiotics can be associated with the selective expansion of *Clostridium difficile* and the development of pseudomembranous colitis.[70] Another explanation may be that the pathogenic bacteria carried in healthy persons are different from those isolated in disease settings. For instance, during nonepidemic periods, approximately 5% to 10% of the population carries *N. meningitidis*, which are mostly nonencapsulated.[71] During epidemics, 30% to 60% of the population may carry meningococci, which are mostly encapsulated and the majority of which are of the same capsular type as the case strain causing the epidemic.[72] A third explanation is that the pathogenic bacteria are effectively confined to the mucosal surface where they do not cause damage or induce inflammation. Group B streptococci are carried asymptomatically in the lower intestine and the female genital tract. In the same host, in the setting of parturition, group B streptococci may access the bloodstream and cause septic infection. A fourth explanation is centered on the differences among hosts. Group B streptococci that colonize the mother may cause life-threatening infection when the same strain is passed to the neonate at or before birth.[73]

Although pathogenic extracellular bacteria can exist asymptomatically in the mucosa, they can passively enter into less-well-defended sites and cause focal infections. For instance, *E. coli*, normally present in the gut, may enter the normally sterile urogenital tract and cause urinary tract infections. *S. pneumoniae* and *H. influenzae* are often carried in the nasopharyngeal space, but they can invade nearby normally sterile cavities (eg, lungs, sinuses, and the middle ear) and cause focal infections. Aspiration of bacteria from the nasopharynx into the lungs most likely occurs frequently with no ill effects; however, aspiration may lead to an infection when there is damage to the epithelial surface, particularly when the protective effects of mucociliary activity are lost, as often occurs in a smoker or during recent viral infection (respiratory syncytial virus or influenza).[7] Some bacteria produce enzymes such as hyaluronidase,[74] which may aid in their passage through tissue barriers.

Bacteria can actively invade deeper tissues by multiple pathways. They can enter through specialized cells. Shigella, for example, can breach the gut mucosa by transcytosing through the M cells in the gut.[75] Alternatively, extracellular bacteria can breach a cellular barrier (epithelium or endothelium) by going through (transcytosis) or between (paracellular pathway) the cells.[75] *Porphyromonas gingivalis*, an organism associated with adult periodontitis, may breach the epithelial layer by the paracellular pathway through the production of enzymes useful in digesting the tight junction.[76] Two different mechanisms of transcytosis have been described for pneumococci. In one, pneumococci may cross the bronchial epithelial cells by binding the polymeric Ig receptor of the epithelial cells and traveling in a retrograde manner by the IgA secretory pathway.[77] In the other, pneumococci may use PC to bind to rPAF, which is abundant on activated endothelial cells, epithelial cells, or pneumocytes.[35,78] In many cases, bacterial adhesion triggers changes in the host cell function, and these changes can assist transcytosis. For instance, nontypeable *H. influenzae* with LPS glycoform-containing PC can bind to rPAF on endothelial cells and initiate signaling

through this receptor.[79]

ANTIGEN-NONSPECIFIC HOST DEFENSE RESPONSE

To protect from infections caused by highly adaptable bacteria, the host employs a multilayered defense. This includes the mechanical barriers and iron sequestration described previously as well as phagocytes, complement fixation, lysozyme, and (cytokine-induced) local inflammation. In addition, the host is protected with antigen-specific antibody (see section on Antigen-Specific Host Defense Response) and T-cell-mediated cellular immunity. Antigen-specific immunity, although exquisitely protective, takes several days to weeks to develop following exposure to a pathogen. As many extracellular pathogens are capable of causing overwhelming infection in periods of hours to days, other more rapidly acting forms of protection are needed. Consequently, the primary defense against bacteria during the early phase of infection remains antigen-nonspecific host immunity. The importance and significance of nonspecific immunity is readily demonstrated by the relative ease with which colonies of SCID mice, which lack antigen-specific immunity, can be maintained.[80] This section describes several antigennonspecific host defense mechanisms, but see the chapter on innate immunity for additional information.

Mucosal Defense

Although mucosal areas are rich with nutrients for bacteria, uncontrolled local proliferation of bacteria is held in check by mechanical cleansing actions and the lack of available iron. In the gastrointestinal tract, normal peristaltic motility, the secretion of mucus, and the detergent action of bile limit the number of bacteria. The normally sterile lower respiratory tract is protected by the movement of mucus by cilia lining the airway, which continually remove aspirated bacteria. Normal epithelial and tissue architecture are essential for drainage and expulsion of bacteria, and disruption of this mechanism by smoking, viral infections (eg, influenza), or bacterial infection (eg, pertussis) makes the host markedly susceptible to infection by bacteria that otherwise exist only as commensals of the upper airway. The increased frequency of lower respiratory tract infections in the elderly is due, in large part, to the loss of function of the mucociliary elevator and the increased aspiration from the upper respiratory tract of secretions containing bacteria.[81,82]

In addition to the removal of bacteria by mucus flow, mucosal fluid contains many antibacterial products such as lactoferrin, lactoperoxidase, mucin, lysozyme, and defensins.[83] Lactoferrin—found in various body fluids such as milk, saliva, and tears—binds iron and lowers the level

of available iron (especially in areas with a low pH).[84] Mucin traps microbes and facilitates their removal.[85] IgA antibodies in mucosal fluid may inhibit colonization by interfering with microbial adherence or by inactivating toxins.[86] In addition, the polymeric structure of secretory IgA promotes agglutination, which in turn facilitates removal by mucus. Lysozyme reduces the bacterial load by cleaving the 1→4 linkage between N-acetylmuramic acid and N-acetylglucosamine of peptidoglycan. A number of antimicrobial peptides, including defensins, disrupt bacterial membranes.[87] In the intestine, Paneth cells at the base of intestinal crypts produce defensins that are important in defense against intestinal

infections.[88] In the lungs, collectin-like surfactant proteins, such as SP-A and SP-D, may be important in host defense by opsonizing bacteria for alveolar macrophages.[89] SP-A-deficient mice, for example, are more susceptible to group B streptococcal infection of the lungs.[90] Epithelial cells that interface with the microbial world must exist in a quiescent state in response to colonizing organisms. If not, chronic inflammation may result in a disease (eg, chronic inflammatory bowel disease). When the epithelial barrier is breached, these cells are able to elaborate cytokines and chemokine as an early trigger to the inflammatory response.

Local Response to Bacterial Invasion (Acute Inflammation)

Upon entry into the host, many bacteria initiate local inflammatory processes by providing various inflammatory products such as peptidoglycan, LPS, LTA, exotoxins, lipoproteins, and glycolipids.[91] Antibiotics used for treatment may destroy bacteria and consequently release additional inflammatory products. These molecules are called pathogen-associated molecular patterns and trigger responses through their interaction with pathogen pattern recognition receptors (PRR), which often reside on the host cell membrane or in the cytoplasm.

The best-known PRRs residing on the cell membrane are the toll-like receptors (TLRs), which have a transmembrane region that separates the cytoplasmic signaling domain from the extracellular ligand binding domain. TLRs are generally most abundant on inflammatory cells but are present in lower levels in the epithelial barrier, which is continuously exposed to microbial products.[92] TLR2 detects lipoproteins and lipoteichoic acid and requires a binding partner (TLR1 or 6) to transmit signals leading to cytokine production.[93] Mice lacking the TLR2 gene are more susceptible to mucosal and systemic infection with staphylococci and streptococci.[94,95] LPS binds to TLR4 with the help of MD2, cluster of differentiation (CD)14, and lipid-binding proteins. Mice without functional TLR4 are unresponsive to LPS. Bacterial flagellin signals through TLR5.[96] Bacterial DNA, rich in unmethylated CpG motif, is a potent inducer of inflammation through its binding to TLR9. TLR9 receptors are found inside the cells as they occur in endocytic vesicle membranes and react to phagocytosed bacteria. TLR activation increases expression of inflammatory cytokines (eg, tumor necrosis factor [TNF]-α) through increased transcription of their genes. The protective effect of TLR can be seen early in an infection. For instance, TLR9 can protect against pneumonia caused by *S. pneumoniae* even before circulating inflammatory cells enter into the lungs.[97]

Bacterial invasion is also detected by various intracellular PRRs. The best-known PRR family may be the nucleotide oligomerization domain (NOD)-like receptors (NLRs). At least 23 NLR family members have been identified in humans, with each member having a central nucleotide-binding domain (NACHT domain), an N-terminal effector domain, and a C-terminal receptor domain with leucine-rich repeats. Ligands may bind the leucine-rich repeat domain and initiate oligomerization of the NATCH domain to form a signaling platform that allows the binding of adaptor and effector molecules, ultimately leading to activation of caspase 1 and then interleukin (IL)-1β.[98,99,100] This molecular assembly is named an “inflammasome,”[101] with the best-known infammasome being Nlrp3 (also known as NALP3 or cyropyrin), which can sense various bacterial products as well as alum, silica, and urate crystals.[101] Another inflammasome is Nlrc4 (also known as CARD12 or IPAF), which can detect flagellin. Flagellin, however, is also detected by TLR5.[102]

Other well-known NLRs are NOD1 and NOD2. NOD1 is expressed in various cell types, but NOD2 is expressed primarily among the epithelial cells of the lungs and intestine, macrophages, and dendritic cells (DCs).[103,104,105,106] NOD1 recognizes peptidoglycan fragments containing *meso*-diaminopimelic acid primarily from gram-negative bacteria,[107] but NOD2 recognizes muramyl dipeptide, the minimal motif of peptidoglycan that is shared by both gram-positive and gram-negative bacteria.[108] Interestingly, the lack of signaling by muramyl dipeptide results from the NOD2 gene mutation involved in Crohn disease.[98,108,109]

During the initial phase of inflammation following a bacterial invasion, many cell types residing in the mucosa or skin (eg, keratinocytes) may produce molecules important in controlling infections. Several studies revealed that mast cells are one of the important resident host cells involved in the innate immune response. Mast cells, classically known for their stores of histamine and serotonin,[110] are abundant along the bronchial tree and the epidermis of the skin. They are now known to both contain preformed TNF-α as well as be a major source of various cytokines. Mast cells account for 90% of IL-4- and IL-6-producing cells in the nasal cavity.[111] Upon exposure to various bacterial products (eg, LPS), mast cells release these cytokines, which are essential for the recruitment of neutrophils to the site of inflammation. The absence of mast cells can increase the susceptibility of animals to bacterial infections in the peritoneum or the lungs; their absence can be partially compensated for by administration of TNF-α.[112]

As the inflammatory process persists, additional cell types come to the site of inflammation. In the case of experimental pneumococcal pneumonia, neutrophils come to the lungs in 12 to 24 hours, followed by the appearance of monocytes and macrophages in 48 hours.[113] Similar phagocyte entry sequence was observed for nasopharyngeal

colonization by *S. pneumoniae.*[114] Few lymphocytes are observed in the lungs during this time period. Upon their arrival at the site of infection, neutrophils and macrophages, which can rapidly phagocytize and kill the bacteria, become activated by the bacterial products (eg, LPS) and chemokines (eg, IL-8). Phagocytosis can occur when phagocytic cells recognize certain native molecular structures of the bacteria such as lectins, PS, and peptides (RGD sequence),[115] or aided by their CR3 and Fc receptors, recognize the host opsonins on the bacterial surface.

Inflammatory processes trigger the cascade of chemokine and cytokine release at the site of inflammation. Sequential appearance of chemokines has been noted in the pneumonia model.[113] The peak levels of chemokines macrophage inflammatory protein (MIP)-2 and KC are achieved in the lungs less than 6 hours after infection. The peak levels of MIP-1a and MCP-1 are observed in 12 to 24 hours. Neutralizing MIP-1a and MCP-1 along with RANTES reduces macrophage recruitment. The cytokines produced during acute inflammation can be divided into two groups: proinflammatory cytokines (eg, IL-1 and TNF-α) and anti-inflammatory cytokines (eg, IL-4). The molecules produced during inflammation can induce the expression of ELAM, ICAM, and VCAM on endothelial cells and of selectins and integrins on leukocytes, thereby modifying the properties of the cells (cell adhesion, vascular permeability, etc.) at the site of inflammation.

Inflammation also draws phagocytes to the site of pathogen invasion, where the phagocytes generally efficiently recognize, ingest, and kill the extracellular pathogens. Among many surface receptors, CR3 may be the most relevant to recognizing extracellular bacteria. Indeed, persons with CR3 deficiency (leukocyte adhesion deficiency type 1) have leukocytes ineffective in phagocytic killing.[116] The phagocytic killing occurs rapidly (generally within 15 minutes) when phagosomes fuse with lysosomes and the ingested bacteria are exposed to lysosomal enzymes, although some extracellular bacteria can survive in phagocytes for a significant period.[117]

In addition to this classic killing mechanism, a new mechanism called “autophagy” has been described. This process is characterized by the engulfment of portions of the cytosol into a characteristic double-membrane vacuole called an “autophagosome.”[118,119] After maturation, autophagosomes fuse with lysosomes followed by degradation of the sequestered structures and recycling of the degraded products.[120] While the autophage is important in controlling infections by intracellular pathogens (eg, virus or intracellular bacteria), it may also be involved in defense against extracellular pathogens. *S. pyogenes* may be killed by autophagy.[121,122] However, *S. aureus* may also exploit autophages to its advantage as *S. aureus* activates an autophagic response to enter the double-membraned autophagosomes but prevents autophagosome maturation.[123,124]

Another phagocyte response involves neutrophil extracellular traps (NETs).[125] In this situation, when phagocytes encounter pathogens, the phagocytes decondense the phagocytes' DNA and release their DNA as well as their cellular contents. This decondensed DNA forms a net with cellular debris with the NET being able to capture and destroy many bacteria. However, some pathogens such as *S. pneumoniae* can escape the NET by destroying it with endonuclease.[126]

Systemic Response to Bacterial Invasion

In response to inflammatory bacterial products, cytokines such as IL-1, TNF-a, and IL-6 are released into the systemic circulation and trigger many systemic changes, such as fever and accumulation of leukocytes at the sites of infection. The cytokines also trigger an acute-phase response by the liver.[127,128] The acute-phase response occurs when hepatocytes, in response to the cytokines, activate transcription factors such as NF-κB and STAT3,[127,128] and increase production and secretion of a variety of molecules that are termed acute-phase reactants, such as coagulation factors, serum amyloid A protein, C-reactive protein (CRP), TREM-1,[129] and collectins.[130]

CRP was named for its ability to bind to pneumococcal C-polysaccharide. Its serum level begins to rise 2 to 3 hours after infection and increases more than 1000-fold within 2 to 3 days after infection.[131] CRP recognizes pathogens by binding to PC, which is expressed on many respiratory tract pathogens, and activates complement on the bacteria or functions like anti-PC antibody by engaging FcR. Indeed, CRP can kill PC-expressing *H. influenzae* in vitro in the presence of complement. In addition, while many pathogens use PC to bind to the host cells via rPAF, CRP also blocks bacterial adhesion that involves this receptor.[132] Transgenic mice expressing human CRP are more resistant to systemic pneumococcal infection.[133]

The liver produces mannan-binding lectin (MBL), which is a member of the collectin family. The structural hallmark of these family members is a cystine-rich N terminus, a collagen-like domain, and a C-type lectin domain. These molecular features allow MBL to assemble into a C1q-like structure. Although it is an acute-phase protein, MBL levels change only two- and threefold during the course of an infection.[134] However, the population distribution of MBL levels ranges between 100- and 1000-fold,[135,136] with about 5% of Europeans being MBL deficient (< 100 ng/mL).[137] MBL uses the lectin domain to recognize the target carbohydrate on a microbe, activates MBL-associated protease-2, and initiates the lectin pathway of the complement system. MBL is the innate opsonin for baker's yeasts, and MBL-deficient individuals may have an increased incidence of infection.[138] MBL significantly reduces bacteremia from *N. meningitides.*[139] Although this relationship is controversial,[140,141] MBL-deficient persons may be more susceptible to infections by *S. pneumoniae* with a low invasion index.[142] Interestingly, transplant patients who received the liver from MBL-deficient donors are more susceptible to infections.[143] The collectin family includes SP-A and SP-D, which may play important roles in lung immunity.[144,145]

The liver produces another group of innate opsonins, called ficolins. Humans produce three ficolins: L- and H-ficolins are from the liver,[146] but M-ficolin is in the secretory granules of neutrophils, monocytes, and type II alveolar

epithelial cells.[147] Ficolins have a fibrinogen-like domain at the C terminus instead of a C-type lectin domain, but they assume an overall structure similar to those of MBL and C1q. Ficolins also trigger the lectin pathway of the complement system by activating MBL-associated protease-2.[148,149] L-ficolin can bind many structures with acetyl groups[150] but many bacterial surface molecules that appear to be the natural ficolin ligands contain carbohydrate moieties. Thus, ficolins display lectin-like functional properties.

Once extracellular bacteria enter the systemic circulation, these opsonins together with antibodies opsonize bacteria for rapid removal by the spleen or the liver.[20,151] Persons lacking splenic function (due to sickle cell disease or splenectomy) are at an increased risk of overwhelming sepsis from encapsulated pathogens (eg, *S. pneumoniae*).[133] Clearance of bacteria from the blood by these organs is facilitated because phagocytes are abundant and blood circulates slowly in these organs. *S. pneumoniae* serotype 27 produce capsular PS-containing PCs. CRP can bind and opsonize serotype 27 pneumococci for phagocytes,[152] which may be why serotype 27 pneumococci are nonpathogenic.[153]

The liver is also the major source of transferrin, which increases iron storage by tissues and lowers the serum concentration of iron. Iron at the site of inflammation may be reduced by neutrophil-secreted lactoferrin. The reduction in the amount of iron available to bacteria can be a significant defensive measure.[154] Moreover, even a moderate reduction in iron intake[155] and the use of an iron chelator have both been shown to be beneficial against infections by extracellular bacteria. In contrast, an excess of iron may predispose an individual to infections.[156]

ANTIGEN-SPECIFIC HOST DEFENSE RESPONSE

Accompanying antigen-nonspecific responses, the host also mounts an adaptive, antigen-specific immune response. For protective responses to extracellular bacteria, B-cell-mediated (but not T-cell-mediated) immune responses are critical, as shown by clinical observations of patients with Bruton agammaglobulinemia. These patients, who have relatively normal T-cell function but lack B cells, suffer primarily from infections caused by extracellular bacteria, infections that can be successfully treated with the passive administration of pooled gammaglobulin.[157] Consequently, protective B-cell responses are described in detail subsequently.

Responses of the Host (B Cell) Immune System to Bacteria

Following an asymptomatic exposure to extracellular bacteria or to an infection, the host develops antibodies to many different bacterial antigens. For instance, the level of antibodies to various pneumococcal antigens increases in young children as they age, even if they never have clinical infections.[158] However, the antibody levels remain low in those young children without evidence of asymptomatic nasopharyngeal carriage of pneumococci. This finding suggests that asymptomatic carriage of pneumococci is sufficient to raise antibody levels.[158]

When an infection occurs, it presents the host with a large load of free antigens released from bacteria such as capsular PSs and proteins (eg, toxins). Bacterial proteins induce strong immune responses in a conventional T-cell-dependent manner; indeed, the antibody response induced by bacterial proteins has been used to diagnose infections.[159] In addition, the released PSs that are readily detectable in the urine of many patients[160] are used to diagnose pneumococcal pneumonia.[161] The released PSs may neutralize the anti-PS antibodies in the host. For example, vaccination with hemophilus vaccines may neutralize preexisting anti-PS antibody and briefly increase disease susceptibility immediately after the vaccination.[162]

In contrast to proteins, bacterial PSs generally elicit antibody responses with minimal help from T cells.[163] As bacterial PSs usually have many repeating units and multiple epitopes, they can efficiently cross-link B-cell receptors and stimulate B cells. The PSs primarily stimulate two subsets of B cells: B1 B cells[164] and marginal zone (MZ) B cells.[165,166] These two types of B cells together with follicular B cells are the three recognized subsets of mature B cells with preferential anatomic locations. B1 B cells are associated with the peritoneum, MZ B cells are found in the splenic marginal zone, and follicular B cells are in splenic follicles. In mice, the subsets can be distinguished by their surface phenotypes. Follicular B cells are IgM^{lo}, IgD^{hi}, CD23+, $CD21^{int}$, and $CD1d^{low}$, whereas MZ B cells are IgM^{hi}, IgD^{lo}, $CD23^{low}$, $CD21^{hi}$, and $CD1d^{hi}$.[167] B1 B cells express CD11b and B220, with CD5 expression being used to divide them into B1a (CD5+) and B1b (CD5-) subsets.[164] Furthermore, these subsets have distinct developmental requirements. MZ B cells require a proline-rich tyrosine kinase (Pyk-2),[165] Aiolos, and Notch2.[167] B1 B-cell deficiency was noted in mice without the regulatory B1 subunit of calcineurin.[168] B1a B cells are absent in CD19-deficient mice,[169] and the development of B1 and follicular B cells requires BTK.[170]

Several observations support the contention that the antibody response to PS antigens is largely independent of T cells. Athymic mice can produce antibodies to PS antigens. PS antigens do not bind class II molecules as protein antigens do[171] and may actually interfere with the presentation of protein antigens.[172] In addition, they do not usually induce the formation of germinal centers,[173] they elicit poor immune memory,[174] and they easily tolerize B cells.[175] Nonetheless, there have been past reports of T-cell involvement in the antibody response to PS antigens,[176] and recent studies suggest that CD40 is involved in this response.[177] Because the PS antigens used for the studies may have had contaminants that affected their immune properties[178] and as zwitter ionic PSs may behave differently from other PSs,[179] additional studies with pure PSs would be needed to define the role of non-B cells in the antibody response to PS antigens.

PS antigens commonly elicit oligoclonal antibodies, which utilize a restricted number of V region genes[180,181] even among genetically unrelated humans.[182] In addition, the antibodies to PS exhibit few somatic mutations[182,183] and generally have a low affinity to the antigen.[184] However, because the capsular PS and LPS O antigens present repeating epitopes, even low-affinity antibodies can bind with enough

avidity to fix complement and cause opsonization and/or bacteriolysis.

Capsular PSs have been used as vaccines because antibodies specific for them are protective. Young children, however, do not produce antibodies to most PS antigens until they are several years old,[185] and they are particularly susceptible to infections by encapsulated bacteria during their first few years of life.[186] However, young children readily produce antibodies to PS when it is conjugated to a protein carrier. The clinical use of “conjugate” vaccines to induce antibodies to *H. influenzae* type b (Hib)-PS in young children has virtually eliminated Hib meningitis as well as oropharyngeal colonization by Hib.[187] Similar “conjugate” vaccine approaches have been used to produce 4-valent meningococcal and 7-, 10-, and 13-valent pneumococcal conjugate vaccines.[188,189,190] The pneumococcal conjugate vaccine has been used for young children since 2000 and has markedly reduced the incidence of invasive pneumococcal infections in both young children as well as old adults.[191]

The immunobiology of conjugate vaccines can differ based on the protein carriers used. Among hemophilus conjugate vaccines, Hib-PS conjugated to the meningococcal outer membrane protein complex can elicit antibody responses after only one immunization,[192] presumably because, unlike other protein molecules used as carriers, outer membrane protein complex stimulates TLR2.[193]

Not all bacterial antigens are presented to the host as free molecules, and some antigens remain associated with the bacteria. When bacteria enter the blood circulation, they preferentially localize at the marginal zone of the spleen. The marginal zone has features useful in capturing particles in the blood: the zone is where the terminal arteriole ends and empties into sinuses and has several characteristic macrophages and DCs.[167] Following the localization of bacteria at the marginal zone of the spleen, even without T cells, within 2 to 3

days MZ B cells can be activated and become plasma cells secreting antibodies to bacterial PSs.[166] MZ B cells have additional unique characteristics. They are rapidly stimulated by LPS,[194] and their maturation may be facilitated by other bacterial molecules as well. MZ B cells may facilitate the activation of follicular B cells as they can capture IgM immune complex and transport it to follicular DCs.[195,196]

Although MZ B cells can mature and differentiate independently of T cells,[166] other cells, including T cells, may help their maturation and antibody responses to various bacterial antigens. MZ B cells can present bacterial (protein) antigens to naïve T cells.[195] In addition to protein antigens, antibody responses to bacterial PSs require cofactors such as B7-2[197] and CD40,[197,198] and can be reduced with the simultaneous injection of anti-CD4 and anti-CD8 antibodies.[199,200] Indeed, studies have shown antibody responses to PSs attached to bacteria to be T-cell-dependent.[201] MZ B-cell response may depend on DCs as well. Upon taking up dead bacteria, $CD11c^{low}$ $CD11b^{high}$ DCs in the blood locate to the spleen and may provide transmembrane activator and CAML interactor ligand(s) helpful in MZ B-cell survival.[202] Adoptive transfer of live DCs after an in vitro exposure to dead pneumococci can transfer antibody responses to pneumococcal proteins and PS antigens.[203] Natural killer T cells may be involved in MZ B-cell maturation as MZ B cells express CD1 and may activate natural killer T cells.[195]

Preimmune animals have antibodies that cross-react with many structurally unrelated antigens. These antibodies are often labeled as “natural antibodies.” The majority of these antibodies is of the IgM isotype and frequently bind autologous antigens. Anti-PC antibodies may be an example of natural antibodies. Recent studies suggest that these natural antibodies are important in the early phase of bacterial and viral infections.[204] For instance, anti-PC antibodies react with a PC epitope found on *S. pneumoniae*, *H. influenzae*, and *Wuchereria bancrofti* (a tissue nematode).[205,206,207] Anti-PC antibodies can reduce the susceptibility of mice to pneumococcal infections.[206] A recent study suggests that the natural antibodies are from B1a B cells. CD19-deficient mice lack B1a B cells and have a reduced number of MZ B cells. These mice also lack anti-PC antibodies and are susceptible to pneumococcal infections.[169] In contrast, another mouse strain that exhibits both a reduced number of MZ B cells and a deficiency of B1b cells can produce anti-PC antibodies and is as resistant to pneumococcal infections as are normal mice.[169]

In addition to natural antibodies, animals often have preexisting antibodies to a PS that cross-react with structurally similar PSs,[208,209,210] probably because many PS molecules have very similar structures. Sometimes it is difficult to distinguish usual “anti-PS antibodies” from “natural antibodies.” Cross-reactions may play an important role in protecting the host against its first exposure to a bacterial species. For instance, human adults carry detectable amounts of antibodies to the Hib-PS—even in the absence of vaccination—and are thus relatively resistant to *H. influenzae* infections.[186] While some of the antibodies may be the result of immunization by subclinical infections, the majority of human preimmune (but not postimmune) anti-Hib-PS antibodies cross-react with *E. coli* K100, the PS capsule of which is an isopolymer of Hib-PS.[211] Experimental colonization of rats with *E. coli* K100 can protect

them against Hib.[212] About 1% of human IgG binds a carbohydrate epitope (galactose [1→3] galactose),[213] and this antibody can kill *Trypanosoma* and *Leishmania* in vitro.[214] Cross-reactive antibodies binding the LPS core components are thought to be responsible for the protection from bacteremic dissemination of gonococci in nonimmune patients,[215] although they cannot prevent infection of the genital tract.[215]

Normal gut flora may be the antigenic stimulus for many of the cross-reactive anti-PS antibodies. About 1% of the human population carries *E. coli* K100 in their gut at any moment.[216] Antibodies to (galactose [1→3] galactose) bind many species of bacteria isolated from normal stool specimens.[213] The gut flora may have additional interesting impacts on the immune system. For example, in some transgenic mice, inflammatory bowel diseases develop in the presence of normal intestinal flora but not in the absence of gut flora. In addition, in some animals, such as chickens and rabbits, microbial colonization of the gut

appears to be necessary for the normal development of antibody V region repertoires.[217] Bacteria should therefore be considered as active participants in shaping the host immune system.

Protective Mechanisms of Antibodies

Antibodies to virulence factors may act by neutralizing the function of those factors. Anti-toxin antibodies can protect a host by blocking the action of the toxins (eg, blocking the binding of the toxins to the host cell receptors) or by increasing the removal rate of the toxins. Antibodies to superantigens or tetanus toxin can inactivate them and thereby provide protection to the host. Antibodies to an *E. coli* adhesin can prevent experimental infections by *E. coli*.[218] Antibodies to M protein neutralize its ability to interfere with complement and provide protection against *S. pyogenes* infections. Antibodies to LPS,[219,220] and perhaps to LTA,[221] can be protective. Antibodies to PspA, pneumolysin, autolysin, or pneumococcal surface protein C can protect animals from fatal pneumococcal sepsis. Although these antigens are being investigated as potential replacements for the expensive pneumococcal conjugate vaccines, the protective mechanisms that they employ are still unclear. The most recent hypothesis suggests that antibodies to PspA may inhibit its decomplementation properties and the antibodies may increase the complement fixation on pneumococci.[33,222] Antibodies to IgA1 protease or iron-transport systems[223,224] can also protect against bacterial infections, most likely by neutralizing the normal functions of the target antigens. Finally, in the presence of antibodies and complement, the ability of the liver to remove bacteria increases significantly.[20] Thus, another protection mechanism provided by antibodies may be to facilitate the in vivo removal of bacteria from circulation by enhancing the ability of the reticuloendothelial system to clear bacteria.

Antibodies to capsule PS can provide protection by fixing complement on the surface of bacteria and by inducing bacteriolysis or opsonization. The bacteriolysis pathway can provide significant in vivo protection against gramnegative bacteria, as illustrated by the susceptibility to *N. meningitidis* infections of persons with deficiencies in C5-9 components.[225] In contrast, antibodies and complement do not lyse gram-positive bacteria but opsonize them for

phagocytic killing, as explained in the following.[226] Host phagocytes cannot readily recognize and kill the intact encapsulated gram-positive bacteria. However, once bacteria are coated with antibodies and complement, the host phagocytes can readily recognize the bacteria via various recognition receptors and engulf them for intracellular killing. The Fc receptor (CD16b) and the complement receptor (CR3) are some of the important recognition receptors. CR3, an integrin molecule, is a heterodimer of CD11b and CD18. Protection mediated by this antibody/complementmediated opsonization is probably important in vivo, as both complement deficiency and agammaglobulinemia predispose individuals to infections by many different extracellular bacteria.[157,225] To be effective for opsonization, the epitope of the surface antigens must be exposed on the surface of the bacteria. Effective antibodies to the porins of *N. meningitidis* recognize the surface loop of the molecule.[227] In most pneumococci, C-polysaccharide (C-PS) is mostly buried underneath the PS capsule. Although antibodies to the C-PS can fix complement,[20] anti-C-PS antibodies were ineffective in protecting mice against most *S. pneumoniae* unlike antibodies to capsular PS, which are protective.[228] However, a recent study found that purified human anti-C-PS antibodies can opsonize pneumococci[229]; thus, additional studies are needed.

Because antibody-mediated opsonization and bacteriolysis are dependent upon the complement-fixing properties of the Fc region, the relative efficacies of antibodies of different Ig isotypes have been compared. IgM antibodies are produced early in the course of infections and should be important in the early phase of infections because they fix complement very efficiently and can opsonize bacteria. Selective deficiency of IgM antibodies was found to increase susceptibility to bacterial infections.[230] Studies found that specific IgM antibodies agglutinate erythrocytes, fix complement, and lyse erythrocytes more readily than IgG antibodies,[231] and IgM antibodies are more effective in complement-mediated bacteriolysis[232]; however, IgG antibodies are more effective than IgM antibodies in preventing pneumococci infections of mice[233] or in opsonizing Hib in vitro.[234] Moreover, antibodies of some IgG subclasses have been reported to be more protective against specific viral[235] and fungal[236] infections than antibodies of other subclasses. These results suggest that optimal opsonization requires not only complement receptors but also Fc receptors for IgG. In the absence of inflammation, IgM antibodies are confined to the intravascular space, whereas IgG antibodies can enter the extracellular space. However, inflammation can make the vessels at the infection site permeable, at which point, antibodies of all isotypes may enter the infection site. Compared with IgM antibodies, IgG antibodies may be especially efficient at neutralizing toxins because they have a longer half-life, generally have a higher affinity, and are already present in extravascular spaces prior to infection.[237]

IgG subclasses differ in their ability to fix complement and to bind Fc receptors.[238,239] It has also been reported that IgG1 mouse monoclonal antibody is protective against *Cryptococcus neoformans* but that IgG3 mouse antibody is not.[236] Consequently, the fact that antibodies to bacterial PS are found to be largely restricted to a single IgG subclass (IgG2 in humans and IgG3 in mice) has led to many studies of the differences in the protective properties of anti-PS antibodies of different isotypes. Mouse IgG3 antibodies (but not antibodies of other IgG subclasses) can associate with each other through their Fc regions.[240] This feature may make the IgG3 antibodies with a low affinity to PS more effective in binding the antigen than

antibodies of other isotypes of the same affinity. Although these observations provide a theoretical advantage for mouse IgG3 antibodies, this same aggregation phenomenon has not been observed for human IgG2 antibodies even though some human IgG2 can form covalently joined dimers.[241] The full significance of IgG3 aggregation is not clear, however, as anti-PS antibodies of the IgG3 isotype have not been observed to be any more efficacious

against pneumococcal infections than antibodies of other isotypes.[242] IgG2 antibody levels can be significant, however. People expressing the Gm23+ IgG2 allele have higher IgG2 antibody levels than people with the Gm23- allele. Among C2-deficient persons, Gm23- persons are more susceptible to bacterial infections than Gm23+ individuals.[243]

Moreover, in contrast to expectations, many studies found that human IgG1 antibodies are slightly more effective at opsonization and bacteriolysis than are human IgG2 antibodies.[239,244] Neither of these isotypes appears to be essential, however, as individuals lacking IgG1 and IgG2 subclass genes are healthy.[245] Furthermore, human IgG2 antibodies bind less strongly to CD16, CD32, and CD64 than do IgG1 or IgG3 antibodies[246] and may not be effective for neutrophil opsonization in individuals homozygous for a specific CD32 allele.[244] These observations, taken together, strongly suggest that the human IgG2 (or mouse IgG3) subclass may not provide any unique advantage in defense against bacteria.

IgA is highly heterogeneous in structure: it can exist as a monomer, a polymer, or in secretory forms. In addition, its function is still unclear. Although it has been reported that IgA can opsonize,[247] fix complement,[248] and facilitate the lysis of *N. meningitides*,[249] other studies have found that IgA does not fix complement in vitro[250] and may even inhibit IgG-mediated complement-dependent killing.[251] The ability of IgA to fix complement may also depend upon its denaturation or its glycosylation status.[252,253] Nevertheless, other studies indicate that IgA antibodies may fix complement by the MBL pathway[254] and that human IgA antibodies against pneumococcal capsular PS can opsonize pneumococci for killing by neutrophils.[255] Bacteria that commonly colonize or infect mucosal areas often produce IgA1 protease, and IgA antibody has been found to provide protection in at least some of these cases.[256] These findings suggest that IgA may play an important role as a part of the complex mucosal immune defense. For example, IgA antibodies may be important in reducing nasopharyngeal colonization by bacteria inasmuch as the mice deficient in IgA or polymeric Ig receptor can carry pneumococci in the nasopharynx even after an immunization against pneumococci.[257] IgA may function by aggregating the bacteria and facilitating their expulsion from mucosal areas. IgA may also block the invasion of bacteria through mucosal epithelial cells, as endocytosed IgA has been found to block the transport of virus through epithelial cells.[258] However, IgA-deficient persons or mice are relatively healthy, and IgA-deficient mice can elicit normal protective immunity to experimental infections with influenza virus. IgM antibodies may function as secretory antibodies in IgA-deficient individuals.[259]

T-Cell Immune Responses to Extracellular Bacteria

Although immune responses to toxins from extracellular bacteria are T-cell-dependent,

antitoxin antibodies mediate protection; therefore, the protective immunity against extracellular bacteria is clearly centered on the B-cell responses. However, recent studies suggest additional roles for T cells in responses to extracellular bacteria and their products. PS associated with lipid can stimulate T cells in association with CD1 molecules.[260] Also, studies of abscess formation in response to *Bacteroides fragilis* infections led to a discovery that zwitterionic PS can be taken up by antigen-presenting cells, which can process the PS via a nitric oxide-dependent mechanism and present it in association with MHC class II molecules[179] to stimulate CD4+ T cells to produce IL-17.[261] IL-17-producing CD4+ T cells are now named "Th17 cells" and are found to be distinct from Th1 and Th2 cells. Th17 cells produce unique set of cytokines, such as IL-17 (IL-17A), IL-17F, IL-21, and IL-22, and require a distinct cytokine milieu (IL-1, IL-6, and TGF-β) for their development.[262,263,264,265]

Th17 cells may be involved in abscess formation by *B. fragilis* infections because Th17 cells are found in these abscess.[266] Several studies found that IL-17 and Th17 cells are important in the nasopharyngeal carriage of *S. pneumoniae* in mice.[114,267] A recent study showed that Th17 cells may recruit monocytes and macrophages to the nasopharynx where the monocytes/macrophages may actually remove pneumococci. Clinical examples clearly demonstrate the importance of IL-17 on some extracellular bacterial infections in humans. Patients with autosomal dominant hyper-IgE syndrome are deficient in Th17 cells and are very susceptible to infections by fungus and *S. aureus.*[268] Patients with mutations in IL-17F or IL-17 receptor A (IL-17RA) are susceptible to fungal and staphylococcal infections.[269] In view of these new findings, some researchers are investigating the possibility of using antigens stimulating Th17 cells as vaccines against *S. pneumoniae.*

DELETERIOUS HOST RESPONSES

Inflammatory responses by the host inevitably cause some tissue damage. In some bacterial infections such as pneumonia and meningitis, this damage plays a significant role in disease pathology and symptoms. For instance, animal models of meningitis have shown that inflammation associated with bacterial products (primarily bacterial cell walls) is the primary cause of neurologic damage. Treatment of animals with antibiotics alone can eradicate the bacteria, but it does not prevent neurologic damage. In contrast, when inflammation was controlled by steroids administered along with the antibiotics, neurologic damage was considerably reduced.[270]

Antigen-Nonspecific Deleterious Response

Uncontrolled inflammation at the systemic level can produce septic shock, which can be triggered by several factors, including exotoxins (eg, staphylococcal enterotoxin B) of gram-positive bacteria, the combination of LTA and peptidoglycan from gram-positive bacteria,[271] or LPS from gram-negative bacteria. The staphylococcal enterotoxin B superantigen binds the host's class II molecules of the MHC region and can stimulate large numbers of helper T cells to release cytokines. Septic shock can also be initiated when LPS from gram-negative bacteria binds CD14 and a TLR and stimulates macrophages or monocytes to secrete inflammatory cytokines. In addition to resulting in the release of cytokines, the stimulation of host cells by bacterial

products leads to the release of other mediators of inflammation, such as arachidonic acid metabolites, activation of the complement cascade, and activation of the coagulation cascade. Excess release of the mediators leads to the failure of the vascular system and, finally, the failure of multiple organ systems. Studies using transgenic mice with defective genes have identified several molecules critical in developing septic shock, such as TNF-α, one of its receptors TNFRI, caspase 1, and ICAM-1.[272] This approach also showed that CD14 and TLR4 are critical for LPS-induced septic shock and that CD28, a T-cell costimulation molecule, is necessary for superantigen-induced septic shock.[272]

Anthrax infections provide another example of uncontrolled host responses. “Lethal factor” binds the “ protective antigen” immobilized on the macrophages and then stimulates the cells to secrete cytokines and reactive oxygen intermediates. These macrophage products are thought to kill the host, as the host dies even when the proliferation of the bacteria is controlled. When macrophage cells are removed from animals, the animals are resistant to anthrax toxins.[273] This suggests that the macrophage response to the toxins is actually responsible for the death of the host.

Although inflammation is a significant cause of morbidity and mortality, it must also be regarded as the host's primary protection against bacterial infections. Evidence for this hypothesis comes from studies with TLR4-deficient mice, which, although nonreactive to LPS and completely resistant to LPS shock, are more susceptible to infection with gram-negative bacteria than are normal mice.[274,275] Perhaps LPS is “toxic” because the host has evolved to use this common bacterial component as a trigger for host responses.

Autoimmune Disorders

Autoimmune diseases are characterized by an overactive host immune response toward self, the host's own cells and tissues. Various factors are involved in autoimmune diseases, including genetic predisposition and environmental triggers. The pathogenesis of autoimmune diseases has at its core the development of autoreactive effector lymphocytes, and these can involve, among others, T-cell bypass and molecular mimicry. T-cell bypass is based on the notion that activated T helper cells provide the necessary factors to activated B cells for the production of antibodies. Some microorganisms can provide the bypass with superantigens, which can bind to many T cells expressing certain types of Vβ regions and stimulate them to create a nonspecific polyclonal T-cell activation.[276,277] The best-studied examples of superantigens are the exotoxins secreted by *S. aureus* and *S. pyogenes.*[278,279,280]

Molecular mimicry occurs when a bacterial antigen shares structural similarities with a host antigen, and hence, antibodies produced against the bacterial antigen could also bind to the host antigen, thereby casuing an autoimmune disease. For instance, the LPS of many strains of *N. meningitidis*, *N. gonorrhoeae*, *H. influenzae*, and *Haemophilus ducreyi* expresses the epitope of blood group antigen pK.[281] The PS capsule of *N. meningitidis* group B mimics epitopes expressed in the central nervous system,[282] such as the N-acetylneuramic acid epitope in the embryonic N-CAM.[283] While infection by these pathogens may cause autoimmune diseases, epidemiologic studies have clearly associated *Campylobacter jejuni* infections, a leading cause of acute gastroenteritis, with development of antiganglioside

antibodies and autoimmune diseases: Guillain-Barre syndrome[284] or its variant Miller-Fisher syndrome. Patients with Miller-Fisher syndrome have ophthalmoplegia and generally have autoantibodies to GQ1b, but Guillain-Barre syndrome is associated with autoantibodies to GM1 or GD1a.[285] Production of the two different types of autoantibodies has been associated with an allelism of sialyl transferase II of *C. jejuni*. One allele produces lipooligosaccharide-mimicking GM1 and GD1a, and infection by *C. jejuni* with this allele has been associated with Guillain-Barre syndrome. On the other hand, the other allele produces lipooligosaccharide-mimicking GQ1b, with its infection being associated with Miller-Fisher syndrome.

Perhaps the most classical example of infection-associated autoimmunity may be rheumatic fever and acute glomerulonephritis associated with *S. pyogenes* infections. Studies found that *S. pyogenes* can be divided into two classes with a monoclonal antibody to M protein[286] and that rheumatic fever develops only after infections with class I strains of *S. pyogenes*.[286] Class I and class II strains of *S. pyogenes* can also be readily distinguished by the linkage relationship of the M protein genes with the genes encoding related surface proteins.[286,287] M proteins from some class I *S. pyogenes* express epitopes highly cross-reactive with epitopes of cardiac myosin, tropomyosin, vimentin, laminin, and keratin.[288,289,290] An antibody molecule may bind to all of these protein molecules because a major portion of these proteins is coiled-coil α-helix.[290] The polyreactive antibodies to M protein may directly damage myocardial and endothelial cells.[291] In addition to antibodies, CD4+ and CD8+ T cells are found at rheumatic heart valves,[292] and the T cells proliferate to M protein peptides and heart proteins.[293] These observations suggest that the T cells with crossreactivity between M protein and myosin may be involved in the pathogenesis of rheumatic fever as well.

CONCLUSION

Because extracellular bacteria can grow rapidly and produce toxins, some are potent pathogens. To combat these bacteria, higher organisms primarily depend on two arms of the immune system: innate immunity and adaptive immunity centered on antibody molecules. The two arms of the immune system are comprised of multiple layers of protection. In the early stage of an infection, innate immunity involving pattern recognition receptors, complement, phagocytes, and natural antibodies cross-reacting with many antigens are important in host defense. During the late stage of an infection, pathogen-specific antibodies appear. These antibodies generally mediate the ultimate protection against extracellular bacteria by triggering the protective effects of complement and phagocytes. Nevertheless, innate and adaptive immune responses may cause damage instead of protection. A better understanding of how our immune system protects against each pathogen will aid in the development of more effective preventive and therapeutic measures against these pathogens.

Chapter 42

Immunology of Human Immunodeficiency Virus Infection

Douglas S. Kwon

Bruce D. Walker

INTRODUCTION

In June 1981, the U.S. Centers for Disease Control and Prevention (CDC) reported five cases of *Pneumocystis* pneumonia (PCP) in otherwise healthy young gay men in Los Angeles, California,[1] representing the first published evidence of what was to become the acquired immunodeficiency syndrome (AIDS) epidemic. At that time PCP was rare, known as an “opportunistic infection” that occurred in the setting of severe immune compromise resulting from cancer treatment. At the same time, there were also reports of an aggressive form of Kaposi sarcoma, a generally benign cancer, in the same demographic, namely young gay men.[2] Like PCP, Kaposi sarcoma was infrequent and was typically seen in older men or those who were immunosuppressed following organ transplantation. It made sense in the setting of severe immune compromise to see PCP or Kaposi sarcoma, but what was alarming in those initial reports was that it was being seen in otherwise seemingly healthy people.

At that time pentamidine, the main drug used to treat PCP, was only available through the CDC. Coincident with the first PCP cases reported in Los Angeles, there was a dramatic increase in requests for pentamidine from many other cities across the United States. A consistent and disturbing pattern was quickly noted—the drug was largely being requested for young men who had no known reason to be immune compromised and at risk for PCP. An emerging epidemic was thus recognized, and already from those first patients there were clues pointing to the central problem induced by what was ultimately recognized to be infection by a new human retrovirus: that human immunodeficiency virus (HIV) is an infection of the immune system.

When an antibody test for HIV became available in 1985, the kinetics of the expanding epidemic first began to be realized through retrospective examination of stored serum samples. Results from analysis of samples from a hepatitis B vaccine trial that had coincidentally been initiated in 1980 in gay and bisexual men in San Francisco, California, were startling.[3] By 1982, the cumulative incidence of infection in those at-risk men had risen to 42.6%. HIV has since gone on to infect over 60 million people worldwide and has caused over 30 million deaths.[4] In some of the most affected areas of the world, HIV prevalence exceeds 50% in certain communities and age groups (Fig. 42.1).[5]

Thankfully, the development of effective HIV drug therapy has turned HIV infection into a

treatable condition for those fortunate to have access to these medications,[6] but viral integration into the host chromosome makes the need for treatment lifelong.[7] Regrettably, for each person who begins antiretroviral therapy (ART) in resource-limited settings, there are two who become newly infected.[4] The ultimate resolution of the epidemic will almost certainly require an effective vaccine, but despite nearly a billion dollars invested annually in AIDS vaccine development, this has remained an elusive goal. Unlike other infections for which effective vaccines exist, for HIV there is a lack of natural clearance and subsequent durable protection.[8] As natural protective immunity does not exist, an effective HIV vaccine will have to do better than nature does.

HUMAN IMMUNODEFICIENCY VIRUS ORIGIN, TRANSMISSION, AND DISEASE PROGRESSION

Origin of Human Immunodeficiency Virus and Relationship to Other Retroviruses

The isolation of a retrovirus in 1983 from a patient with AIDS in France led to wider sampling of at-risk persons and was paralleled by the discovery of other primate retroviruses. Sequencing of HIV revealed enormous variability among isolates, which were ultimately phylogenetically characterized as belonging to four distinct groups. Group M is the largest and accounts for over 98% of infections worldwide.[9] Based on geographically targeted sequencing, it appears that the epicenter of the global group M epidemic was in Kinshasa in the Democratic Republic of the Congo,[10] and that a cross-species transmission of simian immunodeficiency virus (SIV) from chimpanzees occurred in the early 1900s.[11,12] In turn, chimpanzees had acquired SIV from cross-species transmission of two viruses in monkeys that recombined. The actual origin of the group M epidemic in humans appears to have been in a remote region of southeastern Cameroon, likely by exposure through butchering of a chimpanzee.[13] Much less frequent are groups N, O, and P, the result of separate cross-species transmissions from chimpanzees (groups N and O) and gorillas (group P), which have remained localized to Cameroon and neighboring countries in west Africa.[9,14,15]

HIV is a typical retrovirus, morphologically characterized by a core containing the viral ribonucleic acid (RNA) and two copies of reverse transcriptase (RT), surrounded by an outer envelope that is heavily glycosylated. The errorprone RT leads to the rapid generation of new mutations, resulting in enormous genetic variation within group M viruses globally. This is largely due to lack of 3′ exonuclease proofreading activity of RT, which gives rise to the mutation of approximately 1 in every 10,000 nucleotides during viral genome transcription; in other words, once per replication

cycle[16]. Additional factors are the frequent viral recombination and the lifelong nature of infection. Within an individual, this produces an enormously diverse quasispecies of viruses whose intraindividual diversity exceeds the global diversity of influenza in a single season[17] (Fig. 42.2). This represents a significant challenge to the immunologic control of infection and the development of broadly prophylactic vaccines. Currently, there are at least nine distinct clades, or subtypes, of group M HIV-1 worldwide, and many additional subtypes that are the result of recombination events between these major clades.

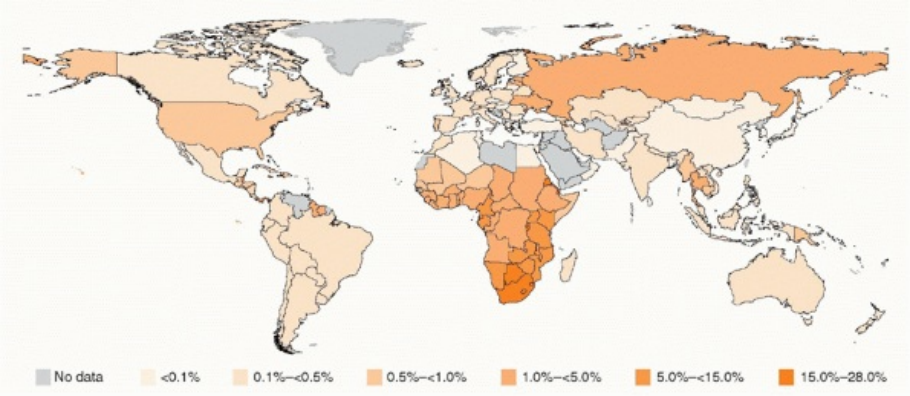

FIG. 42.1. Global Human Immunodeficiency Virus Prevalence by Country. From World Health Organization.[4]

HIV-1 is closely linked to HIV-2, a less pathogenic human retrovirus that is endemic in west Africa. HIV is also closely related to SIVs, a number of nonhuman primate retroviruses.[18] Although SIV was initially considered nonpathogenic in primates, infection of certain wild chimpanzee species results in CD4 T-cell decline and increased mortality. It is important to note that some wild nonhuman primate species tolerate their species-specific SIV infections quite well, including African green monkeys and sooty mangabeys, in whom the infection is characterized by persistent high viral load but a lack of CD4 cell decline or development of immune deficiency.[19]

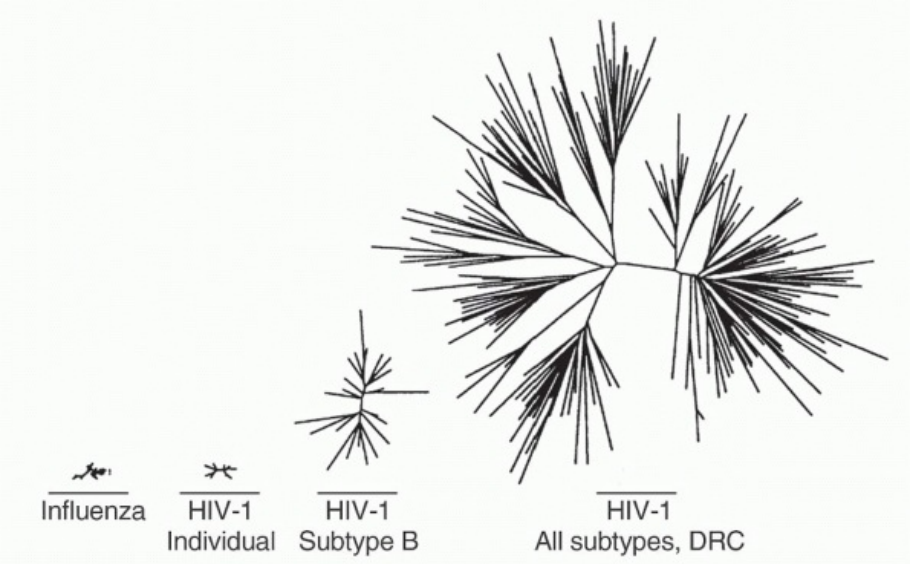

FIG. 42.2. Relative Viral Diversity of Influenza and Human Immunodeficiency Virus (HIV)-1. Comparison of influenza HA1 domain and HIV-1 envelope V2-C5 regions, starting from left with diversity of all H3N2 influenza sequences available from the 1996 influenza season, then HIV-1 subtype B sequence diversity from a single individual, HIV-1 sequences from a subtype B epidemic occurring in Amsterdam in 1990 to 1991, and

finally HIV-1 sequences from the Democratic Republic of Congo obtained in 1997. Adapted from Korber et al.[17]

Exploiting Knowledge of the Viral Life Cycle to Develop Antiviral Agents

Early in the HIV epidemic, it was realized that expression of CD4 was necessary for cells to become infected—a finding that was assisted by the recognition that CD4+ cells were specifically lost in progressive disease. However, it was also clear that CD4 alone was not sufficient. Expression of recombinant CD4 on murine cells failed to allow viral infection. The discovery of chemokine receptors as necessary coreceptors for HIV entry took over a decade to be realized and was facilitated by a remarkable convergence of clinical observation and basic science. Blood samples from persons identified to be very heavily exposed to HIV, who had never become infected, showed that a group of β chemokines: MIP-1α, MIP-1β, and RANTES, were secreted from CD8 T cells and could inhibit HIV replication.[20] These chemokines were known to be linked through a common receptor, CCR5, a member of a family of G-protein coupled seven transmembrane domain chemokine receptors. In the next year, CCR5 and another chemokine receptor, CXCR4, were identified as the long-sought HIV entry coreceptors whose expression along with CD4 were both necessary and sufficient to allow viral entry.[21,22,23] Shortly thereafter, it was discovered that homozygosity of a naturally occurring 32 base pair deletion of

CCR5 (CCR5 δ32) that abrogated surface expression of the protein and occurred in 1% of Caucasians imparted resistance to HIV acquisition, thus demonstrating the biologic significance of chemokine receptors for HIV infection.[24,25,26] As individuals lacking functional CCR5 were found to be largely immunologically intact, CCR5 became an attractive target for ART; in 2007, maraviroc, a negative allosteric modulator of the CCR5 receptor, became the first chemokine receptor antagonist approved for treatment of HIV infection.

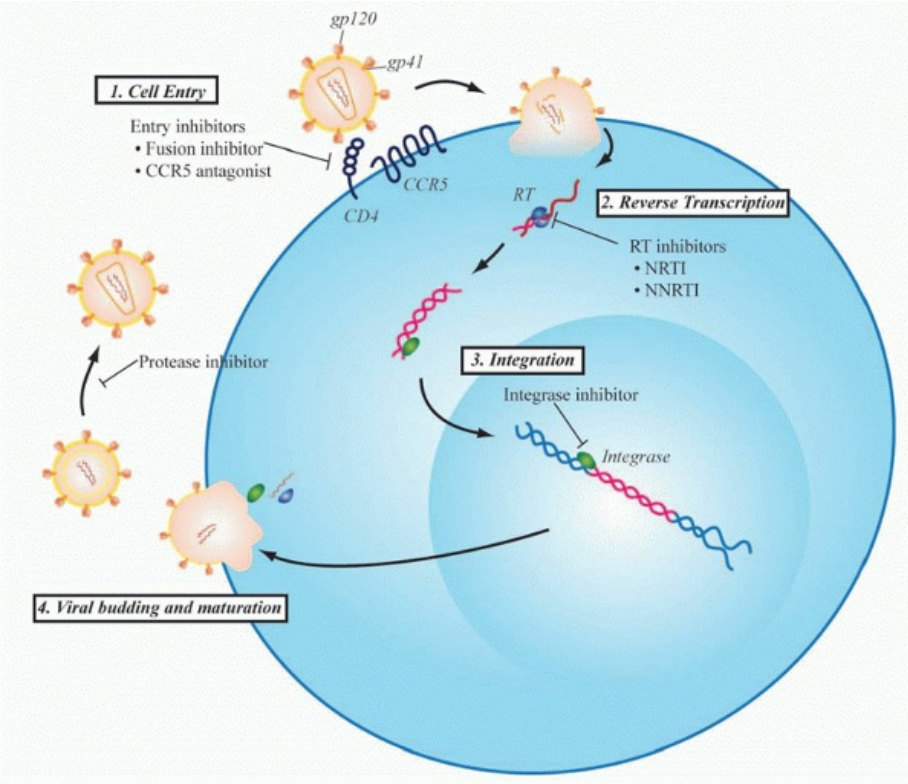

FIG. 42.3. Human Immunodeficiency Virus (HIV) Viral Life Cycle and Targets for Antiretroviral Therapy. The HIV envelope protein gp120 first contacts CD4 on the target cell, which then induces conformational changes in gp120 that exposes the chemokine receptor binding site. Following binding of chemokine receptor, HIV gp41 mediates fusion of target and viral membranes. The viral single-stranded ribonucleic acid genome is then reverse transcribed, and the viral genome is transported to the nucleus where it is integrated in the host genome. Viral genes are then transcribed and translated, and virions then bud from the host membrane. Following budding, virions mature in a process that requires cleavage of HIV polyproteins by the viral protease. Currently approved antiviral agents target entry, reverse transcription, viral genome integration, and viral protease function.

Even before the development of maraviroc, however, multiple viral proteins had been successfully targeted to treat HIV infection based upon a rapidly developing understanding of the viral life cycle (Fig. 42.3). HIV RT was the first viral protein to be successfully targeted by drug therapy, and the class of RT inhibitors remains the backbone of firstline regimens of combination ART strategies used today. Zidovudine was the first clinically approved HIV drug. It is a thymidine analog initially developed in 1964 as a potential anticancer agent. Over 20 years later, however, it was found to inhibit replication of HIV as part of a unique collaboration between the National Cancer Institute and the pharmaceutical company Burroughs Wellcome. When zidovudine was first tested for activity against HIV in 1985, there were over 10,000 people suffering from AIDS, a disease for which there was no available therapy at that time.[27] After proving to be safe in a small phase I trial, zidovudine quickly went on to efficacy studies and remarkably went on to be approved for clinical use by the U.S. Food and Drug Administration just 2 years after its first testing in the laboratory. This would be the first of

several drugs that target RT that now constitute one of the mainstays of HIV treatment.

The next major breakthrough in ART was the development of drugs that target the HIV protease. Protease is required for cleavage of viral polyproteins in immature virions released from the infected cell, a step necessary for virion assembly and maturation. The first protease inhibitor, saquinavir, was approved in 1995, and its development marked the age of modern multidrug ART. Up to that point, only four drugs had been developed, all nucleoside RT inhibitors (NRTIs). However, therapy with these NRTIs showed toxicity, and none of them alone or in combination could durably control HIV. Combination therapy with agents that inhibited both RT and protease showed strong in vitro synergy,[28] could achieve virologic suppression in vivo, and resulted in a dramatic decrease in AIDS deaths (Fig. 42.4).[29] This was quickly followed by the development of non-NRTIs, which also target RT and can also be used effectively with NRTIs to suppress viral replication. This marked the

modern era of combination ART and has changed HIV from a nearly uniformly terminal illness to a chronic treatable disease for those with access to medications.

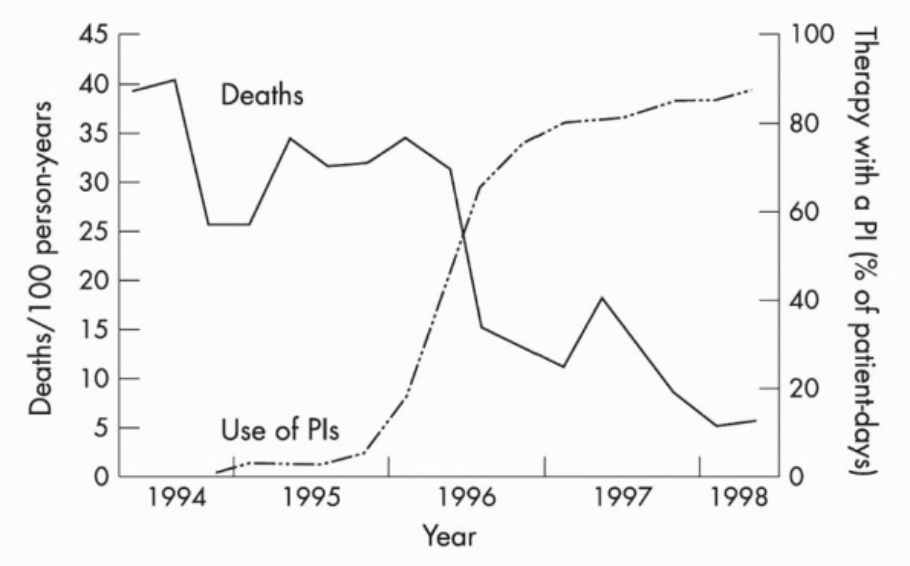

FIG. 42.4. Protease Inhibitors and Decline in Acquired Immunodeficiency Syndrome (AIDS) Mortality. Mortality from AIDS showed a significant decrease following the introduction of protease inhibitors, which were used in combination with agents that target human immunodeficiency virus (HIV) reverse transcriptase to treat HIV-infected individuals with combination therapy to suppress viral replication. From Palella et al.[29]

Since the development of RT and protease inhibitors, two other steps in the viral life cycle, entry and viral genome integration, have been successfully targeted by approved drugs. HIV entry is initiated when the viral envelope protein, gp120, contacts CD4 and a chemokine receptor on the target cell membrane. This triggers conformational changes in the transmembrane envelope glycoprotein, gp41, which leads to fusion of viral and host membranes. There are currently two antiretroviral agents that act at this early stage of entry:

maraviroc, a CCR5 antagonist that blocks the interaction of gp120 with CCR5, and enfuvirtide (Fuzeon, T-20), approved in 2003, a 36 amino acid peptide that binds to gp41 and prevents formation of a hairpin intermediate necessary for fusion of the viral and target cell membranes. Raltegravir targets HIV integrase and represents the newest class of antiretroviral agents to be developed. Integrase is the viral enzyme that catalyzes the deoxyribonucleic acid strand transfer reactions necessary for incorporation of the viral genome into the host genome. It represents one of the most potent of currently available HIV drugs and is generally one of the best tolerated therapies.

Although there are currently over 30 approved antiretroviral drugs in various formulations, demand continues for novel agents, especially as drug resistance becomes increasingly common. Studies in Europe have demonstrated that approximately 10% of all newly diagnosed patients harbor virus with at least one major resistance-associated mutation.[30] New drugs remain in development including maturation inhibitors, CD4 receptor inhibitors, and additional agents in existing classes.[31] The development of suppressive multidrug ART has saved millions of lives and has only been possibly with a detailed understanding of the molecular mechanisms of HIV pathogenesis. These drugs are now being used not only to treat those who are infected, but also are being tested for use in preventing infection in individuals at high risk of acquisition.[32]

Mucosal Transmission and Early Local Viral Replication

Transmission of HIV is relatively inefficient with a risk of approximately 1 in 1,000 sexual acts for male-to-female sexual transmission and 1 in 100 for receptive anal intercourse.[33] Over 90% of HIV transmissions worldwide occur across a mucosal barrier, either through sexual exposure or maternalto-child transmission, with the remaining cases due to direct blood exposure such as injection drug use. These mucosal surfaces are exposed to an enormously diverse quasispecies of genetically distinct virions, and yet the majority of transmissions are mediated by a single founder virus,[34] although as many as 16 viruses have been documented to be transmitted simultaneously.[35] Multiple transmitting founder viruses appear to be more prevalent in transmission occurring via intravenous drug use, suggesting that mucosal-specific factors are an important determinant for this restriction.[35] Following mucosal exposure, a small founder population establishes host infection by initially replicating locally within the exposed mucosal tissue for 7 to 10 days before disseminating to the draining lymph node and then moving quickly into the blood.[36] Once infection has spread to the periphery, a widespread reservoir of latently infected cells is rapidly established at multiple sites and subsequent viral eradication becomes enormously challenging due to this extensive reservoir.

The fact that HIV transmission is inherently inefficient and typically initiated by a single virion that requires days of local expansion before systemic infection can take place suggests that these early events represent a vulnerable stage in the process of transmission. Unfortunately, few HIVspecific B- or T-cell responses are detected locally in the mucosal site of exposure until well after viral dissemination, despite the fact that these sites contain abundant antigenpresenting cells and numerous lymphocytes.[37,38] This lack of early responses likely plays a critical role in the failure of the immune system to contain viral replication within the genital mucosa. Although some studies suggest that a subset of persons with multiple

exposures will develop adaptive immune responses to HIV,[39] and have suggested that these can protect against acquisition, this remains controversial.[40]

Transmission depends on specific properties of the envelope glycoprotein of HIV. Acute infection is typically established with R5 viruses that utilize CCR5 as a coreceptor. Over time, some viruses within the quasispecies of an infected person can evolve to an X4 phenotype, which is characterized by the use of CXCR4 as its coreceptor, but these viruses somehow are either prevented from establishing the initial infection or rapidly revert to R5 viruses upon transmission.

The mechanism of the transmission "bottleneck" remains incompletely understood. The efficiency of HIV transmission is actually quite low and highly linked to the viral load in the donor. A population study of 45 discordant couples, in which one partner is HIV positive and the other is not, showed a complete lack of transmission in the 15 couples in whom the infected partner had a viral load of < 1,500 RNA copies/uL plasma.[41] More recently, treatment of couples discordant for HIV infection has confirmed the impact of viral load on transmission: when the HIV-infected partner is on therapy, the risk of HIV transmission to his or her partner is reduced by 96%.[42] Periods of highest transmissibility tend to be the acute phase of infection, before viral load has declined to a steady state, and end stage disease, when viral load again rises.[43] Importantly, the highest viral loads are seen in acute infection, before antibodies become detectable, such that standard enzyme-linked immunosorbent assay antibody testing is typically negative at the time of highest risk of transmission. This is being addressed at least in part through next generation tests that detect both antibody as well as p24 antigen, decreasing the "window period" when persons are infected but test negative.

Acute Infection Syndrome and Early Infection

Most persons have had the symptoms that could be consistent with acute HIV infection at some point in their lives as these are not specific to HIV but rather are typical of many viral infections. Indeed, the diagnosis of acute HIV infection is frequently missed by health care providers because at the time of acute symptoms, anti-HIV antibodies have not yet

developed and thus persons test negative by the standard antibody tests that are used to diagnose infection. Most but not all patients are symptomatic with their initial acute infection, with fever, sore throat, swollen lymph nodes, fatigue, malaise, and often transient oral or genital ulcers.[44] The syndrome looks very much like acute infectious mononucleosis.

The acute symptoms, which are nonspecific, eventually resolve, and subsequent disease course is characterized by a gradual CD4 cell decline and slowly rising viral load, with the ultimate development of clinical AIDS when the CD4 count is < 200 cells/uL or certain AIDS-defining illnesses arise.

Initial peak viremia in newly infected adults is often 10 million viral particles per mL or more,[45] followed by a decline over the first few months to a quasisteady state at a mean of around 30,000 RNA copies/mL (Fig. 42.5).[46]

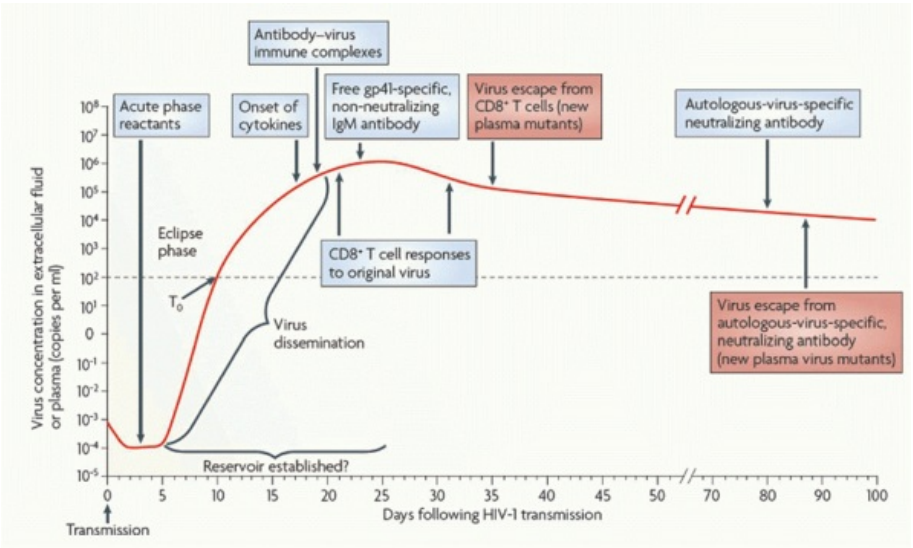

FIG. 42.5. Early Immune Responses in Acute Human Immuno deficiency Virus (HIV)-1 Infection. Acute infection is typically characterized by high viral loads and flu-like symptoms. There is an initial "eclipse phase" in which virus is present but antibody-based HIV tests remain negative. Early adaptive responses are comprised of HIVspecific CD8 T-cell responses and nonneutralizing antibody responses. The emergence of CD8 T-cell responses coincides with the decline of peak viral loads and the establishment of a viral set point. From McMichael et al.[190]

Current views of the very earliest stages in acute infection stem largely from studies in the nonhuman primate model of AIDS virus infection, in which rhesus macaques are infected with SIV. In high-dose challenge models of macaques, virus crosses the mucosal site of exposure within hours and initially establishes a small founder population of infected cells locally.[47] It is unclear how the virus crosses the mucosal epithelial barrier, but studies have suggested a variety of mechanisms, including transcytosis across epithelial cells, facilitation by mucosal dendritic cells (DCs), and/or entry through mechanical disruption or physiological intercellular spaces in the epithelium. Once across, the first cells to be infected are CD4 T cells. Surprisingly, though HIV preferentially infects activated CD4 cells, the first targets appear to be resting CD4 T cells, or cells that have been previously activated and still express CCR5 coreceptor but have entered into a more quiescent state. Once infection within the tissue is established, there is a period of local expansion that lasts for 7 to 10 days before the virus is disseminated to regional lymph nodes. This is then followed by rapid progression to the peripheral circulation and seeding of gut-associated lymphoid tissue (GALT). This gut reservoir contains 60% to 80% of the body's CD4 T cells, a large majority relative to the 2% to 3% of lymphocytes present in the peripheral circulation.

Based upon studies initially conducted in macaques and subsequently corroborated in humans, a hallmark of HIV infection is the rapid and profound depletion of GALT CD4 T cells in the lamina propria within the first weeks of HIV infection (Fig. 42.6). It appears that these cells never fully recover, even with prolonged treatment with antiviral medications that suppress peripheral viral loads and result in

rebound of CD4 T-cell counts in the peripheral blood.[48,49] This CD4 T-cell depletion is accompanied by extensive apoptosis of bystander cells, associated immune activation, and disruption of normal epithelial barrier function in the gut. Recent data suggest that bystander death actually involves abortive infection, with accumulation of cytoplasmic nucleic acids that elicit proapoptotic and proinflammatory responses.[50]

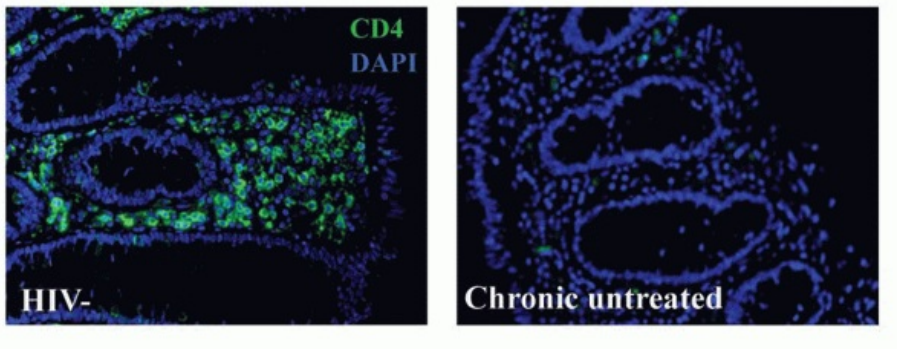

FIG. 42.6. Depletion of CD4 T Cells in the Intestinal Mucosa. Gut-associated lymphoid tissue contains the majority of the body's lymphocytes, which reside within both the lamina propria and lymphoid follicles. Lamina propria CD4 T cells are rapidly and massively depleted early in human immunodeficiency virus (HIV) infection. Shown are representative stains from colonic mucosa from HIV-infected and -uninfected individuals stained by immunofluorescence for CD4 (*green*) and nuclei (4′,6-diamidino-2-phenylindole [DAPI], *blue*).

Natural History of Untreated Infection

The typical course of untreated HIV infection until the development of AIDS, defined as a CD4 count of < 200 cells/μL or the presence of certain AIDS defining illnesses is approximately 10 years[51] and involves progressive immunologic decline. As the epidemic has matured, however, it has become clear that not all persons progress. There are now persons with documented untreated infection for more than 30 years who have maintained normal CD4 cell numbers and an undetectable viral load, whereas others progress from acute infection to AIDS in as little as 6 months without therapy.[52]

The best HIV natural history data derive from the Multicenter AIDS Cohort Study and other population studies established in the early days of the epidemic. The Multicenter AIDS Cohort Study, which involved recruitment of both infected and at risk men in Baltimore, Maryland, Chicago, Illinois, Los Angeles, California, and Pittsburgh, Pennsylvania, was established in 1984 and continues today. The study currently has almost 7,000 participants with an accumulated 87,000 person years of follow-up,[53] with a large repository of archived specimens. These multicenter seroprevalent and seroincident cohorts were pivotal in identifying laboratory predictors of prognosis, including CD4 T-cell count and viral load, which are both independent predictors of disease progression. Following acute infection, viral load reaches a quasi-set point within approximately 6 months of infection, with a median viral load around 30,000 RNA copies/mL and interquartile ranges from 12,000 to 80,000 copies/mL.

There is a marked increase in the development of opportunistic infections when CD4 count drops below 200 cells/μL, which led to the current recommendations that prophylactic treatment of opportunistic infections begin when this level is reached. The sequelae of chronic untreated HIV infection are the development of these opportunistic diseases, which are what led to the original identification of the new epidemic of HIV infection. What was being seen clinically was the end stage of a chronic infection in which immune dysfunction allowed the establishment of a number of otherwise rare illnesses.

Among the CDC AIDS-defining illnesses are candidiasis of the respiratory tract, *Pneumocystis jiroveci* pneumonia, cytomegalovirus disease, extrapulmonary cryptococcal disease, toxoplasmosis of the brain, and mycobacterial infection,[54] all indicative of an underlying defect in cellular immunity. *Mycobacterium tuberculosis* is a particularly devastating coinfection, in part because its widespread prevalence, with almost one-third of HIV-infected individuals globally also infected with tuberculosis. Both infections are far more prevalent in resource-limited settings, and coinfection is associated with worse outcomes, with tuberculosis being the leading cause of death in coinfected individuals.[55] Although opportunistic infections are a hallmark of progressive HIV, AIDS-defining illnesses are not confined to infectious diseases. There are notably several cancers that are also associated with HIV, including Kaposi sarcoma, lymphoma, and cervical cancer, all of which are likely due to loss of protective immune surveillance and the presence of other viral coinfections. Additionally, although not listed by the CDC as AIDS defining, there is also evidence that HIV-infected individuals are at increased risk for anal cancer, hepatocellular carcinoma, and lung cancer.[56] The risks for associated infectious diseases decrease with therapy and subsequent immune reconstitution; however, the risk for some cancers, such as cervical and anal cancer, remains elevated.

With the advent of combination ART, HIV has in many ways become a chronic treatable disease. However, despite the immunologic and virologic benefits of ART, life expectancy in HIV-infected individuals remains approximately 14% shorter than the average for uninfected persons.[57] The ART Cohort Collaboration study, a group composed of 13 independent studies, found that deaths were due largely due to age-related clinical diseases, such as cardiovascular disease, cancer, fractures, and renal dysfunction, despite apparent immune reconstitution with effective ART. Additionally, treated HIV-infected adults older than 50 years old had three times greater risk of death compared to those younger than 30 years. The precise mechanism of this age-related morbidity and mortality is unclear, but it is increasingly relevant as the population of HIV-infected individuals ages, a result of the success of ART. It is projected that by 2015 more than half of all HIV-infected individuals in the United States will be over 50 years of age,[58] and given their increased risk of morbidity and mortality despite what is considered successful treatment, the mechanism of these age-related diseases is an area of critical research. One key to understanding this is the observation that HIV-infected individuals have increased systemic immune activation and that with therapy the activation level decreases but does not reach the same state of those who are uninfected. Persistent immune activation, even at low levels, may therefore be one mechanism by which HIV creates progressive impairment.

Chronic Immune Activation and Immune Dysregulation

Peripheral markers of T-cell activation predict the rate of disease progression and CD4 T-cell

decline in untreated infection more accurately than plasma viral load.[59,60,61] This persistent immune activation is a hallmark of chronic HIV infection; although it is clear that HIV viremia itself plays a direct role, it does not fully account for the entirety of observed T-cell activation seen in infected patients. For example, in sooty mangabeys, a natural host of SIV, high levels of viremia are supported but without a significant increase in immune activation and with the remarkable absence of clinically advanced disease.[62,63,64] Additionally,

patients who are successfully treated with ART and have suppressed viral loads continue to have elevated markers of T-cell activation relative to HIV-uninfected subjects.[65]

Recent studies have suggested that the gut may be critically involved in chronic immune activation. Individuals with untreated HIV infection have been found to exhibit elevated serum levels of bacterial lipopolysaccharide (LPS), which is thought to be a consequence of increased microbial translocation from the intestinal lumen in the setting of a damaged gut mucosa.[66] Serum LPS levels are closely correlated with markers of systemic T-cell activation; in patients who receive allogeneic bone marrow transplants complicated by graft-versus-host disease, it has been shown that plasma LPS levels closely correlate with biochemical and histologic measures of mucosal damage.[67] Thus, elevated serum LPS in HIV-infected subjects is believed to reflect the loss of mucosal epithelial integrity concomitant with HIV infection, and it defines a mechanism by which the gut may play a central role in chronic immune activation through increased microbial translocation. The ultimate anatomic cause of this increased translocation remains to be fully defined The ultimate consequence of this chronic immune activation appears to be higher turnover of CD4 and CD8 T cells, clonal exhaustion, and the progressive impairment of T-cell function.

The development of immune dysfunction or “exhaustion” in the presence of ongoing antigen exposure is a cardinal feature of chronic viral infections with persistent viremia.[68,69] Exhaustion results in the hierarchical impairment of T-cell effector functions, with an initial loss of proliferative capacity and interleukin (IL)-2 production and the late loss of the ability to secrete proinflammatory cytokines such as interferon (IFN)γ.[70] This exhaustion is mediated by several immunoregulatory pathways,[69,71] including programmed death 1 (PD-1), cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), T-cell immunoglobulin and mucin-3 (TIM-3), and IL-10, which are all upregulated in vivo in chronic untreated HIV infection and have been shown to mediate a reversible virus-specific immune dysfunction in vitro. These immunoregulatory pathways are therefore being explored as potential targets for therapeutic intervention in chronic HIV infection.[69,72,73,74]

IMMUNE RESPONSE TO HUMAN IMMUNODEFICIENCY VIRUS

Unlike many other viral infections, there does not appear to be natural clearance of HIV infection. The only known case in which virus has been apparently successfully eliminated occurred in a patient who underwent a bone marrow transplant from a donor who was homozygous for the 32 base pair deletion in CCR5, rendering the newly transplanted cells not susceptible to infection by the R5 virus strain with which he was infected.[75] The fact that people do not spontaneously clear virus indicates by definition that natural immunity is insufficient to eliminate HIV. Despite this, there is clear evidence of initial partial control in the

early stages of infection, when viral load is decreased from peak levels often in excess of 10 million viral particles per mL of plasma to a set point mean of around 30,000 copies/mL.[45] Moreover, some rare individuals termed elite controllers maintain undetectable viral loads and normal CD4 cell counts, in some cases for over 30 or more years, suggesting that partial host control is possible. Evidence exists to implicate both innate and adaptive immune responses in situations of partial control in acute and chronic infection, but the actual correlates of protective immunity remain unclear.

Natural Killer Cell Response

The potential protective role of natural killer (NK) cells in human viral infections is clear from examples of genetic defects in NK cells. For example, severe herpes simplex virus infection was observed in an adolescent with no NK cells.[76] Aside from the fact that NK cells would be the first possible line of defense against HIV, HIV downregulates human leukocyte antigen (HLA)-A and -B molecules on infected cells, which would render them targetable by certain NK-cell subsets. NK-cell interactions with HIV-infected cells do not depend on expression of an antigen-specific receptor, but instead are dependent on alterations in activating and inhibitory signaling between HIV-infected cells and NK cells. This occurs via interactions with a subset of highly polymorphic killer immunoglobulin-like receptors (KIRs) with HLA class I molecules, as well as through indirect mechanisms involving antibody-dependent cellular cytotoxicity and an arsenal of nonspecific inhibitory and activating receptors.[77,78,79]

The evidence for a beneficial effect of NK cells in HIV infection is mounting, both in protection from acquisition and in subsequent control of viremia. A potential functional role for NK cells in blocking viral acquisition is supported by studies in exposed, uninfected persons who appear to be protected from infection. Persons who have been heavily exposed to HIV and yet remain uninfected have increased NK cell activity[80] and a higher KIR3DS1 to KIR3DL1 transcript ratio,[81] consistent with the genetic studies indicating a protective effect of the compound genotype consisting of the activating KIR KIR3DS1 and Bw4-80I.[78] Studies in persons who are acutely infected also support an antiviral role for NK cells. There is an expansion of KIR3DS1+ NK cells in acute infection in persons expressing the putative ligand Bw4-80I, and these cells are able to lyse HIV infected cells in vitro, in a Bw4-80I-dependent manner.[82]

The mechanism of putative protection by NK cells in HIV infection likely relates to the selective downregulation of HLA A and B alleles by HIV. This certainly would be consistent with the role of activating ligands, but the inhibitory KIR allelic association is more challenging to explain. It may relate to the strength of the KIR-HLA interaction during NK-cell licensing, when stronger engagement of inhibitory KIRs by HLA molecules enhances their potential functional capacity. Stronger inhibitory signals during NK-cell development could lead to greater activation when infected cells downregulate HLA-A and -B, thus leading to enhanced function.[78]

There are a number of defects in NK cells that have been identified in HIV-infected persons. There is an inverse correlation between viral load and NK cell-mediated suppression of viral replication, suggesting that NK-cell dysfunction

may contribute to disease progression.[83] NK cells in HIVinfected persons have impaired cytotoxic capacity associated with decreased levels of granzyme A and perforin,[84] whereas other studies suggest that NK cells may be incompletely activated in chronic HIV infection and that functionally anergic subsets may be expanded.[85] It has also been suggested that NK cells can become HIV-infected and might contribute to the persistent HIV reservoir in vivo.[86]

More recently, in vivo evidence for antiviral selection pressure mediated by NK cells has been reported. Functional roles for NK cells are suggested by studies in infected persons, showing expansion of a subset of NK cells in acute infection.[82] But the most compelling data implicating NK cells in the host defense against HIV come from the identification of NK-cell "footprints" in viral sequences obtained from infected persons. Analysis of KIR genotypes and fulllength virus sequencing in a large cohort of persons with chronic HIV infection demonstrated 22 positions throughout the HIV genome in which amino acid polymorphisms were associated with the presence of specific KIR genes.[87] In vitro studies showed that these HIV sequence polymorphisms increased the binding of inhibitory KIRs to HIVinfected cells, suggesting a functional consequence favoring the virus. Moreover, these polymorphisms reduced the antiviral activity of KIR-positive NK cells, indicating not only that NK cells exert immune selection pressure on HIV, but also that HIV evolves to escape from detection by this response.

CD8 T-Cell Response

Systemic spread of HIV infection from an initial localized mucosal infection is associated with a dramatic increase in plasma viremia followed by decline to a quasi-set point level. The appearance of a cytotoxic T-lymphocyte (CTL) response coincides with the drop in viremia a month or more before neutralizing antibodies are detectable, suggesting that these cells may be the main effector mechanism of this decline.[88,89]

The data in support of a primary role of CTL in initial containment of systemic viremia also come from CD8 T-cell depletion studies in SIV-infected macaques. Use of a monoclonal antibody to achieve complete CD8 depletion in peripheral blood and near complete depletion in tissues resulted in persistence of peak viremia in acute infection.[90,91] When CD8 T cells are depleted in chronic infection, well after set point has been established, viral load increases and then declines again as CD8 cells reappear. CD8 depletion also resulted in more rapid disease progression.[90] These studies also may have depleted CD8-bearing NK cells, so one cannot entirely rule out a contribution of the innate immune response. Support for a central role for CTL is also implied from large cohort studies, in which the most striking association with viral load and CD4-cell decline is the expression of certain HLA class I alleles[92] (Fig. 42.7). Among these are so called "protective" alleles associated with natural control, in particular HLA B*57 and B*27,[92,93] and "risk" alleles, such as certain HLA B*35 subtypes associated with higher viral loads and more rapid disease progression.[94]

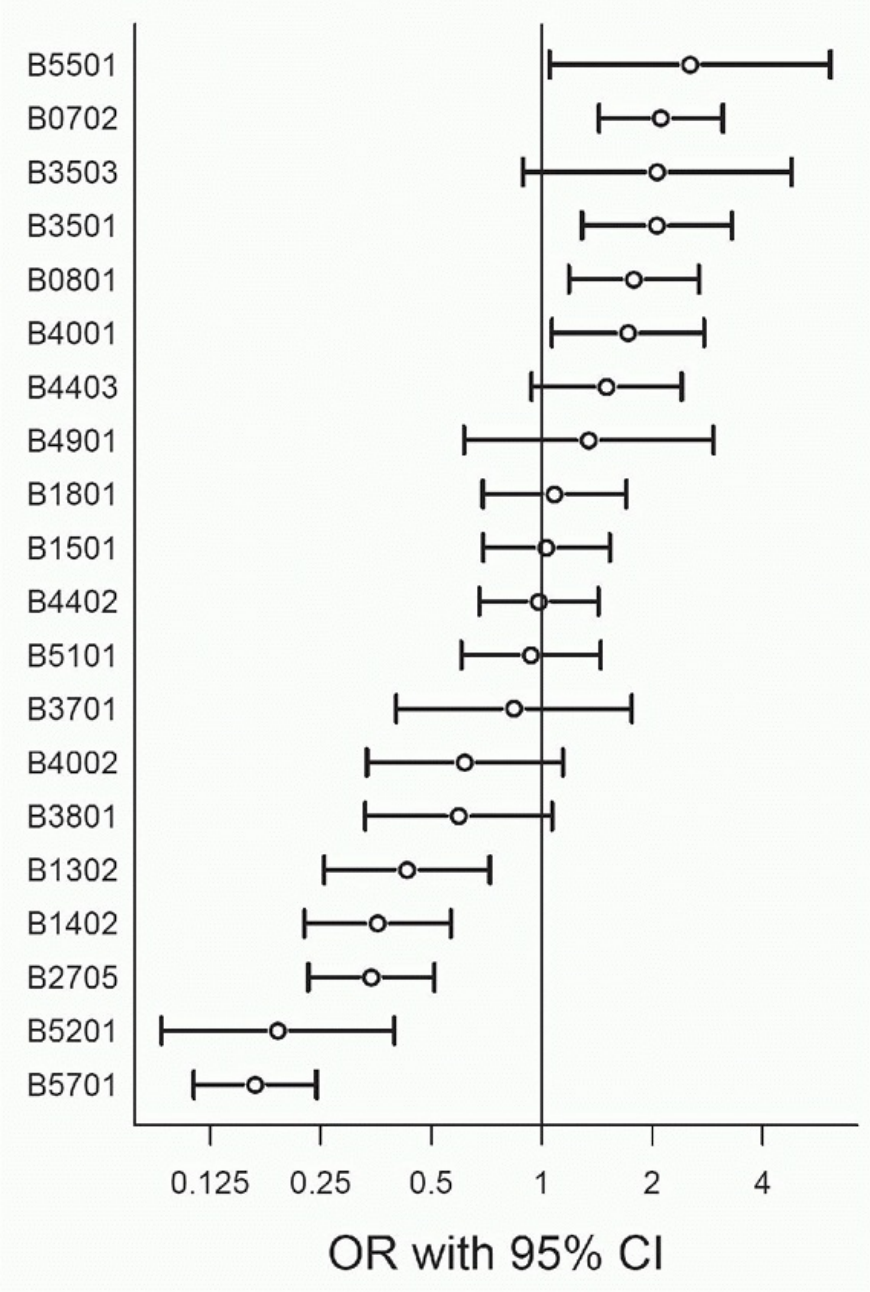

FIG. 42.7. Human Leukocyte Antigen (HLA)-B alleles and Human Immunodeficiency Virus (HIV) Control. Association of HIV immune control and imputed classical HLA-B alleles in a European cohort were calculated using a logistic regression model where all alleles with frequency of 2% or greater were used as covariables in the model. Odds ratio (OR) < 1 indicates association with virologic control of HIV, and OR > 1 indicates association with progression. Raw data was taken from Pereyra et al.[173] Courtesy of M. Carrington.

Because acute HIV infection first becomes symptomatic at the time of peak viremia, very few studies have been able to identify patients early enough to characterize CTL responses during the rapid initial increase in viral load. In the studies that have been done, however, it is clear that the initial CD8 T-cell response is narrowly directed, and it remains narrow when initial set point is achieved.[95,96] Comprehensive screening of cellular immune responses to

sets of 410 overlapping peptides representing the entire HIV proteome at an estimated 28 days after virus exposure revealed an average of only three peptides targeted per person.[96] Because most studies characterizing CD8 T-cell responses have relied on IFNγ ELIspot assays, and have used a reference strain of virus, it is possible that some responses may be missed due to sequence differences in the infecting strain. Indeed, when autologous peptides have been used, the breadth of responses detectable can be up to 30% higher, but even with this caveat most studies

suggest that the initial breadth of responses consists of one to three epitope-specific responses.[95,97] Thus the breadth of responses associated with the dramatic initial decline in viremia is actually quite narrow. The narrowness of these responses is further supported by sequencing of autologous virus in acute infection, where epitopes that subsequently become targeted in the chronic phase of infection are present in wild-type form that should be normally processed and presented, so the lack of detection of responses cannot be ascribed to sequence divergence of the infecting strain from the reference strain used in the assay.[96]

The initial CD8 T-cell response is predominantly targeted to variable regions in the Nef protein, particularly the central region of Nef. Following the transition to chronic infection, targeting of Nef declines, and instead responses to Gag, Pol, and Env become prominent.[98] The fact that these other proteins are subsequently targeted is clear evidence of the preferential immunogenicity of Nef in early infection, although the reason for this remains unclear.

At the time of acute infection, certain HLA alleles predominate in terms of presenting HIV epitopes for CD8 T-cell recognition, and certain epitopes are preferentially targeted, for reasons that remain unclear. For example, of more than a dozen epitopes that have been identified to be presented and targeted through HLA A3 in chronic HIV infection, the same two are consistently dominant in the earliest stages of acute infection, and the other responses arise over time.[99] In genetically identical twins acutely infected with the same virus through injection drug use, the initial dominant and subdominant responses were almost identical, again pointing to a high degree of predictability in terms of the major targets for initial responses.[100] Studies in larger cohorts have confirmed the finding that many epitopes are not targeted in the acute stage of infection, and for each restricting HLA allele there are marked differences in the evolution of responses to different epitopes. Moreover, certain HLA alleles consistently contribute more to the initial CTL response.[101] Interestingly, HLA B*57, the allele most strongly associated with favorable outcome following HIV infection, is associated with less symptomatic acute infection,[97] and the protective alleles were also found to exhibit immunodomination in the early stages of acute infection, in that the presence of protective alleles reduces the absolute magnitude of responses restricted by other alleles.[101,102] The importance of early responses is also reflected in data showing that the immunodominance patterns in acute infection are associated with subsequent viral set point, whereas this relationship is lost during chronic infection.[102]

In addition to differences in terms of epitope targeting in acute compared to chronic infection, the characteristics of the CTL are also different. Functional avidity of responses in acute and chronic infection differ—initial high avidity responses are subsequently lost in persons with

progressive infection, whereas the original clonotypes persist in those who control spontaneously.[103] Studies in persons who control HIV spontaneously, so called "elite controllers,"[52] have shown that the ability of CD8 T cells to proliferate to cognate antigen is associated with control of viremia.[104] Strong proliferative responses by HIV-specific CD8 T cells are detected in acute infection, but decline with the transition to chronic uncontrolled infection.[105] At least part of the proliferative defect in chronic infection is due to a lack of sufficient CD4 T helper cell responses and can be restored in vitro by addition of autologous CD4 T cells obtained at the time of acute infection. The defect in CD8 T-cell proliferation in chronic infection can also be corrected by vaccine-induced HIV-specific CD4 T helper cell responses, suggesting the presence of a reversible defect in CD8 T-cell function.[105,106]

Although Nef is predominantly targeted in acute infection, data from numerous studies indicate that the targeting of Gag during chronic infection is associated with better outcomes. Studies of persons who control virus spontaneously without medication have shown preferential targeting of Gag, whereas responses are more broadly directed in persons with progressive infection.[107] The magnitude and breadth of CD8 T-cell responses to the entire Gag protein or just the p24 protein was found to correlate inversely with viral load and directly with CD4 cell counts; in contrast, there was no association with Env or Nef peptides.[108] In a large study of persons with chronic clade C virus infection in South Africa, the broader the Gag-specific CD8 T-cell response, the lower was the viral load, whereas the broader the targeting of Env, the higher the viral load (Fig. 42.8).[109] Moreover, median viral load in those persons in whom Gag was the dominant target of the CD8 T-cell response was lower than in those in whom the response was predominantly targeted to non-Gag epitopes.[110]

Although the precise correlates of a protective CD8 T-cell response remain to be defined, there is growing consensus that certain functional properties of these cells are associated with better outcome. The ability of CD8 T cells to proliferate in response to cognate antigen is perhaps the strongest association with lower viremia.[104] When CD8 T cells from "low viremic" individuals were exposed to autologous CD4 T cells infected with HIV, not only was the ability to proliferate better maintained, but it was also associated with upregulation of perforin production[104,111] and the ability to load lytic granules upon in vitro stimulation.[112] The ability of cells to produce multiple cytokines, termed polyfunctionality, has also been associated with persistent control of viremia.[113] Analysis of TCR usage comparing persons who control and do not control suggests that TCR clonotypes modulate the antiviral function of CD8 T cells.[113a]

Most studies of HIV-specific CD8 T cells have relied on the use of peptide-pulsed target cells rather than infected cells. As such, multiple steps in antigen processing are not assessed, nor are potential differences in the ability of infected cells to process and present epitopes.[114] When compared to monocytes, CD4 T-lymphocytes have significantly lower proteolytic activity, which impacts epitope generation, but whether this impacts the ability of CTL to clear virus-infected cells is not clear.[114] CTLs clearly have the ability to lyse infected cells and thereby limit virus replication, and in vitro CD8 T cells can actually clear virus infection from infected autologous CD4 T cells.[115] Specificity may make a difference, as preformed Gag protein appears to be processed and presented for recognition,

whereas epitopes in non-Gag proteins must first be synthesized and then processed, making these responses delayed in comparison.[116,117] Similar effects have also been seen with Pol, which is also part of the incoming virus.[117]

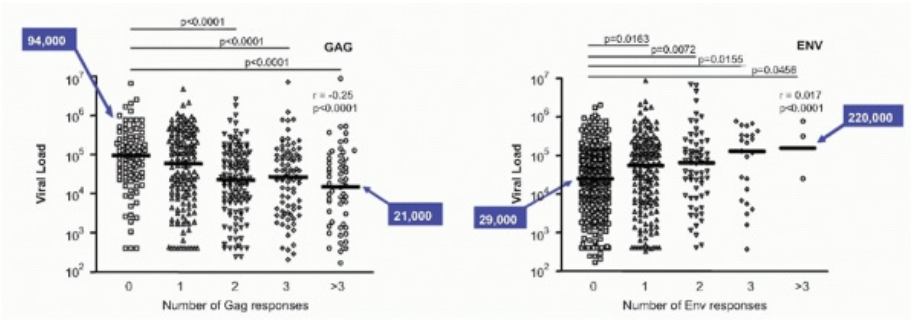

FIG. 42.8. Breadth of Gag and Env CD8 T-Cell Responses and Relation to Viral Load. Broader Gag targeting is associated with lower viral loads whereas dominant Env responses are associated with higher viral loads. Adapted from Kiepiela et al.[109]

In vitro studies show marked differences in the ability of CD8 T cells from different patient groups to inhibit virus replication. CD8 T cells from persons who control HIV spontaneously have the capacity to inhibit virus replication in vitro, without any need for in vitro stimulation, and these cells are phenotypically different from those from progressors, in that they express the activation marker HLA-DR but are negative for another activation marker, CD38. Other studies involving in vitro expansion of CD8 T cells show that lytic granule loading is enhanced in HIV-specific CD8 T cells from controllers compared to progressors.[112] The observed activity appears to be due to a cytotoxic mechanism rather than secretion of soluble factors such as the β chemokines, which are clearly antiviral. Similar studies in persons with chronic infection have revealed that Gag-specific CD8 T cells have enhanced antiviral function compared to those with other specificities.[118] But the relative contribution of lytic activity versus secretion of soluble factors remains controversial, particularly given recent results in animal models suggesting that CD8 T cells can control viremia without reducing the lifespan of infected cells.[119]

CD4 T-Cell Response

Immunologic studies performed at the early stages of the HIV epidemic revealed a striking lack of HIV-specific CD4 T-cell responses in most infected persons. This has long been seen as a central defect in HIV infection, as virus-specific CD4 cells are central to immune control in every setting in which this has been evaluated. They play a major role in immune induction through the production of IL-2 and the activation of antigen-presenting cells via CD40-CD40L interactions and are essential for long-term control of viremia due to help provided to CD8 T cells.[120] HIV preferentially infects CD4 T cells, and during acute infection there is a dramatic loss of CD4 T cells in the GALT as well as the peripheral blood. Unlike the recovery of

peripheral CD4 cell counts when a quasi-set point viremia is achieved, the CD4 cell loss in GALT persists and is not restored even with prolonged antiviral therapy. However, with very early treatment of acute HIV infection, gradual emergence of virus-specific CD4 T-cell responses is observed, and similar responses are characteristic of persons who are able to control virus spontaneously without the need for antiviral therapy.[121,122] It has been hypothesized that these antigen-specific CD4 T cells are preferentially deleted at the time of high-level viremia, as these cells are being maximally activated at this time. However, the majority of HIV-specific CD4 cells remain uninfected, suggesting that these cells may contribute to the level of relative control that is observed.[123]

Renewed interest in HIV-specific CD4 T cells has been sparked in part by results from the RV144 phase III trial of a canarypox prime-recombinant gp120 boost HIV vaccine in which a modest protective effect was correlated with the presence of HIV-specific CD4 T-cell responses but not CD8 T-cell responses.[124] The role of HIV-specific CD4 T cells in immune control and the need to induce these for successful immunization remains controversial. HIV-specific CD4 T cells predominantly target Gag and Env proteins[125] with some interesting associations. A recent study demonstrated that the breadth of total HIV-specific CD4 T-cell responses, and the breadth and magnitude of Gag-specific responses are both inversely correlated with HIV viral load.[125] Additionally, this study suggested that dominant targeting of Gag was more frequently seen in HIV controllers, whereas individuals with progressive disease more frequently targeted Env epitopes. Additional recent data suggest that the presence of cytolytic CD4 T cells at the time of peak and declining viremia in acute infection is associated with a lower viral set point, suggesting an effector role for CD4 T cells.[126]

Immune regulatory networks also appear to play a role and indicate that there is not a total loss of HIV-specific CD4 T cells but rather that these are impaired. In chronic progressive infection, cytotoxic T-lymphocyte-associated antigen 4 is upregulated on CD4 T cells but not CD8 T cells and correlates positively with viral load and negatively

with the ability of HIV-specific CD4 T cells to produce IFNγ.[127,128] Other studies show impaired IL-2 production by HIV-specific CD4 T cells in persons with persistent viremia, although these cells are present in persons who control viremia in the absence of therapy.[128] In settings of relative control, HIV-specific CD4 T cells consist of both central memory cells capable of producing exclusively IL-2 and effector memory cells producing IL-2 and INFγ. In contrast, in viremic patients there are elevated levels of effector memory cells that exclusively produce IFNγ.[128] Functional studies are consistent with a defect in these cells in progressive infection, in that HIV-specific CD4 proliferation is negatively associated with viral load,[122] whereas this association is not seen when one measures the ability to produce IFNγ.[129]

B-Cell Responses

In 1984, Margaret Heckler, the secretary of the Department of Health and Human Services, stated that a vaccine for HIV could be expected within 2 years. Unfortunately, the development of an effective vaccine has proved to be much more challenging. For the majority of currently licensed vaccines, neutralizing viral-specific antibodies have been a

reliable correlate of protection. In HIV, however, several challenges exist to the induction of protective antibody responses. First and foremost is the enormous diversity of the surface Env proteins. This is compounded by the dense glycosylation of the viral Env proteins, which creates a barrier to antibody recognition. This has made it difficult to induce the production of broadly neutralizing antibodies (nAbs) using conventional vaccination strategies. Nonetheless, it appears that 10% to 25% of chronically infected individuals are able to induce antibodies with narrow neutralization properties, with 2% to 4% being able to produce broadly nAbs.[130,131] These antibodies, however, appear to arise only after years of infection. The initial antibody responses shortly after infection are nonneutralizing but are followed by the appearance of responses 12 weeks or more later that are capable of neutralizing autologous viruses, but to which escape mutations quickly develop.[132] These antibody responses do not appear to play a significant role in the control of viremia, as they are directed not against contemporaneous viral populations but against viruses from which escape has quickly developed.

Although antibody responses may not be critical for immunologic control of viremia, they are considered essential to achieve protection from acquisition. There is significant evidence from nonhuman primate models of infection that nAbs are able to prevent HIV acquisition. Passive immunization of rhesus macaques with nAbs protects against infection with vaginal challenge with SIV-HIV chimeric virus.[133,134] Such antibodies have also been shown to be protective when applied directly at the female genital mucosa prior to challenge.[135] Until relatively recently, only a small number of nAbs had been identified. New methods of identification and recovery of single antibody-producing cells, however, have allowed for the identification of many others. This has revealed several sites of vulnerability to nAbs on the Env proteins, including the membrane proximal region of gp41, the CD4 binding site on gp120, Env glycans, and gp120 variable loops, which recognize a quaternary epitope on trimeric gp120 (Fig. 42.9).[136,137,138,139]

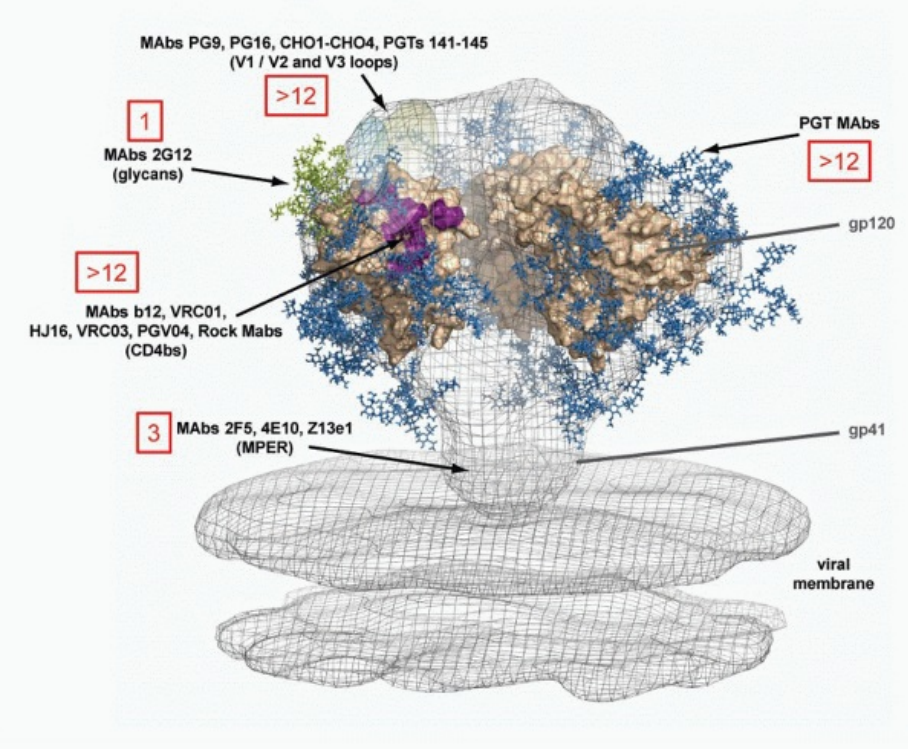

FIG. 42.9. Human Immunodeficiency Virus Envelope Recognition Sites of Broadly Neutralizing Monoclonal Antibodies. Identified neutralizing antibodies target the membrane proximal external region of gp41, and multiple sites on gp120 including the CD4 binding site, a conserved region involving the V2/V3 loops and a patch including a number of high mannose glycans (2G12 and PGT antibodies). In *red* are the approximate number of monoclonal neutralizing antibodies that have been identified that recognize the indicated region of Env. Courtesy of D. Burton.

Although much of the early antibody-directed work was focused on the induction on nAb responses, more recent interest has developed regarding Fc-mediated antibody effector functions such as antibody-dependent cell-mediated cytotoxicity, in part due to studies that show that alterations to the Fcγ receptor binding region of the nAb b12 show reduced protection from SIV-HIV chimeric virus challenge in rhesus macaques.[79,140] Additionally, recent data from the RV144 HIV vaccine trial suggest the possibility of nonneutralizing antibody responses being important in mediating a modest protection from infection. The exact mechanism of this antibody associated protection, however, remains uncertain.

Dendritic Cells in Human Immunodeficiency Virus Infection

A major hallmark of chronic untreated HIV infection is immune suppression. CD4 cell loss certainly contributes to this, but additional dysregulation occurs within DCs, which play a key role in providing cross-talk between innate and adaptive immune responses to viral infections.[141] Both plasmacytoid and conventional DCs can harbor HIV, and both are reduced in numbers in HIV infection; this correlates with increasing viral load and with increased disease progression.[142] This depletion occurs early in acute infection and appears to persist in the chronic phase.

Although DCs express CD4 and conventional coreceptors CCR5 and CXCR4, it remains controversial to what extent these cells are productively infected and

subsequently deleted versus rendered dysfunctional. DC infection ex vivo is inefficient, suggesting that the observed decrease in numbers in HIV may be due to indirect mechanisms or redistribution of DCs to secondary lymphoid tissues. In addition to coreceptors, DC also express the C-type lectin DC-specific intercellular adhesion molecule-3-grabbing nonintegrin (DC-SIGN), which viruses can use to enter DCs through the capacity of gp120 to bind to DC-SIGN. This results in the uptake of virions into early endosomal compartments where HIV is not degraded but maintained and then released after migration to draining lymph nodes to efficiently infect T cells.[143,144] Clusterin, a glycoprotein found in a number of tissues and blood, specifically blocks HIV-DC-SIGN interactions and prevents transmission of HIV to CD4 T cells when present in semen. It may help explain why sexual transmission is less effective than bloodborne exposure, as clusterin in blood is differently glycosylated and does not have this effect.[145]

The HIV single-stranded RNA genome encodes tolllike receptor 7/8 agonists that are recognized by DCs and lead to the induction of inflammatory cytokines through a mechanism that involves internalization of virions.[146,147] There is also evidence that infected DCs may be able to recognize HIV through interaction of newly transcribed HIV capsid with the cellular protein cyclophilin A, which results in the induction of type I IFNs by the transcription factor IFN regulatory factor 3.[148] Although the interaction of DCs and HIV is complex and the overall numbers of DCs appear to be reduced in the blood during HIV infection, the degree to which DCs are functionally impaired during infection remains unclear. Plasmacytoid DCs from persons with progressive disease only partially mature upon stimulation and may contribute to chronic immune activation and further CD4 T-cell infection by production of copious amounts of IFNα that induces a chronic inflammatory response.[149] There is evidence that myeloid DCs from HIVinfected individuals appear to have reduced responsiveness to toll-like receptor agonists and are less efficient at T-cell activation.[150,151,152] However, other studies indicate that both myeloid and plasmacytoid DCs from HIV-infected individuals continue to be capable of activating T cells and producing cytokines in response to toll-like receptor agonists.[153,154] Evidence also exists that DCs can become tolerized in vivo in infected persons, reducing the ability to induce immune responses.[155]

Immune Selection Pressure and Escape from Cellular Immune Responses

HIV has an enormous ability to escape from immune responses, including NK and antibody responses, as discussed previously. However, our most detailed understanding of immune escape comes from the study of viral adaptation to CD8 T-cell responses. In most infected persons, virus continues to replicate in the presence of a CD8 T-cell response that is insufficient to completely contain viremia. In the same way that incomplete control of viral replication leads to emergence of drug-resistant viruses, incomplete immune control is associated with escape mutations that diminish recognition by the established T-cell response. Analysis of large datasets of patient-derived sequences reveals a profound impact of CTL responses in driving HIV evolution.[156,157,158] The clinical significance of this has been shown in infants born to HLA B*27-positive HIV-infected mothers.[159] HLA B*27-positive

infants who received the HLA allele from their fathers and the virus from their mothers were able to control viremia through induction of a strong HLA B*27-restricted T-cell response to a dominant epitope in Gag. In contrast, in B*27-positive infants whose mothers were also B*27-positive, transmitted viruses were found to have already escaped from the dominant B*27-restricted response in the mother, and thus there was no targeting of this otherwise dominant B*27-restricted Gag epitope in their children.

The kinetics of immune escape are just beginning to be understood, in part because of the paucity of studies in the earliest stages of infection, before the decline in viremia from peak levels. What is clear is that escape can occur within days to weeks of infection. In studies in which autologous virus was sequenced and responses screened with peptides representing the autologous strain, clear evidence of immune escape was evident within 25 to 32 days of infection, coinciding with peak viremia.[95] Longitudinal studies in persons with acute infection have shown selection for CTL escape mutations arise at quite variable rates depending on the epitope and the restricting HLA allele.[160] Deep sequencing has revealed that the virus explores multiple pathways to immune escape, and that there can be numerous variants that arise at low levels within targeted epitopes—so low that they are missed by traditional sequencing methods.[161,162] What remain unclear are the factors that contribute to immunodominance and immunodomination. For a given HLA allele, it has become increasingly clear that the earliest immune responses are predictable, as are the pathways to immune escape.[163] Likewise, it is also clear that certain responses do not arise in the presence of other HLA alleles, a phenomenon called immunodomination.[101]

One of the challenges in defining the role of escape mutations in disease progression is defining mutations that lead to an immunologic impact. Mutations within targeted epitopes are most frequent and can lead to full or partial loss of recognition by the T-cell receptor or loss of peptide-binding to the restricting HLA class I allele. Mutations within residues flanking epitopes also account for immune escape through alterations in antigen processing.[164,165] Detection of immune escape presents a potential problem using simple IFNγ ELIspot assays, as these may still indicate recognition because they do not incorporate potential confounding effect of antigen processing. More recent focus on assays that incorporate infected target cells, in which antigen-processing events are required for recognition, may provide a better sense of the true measure of immune escape, and may be needed in order to finally define the contribution of immune escape to disease progression.

It is important to note that immune escape can have either positive or negative impact on viral control, due to the possibility that escape mutations can confer a fitness cost

to the virus. In other words, there are competing factors: on the one hand, escape leads to loss of recognition by an established immune response, and on the other hand, it can result in a virus that is markedly impaired in its pathogenic potential. This effect may be most important in the Gag protein, where recent data suggest multidimensional constraints of HIV evolution due to structural constraints on capsid formation.[166] Indeed, viruses obtained from elite controllers have been shown to be less fit overall, and selective targeting of regions of Gag under multidimensional constraints on evolution by persons who control HIV spontaneously may contribute to durable control.[166] Transmission of escape variants with

reduced fitness has been linked to less severe disease in recipients[167,168] and has also been associated with subsequent reversion to wild type, a clear indication of a fitness cost to the virus that can revert in the absence of ongoing immune selection pressure in a recipient lacking the restricting HLA allele for that epitope.

HUMAN IMMUNODEFICIENCY VIRUS IMMUNOGENETICS

The associations between class I alleles and viral control suggest that class I-restricted CTLs play a role in limiting HIV replication, and large population studies coupling HLA typing with sequence analysis of the viruses circulating in vivo add to this evidence. HLA class I-associated mutational "footprints" have been identified in HIV-1, suggesting that this rapidly mutating virus is adapting to immune selection pressure.[156,169] Given the role of HLA molecules in determining the repertoire and specificity of the immune response, these data point most strongly toward the CD8 T-cell responses being involved in immune control.

Additional insight into the immunogenetics of HIV infection has come from genome-wide association studies. In a study of persons with acute infection, two single nucleotide polymorphisms (SNPs) in the major histocompatibility complex locus were independently associated with viral control, one associated with HLA-C expression and another that is a proxy for HLA B57,[170] already known to be associated with better outcome. These two plus an additional two independently associated SNPs were subsequently identified in genome-wide association study analyses of persons termed HIV controllers, who maintain viral loads of < 2,000 RNA copies/mL in the absence of therapy.[171,172] Genome-wide association study analysis of these HIV controllers also demonstrated that aside from the signal in the region of HLA-B and -C in chromosome 6, most of the previously reported host genetic influences on HIV control could not be replicated (Fig. 42.10A). Indeed, only the chemokine cluster in chromosome 3, which harbors the gene encoding CCR5, the coreceptor associated with HIV entry, was found to be statistically significantly associated with viral control when controlled for population structure and corrected for multiple comparisons.[173,174]

Further insight into the mechanism of the effects of these SNPs has been revealed by the observations that they "tag" specific features within HLA sequences themselves: specific amino acids within the HLA-B peptide binding groove, as well as an independent SNP associated with HLA-C expression.[173] Specific amino acids at the HLA-B positions, particularly positions 67, 70, and 97, are associated with differential ability to control HIV viremia, providing a mechanism of action for the SNP associations and suggesting that the nature of the peptide-HLA-B interaction is key to HIV control (Fig. 42.10B). In addition to these HLA-B associations, a SNP 35 kb upstream of the HLA-C gene was also strongly associated with control of viral load and with levels of HLA-C expression. The mechanism of this effect has been linked to variation with the 3′ untranslated region of HLA-C that is posttranscriptionally regulated by a microRNA, resulting in differences in HLA-C expression. The variant that does not bind this microRNA results in high expression of HLA-C and better control of HIV.[175] Unlike HLA-A and -B, which are downregulated during HIV infection, HLA-C is not.[176] Thus higher levels of HLA-C may prolong the ability of infected cells to be targeted by CTLs, after HLA-A and -B have been downregulated, thereby conferring a benefit. However, the antiviral efficacy of HLA-C-restricted responses does not approach the level of immune selection pressure applied through -A and -B, as evidenced by the paucity of

HLA-C-associated footprints on the viral genome. Another possibility is that high expression of HLA-C may lead to more effective education and maturation of NK

cells due to better engagement of inhibitory NK-cell receptors with their HLA-C ligands, resulting in stronger NK-cell responses to infected cells.

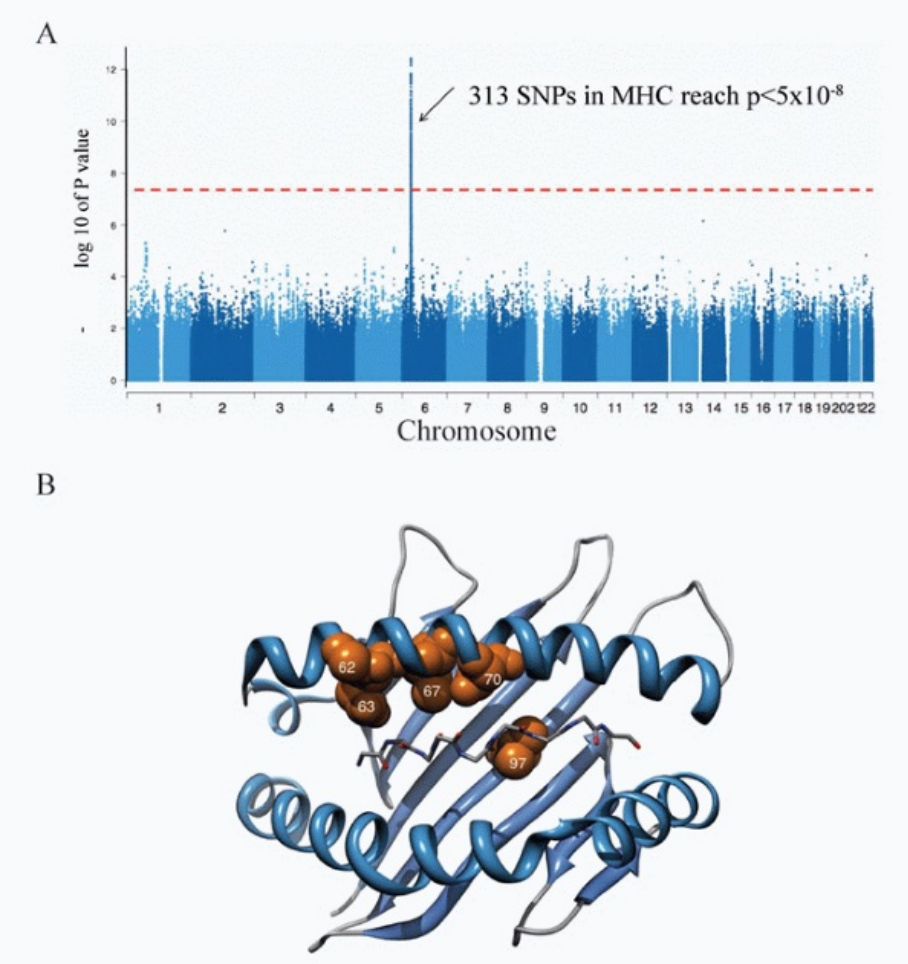

FIG. 42.10. Human Leukocyte Antigen (HLA) and Immune Control of Human Immunodeficiency Virus (HIV). A: Genome-wide association study of 1.3 million single nucleotide polymorphisms show a significant association with a region in chromosome 6 encoding HLA-B and C. **B:** Discrete amino acids within the HLA-B peptide biding groove at positions 67, 70, and 97 are associated with immunologic control of HIV. Adapted from Pereyra et al.[173]

HLA class II associations with HIV disease outcome have also been reported, but the data are less convincing than for class I. Class II "footprints" have not been convincingly identified, suggesting that responses restricted by HLA class II either exert less selection pressure or that epitopes are presented so promiscuously on different class II alleles that clear signatures cannot be discerned.

In addition to HLA class I alleles, the KIR locus has also been implicated in modulating control of HIV viremia, suggesting the potential involvement of NK cells in human control of HIV. KIR,

like HLA, is one of the most polymorphic loci in the human genome. The *KIR* genes, located on chromosome 19, encode molecules that regulate NK-cell activity, with stimulatory and inhibitory effects. Analysis of AIDS progression rates in untreated persons with HIV infection have shown a protective effect of the activating KIR allele *KIR3DS1* and its putative ligand, HLA-B Bw4 alleles that contain an isoleucine at position 80 (Bw4-80I).[77] In contrast, in persons who express KIR3DS1 in the absence of HLA Bw4-80I progression is more rapid, whereas expression of HLA B Bw4-80I in the absence of KIR3DS1 has no effect. In addition to these effects of an activating KIR on disease progression, other studies have shown that certain alleles of the inhibitory receptor KIR3DL1 also provide protection against disease progression, and that protection relates to the relative expression levels of KIR3DL1.[78] Interestingly, this allotype acts synergistically with HLA B*57, which contains the KIR3DS1 ligand Bw4-80I.[78] Thus, data exist suggesting a protective role of both activating and inhibitory KIRs in control of HIV.

HUMAN IMMUNODEFICIENCY VIRUS PREVENTION

Developing a Human Immunodeficiency Virus Vaccine

Despite the success of potent ART, it has been a challenge to deliver medicines to all those in need. Even with billions of dollars spent on rollout of drug delivery in developing regions, only 5 million of the 23 million HIV-infected individuals in sub-Saharan Africa are currently receiving HIV medicines.[177] The prospect of delivering lifelong HIV treatment to individuals living in regions of the world where there is little health care infrastructure and unreliable access to food and safe drinking water is truly daunting. Although treatment is a critical component of the global fight against HIV, the development of an efficacious preventative vaccine remains paramount to ending the AIDS pandemic. It has been estimated that a prophylactic vaccine with only 50% efficacy, delivered to just 30% of the population, could reduce annual infections by up to one-third, averting 17 million infections over the next 15 years.[178] And yet, the HIV vaccine field has not been able to make significant headway toward this goal. To date, only three HIV vaccine candidates have been tested in large-scale trials, and all of them have failed to provide compelling evidence that an effective vaccine will be produced in the near future.[179]

The first candidate vaccine to be tested in a large efficacy trial was the VaxGen recombinant gp120 protein, which was used in over 5,000 participants in the AIDSVAX trial. The vaccine utilized a recombinant subunit protein to induce antibody responses, an approach that is the basis for the currently licensed hepatitis B vaccine. Initial results in chimpanzees were promising, showing that gp120 vaccination could protect from subsequent HIV challenge with a laboratory isolate.[180] Yet after 3 years of follow-up in the AIDSVAX study, acquisition rates in vaccine recipients and those who received a placebo were statistically indistinguishable.[181,182]

In part because of the difficulty in inducing broadly neutralizing antibody responses against HIV and an appreciation of the important role of CD8 T-cell responses in virologic control of infection, interest increased in vaccines that induce T-cell responses. Although such vaccines may not protect from HIV acquisition, they may be able to reduce viral set point and delay development of AIDS. Cohort studies have shown that viral set point inversely correlates with

disease progression and thus such vaccines may be able to delay the time before ART is needed.[183] The STEP trial, the second large HIV vaccine trial to be undertaken, tested the T-cell vaccine concept in a phase IIb trial of an adenovirus serotype 5 vaccine. The vaccine consisted of an equal mixture of three replication defective adenoviral vectors, each containing a near consensus clade B gag, pol, or nef gene. The trial was opened in 2005 and cosponsored by Merck and the National Institute of Allergy and Infectious Disease, but in September 2007 it was halted early when interim analysis showed that the vaccine failed to prevent HIV infection and had no effect on viral load at 3 months after infection.[184,185] Although this test-of-concept vaccine failed to show a result in either of the two primary endpoints (HIV acquisition and viral load), it generally has been seen as a first step and not as a condemnation of the T-cell vaccine approach per se. In the wake of STEP, the most recent efficacy trial was the RV144 "Thai vaccine" trial.[124] This approach utilized a recombinant canarypox vector prime with a recombinant gp120 boost strategy and was designed to induce both antibody and T-cell responses. Although there were no significant differences in acquisition or viral load using intention-to-treat analysis, a modified intention-to-treat analysis showed a 31% decrease in acquisition in vaccine recipients with no effect on viremia or CD4 T-cell count. Interestingly, this effect did not correlate with HIV-specific CD8 T-cell responses as measured by ELIspot or intracellular cytokine staining but did correlate with the presence of nonneutralizing antibody responses and Env directed CD4 T-cell responses.

The path to an effective vaccine is likely to be long. There are few new concepts currently in early-stage clinical trials, and some have argued that more focus needs to be placed on understanding basic immunologic mechanisms of vaccine-induced protection. Nevertheless, the apparent partial efficacy of the Thai trial has boosted morale and has led to a resurgence in vaccine development and testing that hopefully will pay out dividends in the future. Nonetheless, although a vaccine will likely be necessary, it may ultimately

be only one component of efforts to successfully control the epidemic.

Other Human Immunodeficiency Virus Prevention Strategies

Globally, over 90% of HIV is transmitted following heterosexual intercourse. Besides abstinence and barrier contraception, the most effective methods of transmission prevention utilize ART (Fig. 42.11). The best established method of antiretroviral prevention of transmission is in the setting of prevention of mother-to-child transmission. Peripartum treatment of the mother can reduce the risk of transmission to 5% in breastfeeding children and less than 2% in nonbreastfeeding children, even with short-course therapy.[186] The use of ART for prevention of mother-to-child transmission has been widely applied and is the major driver of the global reduction in mother-to-child transmission in the developing world. A newer application of "treatment as prevention" was studied in the HIV Prevention Trails Network 052 study of serodiscordant couples, where ART treatment of the infected partner was shown to reduce transmission by 96%, thus providing compelling evidence that treatment for prevention is effective.[42] A 73% reduction was also seen in the Partners PrEP Study of serodiscordant couples in which the uninfected partner was given ART. Clearly, these strategies makes sense for individuals at high risk of transmitting within serodiscordant couples who do not use barrier contraception, but how widely these strategies should be applied to other populations remains controversial.

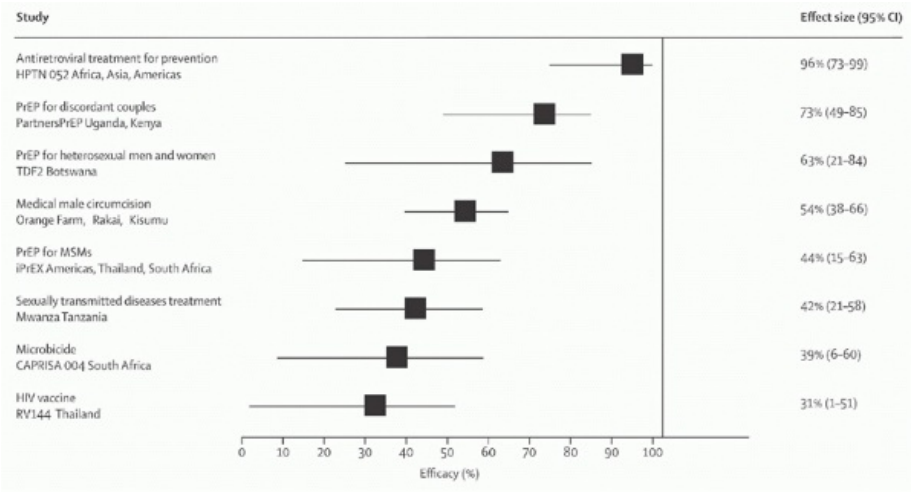

FIG 42.11. Human Immunodeficiency Virus Prevention Methods Testing in Randomized Controlled Trials. From Karim and Karim.[191]

The potential utility of the use of ART in at-risk uninfected individuals as “pre-exposure prophylaxis” to prevent transmission remains uncertain. Initial promising results in the use of an oral daily fixed-dose combination of tenofovir and emtricitabine as pre-exposure prophylaxis in HIV-negative men who have sex with men taking part in the Iniciative Profilaxis Pre Exposicion or Preexposure Prophylaxis (iPrEX) study showed a 44% decrease in risk of HIV acquisition.[187] However, a similar strategy when used in at-risk women exposed via heterosexual intercourse failed to show any protective effects.[188] Researchers have suggested that this difference may have to do with the pharmacologic properties of tenofovir and emtricitabine, or may be related to adherence in the female participants, as the protective effects observed in the men who have sex with men study were only seen in those who took ART regularly. Additional research is underway to better elucidate these differences.

Besides oral therapy, antiretroviral treatment has been incorporated into microbicides to topically delivery drugs at the area of exposure. This approach has the advantage of low toxicity and up to 100× higher levels of drugs within the mucosal site of exposure. The landmark Center for the AIDS Programme of Research in South Africa (CAPRISA) 004 trial of a vaginal microbicide containing tenofovir showed a 39% reduction in HIV acquisition among at-risk heterosexual South African women.[189] However, it was recently announced that a tenofovir microbicide arm of the Vaginal and Oral Interventions to Control the Epidemic (VOICE) trial was halted due to a lack of efficacy. This has generated questions regarding why differences were seen be

tween the two studies, and closer examination of the results are currently underway.

CONCLUSION

Overall, it is clear that although tremendous advances have been made in the treatment and prevention of HIV, much more remains to be done. Halting the AIDS pandemic will require a multipronged approach, relying on expanding treatment rollout, defining the most effective

antiretroviralbased methods for prevention, and implementing structural and behavior interventions such as male circumcision and prevention education and programs to reduce risk behaviors. Importantly, a safe and effective HIV vaccine will also be needed as a primary component of these efforts. However, to produce such a vaccine will require a more detailed understanding of HIV immunity and host interactions. In the first 30 years since the discovery of HIV as the causative agent of AIDS, an enormous amount has been learned, but significant challenges clearly remain. To overcome these challenges will require the continued dedication and support of clinicians, researchers, patients, funders, and the public at large. The pace of discovery continues to be rapid and hopes high that this is a disease that can be eventually prevented in those not yet infected and potentially eradicated in those who are.

Chapter 43

Vaccines

Ennio De Gregorio
Ugo D'Oro
Sylvie Bertholet
Rino Rappuoli

INTRODUCTION

Over the last century, vaccination has been the most effective medical practice to control infectious diseases. Smallpox has been eradicated worldwide, and polio has been almost eliminated. Most viral and bacterial diseases traditionally affecting children worldwide are now preventable with vaccines (see www.who.int/vaccines-documents). Vaccination is estimated to save two to three million lives per year. Traditional vaccines designed following the basic Pasteur principle (isolate, inactivate, and inject) have been extremely successful in preventing infections by pathogens expressing relatively conserved antigens mainly through antibody-mediated mechanisms. However, there is still a long list of diseases that are not preventable by vaccination, and infectious diseases are still a major cause of death and disability worldwide. Some of these diseases are caused by pathogens that have a high degree of antigen variability and cannot be controlled only by antibodies but require a mix of humoral and cellular immune responses. As an example, the world is still waiting for effective vaccines against the three big killers: acquired immunodeficiency syndrome (AIDS), tuberculosis (TB), and malaria, which collectively kill almost five million people per year. Therefore, the development of new vaccines can still have a tremendous impact in reducing the mortality caused by infectious diseases throughout the world. Novel technologies for antigen identification, structural design, and formulation now allow for the development of safer vaccines that can better cope with pathogen diversity. In addition, progress in the field of innate immunity is translating into the development of novel classes of vaccine adjuvants that can promote, better than in the past, protective humoral and cellular immune responses. Significant research efforts are also being applied toward the development of therapeutic vaccines against cancer, allergy, autoimmunity, and other inflammatory disorders that could have a major impact on human health across the world. However, in this context, we will focus mainly on preventive vaccines against infectious diseases, although therapeutic vaccines against cancer will not be covered here. This chapter will give a short overview of the history of vaccine development and will describe most of the existing licensed vaccines for the prevention of infectious diseases. In addition, we will give details on novel approaches to develop effective vaccines against human immunodeficiency virus (HIV), malaria, and TB. One paragraph is dedicated to licensed and experimental vaccine adjuvants, with special focus on their immunologic mechanism of action. Other sections of this chapter will analyze new technologies that can either improve existing vaccines or allow the development of novel effective vaccines where conventional technologies have failed. Another section will concentrate on novel needle-free vaccine delivery systems. Finally, the last paragraph will review the major challenges pertaining to vaccines in the 21st century society.

HISTORICAL PERSPECTIVES

Smallpox: From Variolation to Vaccination

Smallpox, one of the most severe human viral diseases, is transmitted by inhalation of orthopoxvirus *Variola*. Before vaccination, smallpox outbreaks where quite frequent, killing more than 30% of infected people. It is estimated that in the late 18th century in Europe, 400,000 people died annually of smallpox. A method for preventing naturally acquired smallpox was discovered in India before AD 1000 and spread to China and western Asia. This method, called “variolation,” was introduced in Europe in 1721 by Lady Mary Wortley

Montagu after her return to England from Constantinople were she observed the use of the technique. Variolation consisted in the inoculation of pustule material from patients infected with smallpox in the skin or in the nose of noninfected people to protect them from the outbreaks. Of course, the practice was not safe, with a mortality rate ranging from 1% to 2%; however, it generally produced an illness that was less severe than natural *Variola* infection by inhalation. A variolation campaign was introduced in Siena, Italy in 1758 as reported in a dedicated publication by the local Academy of Science in 1760 (Fig. 43.1). The symptoms experienced by a child in the days following variolation are described in the following translated excerpt.

> In the year 1756, on the 8th of June, day on which the weather was very hot, Gherardo, son of Mr. Giovanni Pavolotti, was inoculated with smallpox…. A small cut was performed on each arm, and a wad of cotton wool soaked in the pus of a smallpox pustule of his brother, who had naturally acquired the disease, was applied. His arms were wrapped and the bandages were removed for the first time on the second day to treat the wounds. The cuts were almost dry and showed no change in color or other signs on the surrounding skin. The child showed not even the slightest discomfort; he went about the house enjoying his childish babble as usual; his pulse was steady, normal, the same as before the operation….
>
> Fourth day. The cuts started to hurt occasionally and to a small degree, they were red and started to fester…
>
> Sixth day. All became more serious. He complained a lot about the cuts; they were more open, festering,

> swollen, and quite uneven around the edges. At midday he felt cold, then he became hot, feverish. In the evening, he vomited bitter, biliary fluids. His eyes were teary, light did not bother him very much. The cuts had small blisters in the middle and around the uneven edges. They were fetid. Moderate fever, no thirst. He was kept under watch overnight. Moderate urination with dark yellow sediment.
>
> Seventh day. The cuts were more swollen, more festered, more fetid, the blisters were white, some were open. He complained about shooting pain in the armpits. At midday he became very hot, the fever rose, he was thirsty, somewhat shivering, frightened, spoke senselessly…
>
> Eighth day. At sunrise he slept at length. All was very pleasant. The cuts were very festered. The blisters that had appeared on the sixth day were open. There were some smallpox pustules around the cuts…
>
> Ninth day. No fever at all…
>
> Tenth day. The rash stopped. The blisters started to fester. The child got up from bed and walked about the house.
>
> Sixteenth day. The blisters were dry and the scabs started falling. The cuts were red, there was less pus, which was not so fetid…
>
> Twenty-fourth day. The cuts had cicatrized. On that day, the child went outdoors for a walk and the blister marks were hardly visible.

FIG. 43.1. Front page of the publication by the Academy of Science of Siena reporting the history of the variolation campaign made in Siena between 1758 and 1760. Reproduction by courtesy of the Accademia de' Fisiocritici, Siena, Italy.

A real vaccination practice was introduced when Edward Jenner replaced smallpox-infected material with pustule material from humans infected by cowpox. Cows can be infected by a virus similar to *Variola*, called *Vaccinia* virus, and develop a smallpox-like diseases called cowpox that can be transmitted to humans. It was quite frequent that people in close contact with cows, such as milkmaids, would contract cowpox and develop sores on fingers and hands. In the 18th century, several physicians noticed that people exposed to cowpox were protected from smallpox and did not react to variolation. In 1796, Edward Jenner demonstrated for the first time that pustule material taken from a milkmaid infected by cowpox when inoculated into the skin of another person produced a localized self-limiting infection, which, a few months afterward, was able to protect from smallpox challenge (by variolation). He also demonstrated that the same individual was still protected from smallpox variolation 5 years later, confirming the persistence of immunity. Jenner called the material used for the inoculum *Vaccinia* (from "vacca," the Latin name of cow) and the process "vaccination." For many years, vaccination became a standard practice in several countries and replaced variolation. At the beginning, vaccination was still relying on the arm-to-arm inoculation of human infected material. This process led to a progressive attenuation of the inoculum and was often associated with the transmission of other human diseases from the donor. Therefore, by 1890, human infected material was replaced by the use of

vesicle fluid from infected cows. In 1940, Collier developed a modern commercial process to produce a stable freeze-dried vaccine for large-scale smallpox prevention. Because *Variola* virus is transmitted from human to human and does not have any animal reservoir, it was hypothesized that eradication of smallpox through vaccination was possible. In 1959, the World Health Organization (WHO) set global smallpox eradication as a goal, but it was only in 1966 that a Smallpox Eradication Unit was formed. The global eradication program started in 1967. It is estimated that at that time, there were still 10 to 15 million cases of smallpox worldwide. The vaccination campaign lasted about 10 years and was extremely successful. The last case of naturally contracted smallpox was recorded in 1977 in Somalia, and in 1979, the Global Commission for Smallpox Eradication certified that global smallpox eradication had been achieved.

Nineteenth Century Vaccines

The first successful vaccine was discovered by Jenner without any understanding of its mechanism of action. The microbial origin of infectious diseases was discovered many years later by Louis Pasteur and Robert Koch. Both scientists gave a dramatic impulse to vaccine research. Pasteur discovered that bacteria grown in vitro for a sufficient amount of time lose their virulence and become attenuated. He proposed that these live-attenuated microorganisms could be used to inoculate individuals similarly to what Jenner had done in

the case of cowpox. In honor of Jenner, Pasteur extended the word “vaccine” to all preparations used for immunization. Initially, Pasteur worked on animal models demonstrating that live-attenuated chicken cholera provides immunity against an experimental challenge with virulent organisms. Later, he showed that attenuated anthrax bacilli protected sheep from infection. After demonstrating the vaccination principle in animals, Pasteur worked on an attenuated rabies preparation that was first administered in humans in 1885. This vaccine was prepared by infecting rabbits with rabiesinfected material for several passages and then recovering rabbit spinal cord. The virulence of spinal cord material was further attenuated by exposing it to dry air. Pasteur's rabies vaccine was administered for the first time subcutaneously in 13 doses over a 10-day period to Joseph Meister, a boy who had been bitten by a rabid dog 60 hours before and had no chance to survive. Thanks to vaccination, the patient resisted the development of the disease. At that time, Pasteur did not know that rabies was caused by a virus belonging to the family of *Rhabdoviridae* that takes several days from the time of infection to reach the central nervous system, making postexposure prophylaxis possible. Today, several antirabies vaccines exist and are all made of chemically inactivated virus grown in duck embryos or in cell culture.

Pasteur thought that only live-inactivated pathogens could be used for effective vaccination. The concept of killed vaccines was introduced in 1886. After Robert Koch discovered *Vibrio cholerae*, Daniel Elmer Salomon and Theobald Smith showed that a killed suspension of *V. cholerae* from hogs protected pigeons from the disease. Similar data were presented by a group working at the Pasteur Institute. These findings paved the way for the development of human killed whole-organism vaccines against typhoid fever (1896), cholera (1896), and plague (1897) (Table 43.1).

TABLE 43.1 Development of Human Vaccines

Live Attenuated	Killed Whole Organism	Toxoid/Protein	Polysaccharide	Glycoconjugate	Recombinant	Century
Smallpox						18th
Rabies	Typhoid Cholera Plague					19th
Tuberculosis (BCG) Yellow fever Polio (OPV) Measles Mumps Rubella Typhoid Varicella Rotavirus Cholera	Pertussis Influenza Typhus Polio (IPV) Rabies JE TBE HAV	Diphtheria Tetanus Acellular Pertussis Anthrax Influenza subunit	Pneumococcus Meningococcus Hib Typhoid (Vi)	Hib	HBV Lyme disease Cholera toxin B	20th
Cold-adapted influenza Rotavirus reassortants Zoster				Pneumococcus MenACWY	HPV	21st

BCG, Bacille Calmette-Guérin; HAV, hepatitis A virus; HBV, hepatitis B virus; Hib, *Haemophilus influenzae* type b; IPV, inactivated polio vaccine; JE, Japanese encephalitis; Men, meningococcus; OPV, oral polio vaccine; TBE, tick-borne

encephalitis.

Twentieth Century Vaccines

At the end of the 19th century, the basic principle acknowledged in vaccinology was to isolate the causative agent of disease, attenuate or kill the agent, and immunize. This principle allowed for the development of many live-attenuated and killed vaccines. The first important innovation in vaccinology in the first half of the 20th century was the discovery of vaccines based on inactivated toxins, also called toxoids. Bacterial toxins had already been identified in the 19th century. In 1888, Roux and Yersin identified diphtheria toxin. Two years later, Emil von Behring and Shibasaburo Kitasato discovered the presence of antitoxins in serum. In 1891, passive immunization using sera of animals immunized with low doses of diphtheria and tetanus toxins became available. However, toxins were not used as vaccines because they were too dangerous. At the beginning of the 20th century, Theobald Smith demonstrated that vaccines made from chemically inactivated toxins protected guinea pigs from infection. In 1923, Alexander Glenny showed that diphtheria toxin can be chemically inactivated by formalin, leading to the first human toxoid vaccine against diphtheria. In 1926, another formalin-inactivated toxoid vaccine against tetanus was introduced by Gaston Ramon and Christian Zoeller.

During the same period, the application of Pasteur's principle led to the development of two new live-attenuated vaccines against TB and yellow fever. The TB vaccine was developed by Albert Calmette and Camille Guérin at the Pasteur Institute. They started from a *Mycobacterium bovis* strain that was attenuated for 13 years by 230 passages in culture media. The resulting Bacille Calmette-Guérin (BCG) strain became available for human vaccination in 1927. The first yellow fever vaccine was developed by attenuating the virus in a culture medium made of mouse brain tissue and was introduced in 1932. A few years later, the introduction of embryonated eggs as a medium for growing viruses allowed for the development of a new, safer, more attenuated vaccine to prevent yellow fever infection from a strain called 17D. Embryonated eggs were also used to develop the first two human vaccines against type A influenza. In the same year (1936), a live-attenuated influenza vaccine was introduced by Wilson Smith while a killed whole virus vaccine was developed by Thomas Francis and Thomas Magill. In the first half of the 20th century, two additional whole-killed bacterial vaccines against typhus and pertussis were developed, and in 1948, the first combination vaccine against diphtheria, tetanus, and pertussis became available.

The second half of the 20th century is considered the golden age of vaccine development. Probably, the most important technologies introduced at that time are related to the production of human viruses in controlled cell culture conditions, which allowed for the development of several new virus vaccines. Among them, the two vaccines against poliovirus are perhaps the ones that gained the greatest public interest. Before vaccination, more than 20,000 cases of polio were reported annually in the United States. A formalin-inactivated polio vaccine (IPV), developed by Jonas Salk, was licensed in 1955. A few years later (1960), a liveattenuated polio vaccine for oral administration (oral polio vaccine [OPV]) was developed by Albert Sabin. Owing to global vaccination programs, polio has been eradicated in most countries and remains endemic only in some areas of Afghanistan, India, Pakistan, and Nigeria. Other liveattenuated virus vaccines licensed between 1950 and 1970 are against measles, mumps, rubella, and varicella. More recently (1998), an oral live-attenuated vaccine against rotavirus infection was licensed in the United States, Europe, and other countries. In addition to live-attenuated vaccines, new whole-killed virus vaccines have also been licensed, including a hepatitis A virus (HAV) vaccine in 1979 (Table 43.1).

In the second part of the 20th century, several bacterial vaccines were developed using purified polysaccharides. Monovalent vaccines to prevent meningococcus (Men) group A was first licensed in 1974 followed by a MenC and a bivalent MenAC vaccine in 1975, and a quadrivalent MenACWY later in 1982. A 14-valent pneumococcus vaccine was licensed in 1977 followed by a 23-valent vaccine in 1983, whereas a vaccine against *Haemophilus*

influenzae type b (Hib) was licensed in 1985. However, polysaccharide vaccines are not protective in children younger than 18 months, who are at most risk of contracting the disease. This problem was solved when it was shown that the immunogenicity of polysaccharides could be enhanced by linking them to a carrier protein such as diphtheria toxoid (DT) or tetanus toxoid (TT). This new class of vaccines, called glycoconjugates, is immunogenic in all age groups, including infants. The first glycoconjugate to be licensed was a Hib vaccine developed by Robbins and Schneerson (1987).[1]

Another important innovation in vaccinology introduced in the 20th century has been the use of a genetically modified toxin as a vaccine first applied to pertussis.[2] Finally, the use of recombinant proteins instead of the antigens purified directly from the pathogens has been a major breakthrough. A vaccine made of hepatitis B surface antigen (HBsAg) expressed in yeast and adsorbed to alum was the first recombinant protein vaccine for human use licensed in 1987. The vaccine takes advantage of the property of HBsAg to self-assemble in a viral-like particle (VLP), resulting in an increased immunogenicity. A second recombinant protein vaccine based on the OspA antigen from *Borrelia burgdorferi* expressed in *Escherichia coli* was licensed in 1999 to prevent Lyme disease. However, the vaccine was withdrawn from the market in 2002 due to a lack of demand.

Twenty-first Century Vaccines

Several novel vaccines were licensed in the first decade of the 21st century. Three of them (cold-adapted influenza, novel rotavirus, and zoster) are based on live-attenuated pathogens. Others, such as 7-valent, 10-valent, and 13-valent pneumococcal conjugate vaccines or quadrivalent meningococcal vaccines, are based on the glycoconjugate technology. Finally, two vaccines to prevent human papillomavirus (HPV) infection are based on recombinant antigens (Table 43.1). Most of the vaccines listed in this paragraph will be described in more detail in the section dedicated to licensed vaccines. Another paragraph will describe new experimental vaccines that have not been licensed yet, such as vaccines to prevent AIDS, TB, and malaria.

CLASSIFICATION OF HUMAN VACCINES

To be efficacious, a vaccine needs to generate an immunologic status that is sufficient to block infection by the pathogen or at least to inhibit the establishment of disease. Depending on the type of infection to be prevented, an effective vaccine may require the induction of different humoral and cellular immune effector mechanisms. Protective humoral responses include neutralizing antibodies, opsonizing antibodies, or antibodies able to induce complement-mediated killing. Protective cellular mechanisms include different classes of cluster of differentiation (CD)4+ T cells and CD8+ cytotoxic T cells (CTLs). Based on the type of material from which they are made, licensed vaccines can be broadly classified into three general categories: live-attenuated vaccines, whole-killed vaccines, and subunit vaccines. Subunit vaccines can be further divided into polysaccharide, glycoconjugate, toxoid, or protein subunit and recombinant subunit vaccines. Different types of vaccines target diverse adaptive immune responses (Fig. 43.2). For example, glycoconjugate vaccines elicit high-avidity bactericidal antibodies but do not trigger any antigen-specific effector T-cell responses. Proteinbased vaccines can induce bactericidal and neutralizing antibodies and can also trigger robust CD4+ T-cell responses; however, they are not efficient in inducing CTLs. Finally, live-attenuated vaccines are able to generate all humoral and cellular responses, including CTLs. This section will describe all classes of licensed vaccines with a special focus on their immunologic correlates of protection. In addition, some promising technologies for vaccine design such as viral vectored and nucleic acid-based vaccines will be presented, even if they have not been applied yet to vaccine licensed for use in humans.

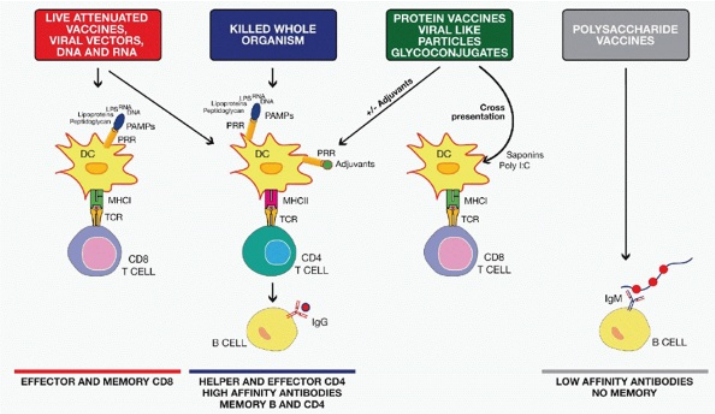

FIG. 43.2. Mode of Action of Different Classes of Vaccines. Live attenuated, viral vectors and nucleic acid vaccines induce both major histocompatibility complex (MHC) class I and MHC class II antigen presentation and activate pattern recognition receptors (PRRs) expressed by dendritic cells (DCs) through several pathogen-associated molecular patterns (PAMPs) including peptidoglycan, lipopolysaccharide, and bacterial or viral ribonucleic acid and deoxyribonucleic acid. They generally induce robust cluster of differentiation (CD)8 and CD4 T-cell responses, high antibody titers, and good memory. Killed whole-organism vaccines activate DCs through the same PAMPs and induce good CD4 and B-cell responses. Protein vaccines, viral-like particles, and glycoconjugate vaccines may need an adjuvant for optimal DC activation and CD4 T-cell priming. Some adjuvants such as polyinosinic:polycytidylic acid or saponins can also induce CD8 T-cell responses to subunit vaccines through cross-presentation mechanisms. Finally, polysaccharide vaccines induce a T-cell-independent antibody response.

Live-Attenuated Vaccines

As described in the previous paragraph on the history of vaccination, the very first vaccine of the modern era, Jenner's vaccine against smallpox, was a live-attenuated viral vaccine, prepared from a natural strain of the cowpox or *Vaccinia* virus, which is not pathogenic for humans, to protect humans against *Variola* virus infection. Indeed, one type of live-attenuated vaccine is prepared from a microorganism that normally infects other animal species and does not cause disease in humans but is similar enough to the human pathogen to trigger a specific immune response that protects against the human infectious organism.

For most pathogens, however, a related animal pathogen that is inoffensive to humans does not exist, but luckily, a live-attenuated vaccine can also be obtained using a mutated strain of the infectious microorganism that has a reduced pathogenicity and therefore is able to infect the human being without inducing disease. It is not uncommon for attenuated strains of a pathogen to spontaneously develop during natural infection of the human population. These attenuated strains can therefore be isolated in order to develop a vaccine.[3] However, attenuated viral strains can also be obtained by culturing the virus in vitro in nonhuman cells and selecting for mutant viruses that are adapted to this environment but are less fit to grow in the human cells. Most of the vaccines against viral infections in use today belong to this group of vaccines (eg, mumps, rubella, measles, varicella, and rotavirus vaccines). Although more difficult to obtain, and thus more rare, live-attenuated vaccines may also be developed against bacterial infections. Examples of live-attenuated bacterial vaccines among the currently licensed products are the vaccine against TB and an oral vaccine against typhoid fever. As the attenuated microorganism is capable of replication in the host mimicking a natural infection, this type of vaccine is generally able to induce strong and persistent antigen-specific immune responses in the vaccinees, resulting in a significant clinical efficacy. On the other hand, these vaccines may cause clinical manifestations associated with the infection, especially in immunocompromised subjects. Another potential risk associated with the use of attenuated strains is that they could revert to virulent form, therefore causing pathology in the vaccinated subject.

Whole-Killed or Inactivated Vaccines

Vaccines in this class contain the entire infectious agent that has been made harmless and incapable of replication by either chemical treatment (eg, formaldehyde) or a physical treatment like heating or radiations. Similar to live-attenuated vaccines, whole-killed or inactivated vaccines target bacterial and viral infections. Although this approach has been widely exploited in the past, only a few of the vaccines in use today are based on whole-killed microorganisms. In particular, only one whole-inactivated bacterial vaccine is still extensively used around the world, the whole-cell pertussis vaccine, whereas an oral vaccine against cholera, containing both heat-killed and formalin-inactivated strains of *V. cholerae*, is currently administered only to specific populations, such as travelers to an area where the infection is endemic. Examples of efficient vaccines prepared with whole-killed viruses are Salk's IPV, rabies vaccine, and HAV vaccine. Inactivated vaccines are not able to cause infection or reproduce in the host, and, therefore they generally induce a lower antigenic stimulation compared to live-attenuated vaccines, requiring multiple immunizations to achieve efficacy. In addition, whole-killed vaccines can be reactogenic because they generally include microbe-derived proinflammatory molecules, also known as pathogen-associated molecular patterns (PAMPs). The high reactogenicity associated with some vaccines containing killed microorganisms has led to a progressive reduction of their use in favor of more purified vaccine preparations represented by the subunit vaccines.

Subunit Vaccines

A vaccine can be made of single or multiple antigenic components of a microorganism that are capable of stimulating a specific immune response sufficient to protect from the relevant pathogen infection or from the clinical manifestation of the disease. Depending on the molecular composition of the purified antigen used to prepare the vaccine, and on the techniques applied to obtain the final material used as a vaccine, different types of subunit vaccines can be defined.

Toxoids

Toxoids are toxins that are inactivated by chemical or physical treatment, but that nonetheless preserve their antigenic structure. This approach allows the formation of a protein that has completely lost toxic activity but is still capable of inducing the production of antibodies that will recognize and block the native toxin. This approach can be applied in case of infections in which the pathology exclusively depends on the damage induced by a single toxin produced by a pathogen, and, therefore, production of antibodies neutralizing the activity of the toxin or rapidly causing its elimination will be enough to avoid any disease. Vaccines against tetanus and diphtheria are based on toxoids; as in both cases, the pathology is caused entirely by a single toxic protein secreted by *Clostridium tetani* or *Corynebacterium diphtheriae*, respectively. Another commonly used toxoid is the inactivated pertussis toxin from *Bordetella pertussis*, which is one of the components of the acellular pertussis vaccine.

Protein Vaccines

In case immunization with a single protein or a combination of proteins from a pathogen is sufficient to stimulate a protective immune response against that particular microorganism, the approach of a protein-based vaccine is appropriate. Proteins can be purified from in vitro cultures of a pathogenic microorganism. The resulting vaccine preparations contain different amounts of contaminants depending on the efficiency of the purification process. Licensed acellular pertussis vaccines currently available contain from two to four different proteins purified from *B. pertussis* and are able to confer protection against whooping cough comparable to that obtained with the whole cell vaccine. One of the most widely used subunit protein vaccines is the influenza vaccine composed of hemagglutinin (HA) and neuraminidase (NA) purified from the inactivated influenza virus.

Recombinant Protein Vaccines

Development of the recombinant deoxyribonucleic acid (DNA) technology has made possible the expression of protective protein antigens in heterologous expression systems such as *E. coli*, yeast, mammalian cells, or baculovirus. This technology avoids the problems related to growing and manipulating large amounts of a pathogen from which the antigen is purified. Moreover, recombinant proteins are generally better purified from cultured microorganisms

resulting in cleaner vaccine preparations with a better safety

profile. A drawback of a clean vaccine preparation containing pure recombinant protein(s) is their reduced immunogenicity that may require the addition of an adjuvant to achieve enhanced efficacy.

Viral-Like Particles

VLPs are supramolecular protein structures formed by viral proteins in vitro in the absence of a viral genome, which are structurally similar to the natural viral infectious particles while they are not infectious. One example of a VLP is the vaccine used to prevent hepatitis B virus (HBV). HBsAg spontaneously assembles into spherical particles of 22 nm diameter when expressed in yeast or mammalian cells.[4,5,6] Many theoretical and practical aspects of VLP technology make this approach attractive to vaccine design. The viral antigens expressed in VLPs usually exhibit a conformational structure that is similar to what they present in the real virus, and this is usually associated with conservation of critical conformational epitopes that are targets of a neutralizing immune response. Another important characteristic of VLPs is that they express the antigenic epitopes in multiple repetitive structures in one single particle, which potentially can induce an efficient engagement of the antigen receptor on the surface of B cells, resulting in an improved antibody response compared to what is obtained with soluble protein antigens. As VLPs are not infectious, there are no issues related to manipulation of high amounts of infectious material. Moreover, no inactivation procedures, which may result in damage of important immune relevant epitopes, are required. VLPs are at the base of the two HPV licensed vaccines. The VLP approach has been applied to many vaccine candidates, some of which are currently being tested in clinical trials.[7,8] This approach has also been used for antigens that do not naturally form VLPs by developing chimeric VLPs using two different methods. In one case using DNA recombinant techniques, a candidate vaccine antigen is genetically fused with a protein that is able to form VLPs, resulting in its expression in the context of the VLP structure. Alternatively, an antigen is chemically linked to heterologous VLPs that will provide the multimeric structure able to induce an appropriate immune stimulation. When these chimeric particles are administered, they are able to elicit a strong immune response to all components in the VLPs, including the epitopes from the fused candidate vaccine antigen. The chimeric VLP approach has been evaluated for development of vaccines against viral infections such as hepatitis C virus (HCV)[9] and HIV,[10] or against malaria,[11] as well as of therapeutic vaccines for cancer or for addictive substances such as nicotine.[12] However, thus far, none of these experimental chimeric VLP vaccines have progressed beyond phase I/II clinical trials.

Polysaccharide-Based Vaccines

The surface of many pathogenic bacteria is covered by a capsular shell that is mainly assembled from ordered polymeric glycans. This extensive polysaccharide coat entirely shields the bacteria outer membrane, preventing other surface bacterial components from becoming a target of the host immune response. Nevertheless, antibodies to bacterial surface polysaccharides can clear the bacteria from the host by different mechanisms, such as complement-mediated killing and opsonophagocytosis. Hence, stimulation of an antibody response against the surface polysaccharide of pathogenic bacteria is a valid strategy for the development of vaccines against capsulated bacteria. Experiments using the capsular polysaccharide isolated from *Streptococcus pneumoniae* demonstrated for the first time the immunogenicity of a bacterial carbohydrate and a protective effect of a polysaccharide-based vaccination.[13] The chemical structure of capsular polysaccharides varies not only between bacteria of different species but also between different strains within a single species, which are usually differentiated and typed based on their capsular polysaccharides. As a consequence, a limitation of polysaccharide-based vaccine is that the immune responses they elicit are often serotype specific. Thus, if disease burden is caused by multiple polysaccharide types, a vaccine would optimally contain multiple polysaccharides in order to confer broad protection. In addition to *S. pneumoniae*, for which a vaccine against 23 serotypes is available, polysaccharide-based vaccines have been developed for MenACWY, Hib, and *Salmonella typhimurium*.

Glycoconjugate-Based Vaccines

Purified polysaccharides are able to stimulate only B-cell responses because they cannot enter the major histocompatibility complex (MHC) cavity (which evolved to bind peptides) and cannot be presented to T cells. For this reason, they are classically known as “T-independent” antigens. Thus, the antibody response generated by a polysaccharide vaccine is a typical T-cell-independent response that presents two major disadvantages from a vaccine point of view. First, the response does not take place in germinal centers, and it is therefore not associated with affinity maturation of the antibodies or the generation of memory B cells. As a consequence, a polysaccharide vaccine will induce low- to intermediate-affinity antibody responses that is not followed by immunologic memory, resulting in the need for booster administration to maintain immunity. Moreover, a T-cell-independent antibody response is deficient or absent in young children (younger than 18 months of age) and in the elderly, two populations at risk of infection with capsulated bacteria such as pneumococcus or meningococcus, and for which a polysaccharide-based vaccine is not efficacious. A way to circumvent the limitations of these vaccines is to conjugate a polysaccharide to a carrier protein, such as TT or DT, in order to induce a carrier-specific T-cell response. Following vaccination with glycoconjugate vaccines, T follicular helper cells promote differentiation of the polysaccharide-specific B cells in the germinal center, where somatic mutation and affinity maturation take place, resulting in higher affinity antibody response and generation of long-lived memory B cells conferring long-term protection. The first demonstration that conjugation to a protein increases immunogenicity of a capsular polysaccharide was obtained in 1929; however, it took 50 years for this strategy to be applied to vaccine design, when a glycoconjugated vaccine for Hib was first tested in animals.[1] Compared to polysaccharide vaccines, glycoconjugated vaccines are indeed

more efficacious, being able to induce a long-lasting antibody response not only in adults but also in infants, young children, and the elderly. Similarly to the polysaccharidebased vaccines, the glycoconjugate vaccines are also serotype specific, and, therefore, multivalent formulations are required to achieve protection against multiple serotypes.

Combination Vaccine

In clinical practice, vaccines for different pathogens or for different strains of a particular pathogen are combined in one single formulation, allowing a reduction in the number of injections administered, with a concomitant reduction in costs and distress for the individuals. This last advantage is particularly important for childhood vaccinations that are frequently associated with psychological distress for parents, which may affect compliance with the vaccination schedule and be accompanied by possible negative effects on vaccination coverage. Indeed, it has been reported that the use of combination vaccines has improved both coverage rates and timeliness of vaccination.[14,15] A combination of diphtheria and tetanus toxoids with the whole-killed pertussis vaccine (DTwP) was the first multipathogen vaccine to be licensed. Years later, a similar combination containing the acellular pertussis component (DTaP) has been used as the basis to build new expanded combinations that may include one or more components such as IPV, HBsAg, and Hib glycoconjugate. Another commonly used pediatric combination is a mix of measles, mumps, and rubella vaccine, although a quadrivalent vaccine containing also the varicella vaccine became available only recently after solving problems related to compatibility and stability of the different components. Together with the continuous development of new vaccines, demands for additional combinations will be increasing with the aim of reducing costs and simplifying the vaccination schedule, in particular in the infant population. However, the increase in complexity of combination vaccines will raise the risk of a possible interference on antigen stability and immunogenicity.

Novel Technologies for Vaccine Design

Novel technologies and new strategies are continuously tested in preclinical research and applied to the development of new candidate vaccines. Novel types of vaccines can therefore be identified among the experimental vaccines currently evaluated in both preclinical and clinical research, some of which may become established products in the future.

Viral Vector-Based Vaccines

Priming of CTL responses requires presentation of the antigen by the MHC class I molecules, a pathway usually followed by endogenously synthesized proteins (eg, viral antigens) but not by exogenously administered antigens. For this reason, inactivated or subunit vaccines are not per se able to stimulate a CTL response, which is instead induced by live-attenuated viral vaccines. The observation that a gene encoding an external antigen could be inserted in the genome of the *Vaccinia* virus and expressed in the virus-infected cells has prompted the idea of genetically manipulating an attenuated or nonpathogenic virus to express an exogenous antigen from a pathogenic virus against which vaccines need to be developed. Because these antigens are synthesized by the host cells, they undergo all posttranslational modifications and acquire a correct conformation and should be able to stimulate a strong neutralizing antibody response. Moreover, antigens are presented in the context of the MHC class I pathway generating therefore a CTL response. Examples of attenuated strains of *Vaccinia* virus are the modified *Vaccinia* Ankara (MVA) strain obtained by repetitive passages through in vitro cell cultures and the New York *Vaccinia* strain obtained by genetic manipulation of the viral genome. These strains have been evaluated in both nonhuman primates and humans as vector vaccines for HIV, malaria, influenza, TB, and other infectious diseases.[16,17,18] Other poxviruses tested as vector vaccines include fowlpox and canarypox.[19] Despite extensive testing of these vectors as vaccine candidates, so far, no successful vaccine has been developed using this approach.

Because of their immunogenicity and efficacy in the induction of a robust cellular response, replication-incompetent recombinant adenoviral vectors (rAds) have been successfully tested in many animal models as vaccine vectors for many pathogens such as Ebola, HIV, anthrax, influenza, and malaria.[20,21,22,23] Adenoviral vaccine vectors have also been evaluated in many human clinical trials, particularly for HIV and cancer. On the other hand, natural adenovirus circulates in the human population, and, therefore, preexisting immunity, in particular neutralizing antibodies, may be present in the subject who will receive the vaccine, compromising efficacy of these vaccines.[24] It is important to note that tens of adenovirus serotypes exist but most of the clinical studies have used a vector derived from a single serotype (Ad5). Serotype 5 is one of the most common serotypes spread in the human population, and a high frequency of subjects possesses anti-Ad5 antibodies. In order to overcome potential problems related to preexisting anti-Ad5 antibodies, new vectors based on different human serotypes[25] or on adenovirus from other species[26,27,28] were developed. At the present, the most promising are the chimpanzee-derived adenoviruses.[27]

Alphaviruses are positive single-stranded ribonucleic acid (RNA) viruses in which the genome can be manipulated to obtain replication-defective infectious particles that express an exogenous antigen. Besides this favorable safety feature, upon entering the target cell, alphavirus RNA self-replicates, producing many copies of the coding RNA, which can then direct the synthesis of a very high amount of the antigen, making it a promising platform for a vector-based vaccine.[29] Alphavirus-based vaccines have been tested in animal models for several pathogens and have demonstrated excellent immunogenicity.[30,31,32,33] Some clinical trials have been conducted, but the results have not been published.

The prime-boost vaccination strategy using viral vectors has received wide evaluation in the vaccine field. Heterologous prime-boost regimens mainly use a viral vector or a DNA vaccine (see subsequent discussion) at priming

followed by a boost with a protein-based vaccine, although other options have also been used. This unconventional immunization schedule usually results in the induction of a strong cellular immune response, with generation of both CD4+ and CD8+ antigen-specific T cells. This is in turn associated with a higher and more specific antibody response against the vaccine target compared to homologous immunization with either DNA or viral vector. The immunologic mechanisms responsible for these improved responses are not entirely known. It is hypothesized that while DNA or viral vector priming is required to induce a strong T-cell response, boosting with only the target protein focuses the B-cell response on a single protein antigen for which high-affinity antibodies are desirable and at the same time avoiding interference by antivector immunity.[34]

Nucleic Acid-Based Vaccines

At the beginning of the 1990s, experiments designed to evaluate new approaches for gene therapy were performed to test if intramuscular injection of a liposome formulation containing a plasmid DNA or a messenger RNA coding for a reporter protein could result in in vivo expression of the protein. Surprisingly, animals in control groups that were injected with pure DNA or RNA showed a significant and prolonged expression of the reporter protein in muscle cells.[35] This observation inspired a series of studies that demonstrated that mouse immunization with an antigen encoded by DNA could induce a strong antigen-specific immune response characterized by antibody production and generation of both T-helper and CTL responses.[36,37,38] One of these studies also established the protective effect of a DNA-mediated immune response, showing that mice injected with a plasmid encoding the nucleoprotein from a H1N1 strain of influenza A virus were completely protected from challenge with a virulent H3N2 strain.[38] Based on these promising results, a huge amount of experimental work has been performed in the last two decades to apply DNA vaccination to many disease targets with both prophylactic and therapeutic approaches. As with vector-based vaccines, the advantage of a DNA-encoded vaccine is that the antigen is synthesized within host cells, facilitating correct folding of conformational neutralizing epitopes and MHC class I antigen presentation, allowing generation of CTL responses. An additional advantage of DNA vaccines compared to viral vectors is that the former contains only DNA, therefore nullifying any effects of preexisting vector immunity. DNAbased vaccines are composed of plasmid DNA containing an antigen gene sequence. To be efficiently expressed in the host mammalian cells, the antigen sequence has to be under the control of a strong eukaryotic promoter, such as those present in many viral genomes (eg, the early promoter of the human cytomegalovirus [HCMV]). Classical plasmids used for DNA vaccination also contain antibiotic resistance genes and prokaryotic origin of replication sequences, both required for selection and replication in bacteria. These prokaryotic sequences may contain unmethylated CpG motifs that are recognized by toll-like receptor (TLR)9 and were originally shown to play an immunostimulatory role during DNA vaccination.[39] However, subsequent investigations have excluded a role for TLR9 and CpG motifs in the immunogenicity of DNA vaccines and have suggested that the immunostimulatory activity might be due to the double-stranded structure of DNA and its capacity to activate other innate immune receptors.[40,41,42,43] After intramuscular injection, DNA is primarily localized within myocytes where the encoded antigens are expressed, although expression can also be observed in antigen-presenting cells (APCs).[44,45] Indeed, several studies have demonstrated that expression of antigen by myocytes is critical for induction of a CTL response, although they do not directly present the antigen to T cells. Experiments using parental bone marrow transplantation into F1 mice established that generation of antigen-specific CTL responses by DNA immunization depends on a cross-priming mechanism. Transfected myocytes transfer the antigen to professional APC, driving its processing and presentation by MHC class I molecules, which then leads to triggering of a CD8+ T-cell response.[46,47] Manufacturing of DNA vaccines has several benefits over all other type of vaccines: 1) design of DNA construct is straightforward; 2) production of DNA plasmids is uncomplicated and cheap and does not require manipulation of infectious materials; and 3) plasmids are stable even at room temperature, reducing the complexity and the cost of distribution. Because of the potential advantages of a DNAbased vaccine, this approach has been extensively tested for many pathogen such as rabies, HBV, and HIV in different animal models with promising immunogenicity results.[48,49,50] Furthermore, the approach has also been evaluated in humans in several clinical trials.[51,52] The human studies have demonstrated that DNA vaccination is generally safe and able to stimulate an immune response; however, immunogenicity is usually lower than expected based on the results of animal studies, resulting in a diminished confidence in this approach. The initial failure of DNA vaccine in the clinical setting led to the exploration of a series of techniques to improve their immunogenicity. To improve expression in vivo, the antigen-coding sequences were modified in order to contain only codons that match transfer RNAs with high frequency in mammalian cells, whereas stronger promoters were included in the plasmids. In an attempt to increase stability of the administered plasmid, different formulations and delivery systems, such as liposomes or microparticles, have also been

used.[53] In addition, several new injection techniques have been tested to improve in vivo transfection efficiency. A forced delivery of DNA into the skin can be obtained by the use of gold microparticles in gene gun techniques[54] or by a high-pressure liquid stream created by the Biojector device (Bioject Medical Technologies, Inc., Tigard, OR, U.S.A.),[55] whereas electroporation can greatly increase efficiency of intramuscular injection of DNA.[56]

Peptide-Based Vaccines

Although B cells can recognize linear epitopes within a protein, most of the epitopes recognized by a protective antibody response during a natural infection are conformational. Linear epitopes are usually not efficient at inducing a good neutralizing response. The goal of peptide vaccines is therefore to create T-cell epitopes capable of stimulating

T-cell responses and in particular CTLs, in cases of viral infections[57] or cancer,[58] where these type of immune responses are required to obtain a complete protection. Although the peptide approach is able to induce protection from viral infections and cancer in the mouse model, polymorphism of the MHC system has limited the application of peptides to human preventive vaccines. The use of peptides has been mostly restricted to therapeutic vaccines against cancer.[59]
