studying geriatric changes to vision lies in identifying the first lesions as early as possible. Not that it is possible, at least up to now, to impede the inexorable evolution of the degenerative phenomena, but an early diagnosis can at least allow us to greatly slow this process. With the passing of the years, the normal architecture of the retina undergoes modifications starting from the ora serata toward the posterior pole for a variable distance. At the posterior pole of the Bruch's membrane (drusen), lipid or calcium carbonate soap deposits and capillarosis (obliterated aneurisms) are seen. Dry and wet macular degeneration are clinical pictures often discussed in pathology. Finally, the cystoids of the macula begin with an edema with brilliant irregular foveal reflexes, which surround the macula. In the macula there may be an isolated vesicle, dark red in color, with sharply defined edges. In the periphery, the most frequent lesions are cystic degeneration and Blessig-Iwanoff holes, localized in the ora serrata (Owsley *et al.*, 2000).

### CYSTIC DEGENERATION

The retina shows two types of cystic degeneration, typical and reticular. Typical cystic degeneration originates on the outer plexiform layer, and reticular originates in the nervous fiber layer. These changes are very common after 70 years of age. The typical peripheral cystoid degeneration (TPCD) (Blessig-Iwanoff cysts) is characterized by cysts of the outer plexiform layer containing hyaluronic acid that can also coagulate, producing a globular form with winding channels that branch irregularly. Complications are rare; the retinal holes do not produce detachment of the retina as the vitreous is normally complete over the lesion. The extension of the lesion beyond the equator is rare. The breakage of the walls of the cysts or gaps causes the formation of peripheral lamellar holes. The retina is not detached; there is not the operculum of real retinal holes. Rare, but possible, is the formation of real retinal holes, with operculum to which vitreous body filaments adhere following a filamentous degeneration of the vitreous body and unsticking from the ora serrata. This can lead to another peripheral alteration: degenerative retinoschisis. The second type of modification is retinal periphery cystoid degeneration, which is almost always continuous and located behind areas of typical peripheral cystoid degeneration, and usually is found in the inferotemporal quadrant. This has a reticular aspect that corresponds to the retinal vessels of the inner layers. A finely punctured inner surface corresponds to the attachment points of the tissue cushions to the inner layer. The cystic spaces are localized in the nervous fiber layer. This process occurs in 18% of adults, in bilateral form, in 41%. It can evolve into degenerative reticular retinoschisis (O'Malley and Allen, 1967).

### RETINOSCHISIS

Two degenerative forms of retinoschisis have been described; they are both most frequently seen in the

inferotemporal quadrant and derive from a preexisting form of peripheral cystoid degeneration. Typical peripheral cystoid degeneration can evolve into typical degenerative retinoschisis, whereas both the typical and reticular forms of peripheral cystoid degeneration can transform into reticular degenerative retinoschisis. Typical degenerative retinoschisis causes a smooth raising of the retina in 1% of the adult population (bilateral in 33% of cases). Typical peripheral cystoid degeneration surrounds the lesions. The retina is divided along the outer plexiform layer, and consequently the inner layer comprises the ILM, the nervous fiber layer, the retinal vessels, the ganglion cells, the inner plexiform layer, and the inner nuclear layer; normally only the ILM, the nervous fiber layer, and part of the inner nuclear layer are visible. The outer layer is thicker, with cavities and is made up of the external nuclear layer and the photoreceptors (Foos, 1970). Reticular degenerative retinoschisis develops from the concurrent presence of typical and reticular cystoid degeneration of the peripheral retina. It is characterized by oval or round areas of detached retina in which a lump is in the very thin inner layer, and is observed in 1.6% of the adult population (in bilateral form in 15% of cases). Normally, typical peripheral cystoid degeneration is localized anterior to the reticular degenerative retinoschisis, whereas the reticular form is adjacent.

The detachment occurs in the nervous fiber layer; the inner portion contains only the ILM, some retinal vessels, and a variable portion of the nervous fiber layer. The outer portion contains the remaining relatively complete retinal layers. Sometimes typical and reticular retinoschisis are seen at the same time. It is not always easy to differentiate between the two forms on a clinical basis, unless there are lumpy aspects. The presence of holes in the outer margin or posterior extension are characteristics more common of the reticular form than the typical form.

### LATEX DEGENERATION

The frequency of latex degeneration was found to be 8% in an ample clinical study and 10.7% in autopsy studies. The lesions are bilateral and symmetrical in 48.1% of cases, and the frequency increases after the second decade of life. The majority of the lesions, located in the preequatorial region, are orientated according to the circumference and more frequently in the vertical meridian (Byer, 1989). Latex lesions appear like a thinning of the retina; they can also look like a plait caused by sclerotic vessels and may have variable pigmentation resulting from hypertrophy of the RPE. Histological latex degeneration is characterized by an overlying sack of vitreous fluid, absence of the ILM, vitreous condensation at the margins, hyperplasia of the glial cells and at the edges of the RPE, in some cases, thinning and the formation of retinal holes at the center of the lesion, sclerosis of the major blood vessels, sclerosis

and acellularity of the capillaries hypertrophy, and hyperplasia of the RPE.

#### COBBLESTONE DEGENERATION

This common degenerative chorio-retinal process is found in up to 27% of subjects after the thirtieth year. It is localized between the ora serrata and the real side of the equator and represents a boundary zone between the posterior choroidal circulation and the anterior ciliary circulation. Ophthalmoscopically, it looks like a small and discrete yellow-white area, with very visible choroidal blood vessels, sometimes with hypertrophic and dark RPE at the margins. The lesions can join together to form a band of depigmentation behind the ora serrata. Histopathologic studies show signs of ischemic atrophy of the outer retina, with attenuation or disappearance of the choriocapillaries, loss of the RPE and the outer retinal layer up to and including the external part of the inner nuclear layer. These changes are limited to the portion of the retina that is supplied by the choriocapillaries, and can be reproduced in rabbits after binding the choroidal blood supply (Stratsma *et al.*, 1980). Cobblestone degeneration is a characteristic that suggests peripheral vasculopathy and can be highly extended in carotid stenosis (O'Malley and Allen, 1967).

#### SENILE PERIPHERAL PIGMENT DEGENERATION

Senile peripheral pigment degeneration is associated with wartiness of the Bruch's membrane, and sclerosis of the choroid. It is often bilateral. One type of pigment alteration that is not peripheral, however, comes from moniliform pigmented scratches of the chorioretina. These are pigment granules that seem to be localized on sclerotic choroidal blood vessels in the nasal inferior quadrant (De Laey, 1988).

#### SENILE RETINA DETACHMENT

It is not easy to define retinal detachment as senile. There are chorioretinal and vitreal alterations that are typically geriatric and may cause detachment of the retina:

1. Cystic degeneration of the periphery of the retina. On one hand, cystic degeneration causes a thinning and weakening of the retina, and on the other, it favors the formation of pathological adherence with the vitreo and therefore creates a predisposition to retinal rupture at the margin or at the operculum. Furthermore, the walls of the cysts may break and therefore retinal holes may form (Foulds, 1980).
2. Paved, cobblestone, or pavement degeneration as proposed by Straatsma *et al.* (1980) or Gonin's foci of atrophic choroidosis. From a histological point of view these lesions show the disappearance of the choriocapillaries and the pigment epithelium, atrophy of the inner layers of the retina—that is, those which depend on the trophism of the

choriocapillaries for nutrition. The retina is strongly held to the choroid in these degenerative foci. They almost never form holes or ruptures of the retina. This type of degeneration does not favor the detachment of the retina per se, but shows that there is wear and choroidal and retinal degeneration at the periphery that may favor the onset of retinal detachment. In fact, O'Malley and Allen (1967) observed that numerous patients who show cobblestone degeneration also have, near to these lesions, cystic degeneration of the retina, fence degeneration, retinoschisis, retinal holes and ruptures, and cysts of the pars plana.

3. Senile degeneration of the vitreous. After 50 years of age, in emmetropic eyes, a fibrillar and lacunar degeneration of the vitreous begins, slowly progressing, and may result in the posterior detachment of the vitreous with its collapse. This is a typical senile disease that is found in 65% of individuals over 65 years old and more or less 100% of individuals over 77 years. The posterior detachment of the vitreous may cause, where there is an adherence between the vitreous and the retina, rupture of the retina by traction. The retinal rupture may be secondary to a choroidal exudation of congestive or allergic inflammatory origin, which passes the pigment epithelium, applying pressure to the retina toward the inside of the eye bulb, causing its rupture at a weak point. On contact with the choroidal exudation liquid, the vitreous then coagulates. Senile retinal detachment seems to be essentially caused by cystic degeneration of the retina and posterior detachment of the vitreous with collapse, due to the fact that in cases of senile detachment, posterior detachment of the vitreous with collapse is nearly always found. If we consider, however, the rarity of retinal detachment with respect to posterior detachment of the vitreous and cystic degeneration of the retina in senility, we must admit that many other factors must be relevant in retinal detachment such as genetic predisposition, vascular-retinal-choroidal factors, and abiotrophic factors.

The changes that lead to retinal detachment in senile eyes are very similar to those in myopic eyes. A study performed on 829 patients affected by retinal detachment and surveyed over three years found that about 34% were myopic and 66% were not. Of these, around 63% were individuals more than 40 years old. This shows therefore that senility plays an important role in the initiation of retinal detachment. Without doubt, retinal detachment results from degenerative lesions of the retina and the choroid, lesions which normally do not have characteristics appreciably different from degenerative myopic lesions. In the case of senility, the lesions are related to obstructions of the retinal and sometimes choroidal capillaries. The study of the cases in which the retinal

detachment occurred in nonmyopic individuals in senile age confirms that normally in these degenerative lesions there is evidence of vascular obstruction in the form of thin obliterated blood vessels that prevail in the superior temporal quadrant. In the eyes of nonmyopic senile age subjects, it is possible to see, more frequently than in young subjects, small pigmented equatorial spots that are often hexagonal in appearance. These are often the starting point of horseshoe ruptures, on the borders of which pigment deposits are found. Finally, there can be interruptions in the continuity of the macula deriving from senile alterations. In senile degeneration of the macula, pits may form in the macular lamella, which, although not very frequent, become perforations with consequent retinal detachment. Senility, as well as favoring the arrival of regmatogenous retinal alterations, is also responsible for the degenerative vitreal changes that can produce traction, rupture, and therefore detachment of the retina (Marshall, 1987).

The influence of vascular alterations in the pathogenesis of senile retinal detachment is without doubt to be taken into consideration. As aging causes a reduction in cardiac and lung performance, so it may cause a decrease of the retinal integrity. A parallel can be seen between the atherosclerotic lesions of the retinal blood vessels, and those of the other organs. We should remember, finally, that aphakia, not often seen these days as a result of good cataract operations, has a tight correlation with retinal detachment. It originates from small ruptures or holes in the ora serrata. In senile aphakic eyes, retinal degeneration very often is seen at the periphery and particularly at the ora serrata, with small holes generally located in the meridional folds of the retina.

## PREVENTION

Considering what just has been described, prevention of the degenerative factors induced by aging points to the application of an anti-apoptotic action to the nervous cells and glia of the human retina. One possible drug to perform this is acetyl-carnitine (ALCAR). In recent years attention has been focused on the advantageous influence of carnitine as an anti-apoptotic agent, above all as a molecule able to block the mitochondrial pathway in programmed cell death. Moreover ALCAR seems to have a major protective role in the senile retina decay. The anti-apoptotic action caused by carnitine includes induction of growth factors, increase in mitochondrial metabolism, protective action on the mitochondrial membrane integrity, inhibition of caspase activity, and finally, an antioxidant activity.

## Conclusion

The aim of this study is not only to fully understand the senile involution of retinal structures, which allows us to observe the wonders of the world, but also to keep these

structures intact for as long as possible. According to the theory of aging, the level of senescence is determined by the interaction between factors that promote aging and those that counteract it, in practice by the cellular regeneration capacity that is under genetic control. From this point of view, the “theory of physical deterioration” can be unified with another aging theory, that of the “biological clock.” This theory asserts that the life expectancy of each species is genetically determined and that variations are the result of environmental influence or genetic mutations.

# Models of Age-Related Vision Problems

J. Fielding Hejtmancik, Marc Kantorow, and Takeshi Iwata

*The visual system provides unique opportunities to study the aging process, as well as challenges in understanding and developing therapies for age-related eye diseases. Exposure of the lens to high levels of photo-oxidative stress and the lack of protein turnover in the lens nucleus make it an optimal system in which to study protein modifications in aging. Similarly, the high level of metabolic activity in the retina and the necessity for turning over large amounts of lipids provide particular research opportunities as well. Finally, visual diseases associated with aging are among the most common threats to the quality of life in the elderly. Of age-related visual diseases, three result in a particularly high burden on the population: age-related cataracts, age-related macular degeneration, and progressive open angle glaucoma. Thus, these are dealt with in some detail in this brief review. Because of space and formatting limitations, much work described in this review could not be cited directly. The citations for most of these can be found in the references and general sources given in the chapter, and we apologize to those authors whose work is not cited directly. In addition, parts of this review draw from previous work by the three authors, reflecting their continuing preferences in style and arrangement.*

## Overview of the Visual System

### BASIC ANATOMY/PHYSIOLOGY/BRIEF BIOCHEMISTRY

Components of the visual system include the optical components of the anterior eye (cornea, aqueous humor, lens, and vitreous body), retina, optic nerves, optic tracts, optic radiations, visual cortex, and a variety of nuclei (see Figure 68.1). The optical components of the eye focus light on the retina, which transduces the light signal into neural signals, and passes these neural signals through the optic nerves and tracts to central structures that perform more elaborate processing, integrating their information with that of the other senses. Any disease that interferes with the function of these components will cause loss of vision and blindness, and each part of the visual system has specific susceptibilities to age-related diseases or damage.

### TYPES OF AGE-RELATED VISUAL DISEASES AND THEIR IMPACT ON SOCIETY

The predominant causes of age-related visual impairment and blindness vary between the developed and developing countries, and even within various demographic and ethnic groups within single countries (Thylefors *et al.*, 1995). There are many causes of visual loss in elderly patients, including diabetic retinopathy, stroke, and retinal vascular occlusive disease, along with other age-related visual diseases including pterygia and presbyopia. However, in most populations the greatest causes of blindness and vision loss in the elderly include cataracts, glaucoma, and age-related macular degeneration (Congdon, Friedman, and Lietman, 2003; Buch *et al.*, 2004).

Cataracts are the leading cause of blindness across the world, blinding 17 million persons worldwide. Cataracts are usually correctable by surgery in developed countries, with about 5% of the American population over 40 years old having undergone cataract surgery. However, they remain a significant cause of visual disability even in developed countries, being the leading cause of low vision in the United States (Congdon, Friedman, and Lietman, 2003). Glaucoma is an optic neuropathy, often related to elevated intraocular pressure, which is responsible for blindness in 6.7 million people across the world. Glaucoma is more common in

**Figure 68.1** Diagram of the eye with principal structures of the anterior segment, retina, and optic nerve indicated. Courtesy of the National Eye Institute, National Institutes of Health.

African-derived populations, and increases with age. Finally, the greatest age-related cause of blindness in European-derived populations of developed countries is age-related macular degeneration (AMD). This degenerative disease progresses from fatty retinal deposits called drusen to neovascularization and retinal hemorrhage, resulting in irreversible loss of central vision.

## Lens and Cataracts

The eye lens (see Figure 68.2), which contains perhaps the highest concentration of proteins found in any tissue, transmits and focuses light onto the retina. It is formed of a single cell type that differentiates from an anterior layer of cuboidal epithelia and migrates posteriorly to form elongated lens fiber cells that make up the lens nucleus. In this process, the developing fiber cells synthesize high levels of lens crystallins before losing their nuclei and mitochondria. Thus, the lens fiber cells lack aerobic metabolism and contain high concentrations of  $\alpha$ -crystallins, which are members of the small heat shock protein family and have chaperone activity; and  $\beta\gamma$ -crystallins, which are related to prokaryotic structural proteins.

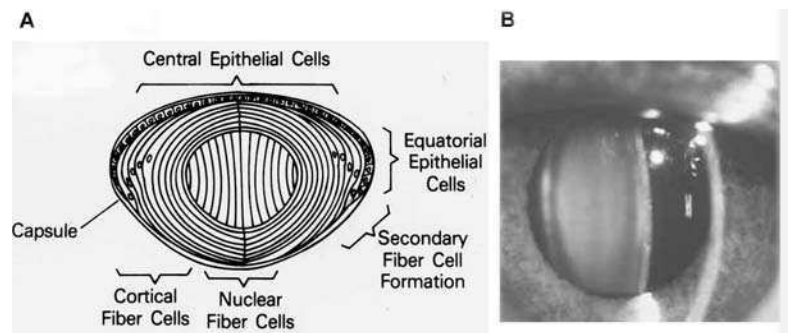

### BRIEF OVERVIEW

The lens is susceptible to damage with aging since its cells cannot be replaced in this encapsulated tissue and its proteins cannot turn over in the nonnucleated fiber cells. Not only does this result in a decrease in function of the normal aged lens, but it also sets the stage for development of senescent cataract in individuals with additional environmental insult or genetic proclivity. As the lens ages, vacuoles and multilamellar bodies appear between fiber cells, and occasionally the fiber plasma membrane is disrupted. Most of the elaborate cytoskeletal structure of the lens cells disappears with aging, and by the fifth decade the ability to accommodate is essentially lost. There is a decrease in transparency of the normal lens with aging so that the intensity of

light reaching the retina is reduced by about ten-fold by 80 years of age.

Cataracts which can be defined as any opacity of the crystalline lens, result when the refractive index of the lens varies significantly over distances approximating the wavelength of the transmitted light. Variation in the refractive index over these distances can result from changes in lens cell structure, changes in lens protein constituents, or both (Hejtmancik, Kaiser-Kupfer, and Piatigorsky, 2001). Cataracts are generally associated with breakdown of the lens micro-architecture. Vacuole formation can cause large fluctuations in optical density, resulting in light scattering. Light scattering and opacity also can occur if there are significant high molecular weight protein aggregates roughly 1000 Å or more in size. The short-range ordered packing of the crystallins, which make up over 90% of soluble lens proteins, is important in this regard; to achieve and maintain lens transparency crystallins must exist in a homogeneous phase.

A variety of biochemical or physical insults can cause phase separation of crystallins into protein-rich and protein-poor regions within the lens fibers. The proteins either remain in solution or form insoluble aggregates or even crystals, any of which can result in light scattering. When mutations in crystallins are sufficient in and of themselves to cause aggregation, they usually result in congenital cataracts, but if they merely increase susceptibility to environmental insults such as light, hyperglycemic, or oxidative damage, they might contribute to age-related cataracts (Hejtmancik and Smaoui, 2003). Thus, congenital cataracts tend to be inherited in a Mendelian fashion with high penetrance, whereas age-related cataracts tend to be multifactorial, with both multiple genes and environmental factors influencing the phenotype. This makes them significantly less amenable to genetic and biochemical study. Finally, although the young human lens is colorless, a gradual increase in yellow pigmentation occurs with age. As this pigmentation increases, it can result in brunescient or brown cataracts.

**Figure 68.2** A. A diagram showing lens structure including the anterior epithelial cells; the cortical fiber cells, which elongate and loosen their nuclei and mitochondria; and the nuclear cells, in which this process has been completed. The ends of the nuclear fiber cells abut each other in a complex pattern to form the lens sutures. B. *Lens proteins and their age-related modifications*

Enzymatic activity in the lens tends to decrease with age and to be lower in the central cells of the lens nucleus than in the cortical and anterior epithelial cells. As the lens ages, the  $\text{Na}^+$  and  $\text{Ca}^{2+}$  concentrations rise, reflecting an increase in lens permeability or a decrease in pumping efficiency. With aging, both the N- and C-terminal arms of half of the intrinsic membrane protein (MP26) molecules undergo proteolysis to form MP22. The lens contains neutral proteinase, also called the *multicatalytic-proteinase complex*, which preferentially degrades oxidized proteins, leucine aminopeptidase, calpains, and the protease cofactor ubiquitin, whose activation increases after oxidative stress. The activity of these proteinases is controlled by inhibitors, which appear to be concentrated at the periphery of the lens.

Aging also leads to an increase in high-molecular-weight aggregates and water-insoluble protein between 10 and 50 years of age, especially in the  $\alpha$ -crystallins, but also in the  $\beta$ - and  $\gamma$ -crystallins. There is also partial degradation of crystallins and covalent modifications of crystallins and other lens proteins, including an increase in disulfide bridges, deamidation of asparagine and glutamine residues, and racemization of aspartic acid residues.  $\alpha$ A-Crystallin is cleaved nonenzymatically, particularly between Asn 101 and Glu 102. An aspartate residue in  $\alpha$ A-crystallin appears especially susceptible because it easily forms a succinimide intermediate. Phosphorylation of lens proteins also occurs. Non-enzymatic glycosylation (glycation) occurs, especially of the  $\epsilon$ -amino groups of lysine. Through the Maillard reaction, the glycation products can result in increased pigmentation, nontryptophan fluorescence, and nondisulfide covalent crosslinks. Lens proteins can also undergo carbamylation, which can induce cataracts, and may be the mechanism for the association of cataracts with chronic diarrhea and uremia.  $\gamma$ -Crystallins, and especially  $\gamma$ S-crystallin, are particularly susceptible to degradation and modification in age-dependent and other cataracts, largely being degraded to low-molecular-weight peptides by increased proteolysis in the cataractous lens.

In age-related cataracts the lens presumably develops reasonably normally during infancy and remains clear in childhood. Then, by somewhat arbitrary definition, at some time after 40 years of age, progressive opacities begin to form in the lens. As mentioned earlier, these opacities almost certainly result at least in part from the cumulative damage of environmental insults on lens proteins and cells. Many of the age-related changes seen in crystallins are accelerated in the presence of oxidative, photo-oxidative, osmotic, or other stresses, which are known to be associated with cataracts. Susceptibility to these alterations may be exacerbated by barriers to movement of small molecules between the central lens nucleus and the metabolically more active epithelium. Many of these changes can be induced *in vitro* or in model systems

by the same stresses epidemiologically associated with cataracts (Davies and Truscott, 2001; Spector, 1995). In contrast, some changes do not appear to be implicated in cataractogenesis and may even serve to protect crystallins from harmful modifications.

The lens crystallins form one obvious target for this accumulated damage, although they are certainly not the only one. Thus, as the  $\beta$ - and  $\gamma$ -crystallins slowly accumulate damage over the lifetime of an individual, they lose the ability to participate in appropriate intermolecular interactions, and even to remain in solution. As these crystallins begin to denature and precipitate, they are bound by the  $\alpha$ -crystallins, which have a chaperone-like activity. Binding by  $\alpha$ -crystallins maintains the solubility of  $\beta\gamma$ -crystallins and reduces light scattering, but the  $\alpha$ -crystallins appear not to renature their target proteins and release them into the cytoplasm, as do true chaperones. Rather, they hold them in complexes that, though soluble, increase in size as additional damaged protein is bound over time until they themselves begin to approach sizes sufficient to scatter light. Eventually, it seems likely that the available  $\alpha$ -crystallin is overwhelmed by increasing amounts of modified  $\beta\gamma$ -crystallin and the complexes precipitate within the lens cell, forming the insoluble protein fraction that is known to increase with age and in cataractous lenses.

*Brief epidemiology of age-related cataracts*

Age-related cataracts are associated with a number of environmental risk factors, including cigarette smoking or chronic exposure to wood smoke, obesity or elevated blood glucose levels, poor infantile growth, exposure to ultraviolet light, and alcohol consumption (The Italian-American Cataract Study Group, 1991). Conversely, antioxidant vitamins seem to have a protective effect, although this has not been borne out by all studies.

There is increasing epidemiological evidence that genetic factors are important in the pathogenesis of age-related cataracts (McCarty and Taylor, 2001). In 1991, the Lens Opacity Case Control Study indicated that a positive family history was a risk factor for mixed nuclear and cortical cataracts, and the Italian-American cataract study group supported a similar role for family history as a risk factor in cortical, mixed nuclear and cortical, and posterior subcapsular cataracts. In 1994, the Framingham Offspring Eye Study showed that individuals with an affected sibling had three times the likelihood of also having a cataract. The Beaver Dam Eye Study examined nuclear sclerotic cataracts using sibling correlations and segregation analysis. Although a random environmental major effect was rejected by this study, Mendelian transmission was not rejected, and the results suggested that a single major gene could account for as much as 35% of nuclear and up to 75% of cortical cataract variability. Most recently, the twin eye study demonstrated significant genetic influence of age-related cortical cataracts,

with heritability accounting for 53 to 58% of the liability for age-related cortical cataracts. This hereditary tendency was consistent with a combination of additive and dominant genes, with dominant genes accounting for 38 to 53% of the genetic effect, depending on whether cataracts were scored using the Oxford or Wilmer grading systems. Similarly, genetic factors were found to account for approximately 48% of the risk for nuclear cataracts.

## HUMAN STUDIES ON AGE-RELATED CATARACTS

### *Linkage studies*

In addition to epidemiological evidence implicating genetic factors in age-related cataracts, a number of inherited cataracts with post-infantile age of onset or progression of the opacity throughout life have been described. Mutations in beaded filament specific protein 2 (BFSP2) can cause juvenile cataracts, the Marner and Volkmann cataracts can be progressive, mutations in aquaporin 0 (MIP) and  $\gamma$ C-crystallin can cause progressive cataracts, and the CAAR locus is linked to familial adult onset pulverulent cataracts. These all suggest that for at least some genes, a mutation that severely disrupts the protein or inhibits its function might result in congenital cataracts inherited in a highly penetrant Mendelian fashion, whereas a mutation that causes less severe damage to the same protein or impairs its function only mildly might contribute to age-related cataracts in a more complex multifactorial fashion. Similarly, mutations that severely disrupt the lens cell architecture or environment might produce congenital cataracts, whereas others that cause relatively mild disruption of lens cell homeostasis might contribute to age-related cataracts.

### *Association studies*

The hyperferritinemia-cataract syndrome is a recently described disorder in which cataracts are associated with hyperferritinemia without iron overload. Ferritin L levels in the lens can increase dramatically. The molecular pathology lies in the ferritin L iron responsive element, a stem loop structure in the 5' untranslated region of the ferritin mRNA. Normally, this structure binds a cytoplasmic protein, the iron regulatory protein, which then inhibits translation of ferritin mRNA, which may exist in the lens at levels approaching that of a lens crystallin. Mutation of this structure and overexpression of ferritin by loss of translational control in the hyperferritinemia-cataract syndrome results in crystallization of ferritin in the lens, and other tissues as well. Ferritin crystals appear as breadcrumb-like opacities in the cortex and nucleus. Ferritin cataracts serve as an example that the presence of crystallin proteins at such high levels in the protein-rich lens cytoplasm requires that they must be exceptionally soluble. This is emphasized by the occurrence of cataracts

resulting from single base changes decreasing crystallin solubility but not stability.

Lamellar and polymorphic cataracts have been associated with missense mutations in the MIP gene. One mutation, E134G, is associated with a nonprogressive congenital lamellar cataract, and the second T138R is associated with multifocal opacities that increase in severity throughout life. When expressed in *Xenopus laevis* oocytes, both of these mutations appear to act by interfering with normal trafficking of MIP to the plasma membrane and thus with water channel activity. In addition, both mutant proteins appear to interfere with water channel activity by normal MIP, consistent with the autosomal dominant inheritance of the cataracts.

Galactosemic cataracts provide an interesting example of mutations that severely affect a gene causing congenital cataracts, and of milder mutations that contribute to age-related cataracts. Deficiencies of galactokinase, galactose-1-phosphate uridyl transferase, and severe deficiencies of uridine diphosphate 1-4 epimerase cause cataracts as a result of galactitol accumulation and subsequent osmotic swelling. The latter two are also associated with vomiting, failure to thrive, liver disease, and mental retardation if untreated, whereas the cataracts in galactokinase deficiency are isolated. Interestingly, galactosemic cataracts initially are reversible both in human patients and in animal models. In 2001, a novel variant of galactokinase, the Osaka variant with an A198V substitution, was shown to be associated with a significant increase in bilateral cataracts in adults (Okano *et al.*, 2001). It results in instability of the mutant protein and is responsible for mild galactokinase deficiency, leaving about 20% of normal levels. This variant allele frequency occurs in 4.1% in Japanese overall and 7.1% of Japanese with cataracts. The allele was also present in 2.8% of Koreans but had a lower incidence in Chinese and was not seen in blacks or whites from the United States. This and other GALK1 variants appeared to be absent from Northern Italians with age-related cataracts, suggesting that the genetic contributions cataract might vary in different populations.

The GALK1 results fit in well with the known influence of hyperglycemia on age-related cataracts. That these cataracts result from polyol accumulation is suggested by work in galactosemic dogs and transgenic and knockout mice. Dogs have aldose reductase levels similar to those in humans and when stressed readily develop sugar cataracts that are prevented by aldose reductase inhibitors. Mice, which have very low aldose reductase activity in the lens, are naturally resistant to sugar cataracts, either galactosemic or hyperglycemic. However, upon transgenic expression of aldose reductase, mice readily develop cataracts, especially when the galactokinase or sorbitol dehydrogenase gene is deleted. Consistent with these animal data are the recent findings that susceptibility to cataracts as a diabetic complication in humans is associated with specific allele Z of the

microsatellite polymorphism at 5' of the aldose reductase gene.

## BIOCHEMICAL STUDIES OF AGE-RELATED CATARACTS

### *Crystallin modifications associated with cataracts*

The lens crystallins are a major potential target for accumulating damage associated with age-related cataracts, although there are certainly others. Thus, as the crystallins accumulate modifications and damage over the lifetime of an individual, their ability to participate in appropriate intermolecular interactions, and even to remain in solution, decreases. Whether proteins in age-related cataracts become insoluble as a result of complete or partial denaturation, or whether they simply become less soluble due to modifications that leave their protein folds largely intact or both, is not currently known. However, it seems clear that modifications to crystallin proteins accumulate with aging and accelerate during cataractogenesis, and the combination of crystallin modification, disulfide-crosslinking, denaturation, and aggregation results in loss of lens transparency and cataract formation (Hanson *et al.*, 2000). The protein modifications involved in this process include, but are not limited to, proteolysis, racemation, oxidative changes, and glycation. The many factors believed to induce these modifications include free radicals and superoxides, along with a loss of the lens' reducing state causing oxidation and disulfide-crosslinking, sugar accumulation causing glycation, and cyanate causing carbamylation.

Protein modifications in age-related cataracts are believed to arise from a combination of environmental and endogenous factors. For instance, considerable evidence suggests that oxidative modifications are a hallmark of age-related cataracts and oxidation of crystallins and other lens proteins likely results from reactive oxygen species that are produced by both UV-light exposure and are also a byproduct of mitochondrial respiration during which as much as 2% of respiratory oxygen is converted to reactive oxygen species. A major result of oxidation is conversion of methionine to methionine sulfoxide, which increases with age in the human lens and reaches levels as high as 60% in age-related cataracts relative to clear lenses.

Multiple identified and yet unidentified proteases are present in the lens and proteolyzed crystallins are a predominate feature of age-related cataracts. Among multiple lens proteases that have been identified to act on crystallin proteins, calcium-activated proteases are believed to play major roles. Proteolysis of specific crystallins is believed to result in protein aggregation and cataracts.

Proteins in age-related cataracts become insoluble as a result of complete or partial denaturation or by becoming less soluble due to modifications that leave their protein folds largely intact, or perhaps by a combination

of these processes. Many highly studied Mendelian congenital cataract models support both denaturation, as is seen in the association of some severe crystallin mutations with cataracts, and simple insolubility with maintained protein folds as is seen in other cataracts. Many classical studies have demonstrated that lens proteins become insoluble because they are denatured as the lens ages. Insoluble protein in the aged cataractous lens not only is denatured and crosslinked, but a fraction exists as relatively short peptides cleaved from larger proteins. It seems likely that the presence of large amounts of unstable or precipitated crystallin, or other protein, does damage to the lens cell and its proteins and eventually contributes to cataracts not only directly through light scattering by protein aggregates but eventually also through disruption of cellular metabolism and damage to the cellular architecture. This is clear from numerous mouse models of cataracts resulting from crystallin mutations (Graw and Loster, 2003).

### *Gene expression changes in cataract*

In addition to crystallin modifications, age-related cataracts are also associated with changes in gene expression detected at the level of increased or decreased mRNA in the lens epithelium (Hejtmancik and Kantorow, 2004). Since the lens epithelial cells cover the anterior surface of the lens, whereas in age-related cataracts the opacities tend to occur in the nuclear or cortical fiber cells, these gene expression changes likely reflect responses of lens epithelial cells to the presence of underlying cataracts and/or altered epithelial function in the presence of cataracts. These gene expression changes nevertheless point to altered lens pathways associated with this disease. For instance, the mRNAs encoding metallothionein and osteonectin (also known as SPARC, secreted acidic protein rich in cysteines) are increased in cataracts, whereas those for protein phosphatase 2A regulatory subunit and some ribosomal proteins including L21, L15, L13a, and L7a are decreased. These alterations suggest that increased binding of toxic metals and Ca<sup>++</sup> with a concomitant decrease in growth pathways and protein synthesis are features of cataract.

In addition to the identification of individual alterations in gene expression, more recent studies have sought to identify the full range of gene expression changes that occur in the lens epithelium upon cataract formation using DNA microarrays. Although literally thousands of genes whose expression is altered in cataract have been identified in these studies, some specific examples of genes increased in cataract include SP1 required cofactor for transcriptional regulation, osteomodulin, chloride channel 3, Na<sup>+</sup>/K<sup>+</sup> transporting polypeptide beta 1, and Ca<sup>++</sup> transporting ATPase, whereas genes decreased include  $\alpha$ A-crystallin, multiple glutathione peroxidases, multiple ribosomal subunits, HSP 27, Na<sup>+</sup>/K<sup>+</sup> ATPase and transketolase. The majority of the identified genes are decreased in cataract, suggesting loss of gene expression

as a consequence of lens damage. Functional clustering of the identified genes suggests that the genes increased in cataract tend to be associated with transcriptional control, ionic and cytoplasmic transport, protein salvaging pathways, and extracellular matrix components; transcripts decreased in cataract tend to be associated with protein synthesis, defense against oxidative stress, heat shock/chaperone activity, structural components of the lens, and cell cycle control (Hejtmancik and Kantorow, 2004).

#### *Enzyme changes associated with cataracts*

In addition to the protein modification and gene expression changes noted earlier, numerous metabolic and enzyme activity changes are also associated with age-related cataracts. These changes include decreased reduced glutathione content, decreased NADPH levels, increased free  $\text{Ca}^{++}$  levels, increased activity of specific proteases, and decreased ionic balance, among others. Considerable evidence suggests that many of these changes, other metabolic changes, and loss of lens protein function results from loss of the activities of specific lens protective and repair enzymes and other homeostatic systems. Although the evidence for these changes has been almost exclusively derived from animal, cell, and organ culture experimental systems, loss of the activities of multiple protective systems including  $\alpha$ -crystallins, MnSOD, catalase, glutathione peroxidase, and  $\gamma$ -glutamylcysteine synthetase among many others are believed to contribute to loss of lens function and ultimately cataract formation. In addition to the loss of lens protective and homeostatic systems, the loss of key repair systems including thioltransferase and methionine sulfoxide reductases are also believed to be key events in cataract formation.

## ANIMAL MODELS OF AGE-RELATED CATARACTS

### *Overview*

Since cataractogenesis is a complex process accompanied by numerous secondary changes, animal models may provide useful information for delineating the causes of senescent and other cataracts. Hereditary cataracts in rodents have been especially useful in this regard (Graw and Loster, 2003). One example is the Philly mouse, which displays an autosomal dominant cataract in which there is a deficiency of  $\beta\text{B2}$ -crystallin polypeptide. The  $\beta\text{B2}$ -crystallin mRNA has a deletion of 12 nucleotides, resulting in a four-amino-acid deletion in the encoded protein. It has been hypothesized that this causes aberrant folding of the protein and that cataract formation occurs as a result of the molecular instability of this crystallin and is therefore a good model to examine the roles of crystallin proteolysis and aggregation in age-related cataract formation. Other models suggest that some metabolic lesions can also cause cataracts. The Nakano mouse, which has autosomal recessive cataracts

mapping to chromosome 16, shows reduced synthesis of  $\alpha$ - and  $\beta$ -crystallins. This is probably due to an increase in the  $\text{Na}^+/\text{K}^+$  ratio occurring because of inhibition of the sodium-potassium pump. The Fraser mouse, which displays an autosomal dominant cataract, shows preferential loss of  $\gamma$ -crystallins and their mRNAs. However, the gene causing this cataract segregates independently of the  $\gamma$ -crystallin gene cluster, suggesting that changes in crystallin expression must be secondary in this cataract. It resides on chromosome 10 and has been suggested to be allelic with the mouse lens opacity gene (LOP).

### *Emory mouse*

Unlike the animal cataract models earlier, the Emory mouse is an interesting model for age-related cataracts that has been phenotypically but not molecularly or genetically well-characterized (Kuck, 1990). Two substrains of Emory mice in which cataracts develop at five to six months (early cataract strain) and six to eight months (late-ataract strain) are known. Emory mouse cataracts increase in severity with age and are initiated in the lens superficial cortex. They eventually progress into the deep anterior cortex and ultimately result in complete opacification. Emory mouse cataracts exhibit multiple changes that appear to mimic accelerated aging including abnormal lens growth, decreased protein accumulation, conversion of soluble to insoluble protein, decreased reduced glutathione, decreased protein sulfhydryl levels, decreased superoxide dismutase activities, decreased catalase activity, decreased glutathione peroxidase activity, decreased  $\gamma$ -glutamylcysteine synthetase activity, and accelerated conversion of MP26 to MP24. The Emory mouse is also associated with changes in gene expression including decreased synthesis of crystallins and increased expression of ARK tyrosine kinase, which is believed to be a major upstream activator of the stress response in many cell types.

### *In vivo hyperbaric oxygen treatment*

Many of the modifications undergone by lens proteins in aging and cataractous lenses are consistent with those seen in photo-oxidative stress, and oxidative stress is known to be a risk factor in age-related cataracts (Giblin *et al.*, 1995). Thus, exposing animals to increased oxygen tension to simulate the more prolonged oxidative stress associated with aging is an attractive and logical model system for understanding human cataract. In these studies, animals are exposed to 100% oxygen at increased pressure several times weekly for two to three months, and lens opacities are monitored by imaging with a slit lamp. Molecular and biochemical changes in the treated animals subsequently are correlated with lens opacity and oxygen treatment. Hyperbaric oxygen treatment *in vivo* accelerates lens opacity in the nuclear region of the guinea pig lens including loss of water soluble and cytoskeletal proteins, formation of protein disulfides, and

degradation of MIP26. Such modifications are similar to modifications reported to occur in the nuclei of aging and cataractous human lenses, confirming that hyperbaric oxygen treatment is an excellent model to study those processes occurring in human cataracts.

#### Other

In addition to the preceding models, cell culture, organ culture, and transgenic mice provide powerful tools for the study of lens transparency. Multiple lens epithelial cell lines have been used to identify and functionally analyze those enzymes and other proteins important for resistance to oxidative stress, chaperone function, and other processes associated with cataractogenesis. For instance, the importance of specific enzymes such as methionine sulfoxide reductase and MnSOD for maintaining lens cell viability and resistance to oxidative stress have been identified through the over-expression or silencing of these enzymes in lens cells, which are subsequently treated with H<sub>2</sub>O<sub>2</sub> and/or other oxidants associated with cataracts. Other approaches include similar experiments using lens cells cultured from animal knockouts deleted for specific lens proteins such as  $\alpha$ A-crystallin. In addition to cultured lens cells, cultured whole lenses also have been employed to monitor multiple biological events associated with cataracts.

In practice, creation of cataractous transgenic mouse lines is facilitated by the lens being readily examined for transparency, providing a rapid and efficient means to screen for phenotypic effects of transgenic insertions. Most cataracts in transgenic mice are associated with abnormalities of lens development, especially uncontrolled growth, toxic ablation of specific lens cells, or immune destruction of the lens. Lens abnormalities have been caused in transgenic mice using a variety of strategies. Expression of diphtheria toxin or ricin under the control of a lens-specific  $\alpha$ -crystallin or  $\gamma$ -crystallin promoter, respectively, has caused ablations within the lens.

In addition to transgenic expression of normal or modified proteins, disrupted expression of a protein normally found in the lens has been shown to cause cataracts. Lack of  $\alpha$ A-crystallin expression causes cataracts with inclusion bodies in central lens fiber cells (Brady *et al.*, 1997). Other knockouts associated with cataracts include osteonectin, connexins, and glutathione peroxidase. Collectively, these engineered cataract models emphasize the importance of the crystallins, cytoskeleton, and intercellular matrix for lens transparency.

## Macular Degeneration

### BRIEF OVERVIEW

Macular degenerations are a phenotypically and genotypically heterogeneous group of blinding disorders characterized by central vision loss associated with RPE

atrophy with or without choroidal neovascularization. Of these, age-related macular degeneration (AMD) is a degenerative disorder of the cone-rich macular and perimacular regions of the retina with resulting loss of central visual acuity. Although AMD principally affects the supporting and metabolic structures of the retina including the retinal pigment epithelial (RPE) cells, the choriocapillaris, and Bruch's membrane, vision loss comes from the resulting retinal atrophy and its associated photoreceptor dysfunction (see Figure 68.3). Visual dysfunction is made worse by neovascularization, the ingrowth of choroidal vessels through defects in Bruch's membrane, with secondary hemorrhage, and retinal detachment that characterize the "wet" form of AMD. This is contrasted to the "dry" or nonneovascular form, which comprises 80% of the disease but results in only roughly 20% of its associated blindness. Drusen, small yellow-white deposits below the retina, are increased in individuals with AMD. Although they do not cause visual loss by themselves, drusen represent a risk factor for development of both the geographical atrophy (dry) and neovascularization (wet) types of AMD, especially when they are soft or indistinct. Recent results from the Age-Related Eye Disease Study suggest that the incidence of AMD could be lowered significantly by diet supplementation with high-dose antioxidant vitamins and zinc.

The clinical terms *dry* and *wet* typically are used to refer to different forms of AMD, with the dry form sometimes progressing to the wet form. Early stages of the dry form are characterized by focal pigmentation and accumulation of drusen between the RPE and Bruch's membrane. In later stages, the wet form is characterized by choroidal neovascularization, detachment of the RPE, and geographic atrophy of the RPE in the macular region. Drusen are classified as hard and soft, based on their shape, diameter, and color. Hard drusen are yellowish,

**Figure 68.3** Histological section of the retina showing macular degeneration. Although the ganglion cell layer (GCL), inner nuclear layer (INL) and choroid are well preserved, the outer nuclear layer, which should appear similar to the INL, has been in large part replaced by fibrovascular choroidal neovascularization (CNV). Courtesy of Dr. Chi Chao Chan, National Eye Institute, National Institutes of Health.

smaller (with diameters of less than 50  $\mu\text{m}$ ), and less likely to progress to later stages of the disease. Soft drusen are larger, dark yellowish in color, and more likely to be associated with more advanced stages of the disease. In later stages of AMD, choroidal neovascularization and leakage of serous fluid into the subretinal (occult CNV) or intraretinal (classical CNV) regions leads to cell death and detachment of the RPE. Visual acuity is significantly affected when geographic atrophy of the RPE takes place in the fovea.

#### *Epidemiology of macular degeneration*

AMD has a multifactorial (or complex) etiology with contributions from a combination of environmental and genetic factors and a strong age effect. The prevalence of AMD increases dramatically with age, although the prevalence cited in various reports is highly dependent on the definition used for AMD. Overall, AMD increases from less than 1 to 2% at 50 years of age to as high as 15% at 90 years old. It has been suggested that increased skin pigmentation tends to protect from AMD, and this correlates to lower prevalence of AMD in African derived populations than Caucasians in some, but not all, studies. Various other risk factors may predispose to AMD including systemic hypertension and atherosclerosis, as well as cigarette smoking. Both photo-oxidation and inflammation have been suggested as possible pathogenic mechanisms for AMD, although the precise mechanism through which these result in disease has not been delineated.

Genetic factors have been implicated in AMD by epidemiological studies including twin studies and formal segregation analyses (Heiba *et al.*, 1994; Hammond *et al.*, 2002; Seddon, Ajani, and Mitchell, 1997). First degree relatives of individuals with AMD appear to have a two- to four-fold increased incidence of AMD over control individuals without a family history of AMD. Twin studies suggest that concordance for AMD in monozygotic twins is approximately twice that in dizygotic twins. Formal segregation analysis suggests that there is a major gene effect accounting for approximately 60% of AMD with a single major gene accounting for about 55% of AMD risk. Overall, these data suggest that the etiology of AMD has a significant genetic component.

### HUMAN STUDIES OF MACULAR DEGENERATION

#### *Mendelian linkage and association studies*

In addition to ARMD, several Mendelian forms of macular degenerations have been described. The age of onset, pattern of inheritance, and clinical characteristics of these diseases vary widely. To date, about 17 human Mendelian macular degeneration genes have been mapped (Tuo, Bojanowski, and Chan, 2004). So far genes for nine different forms of human Mendelian macular degenerations have been identified using a positional

cloning approach. These genes can be broadly classified into two groups: genes that are expressed in photoreceptors (ELOVL4, RDS/peripherin, RPGR, and ABCA4) and genes expressed in RPE (Bestrophin, EFEMP1, TIMP3, Hemicentin-1, and CTRP5). The genes ELOVL4, RDS, RPGR, and ABCA4 are expressed in both rod and cone photoreceptors. Except for the ELOVL4 gene, mutations in the remaining three genes were shown to be associated with retinitis pigmentosa (RP) in addition to macular degeneration. Mutations in TIMP3, EFEMP1, Hemicentin-1, CTRP5, and Bestrophin have not been implicated in RP. Of the genes involved in causing macular degeneration, all four photoreceptor-expressed genes are associated with an atrophic phenotype, whereas the RPE-expressed genes are associated with subretinal deposits and drusen in the early stages of the disease, which then progresses to neovascularization at later stages. The genes EFEMP1, TIMP3, Hemicentin-1, and CTRP5 share structural homology and are components of the extracellular matrix, and Bestrophin was reported to be a membrane channel. Recently, Fibulin-5, which also belongs to the fibulin family of extracellular proteins and shares homology with the EFEMP1 and CTRP5 proteins, was shown to be associated with AMD.

#### *Linkage and association studies of AMD*

Although some families show Mendelian inheritance of AMD, the disease in the general population is inherited in a complex or multifactorial fashion. In attempts to identify the genes that contribute to AMD risk in the population at large, investigators have looked at inheritance of AMD in small families or even pairs of affected siblings. A number of studies have examined families in which more than one member is affected with AMD, to determine whether polymorphic genetic markers at known positions in the human genome are co-inherited with the disease. These genome-wide scans have identified at least 21 linked regions on multiple chromosomes, including most consistently regions on chromosomes 1q, 9q, 10q, 12q, and 16q. However, AMD has not been associated with mutations in genes in any of these regions except complement factor H.

Three genes, ATP binding cassette subfamily A member 4 (ABCA4), apolipoprotein E (APOE), and complement factor H (HF1), have been reported to be associated with susceptibility to AMD in the general population (Tuo, Bojanowski, and Chan, 2004). However, the role of ABCA4 is somewhat controversial, and it probably is responsible for a few percent of AMD cases at most. Involvement of APOE in AMD seems to be more solid, with most studies showing a risk ratio of individuals carrying at least one APOE- $\epsilon$ 4 allele reduced to about 40 to 50% of control values, although some studies could not replicate this finding. Recently, a Y402H polymorphism in the complement factor H protein has been shown to be associated with a two- to seven-fold increase in risk for AMD in two studies of unrelated individuals.

The gene encoding complement factor H lies in the chromosome 1q25-31 region implicated in linkage studies of both a large single family and of multiple small families and sibling pairs. One study suggested that this gene might account for as much as 50% of the hereditary tendency of AMD in the general population (Edwards *et al.*, 2005). In addition, the biochemical activities of both APOE and HF1 are consistent with the proposed atherosclerotic and inflammatory associations of AMD and the histological and biochemical analysis of the subretinal deposits. Thus, significant progress is being made in understanding the biological nature of the genes associated with macular degenerations and their roles in the disease. However, despite these advances little is understood about the overall mechanism underlying the disease process.

## BIOCHEMISTRY AND PATHOLOGY OF MACULAR DEGENERATION

### *Histological changes*

Among the early hallmarks of AMD are drusen, which are complex deposits of lipids, proteins, glycoproteins, and glycosaminoglycans that accumulate in the extracellular and inner aspects of Bruch's membrane (Anderson *et al.*, 2002). These subretinal deposits, accompanied by a diffuse thickening of Bruch's membrane, have been speculated to form a physical barrier between the RPE and choroid, obstructing the flow of nutrients from choroid to RPE, or possibly resulting in loss of cell-cell contact between RPE and Bruch's membrane and causing degeneration of retinal tissue. The RPE cells are responsible for phagocytosis and degradation of outer segment disks shed by photoreceptors. As they age and undergo oxidative stress, lipofuscin accumulates in the lysosomal compartment and leads to cellular damage and further impaired function. Though the origin of drusen remains controversial, current opinions are beginning to favor the vasculature of the choriocapillaris as a primary source rather than an intracellular source from the RPE. It is possible that the presence of lipofuscin and cellular debris excites an immune reaction and leads to the formation of drusen. This is reflected by the presence of immune components in drusen (Anderson *et al.*, 2002; see later).

Chorioretinal neovascularization (CNV) is the most common cause of vision loss in AMD. New vessels from the choriocapillaris grow through Bruch's membrane and branch horizontally through the RPE cell layer (termed classic CNV) or between the inner Bruch's membrane and RPE (termed occult CNV because it doesn't show up on angiography). Although the impetus for CNV has not been definitively determined, there are suggestions that imbalances in growth factors include pigment epithelial derived factor (PEDF, which inhibits vascular outgrowth) and vascular endothelial growth factor (VEGF, which stimulates vascular growth), possibly as

a result of hypoxia and inflammation of the RPE. Even in the absence of CNV, the changes to the RPE Bruch's membrane and the outer plexiform layer of the retina result in scar formation at that level with concomitant damage to the neurosensory outer retina, termed geographic atrophy, which can also result in loss of central vision.

### *Composition of drusen and its implications*

Understanding the composition of drusen provides important clues to the molecular pathology of the disease. In addition to classical immunohistochemical techniques, several advanced proteome analysis tools have begun to provide detailed information about the nature and composition of drusen. Perhaps the most significant of the new findings is that drusen contain protein molecules that mediate inflammatory and immune processes. These include immunoglobulins, components of complement pathway, and modulators for complement activation (e.g., vitronectin, clusterin, membrane cofactor protein, and complement receptor-1), molecules involved in the acute-phase response to inflammation (e.g., amyloid P component,  $\alpha$ 1-antitrypsin, and apolipoprotein E), major histocompatibility complex class II antigens, and HLA-DR antigens (Crabb *et al.*, 2002). Cellular components also have been identified in drusen, including RPE debris, lipofuscin, and melanin, as well as processes of choroidal dendritic cells, which are felt to contribute to the inflammatory response (Mullins *et al.*, 2000).

In addition to immune components, a number of other proteins occur in drusen, some of them also found in atherosclerotic plaques and other age-related diseases in which protein deposits occur. The most common of these appear to be TIMP-3, clusterin, vitronectin, and serum albumin. Other proteins found in drusen include serum amyloid P component, apolipoprotein E, IgG, Factor X, and some complement proteins (Mullins *et al.*, 2000). A number of proteins are found exclusively or in increased amounts in drusen associated with AMD than in drusen from individuals unaffected by AMD. These include some crystallins, EEFMP1, and amyloid-beta. In addition, the presence of immunoreactive proteins and oxidative modifications of many proteins found in drusen implicate both oxidation and immune functions in the pathogenesis of AMD.

### *Immune aspects*

These findings have led to the suggestion that immune complex-mediated inflammation damages RPE cells, and choroidal dendritic cells are activated and recruited by injured RPE, whereas RPE cells respond to control dendritic cell activation by secreting proteins that modulate the immune response. Shed or phagocytosed cell membranes of injured RPE or dendritic cells are postulated to function as cores for these secreted components to accumulate and form extracellular deposits.

Furthermore, the codistribution of IgG and terminal complement complexes in drusen implicates an immune response directed against retinal antigens, and the immune complex formation might be taking place at the site of drusen formation. This hypothesis is supported by the presence of putative anti-retinal autoantibodies in the sera of patients with ARMD. Anti-retinal autoantibodies previously have been reported in a number of ocular disorders, including retinitis pigmentosa, paraneoplastic retinopathies, and retinal vasculitis (Anderson *et al.*, 2002). In addition, patients with membranoproliferative glomerulonephritis, in which complement activation and immune complex deposition cause glomerular injury, develop drusen deposits resembling those in ARMD in ultrastructure and composition including C5 and IgG. However, the role of antiretinal autoantibodies in the pathogenesis of ARMD has not been examined in detail. It remains unknown whether the initiation of chronic inflammation and subsequent drusen formation requires autoimmune-mediated events as a primary factor. To clarify the role of autoimmunity, immunogenic molecules for circulating antiretinal autoantibodies in patients need to be identified.

#### *Oxidative aspects*

Oxidative damage is implicated in the pathogenesis of AMD by both theoretical considerations and experimental data (Roth, Bindewald, and Holz, 2004). The retina has a highly active metabolism with a resultant high oxygen demand, and is exposed to light and polyunsaturated fatty acids, all of which tend to increase its susceptibility to photo-oxidative damage. In a fashion somewhat analogous to that seen in the lens, as the retina ages its antioxidant defenses begin to decline, here including both antioxidant enzymes and antioxidants such as lutein, and macular pigment density. As the RPE age oxidation of lipids and other cellular components result in accumulation of nonmetabolizable material as lipofuscin in the lysosomes, leading to their enlargement and formation of lipofuscin granules. These closely parallel drusen formation in time and distribution in the retina. In addition, epidemiological correlation of AMD with light exposure, age, and light pigmentation as well as the prevention or delay of AMD by antioxidant vitamins in the AREDS trial also support an oxidative role in AMD.

## ANIMAL MODELS OF MACULAR DEGENERATION

### *Overview*

Limited access to appropriate biological materials, especially eye samples from affected donors at different stages of the disease, are an absolute necessity to study mechanisms underlying the macular degenerations. Because it is nearly impossible to obtain these human retinal tissues from patients or from normal controls, animal models play a crucial role for investigating the

biological pathway of disease development and for testing therapeutic strategies. Because age-related macular degeneration shares phenotypic similarities with monogenic macular degenerations, manipulation of these genes associated with monogenic macular degenerations to develop transgenic mouse models has been popular. Over the past few years, genetic engineering technologies has allowed the generation of a rapidly growing number of animal models for retinal diseases (Chader, 2002). Animal models have been used to investigate potentially protective therapeutic agents to treat photoreceptor degeneration, stem cell technology, or to test somatic gene therapy strategies (Ali *et al.*, 2000). They are also valuable for studying environmental effects like diet or light on the degeneration process. The animals that have been used to evaluate therapeutic strategies involve rodents, rabbits, pigs, and dogs. However, macula is found only in primates and birds; a monkey model with macular degeneration would be extremely valuable as they not only have a defined macula, but they are also evolutionarily close to humans.

Macular degeneration in monkeys was first described by Stafford in 1974 (Stafford, Anness, and Fine, 1984). He reported that 6.6% of elderly monkeys showed pigmentary disorders and/or drusen-like spots. El-Mofty and colleagues reported 50% incidence of maculopathy in a rhesus monkey colony at the Caribbean Primate Research Center of the University of Puerto Rico in 1978. The following report from the center indicated that specific maternal lineages had a statistically significant higher prevalence of drusen. Researchers have described a cynomolgus monkey (*Macaca fascicularis*) colony at the Tsukuba Primate Research Center (Tsukuba city, Japan) with a high incidence of macular degeneration and its pattern of inheritance (Umeda *et al.*, 2005).

Several other naturally occurring animal models have been described for retinal diseases. Rodents, mainly mice, are the most popular animal models as maintenance is less expensive compared to larger animals. However, a low cone:rod ratio and lack of a macula make mice less suitable for studying cone diseases and macular degenerations. Although the pathology in human ARMD is pronounced in the macula area, it is not confined to this central region alone. Abnormal accumulation of drusen and progressive degeneration of the retina, RPE, and underlying choroid characteristics were observed in mouse models generated by candidate gene manipulation or senescence acceleration (Ambati *et al.*, 2003). Choroidal neovascularization also has been described in naturally occurring mouse models. These observations suggest that the lack of a macula in mice may not be a disadvantage when considering the advantages of using the mouse as a model for studying macular degenerations with drusen.

Although monkey models are extremely important for macular degeneration study, there are limitations

using nonhuman primates as animal models, such as longer gestation and life span, slow rate of expanding the pedigree, and cost of maintenance. These limitations can be overcome only by utilizing the mouse model parallel to the monkey model. One such model is a mouse line expressing an inactive form of cathepsin D. The impaired enzymatic activity affects phagocytosis of photoreceptor outer segments in the RPE cells, and the mice demonstrate basal laminar and linear deposits.

*Animal model of early and late onset macular degeneration monkey*

In 1986, a single cynomolgus monkey (*Macaca fascicularis*) with heavy drusen was found in the Tsukuba Primate Research Center. After 19 years of mating experiments, that single pedigree has grown to having 57 affected and 182 unaffected monkeys. Macular changes are observed as early as two years after birth, with basal laminar deposits first appearing in the macular region and progressing toward the peripheral retina throughout the lifetime (see Figure 68.4). In all the cases examined no abnormalities were found in the optic disc, retinal blood vessels, or choroidal vasculatures. The affected monkeys share phenotypic similarities with the early stages of ARMD, such as drusen and accumulation of lipofuscin. The immunohistochemical and proteome analysis of drusen in these monkeys share significant similarity with composition of age-related macular degeneration monkeys and also with previously reported human drusen composition. The meaning of this observation is that early onset monkeys produce the same drusen as ARMD patients at an accelerated rate of 25 times. Thirteen human candidate gene loci have been excluded by linkage and haplotype analysis. Therefore, the gene associated with macular degeneration in these monkeys is likely to be novel and the genes involved in causing drusen phenotype in humans and monkeys could be either the same or belong to the same biological pathway.

Studies involving early-onset and late-onset macular degeneration monkeys present a unique opportunity to study two independent target points in the biological pathway of retinal tissue that lead to degeneration of the macula at different stages of life. The gene associated with monkey macular degeneration is likely to be a novel

gene as we have excluded most of the known macular degeneration loci. Cloning of the monkey macular degeneration gene will allow us to study the biological processes causing degeneration of retina. Due to high conservation between human and macaque genomes, genes associated with macular degeneration in monkeys should possibly play a key role in maintaining the normal function of retina in humans and is likely to be associated with macular degeneration in humans. Although some of the monogenic macular degeneration genes are not associated with ARMD, the phenotype observed in monkeys strongly suggests that this gene may play a role in human ARMD, and this cannot be established until validated by screening patients with ARMD. Understanding the mechanism underlying macular degeneration in these monkeys will enhance our understanding of the disease, identify clinical or molecular markers for early detection, and provide critical information needed to develop therapies for these diseases.

## Progressive Open Angle Glaucoma (POAG)

### BRIEF OVERVIEW

*Epidemiology of POAG*

Primary open angle glaucoma is a major cause of blindness throughout the world, affecting between 1 and 2% of individuals over 40 years of age (Klein *et al.*, 1992). The greatest risk factor for the development of POAG is ocular hypertension, to the extent that an elevated intraocular pressure (IOP) is often incorporated into the definition of glaucoma. In addition, the evidence implicating a genetic influence in glaucoma is very strong, and has been borne out in both model-based and model-free linkage studies. Finally, diabetes and myopia have been suggested to be related to development of POAG, but the evidence for this is inconsistent, although it seems likely that high myopia might contribute to development of POAG.

*Pathology and physiology of POAG*

Although the etiology and even the pathophysiology of glaucoma are still poorly understood, risk factors for glaucoma can be thought of as including both those in the anterior chamber, which tend to increase intraocular

**Figure 68.4** Fundusoscopic view of the retina in Tsukuba primate model of macular degeneration showing drusen and macular changes.

pressure, and those in the retina and optic nerve, which tend to increase susceptibility to damage from elevated or even normal intraocular pressure. Clinically, glaucoma generally is characterized by excavation of the optic disc as seen on fundusoscopic examination and visual field defects with elevated intraocular pressure included either as a part of the disease or a risk factor. In a simplified schema, one might think of increased resistance of the trabecular meshwork or Schlemm's canal to outflow of the aqueous humor causing an increase in intraocular pressure, which then acts upon sensitive retinal ganglion cells. These cells then degenerate, resulting in both the increased depth and width of the optic cup and the visual field defects. If the increased pressure is acute as it usually is in juvenile onset glaucoma, this process can be painful, but generally POAG is an insidious disease in which the first recognized symptom may be irreversible visual field changes.

Although primary open angle glaucoma (POAG) is characterized by visual field loss corresponding to the excavation of the optic disc (see Figure 68.5), it is usually associated with an elevation of the intraocular pressure (IOP) over 21 mmHg. Although the pathogenesis of glaucomatous optic neuropathy is poorly understood, it is generally accepted that the IOP is a major risk factor. By definition, there is no increase in IOP over 21 mmHg at any time in eyes with normal-tension glaucoma (NTG), although it is difficult to rule out fleeting or previous elevations of IOP. IOP is heavily influenced by the inflow and outflow of aqueous humor, a plasma filtrate actively generated at stroma of ciliary body and filtered across the blood-aqueous barrier. The aqueous flows from the posterior chamber to the anterior chamber via the pupil and is released through two routes, the trabecular route and uveoscleral route. Any disturbance in the flow can cause abnormal IOP leading to a death of retinal ganglion cells (RGC), and damage to the surrounding structure of the optic nerve head where optic nerve fibers leave the eye for visual cortex.

## HUMAN STUDIES OF POAG

### Linkage studies

At least six loci for autosomal dominant POAG have been mapped through linkage studies, termed GLC1A-F, on chromosomes 1q23, 2cen-q13, 3q21-q24, 8q23, 10p15-p14, and 7q35-q36. A genome-wide scan in multiple small families from an Afro-Caribbean population provided significant evidence for linkage to regions on chromosomes 2q (but separate from the Mendelian POAG locus GLC2B and the infantile glaucoma locus GLC3A on chromosome 2) and 10p. Presumably, these represent loci for glaucoma risk factors common in the general population, as do the loci on chromosomes 2, 14, 17, and 19, identified by examining siblings in an American population of European descent. It is particularly important to note that few of these studies have been confirmed; especially the technically more difficult and laborious studies of POAG in the general population.

### Association studies

In addition to the identification of myocilin as a causative gene in glaucoma described earlier, which was carried out by linkage studies primarily in families with juvenile glaucoma and very elevated intraocular pressure, association studies have identified sequence changes in myocilin as a risk factor in a small percentage of POAG cases. Two additional genes have been shown to be involved in glaucoma by demonstrating an association between sequence changes in those genes and glaucoma in population studies. One of these genes is optineurin, for which the strongest associations have been obtained with normal tension glaucoma, but which also might be associated with POAG in some populations. A second is the OPA1 gene, which is known primarily as a cause of optic atrophy, but is also associated with normal tension glaucoma, though not with high tension primary open angle glaucoma in most studies. Association of both these genes with normal tension glaucoma suggests that

**Figure 68.5** **A.** Diagram depicting the flow of aqueous humor from synthesis in the ciliary body to exit from the anterior chamber through the trabecular meshwork and Schlemm's canal. **B.** Histological section showing an excavated optic cup in an individual with glaucoma. Courtesy of Dr. Chi Chao Chan, National Eye Institute, National Institutes of Health, from the collection of Dr. W. R. Green.

there may be some relationship between normal tension glaucoma and optic atrophy, and also emphasizes the importance of genetic changes that sensitize the retina and optic nerve to minor elevations of even normal intraocular pressure.

## BIOCHEMISTRY AND PATHOLOGY OF POAG

### *Histological changes*

It is estimated that roughly 20 to 50% of the large retinal ganglion cells (RGC) are lost in POAG. Although the reduction of RGC density occurs equally throughout the retina, visual sensitivity is first lost in areas where the initial RGC density is low, especially in the peripheral regions of the retina. As the disease progresses, atrophy of the nerve fiber layer is usually observed as additional RGC is lost. Typically, vertical collapse of the optic nerve head (ONH), loss of the neural rim at the ONH, rearrangement of central blood vessels, and loss of supporting tissue occur. Scanning electron microscopy of retinas with early stages of glaucoma shows evidence of initial collapse of the anterior lamina cribrosa, primarily in the vertical poles of the optic nerve head. Based on primate studies, optic cups with larger diameters are more susceptible to high ocular pressure and thus to glaucoma.

### *Role of the trabecular meshwork*

Trabecular meshwork (TM) is a lamellated sheet of complex tissue that covers the inner wall of Schlemm's canal. TM has uniquely developed at the angle of primates, filtering the aqueous humor out of the eye. TM consists of two parts: the nonfiltering portion mainly occupied by trabecular cells and the filtering portion. Trabecular cells are highly phagocytic cells removing particles, cell debris, and protein from the aqueous humor. The first glaucoma locus, the *trabecular meshwork inducible glucocorticoid response* (TIGR), also known as myocilin, initially was identified by looking at genes whose transcription is highly induced by steroids in these cells. The filtering portion consists of three tissues: the cribriform layer, the corneoscleral meshwork, and the uveal meshwork. These trabecular beams or strands are intertwiningly connected to each other, forming a complex filtering mesh surrounding Schlemm's canal. The trabecular beams are thickened by accumulation of extracellular materials and decrease of cell density within the corneoscleral and uveal meshwork in aged eyes.

## ANIMAL MODELS OF POAG

### *Overview: Difficulty of modeling the human eye*

Limited access to appropriate biological materials, especially eye samples from affected donors at different stages of the POAG, is an impediment to the study of mechanisms underlying the disease. Because of the extreme difficulty in obtaining such diseased eyes from

both patients and normal controls, animal models play a crucial role in investigating the biological pathway of disease development and in testing therapeutic strategies.

Different types of animal models for POAG have been found or created to mimic the optic nerve damage to resemble POAG phenotypes in humans. The greatest difficulty in constructing an animal model for POAG lies in the diversity of the anterior structures of the eye among different species (Tripathi and Tripathi, 1972, 1973). These structural differences include different iridocorneal angles or absence of specific quadrants from the TM. Nevertheless, within the limited areas in which interpretation of the data from a specific animal model parallels that in the human, various animals including the cow, dog, cat, horse, rabbit, chicken, and monkey can be used to observe POAG under various experimental conditions.

### *Animal models of POAG*

Various animal models for inducible glaucoma have been reported. Argon laser photocoagulation of the TM in rhesus monkeys results in sustained elevation of IOP and has been used extensively to study early damage to the optic nerve head (May *et al.*, 1997). Corticosteroids such as betamethasone and dexamethasone have been used to treat rabbits, dogs, and cats to develop ocular hypertension (Bonomi *et al.*, 1978). Steroid treatment generally produces progressive glaucoma, but this process is reversed after about two months after cessation of the steroid. Trabecular blockage caused by inflammation after  $\alpha$ -chymotrypsin treatment also has been used to produce elevated IOP in rabbit and monkey eyes (Vareilles *et al.*, 1977). Some types of avian species (chicken, quail, and turkey) have been known to develop elevated IOP as a consequence of continuous exposure to light.

### *Mouse models of glaucoma*

Naturally occurring inherited animal glaucoma models are rare. However, extensive classification of IOP in mouse strains and molecular biological techniques to manipulate certain genes to produce transgenic or knockout/knockin mice recently have resulted in the development of a number of animal models with definitely known genetic causes for their disease (Chang *et al.*, 1999). As discussed earlier, four genes, myocilin (MYOC, TIGR), cytochrome P4501B1 (CYP1B1), optineurin (OPTN), and WDR36, currently are associated with glaucoma. OPTN, mutations of which are responsible for 16.7% of families with hereditary human NTG, is homologous to an inhibitory regulatory subunit of the high molecular kinase complex for the phosphorylation of NF- $\kappa$ B. Some of its known functions include inhibition of the tumor necrosis factor- $\alpha$  pathway, interaction with transcription factor IIIA, and mediation of the Huntington and Rab8 interaction for regulation of

membrane trafficking and cellular morphogenesis. OPTN is induced by TNF- $\alpha$  and binds to an inhibitor of TNF- $\alpha$  and the adenovirus E3-14.7 kDa protein. To determine the effects of human glaucoma mutations in a transgenic mouse system, mice over-expressing wild type OPTN, OPTN carrying the glaucoma associated mutation E50K, and OPTN with exon5 deleted were constructed. Although wild-type OPTN do not show any abnormalities and the exon 5 deleted construction was found to be lethal prenatally, mice transgenic for the E50K mutant OPTN show steep optic nerve cupping with rearrangement of supporting tissue and blood vessels 18 weeks after birth (see Figure 68.6). The RGC and astrocyte loss observed is similar to the end phase changes seen in human glaucoma patients. Understanding the mechanism underlying normal tension glaucoma in these transgenic mice will enhance our understanding of each step leading to optic nerve cupping and how to prevent it. Based on the success of the mouse model, use of larger animals such as transgenic rabbits or pigs, in which more precise measurement of IOP and trials of surgical procedures suitable for therapy in humans are possible are currently being investigated.

Other glaucoma mouse models have been made through genetic manipulation. Knockout and transgenic mouse models of myocilin were made to answer the question whether elevated expression of the myocilin

**Figure 68.6** Histological section demonstrating excavation of the optic disc in an 18-week-old E50K mutant OPTN transgenic mouse.

protein can influence the IOP (Gould *et al.*, 2004). Up to a fifteen-fold increase in myocilin expression failed to result in elevation of the IOP, any abnormality of retinal ganglion cells, or cupping of the optic nerve head. Mice lacking the cytochrome P450 1B1 (CYP1B1) gene were generated on B6 and 129X1/SvJ mouse strains (Libby *et al.*, 2003). Both strains were affected by the CYP1B1 deficiency with focal angle abnormalities, but 129X1/SvJ albino strains lacking tyrosinase were more severely affected, suggesting the presence of tyrosinase as an important developmental molecule.

## Conclusion

In this chapter we have provided a brief overview of age-related eye diseases and the current state of knowledge and research on three of these. Age-related cataracts, age-related macular degeneration, and progressive open angle glaucoma account for much of the population burden imposed by age-related eye diseases. Although no perfect system to study these diseases exists today, an increasing number of experimental models are being developed. Although none is an exact replica of the clinical disease and should not be applied indiscriminately, each of these can provide useful information on some aspects of the disease in humans. They promise to accelerate the pace of research and provide mechanistic and therapeutic insights into the diseases that threaten sight in our aging population.

# Health, Functional, and Therapeutic Implications of Obesity in Aging

R.L. Kennedy and E.Y.H. Khoo

*Body weight generally increases from puberty through middle life. Some of this is due to muscle gain in the early years, but mostly it is fat. When weight gain is excessive, there is increased morbidity and mortality from diabetes, vascular disease, other chronic diseases, and malignancy. Although the prevalence of obesity is increasing, prognosis from associated chronic diseases is also improving. The consequence is that increasing proportions of the population reach old age and are either overweight or obese, or they become so in later life. The relationship between obesity and risk of death in later years of life is less clearcut than in younger subjects. There are no evidence-based guidelines for desirable body weight or managing obesity in the elderly. We do not really know how to measure obesity meaningfully in this age group. In fact, low body weight or weight loss appears to be a much more significant determinant of health in older subjects. However, obesity is associated with changes in metabolism and hormone levels, and with a low-grade inflammatory state. These changes are intimately involved with functional decline and provide opportunities for new therapeutic targets. Medical and surgical treatments for obesity have become widely available. There is a lack of specific data on their benefits in the aged population, but the benefits of exercise have become clear. Overall, the general increase in body weight in aging subjects may be a sign of improved nutrition, social environment, and medical care, and we should not simply regard it as a sign of ill health.*

## Introduction

Over the past few decades, there has been a worrying increase in obesity in human populations throughout the world. Increasing numbers of children are overweight or obese, and we are beginning to see the precursors of adult chronic diseases such as type 2 diabetes in many young subjects. The risks associated with obesity in adult life have been well documented in recent years. Diabetes risk increases in direct relation to body weight with a doubling of risk at a body mass index of as little as

28 Kg/m<sup>2</sup> compared with normal weight subjects. It is associated with multiple vascular risk factors including diabetes, dyslipidemia, and hypertension, accounting for the marked association with ischemic heart disease, stroke, and peripheral vascular disease. The risk of most malignancies is increased in the obese, and obesity is now thought to account for the equivalent of one in 10 cancers. Many other disorders associated with poor health and premature functional decline including osteoarthritis, affective disorders, and dementia are now firmly linked to obesity. Metabolic syndrome is a cluster of cardiovascular risk factors that is now present in one in four adults in the United States. The relationship between obesity and ill health is not in question.

Improved health and social care, control of infections, and better education have all contributed to a major increase in the general health of the population and an increasing proportion reaching old age in a better state of health. In health, body weight tends to increase as we age. We should not, therefore, be surprised that the proportion of the population that is both elderly and either overweight or obese is increasing. On the other hand, being underweight or losing weight unintentionally is associated with a poorer prognosis. Aging is associated with a range of endocrine changes, altered metabolism, and body composition, and often with low-grade inflammatory changes. All these help to explain the association between aging and a variety of chronic diseases, and with decreased mental and physical function. But should we regard being overweight as a sign of ill health in the elderly, and is it then a target for therapy? If it is, should the approaches be the same as in the younger sector of the population? This chapter will try to address these issues.

## Epidemiology of Obesity and Aging

The prevalence of obesity in human populations increased markedly in the last four decades of the second millennium. On average, body weight increases throughout adult life up to the age of about 60 years. Most of the increase in weight with aging is due to fat accumulation in several depots in the body. After the age of 60, average

body weight begins to decline and by the age of 80 the prevalence of obesity is only about a third of that at age 60. The factors responsible for the decline in body weight with age are complex and incompletely understood. They include loss of muscle (sarcopenia), due in part to decreased activity and the endocrine changes that accompany aging. There is also an element of selection since obesity increases risk of conditions, including cardiovascular diseases and cancer, which shorten life. Furthermore, there is a well-established association between calorie restriction and longevity. Influences on the body weight of aging cohorts are multiple and need to be documented better.

Increased prevalence of obesity in the past 50 years has arisen because of increased calorie intake in the face of declining levels of physical activity. Decreased physical activity with aging may relate to changes in body composition (loss of muscle) and limitations imposed by diseases such as arthritis and vascular disorders. The link between obesity and ill health and risk, particularly of vascular disorders, has been long recognized and amply documented in a large number of recent studies. Awareness of the risks of obesity has increased, leading to development of a range of public health or treatment interventions to either prevent or treat the condition. In spite of these, available evidence suggests that the prevalence of obesity is still increasing. Mokdad *et al.* (2003) conducted a survey of over 195,000 adults in the United States in 2001. Compared with the preceding year, the prevalence of obesity had increased from 19.85 to 20.9%, an increase of 5.6%. Diabetes prevalence increased from 7.3 to 7.8% of the population, an increase of 8.2%. Diabetes and cardiovascular risk factors were much more common in obese individuals. Recent studies from Spain and Canada also confirm increases in obesity in the elderly, with up to 40% of the population affected. Even in societies where obesity has traditionally been less common, such as Japan, an increasing proportion of the elderly population is either overweight or obese. At all ages, including the elderly, obesity is more common in women than in men. For this reason, the relative protection that women have enjoyed against vascular disorders is being lost.

The relationship between obesity and socioeconomic status is also changing: Zhang and Wang (2004) have studied the link between educational attainment (as a surrogate marker for social status) and obesity in four cohorts of the National Health and Nutrition Examination Surveys (NHANES) between 1971 and 2000. There has been a progressive diminution in the excess of obesity in low socioeconomic groups. A recent study from Finland (Sulander *et al.*, 2004) has confirmed the rising prevalence of obesity among the elderly, and also that this increase is not as markedly related to socioeconomic status as would have been expected 10 years ago. Obesity is still a disorder associated with poverty and poor education, but it is also a disease of affluence.

Recent studies also suggest that improved survival among institutionalized elders and those with special needs such as severe learning difficulties might also be contributing to the increased prevalence of weight problems in the elderly. Projections of the likely rise in obesity prevalence have been based on a combination of surveys (Arterburn *et al.*, 2004). It is estimated that the proportion of those aged 60 years and over who are obese will increase from 32.0% in 2000 to 37.4% in 2010. In the United States, this means an increase in the number of elderly obese subjects from 14.6 million to 20.9 million. Correspondingly, it is estimated that, over the next decade, the proportion of subjects aged 60 and over who are in the range of weight regarded as ideal will decrease from 30.6 to 26.7%.

### Influence on Mortality

The most extensive study of the relationship between obesity and risk of death was published in 1999 by Calle and colleagues (1999). Over a million subjects were followed up for a mean period of 14 years. Among nonsmokers, those with the highest body mass index had a relative risk of death that was two- to three-fold greater than that of subjects who were in the desirable body mass index (BMI) range. The risk of death was greater in men than in women, but tended to be overshadowed by the effect of smoking on premature mortality. Obesity posed a greater risk for white than for black subjects. As expected, cardiovascular disease and cancer were the leading causes of death. In this study, the relationship between obesity and likelihood of death was much less marked in the elderly. Estimates of years of life lost due to obesity are based on considerations of younger populations. Thus, Fontaine *et al.* (2003), using data from the NHANES study, estimated that young white males with a BMI of 35 or above could expect to live eight to 13 years less than individuals who were in the desirable weight range. Again, the risk for young black males appeared to be less.

Most deaths occur in the older age group. Some studies have confirmed an association between higher than desirable body weight and life expectancy in the elderly, but this has not been a consistent finding. It is hard to control for the influence of baseline health status, lifestyle factors such as smoking, and influence of social environment (Flegal *et al.*, 2004). It seems clear that obesity does reduce life expectancy in older subjects; the effect has not been precisely quantified and is almost certainly less than that documented for younger obese subjects. The major causes of obesity-related deaths in the elderly are cardiovascular diseases (see later) and neoplastic conditions. Prevention of morbidity and mortality from cancer is seen as one of the most significant goals in improving quality, as well as quantity, of life in the older population (Hajjar, 2004). In a recent study of over 900,000 adults over 16 years,

Calle *et al.* (2003) demonstrated that, comparing the heaviest cohort with subjects of normal weight, obesity increased the risk of malignancy by 52% in men and 62% in women. The increase related not only to the hormonally responsive cancers such as breast and prostate, but to virtually every malignant disease with hepatocellular carcinoma, showing the most marked association with obesity. The exception was lung cancer, but the cachexia of patients with chronic lung disease and the confounding effect of smoking on body weight make it not surprising that this disease is not overall linked with obesity. The authors projected that the equivalent of 14% of all malignancies in men and 20% in women could be attributable to obesity.

Data from the Rotterdam study (Visscher *et al.*, 2001) illustrate the difficulty in defining obesity in the elderly and the importance of considering visceral adiposity as the major risk factor. In this study of around 6,300 elderly subjects followed for three years, the overall influence of BMI on mortality was modest, but increased waist circumference showed a more marked association with poor prognosis during the follow-up period. In summary, obesity does reduce life expectancy, but there is a survival bias in subjects who are obese and survive into old age, and the effect of obesity acquired later in life on life expectancy is not known. Although obesity is a determinant of life expectancy in the elderly, its effect is much less than in younger cohorts. It is possible, with the rise in obesity in the elderly, that life expectancy may reach a peak and then begin to decrease because of the high prevalence of obesity in this age group.

### Energy Balance and Body Composition

Although we are seeing a marked increase in the number of elderly subjects in the population who are either overweight or obese, it is important to recognize that involuntary weight loss is a common feature of aging and is more common than weight gain. There are a number of reasons for this weight loss, including increased energy expenditure and decreased appetite arising from disease states that are common in the elderly. Involuntary weight loss in the elderly is associated with functional decline and with increased morbidity and mortality (Sahyoun *et al.*, 2004). A recent extensive Scandinavian study has confirmed that there is no association between weight gain in the elderly and excess mortality, whereas weight loss did relate to increased risk of death in both men and women (Drøyvold *et al.*, 2005). Chronic degenerative diseases, including Alzheimer's and Parkinson's diseases, are commonly accompanied by decreased resting energy expenditure (REE) and decreased total energy expenditure (TEE). In these conditions, altered body composition with loss of skeletal muscle, decreased food intake, and reduced mobility all contribute to decreased energy expenditure. The relationship between energy balance, body composition,

and health in the elderly is complex (Wilson and Morley, 2003). A number of recent studies have confirmed that calorie restriction and decreased adiposity are significant determinants of longevity. Although involuntary weight loss is often a sign of illness, there is every reason to believe that regulated and deliberate weight loss in subjects who are obese will lead to health gains similar to those found at a younger age.

Body weight and composition are dependent on the balance between calorie intake and calorie expenditure. The reasons for decreased food intake with aging are several:

- Social and behavioral factors including economic status, isolation and mobility affecting access to food, loss of the social dimension to eating
- Decreased activity due to altered fitness and effects of chronic diseases leading to decreased appetite and energy requirements
- Diminished sense of smell and of taste and, therefore, enjoyment of food

Addition of the taste enhancer monosodium glutamate to food has been associated with weight gain in the elderly. Decreased relaxation of the antrum of the stomach may, in part, be responsible for the elderly experiencing earlier satiety; cholecystokinin (CCK) is released from the duodenum, particularly in response to fat, and leads to satiety. There is enhanced basal and stimulated release of CCK in elderly subjects; ghrelin is released from the stomach and stimulates desire for food intake and growth hormone release. Levels of this hormone are decreased in the elderly.

Energy expenditure is determined by REE, level of physical activity, and energy expenditure related to food intake—diet-induced thermogenesis. The decline in physical activity with aging accounts for at least half of the decrease in TEE. Not only does muscle mass and activity decrease, but changes in muscle metabolism with decreased protein turnover, decreased  $\text{Na}^+\text{-K}^+$ -ATPase activity, and changes in the proton pumping activity at the mitochondrial membrane also play a part. Diet-induced thermogenesis is a means of dissipating energy intake that is in excess of requirement and is higher in response to protein and carbohydrate than in response to fat. It is reduced, or delayed, in elderly subjects perhaps because of slower gastric emptying. This and decreased activity with aging may account for an exaggerated positive calorie balance in those who decrease their activity but continue to eat the same quantities they did when they were younger. The size of the internal organs, including liver and kidneys, diminishes with aging, and this factor contributes to the decrease in energy expenditure with aging (Wang *et al.*, 2005). Energy expenditure is higher in those who are obese, and may be higher in those who have diabetes. It follows that, in those individuals who are maintaining their body weight, food intake will need to be much

higher in the obese and, though obesity may be an important determinant of poor health and poor function, the ability to maintain appetite and energy balance at levels comparable to those seen at a younger age should be recognized, to an extent, as a sign of health rather than of disease.

There are two important changes in body composition to consider—loss of skeletal muscle (sarcopenia) and increased accumulation and redistribution of adipose tissue. Sarcopenia leads to decreased muscular strength, impaired physical performance, and decreased quality of life. Since skeletal muscle is the most metabolically active tissue in the body, loss of muscle with aging is likely to be a major factor in determining resting and stimulated energy expenditure. Hormonal treatments to increase muscle mass and improve muscular strength have been considered and studied in a number of trials (Borst, 2004). To date, improvements in body composition have been demonstrated in a number of trials, but improvements in muscular strength in these trials have been relatively modest. Hormone therapy has enormous potential in patients with sarcopenic obesity (see later), but maximum benefit may be obtained only when it is combined with suitable nutritional and exercise interventions that take into account the particular needs of elderly subjects.

Women and the elderly have lower whole body fat oxidation, and this may favor fat accumulation under conditions of positive energy balance. In the Study of Women's Health Across the Nation (SWAN), Sternfeld *et al.* (2004) demonstrated that aging women experienced both increased total fat gain and increased visceral adiposity, with accompanying decreased muscular strength and performance. Regular exercise was protective against these changes. There has been debate about the role of visceral adiposity in predisposing to the metabolic syndrome in the elderly since, in many studies, the changes of metabolic syndrome are common, even among subjects who are not obese. A recent study of a large cohort of elderly individuals using dual X-ray absorptiometry (DEXA) and computerized tomography (CT) has confirmed the relationship between visceral obesity and the metabolic syndrome (Goodpaster *et al.*, 2003). Increased intra-abdominal fat not only predisposes to glucose intolerance, but also to hypertension (Ding *et al.*, 2004). Furthermore, this study demonstrated increased fat in the skeletal muscle in patients with either impaired glucose tolerance or diabetes. Increased fat in skeletal muscle depots of obese and diabetic patients, along with abnormal lipid metabolism, may contribute to insulin resistance and thus impaired muscle function, and has now been confirmed in a number of studies. Ritov *et al.* (2005) have shown that this phenomenon is accompanied by decreased electron transport chain activity in the mitochondria of skeletal muscle, and thus may be a direct or indirect cause of impaired substrate oxidation in muscle. Similar processes may

operate in both the liver and in skeletal muscle, the two major sites of substrate utilization in the body (Cree *et al.*, 2004).

Adipose tissue is very active in producing cytokines and a variety of hormones that are important in regulating food intake and energy balance. It is important to recognize that expression of regulatory molecules differs between fat depots. Adiponectin is a major regulator of insulin sensitivity, and is one of the major secretory products of adipose tissue. Decreased adiponectin in patients who are obese associates closely with risk of diabetes and other cardiovascular risk factors. Resistin is also a product of adipose tissue, and increased expression is linked with increased peripheral insulin resistance. The main target for lifestyle interventions and other treatments for obesity should be visceral fat. In fact, the typical feminine distribution of fat peripherally, and particularly around the buttocks, may be protective against vascular disease (Tankó *et al.*, 2003) and cognitive decline (Bagger *et al.*, 2004).

## Endocrine Changes

Many of the changes in function of the endocrine glands that are seen in obese subjects are really just the changes that accompany normal aging. However, as with inflammatory changes, the aging process appears to be accelerated in subjects who are either overweight or obese. Some of the changes that accompany obesity and aging are summarized in Table 69.1. We have termed this complex of endocrine changes Obesity-related Endocrinopathy (ORE), and we feel that these changes are important because they not only account for some of the alterations in body composition and energy balance that are seen, but could also be seen as potential therapeutic targets. Indeed, clinical trials have been conducted, or are under way, in a number of areas.

Low levels of testosterone, along with low body mass, smoking, and low vitamin D status, are important determinants of sarcopenia in elderly men (Szulc *et al.*, 2004). Although men do not experience a dramatic decline in sex steroid levels in midlife akin to the female menopause, there is a steady decline with aging. Around a third of men aged 70 years and over has levels of testosterone in the range that would normally be regarded as hypogonadal. Levels of the major adrenal androgen dehydroepiandrosterone also decline steadily with age. This decrease in androgen status is accompanied by, but does not entirely cause, increased fat mass, decreased muscle mass and decreased bone mineral density. Decreased androgen status often is seen particularly in patients with diabetes and is a common feature of poorly controlled diabetes, even in the young. The decline in testosterone status with aging and obesity is due partly to loss of function and number of Leydig cells. There is also a central component with reduced hypothalamic release of gonadotrophin releasing hormone (GnRH),

## 69. Health, Functional, and Therapeutic Implications of Obesity in Aging

TABLE 69.1  
Obesity-related endocrinopathy (ORE)

Hormone Change	Possible Consequence
↑ catecholamines	Insulin resistance Increased blood pressure Vascular changes
↓ growth hormone ↓ IGF-1	Decreased muscle mass Increased fat mass
↓ testosterone (particularly men)	Decreased muscle mass and increased fat Less active Decreased quality of life
↓ estrogen (women)	More susceptible to vascular disease Bone health Quality of life impaired
↑ cortisol	Changes in fat distribution Decreased muscle mass and strength Mood and cognitive impairment
Thyroid function (↑ TSH, ↓ FT <sub>3</sub> and FT <sub>4</sub> )	Metabolic changes Mood and cognitive changes Cardiac function
↑ prolactin	Reflection of brain dopaminergic tone and related to feeding behavior

Changes associated with obesity and aging. Sex steroids and the growth hormone axis particularly show promise as areas where therapeutic intervention might improve aspects of health and well being.

leading to a decrease in the frequency and amplitude of gonadotrophin pulses. Testosterone replacement will reverse some of the changes in fat mass and fat free mass that accompany aging (Liu *et al.*, 2004). However, variable results in relation to changes in muscle strength, physical functioning, bone mineral density, and insulin sensitivity have been reported. It is often tempting in practice to treat men who are extremely hypogonadal, but firm recommendations on this will rely on more extensive clinical trials, and safety considerations will need to be taken into account. From available evidence, it is not clear whether dehydroepiandrosterone or testosterone is to be the preferred androgen replacement.

The role of sex steroids and replacement therapy with these is even more controversial in females. Males generally have a lower life expectancy and tend to develop cardiovascular disease at an earlier age. The relative protection enjoyed particularly by premenopausal women has been ascribed to their estrogen status. However, even though estrogen levels decline dramatically after menopause, the role of estrogen replacement in protecting against cardiovascular disease remains controversial, and is overshadowed by the increased risk of breast cancer with replacement. Consequently, estrogen replacement is currently recommended only as a short-term treatment for those with symptoms of estrogen withdrawal. The effects of sex steroids on vascular tissues are complex (Orshal *et al.*, 2004). Estrogen withdrawal at the time of menopause increases fat mass and decreases muscle mass. Although males are at increased risk of vascular disorders,

low levels of testosterone increase the risk of vascular disease and testosterone replacement in hypogonadal men protects against cardiac ischemia. Sex steroids are able to modify processes at the vascular endothelium that regulate constriction or vasodilatation of vessels and can also regulate the proliferation of endothelial or smooth muscle cells. Circulating sex steroid status is only a partial reflection of activity at the tissue level where androgen status may be amplified by the action of the enzyme 5 $\alpha$ -reductase, which converts testosterone to the more active hormone dihydrotestosterone. Testosterone is also converted to estrogen peripherally by the action of aromatase. The activity of aromatase is increased in obesity. In men and in postmenopausal women, estrogen is more of a local hormone than a circulating hormone, but concentrations and activities at the tissue level are relatively hard to study.

Circulating levels of growth hormone (GH), and of insulin-like growth factor-1 (IGF-1), decline with aging. Factors responsible for this include changes in the hypothalamic-pituitary axis, inhibition of GH release due to increased levels of free fatty acids, decreased secretion of the endogenous growth hormone secretagogue ghrelin, and changes in IGF-1 binding proteins. As with testosterone, GH treatment has been shown, in the short term, to reverse some of the changes in body composition that occur in obesity and aging. However, used alone, it appears to have limited ability to improve function and there is certainly no evidence of increased longevity with GH treatment (Borst, 2004).

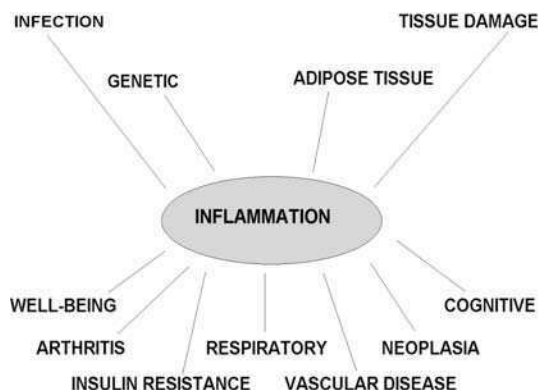

New treatments under consideration include use of growth-hormone releasing hormones or IGF-1 complexed with its major circulating binding protein (IGFBP-3). For maximum effect, treatments that enhance growth-hormone action may need to be combined with high protein diet and programs of exercise that encourage skeletal muscle hypertrophy.

Thyroid function is not generally markedly abnormal in severe obesity, and hormone levels are generally within the normal reference ranges. Thyroid volume and thyroid-stimulating hormone (TSH) may be increased, whereas levels of thyroxine (T<sub>4</sub>) and triiodothyronine (T<sub>3</sub>) are often lower than in nonobese subjects (Sari *et al.*, 2003). Elevated prolactin concentrations may partly reflect stress, but feeding behavior is related to central dopaminergic tone and loss of the inhibitory influence of dopamine on prolactin secretion may also contribute to changes in prolactin. Chronic elevation of cortisol, also seen in nonhuman models of aging (Erwin *et al.*, 2004), may be a reflection of chronic stress and may be driven to an extent by the cytokine changes seen in obesity and aging. It also may reflect altered metabolism of cortisol in adipose tissue. Increased cortisol may contribute to the change in body habitus with increased central fat accumulation and loss of muscle tissue (in effect a subclinical form of Cushing's syndrome). It may also be partly responsible for cognitive decline.

## Changes in Inflammatory Cytokines

A low-grade inflammatory state is an integral part of the aging process and occurs at an earlier age in subjects who are overweight or obese. Adipose tissue itself is a source of many of the pro-inflammatory cytokines that can be detected in the circulation. Apart from adipocytes, damaged organs and tissues, including the vasculature, may be sources of cytokines. The causes and consequences of the inflammatory changes are summarized in Figure 69.1.

There has been considerable interest that low grade infections may result in chronic activation of the immune system and that this may predispose to a variety of chronic disease states, including insulin resistance and atherosclerosis. Organisms that have attracted attention include those that cause dental and gum disease, *Helicobacter pylori*, *Chlamydia pneumoniae*, and viral infections including cytomegalovirus. A genetic component has also been recognized with polymorphisms in the genes or promoters for many of the cytokines accounting for variation in expression between individuals. For example, the common -174G/C polymorphism in the gene for interleukin-6 (IL-6) has recently been linked with longevity as the distribution of genotypes in the very elderly and appears to be different from that of the general population (Hurme *et al.*, 2005). The biological processes involved are obviously very complex, and no single genetic abnormality is going to account for the

**Figure 69.1** Inflammatory markers are increased as a result of production in adipose tissue and in other tissues damaged by the processes of aging. Genetic influences may also be important, as may infectious agents. Inflammation predisposes to, and is involved in, the progress of many of the disease states we associate with obesity and aging.

changes of aging and obesity, but with technological advances the interactions between different genetic polymorphisms will become progressively better understood.

It has now been confirmed in a range of studies that low-grade inflammation, as evidenced by increased circulating levels of C-reactive protein and other acute phase proteins, predicts the development of vascular disease and is of prognostic importance in patients with vascular disease. These changes also precede development of diabetes and are predictive for development of the condition. A variety of molecules has been implicated, and a full review is beyond the scope of this chapter. Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) is thought to be one of the mediators responsible for the metabolic syndrome. Its actions in the liver and other target tissues oppose that of the protective molecule adiponectin. TNF- $\alpha$  levels in the circulation tend to rise progressively with age, and they correlate with the degree of metabolic control in patients with type 2 diabetes. Increased TNF- $\alpha$  expression has also been documented in other pathological states, including atherosclerotic disease and Alzheimer's disease, and in patients with general frailty and cognitive decline. About a third of circulating IL-6 is derived from visceral adipose tissue in obese subjects. The molecule is involved in the normal cross talk between tissues such as adipose and muscle, and has a role in regulating substrate flux during exercise. Increased IL-6 production relates to body composition and the presence of disease states, including infections, and is genetically modulated. IL-6 is involved in the pathogenesis of the metabolic syndrome, vascular diseases, neoplastic conditions, and other disease states and may be an important regulator of the endocrine and physiological adaptations to obesity. The range of cytokines recognized to be involved in these processes is widening rapidly. For example, interleukin-4 (IL-4) has recently been hypothesized to have a role in regulating function of the hippocampus in aging (Nolan *et al.*, 2005).

A large number of clinical studies have now demonstrated the role of inflammatory cytokines in the pathogenesis of, and as potential markers for, pathological and functional states that occur in aging. The Rotterdam study (Hak *et al.*, 2001) demonstrated that circulating levels of CRP, IL-6,  $\alpha$ -1-antichymotrypsin, and intercellular adhesion molecule-1 (ICAM1) were increased in elderly subjects with insulin resistance and high cardiovascular risk. A recent U.S. study (Penninx *et al.*, 2004) of nearly 3,000 aging subjects reported that levels of TNF- $\alpha$ , IL-6, CRP, and soluble cytokine receptors were predictive of decline in mobility over a 30-month period. Other studies have related inflammatory changes to muscular strength and power (Barbieri *et al.*, 2003) and to cognitive decline in the elderly (Yaffe *et al.*, 2003). In summary, aging and chronic inflammation go hand in hand. The association is stronger in the obese who develop inflammatory changes at an earlier age. The presence of inflammatory markers is predictive of and relates to a variety of chronic disease states, and increased expression of these markers is also seen in subjects who are likely to experience decline in physical and mental functions.

### Metabolic Syndrome and Cardiovascular Risk

The disease most studied in relation to obesity is diabetes. The precursor to type 2 diabetes and to cardiovascular disease in many patients is the metabolic syndrome. By definition, this is said to be present if three or more of the following five conditions are met:

- Abdominal obesity: waist circumference >102 cm in men and >88 cm in women
- High triglyceride levels:  $\geq 150$  mg/dl,  $\geq 1.7$  mmol/L
- Low HDL cholesterol: <40 mg/dl (<1.04 mmol/L) in men and <50 mg/dl (<1.30 mmol/L) in women
- High blood pressure:  $\geq 130/85$  mmHg
- High fasting glucose:  $\geq 110$  mg/dl ( $\geq 6.1$  mmol/L)

This was the accepted definition of the metabolic syndrome until recently, and, using these criteria, a variety of studies in North America demonstrated that the syndrome was present in 21 to 33% of the population, with even higher prevalence in certain ethnic groups. A recent study (Ford *et al.*, 2004) using the NHANES cohorts compared the prevalence of metabolic syndrome in the 1988–1994 (NHANES III) cohort with the 1999–2000 cohort. The prevalence increased overall, but particularly in women who experienced a 23.5% increase. In fact, the definition of metabolic syndrome is changing with lower cut-off points for waist circumference and for fasting glucose ( $\geq 100$  mg/dl,  $\geq 5.6$  mmol/L), meaning that an even larger proportion of the population will have the syndrome and thus be deemed to be at risk. Much of this increase will be among the elderly. Indeed, in the

elderly, metabolic syndrome will be the norm, except in subjects who are underweight. So, should we be regarding it as a disease state?

In a study of over 12,000 Japanese subjects (Hasegawa *et al.*, 2005), factor analysis was used to examine the relationship between cardiovascular risk factors. In this extensive study, the major influence of BMI was in younger subjects. Similarly, in another Japanese study involving nearly 160,000 subjects (Wakabayashi *et al.*, 2004), the influence of BMI on blood pressure was much weaker in the elderly. The concept of the metabolic syndrome has been useful in screening populations who are at risk from diabetes and cardiovascular disease. It is important to realize, however, that susceptibility to the individual risk factors and disease states that relate to the syndrome are caused by multiple factors, not all of which relate to obesity. Around a quarter of patients with type 2 diabetes do not have the metabolic syndrome. There is no question that the accumulation of multiple risk factors places individuals at risk of morbidity and mortality from vascular disease, as shown in the recently published Casale Monteferrato Study (Bruno *et al.*, 2004). Furthermore, development of multiple risk factors, whether or not the individual is classified as having the metabolic syndrome, is a sign of deteriorating health and is also associated with cognitive and functional decline (Crooks *et al.*, 2003). Risk of diabetes is attenuated or accelerated by other factors such as adiponectin, high levels of which appear to confer a reduced risk of diabetes (Kanaya *et al.*, 2004). The role of leptin, an exclusive product of adipose tissue in regulating appetite and food intake, is now well established. There is evidence that responses to leptin may become blunted in elderly subjects. This may contribute to continuing food intake in excess of requirements in individuals whose functional and exercise capacity, and therefore, calorie requirements, are decreasing as they age.

### Other Aspects of Health and Function

The study of obesity as a human disease state and efforts to treat the condition have gained momentum as it has become increasingly appreciated that obesity impinges on many aspects of health and functioning. The relationship between obesity and malignant disease has already been discussed (Calle *et al.*, 2003). Predisposition to malignant disease increases as we age, and disability from malignant disease, or fear of developing malignant disease, is a major factor in determining the well-being of the elderly. After malignancy and cardiovascular disease, osteoarthritis is the third leading cause of years lost due to disability. In fact, obesity has a relatively modest part to play in the pathogenesis of osteoarthritis (Lieveense *et al.*, 2003). However, for a given severity of arthritis, the level of pain and disability is much greater in patients who are obese. Apart from the symptoms directly attributable to the arthritis, there are strong associations

with mood disturbances, gastrointestinal symptoms, and disability from ischemic heart disease. Weight loss and regular exercise improve mobility, well-being, and reduce pain. Decreased cardio-respiratory fitness shows a strong association with obesity and the metabolic syndrome. Waist-hip ratio shows an inverse relationship with forced vital capacity (FVC) and forced expiratory volume (FEV<sub>1</sub>), even after adjusting for confounding variables such as age and smoking habit. Sleep disturbance is now recognized to be a major cause of ill health, and up to 4% of the population have obstructive sleep apnea. Decreased lung function and sleep apnea have been linked to vascular dysfunction, cardiovascular events, and decreased life expectancy. Obesity has also been linked to risk of developing lens opacities and to increased risk of age-related macular degeneration.

Thus, chronic pain, decreased cardio-respiratory performance, and diminished mobility arising from a range of disease states may all contribute to poor health. Quality of life among the elderly is determined by other factors including social circumstances, cognitive function, and whether or not they are engaging in physical activity (Borowiak *et al.*, 2004). The latter may be determined by choice and circumstances but is also a general measure of functional ability. Jensen and Friedmann (2002) followed a large cohort of people over three years. Obesity was highly correlated with poor functional status at baseline and was a major determinant of functional decline during the three years of the study. Relationship between obesity and poor functioning was more marked in women. Other studies have confirmed this relationship between obesity and declining functional status, and the association does not entirely relate to changes in body composition. Visscher *et al.* (2004) followed 19,518 Finnish men from a wide age range and demonstrated that obese subjects had more years of ischemic heart disease, greater disability, and were more likely to use medicines regularly.

## Treatment

The increasing prevalence of the obesity in the young is one of the most pressing public health problems facing us at present. With obesity comes the cluster of risk factors we call the metabolic syndrome. There is no question that, in younger subjects, weight management to deal with the multiple risk factors, and thus to decrease long-term risk, is the preferred approach. However, there is an inconsistent relationship between obesity and the components of the metabolic syndrome, particularly in the elderly. Many people who are obese do not develop diabetes and do not develop hypertension. Other factors, including the aging process itself and the endocrine and inflammatory changes that accompany it, are also important. There is now compelling evidence that not only obesity *per se* but weight gain, particularly

around the waist, is an important determinant of risk of diabetes and cardiovascular disease.

One of the dangers of vigorous attempts to encourage weight loss in the elderly is that they may lose muscle mass as well as fat. Worsening the preexisting sarcopenia may further decrease their functional capacity and their general health status. Severe calorie restriction for prolonged periods should be avoided, except in circumstances where marked weight loss is deemed to be desirable in the short term, and only then if the diet proves to be effective and tolerated by the patient. It is common for patients to be told to lose weight before an operation (such as knee replacement) can be carried out. There is really no evidence that such acute weight loss either improves long-term prognosis or decreases risk from surgical procedures. Since weight gain and weight loss are each associated with poorer prognosis in the elderly, weight maintenance is the preferred approach for many, even if they are overweight. Vigorous management of individual risk factors including diabetes, dyslipidemia, and hypertension is entirely appropriate, particularly in the context of secondary prevention. We have recently reviewed the treatment considerations around obesity in the elderly (Kennedy *et al.*, 2004).

In terms of available evidence, the best treatment for elderly obese patients is exercise. Cardio-respiratory fitness is an important determinant of health status in the elderly and can be improved by exercise. The majority of elderly women actually achieve the currently recommended levels of exercise during activities of daily living, including housework. However, this level of activity does not appear to be protective against obesity and its consequences. There is now evidence from a large number of studies that exercise in the elderly is beneficial in terms of glucose tolerance, cardiac and respiratory function, improved function and quality of life. Patients have traditionally been instructed that aerobic exercise is most beneficial. Meaningful amounts of aerobic exercise may not be achievable in many with functional limitation and severe obesity. Furthermore, there is often a worsening of symptoms and well-being in the short term, and this may decrease adherence to programs of exercise. Progressive resistance training has the same benefits in the elderly as it does in the young. These benefits include increased muscular strength and function, along with reversal of some of the metabolic changes that accompany sarcopenic obesity. Testosterone levels are increased (both in males and females). Levels of GH and IGF-1 are also increased with exercise, and, together, these changes may contribute to improvements in bone health as well as favorably influencing body composition and energy balance. The other form of exercise that is useful in the elderly is endurance training. Several studies have demonstrated considerable health benefits from home-based programs of exercise where low-level exercise is undertaken over more prolonged periods than would be possible for aerobic exercise. We find that

a pedometer is a useful way to encourage low-level exercise and to increase activity. Endurance exercise not only increases energy expenditure during exercise but also increases REE by up to 10%. Since they start from the lowest baseline, elderly subjects may, in relative terms, show the greatest benefit from endurance exercise interventions (Sartorio *et al.*, 2004).

A full review of dietary interventions cannot be undertaken here. In relation to glucose tolerance and the metabolic syndrome, there has been a move away from traditional low-fat diets. Restricted carbohydrate diets have gained in popularity, and available evidence, which is now considerable, suggests that they are both safe and effective when used for periods up to six months. In terms of sarcopenic obesity, one of the benefits of such diets is that subjects adhere to a relatively high protein intake. Maintaining positive protein balance and intake of essential amino acids is important during any treatment of obesity in the elderly so that muscle mass is not lost during calorie restriction. Several important studies published over the past two years have confirmed that diets high in fiber and wholegrain and low in refined carbohydrate improve glucose tolerance and protect against development of diabetes. Furthermore, such diets also decrease circulating CRP, IL-6, and other inflammatory markers and may thus influence the development or progression of a variety of disease states (Ajani *et al.*, 2004). The multiple benefits of lifestyle intervention programs, including their effects on systemic inflammation, have been reviewed recently (Nicklas *et al.*, 2005). Lifestyle interventions are also highly effective and cost effective in preventing or delaying the onset of diabetes and its associated complications (Knowler *et al.*, 2002).

Only two drugs are in widespread use for treatment of obesity—sibutramine and orlistat. Very limited information on their use in the elderly has been published; indeed the trials have tended to exclude elderly subjects. There is no reason to believe that their benefit is any less than in younger subjects. Sibutramine is a centrally acting inhibitor of noradrenalin and serotonin uptake. It acts by promoting satiety, thus decreasing food intake. The drug fairly consistently increases blood pressure and pulse rate, making it undesirable for long-term use. Blood pressure needs to be reviewed every six weeks or so. It can be used in hypertensive patients when the blood pressure is under control but should be avoided in patients with ischemic heart disease. Orlistat is a gastrointestinal lipase inhibitor that acts by decreasing fat absorption by the gut by about 30%. Its use is associated with a high frequency of gastrointestinal side effects, particularly if the patient does not adhere to a low-fat diet, but it is safe for long-term use, and the potential to prevent development of diabetes has recently been demonstrated. Other drug therapies, including metformin and thiazolidinediones have also been shown recently to prevent or retard the onset of type 2 diabetes (Knowler

*et al.*, 2005). Controversies around the use of hormone replacement (sex steroids and GH) have been discussed earlier, but this line of treatment clearly has potential. Direct treatment on the immune activation that accompanies obesity and aging with anti-inflammatory drugs has also been supported by some recent evidence demonstrating beneficial effects on cognitive function.

Bariatric surgery for the extremely obese patient is now becoming more widely available and more accepted as a form of therapy as evidence regarding its safety and efficacy accumulates. Nonetheless, experience of using this type of surgery in the elderly is still quite limited. The procedures fall into two categories. Restrictive procedures decrease the effective size of the stomach, thus reducing the amount that can be eaten and indirectly diminishing appetite. Currently, the most widely used technique of this sort is laparoscopic gastric banding. This is a safe, minimally invasive and reversible technique with a very low peri-operative morbidity and mortality risk. Limited literature and clinical experience with this procedure in the elderly suggests that it is safe and can be effective. The other approach is a bypass procedure that limits the absorption of calories from the stomach and small bowel. This is the preferred procedure for the extremely obese and for those with eating disorders. This procedure is now often carried out laparoscopically, thus limiting risk. This approach is effective in the elderly and decreases use of medicines for the complications of obesity (St. Peter *et al.*, 2005).

## Conclusion

Until now, the greatest impact of the global increase in obesity prevalence has been in the working years of life with premature death and disability from chronic diseases, loss of time at work, and increasing health costs. With improving health and social care as factors, we are now experiencing an exponential increase in obesity among the elderly. This increase is projected to continue, at least over the next decade, and probably beyond. Because of the influence of factors other than obesity, the risk of death attributable to obesity is less marked in the elderly than it is for younger subjects. The major risks are from cardiovascular disease and malignancy. Distribution of body fat needs to be considered: abdominal obesity is most closely linked to mortality risk, whereas peripheral adiposity may actually be protective. The ability to maintain body weight, albeit at a level that is higher than desirable, should be seen as a sign of health in the elderly; involuntary weight loss is associated with poor function and poor prognosis.

Metabolic activities vary among different fat depots. The evidence is not so clear cut as in younger age groups, but accumulation of visceral fat is associated with increased insulin resistance and hypertension. Peripheral fat, particularly in the female distribution, may even have

a protective role and thus should not be regarded as a target for treatment, except for cosmetic reasons. One important recent development has been the realization that lipid accumulation within the liver and within skeletal muscle is a potent determinant of peripheral insulin sensitivity and of impaired substrate oxidation in these tissues. Sarcopenia, along with the changes in body fat accumulation and distribution, accounts for changes in function and energy balance with aging. Endocrine changes, particularly decreased levels of sex steroids and reduced activity in the growth hormone axis, are significant determinants of the behavioral and morphological changes that occur with obesity and aging. Sex steroid replacement and treatment with either growth hormone or insulin-like growth factor-1 remain treatment options, but a number of controversies need to be resolved before their use can be widely recommended. However, there is no evidence to suggest that elderly subjects are less likely to benefit from these treatments, if there is long-term benefit, than their younger counterparts.

Chronic low-grade inflammation accompanies both obesity and aging, and its presence is related to development of insulin resistance, neoplasia, vascular disease, and cognitive decline, among other complications of obesity. Measurement of markers of inflammation, including C-reactive protein and interleukin-6, allows us to identify individuals who are at high risk, and the inflammatory component has been of recent interest as a potential therapeutic target. Adipose tissue is highly adaptive and is the most variable component of body composition. A variety of cytokines, adipokines, and hormonal mediators produced in adipose tissue modify risk of insulin resistance and other phenomena associated with aging.

There is controversy about whether, and when, obesity should be treated in the elderly. There are no clear recommendations about what constitutes an ideal body weight and how obesity should be assessed. The relationship with excess mortality is not so clear cut as it is in the young. Metabolic syndrome is an important determinant of health but, as currently defined, is an almost inevitable consequence of aging. Metabolic syndrome does predispose to a variety of chronic disease states and is associated with functional decline, but we may need to consider different definitions for young and older subjects. There is a limited place currently for pharmacological and surgical treatment of obesity in the elderly, and experience with these, and the range of treatments, is growing. The influence of micro- and macro-nutrient components of the diet is being increasingly appreciated, and this should lead to development of dietary interventions that do not severely restrict calories and are sustainable. This, along with exercise programs with endurance exercise and progressive resistance training, offers the best prospect for improving the health and reducing the risk of the increasing number of people who are both overweight and elderly.

# Age and Joints

Klaus Bobacz and Ilse-Gerlinde Sunk

*During lifetime the joints of the human body are subjected to a number of age-related alterations. These changes may affect all joint structures, muscles, tendons, ligaments, cartilage, synovial membrane, or joint capsules, and occur on the biomechanical, molecular, or cellular level. Due to the longevity of the population, joint disorders are among the most prevalent and symptomatic healthcare problems of middle-aged and old people.*

*This chapter focuses on the effects of aging on the soft tissues of which joints are composed. Generally, alterations comprise a change in tissue cellularity, metabolic cell activity, and extracellular matrix composition. These structure impairments may influence the functionality of the joints and may lead to a decline in mobility, resulting in a loss of independence and finally in a retreat from social life.*

*Thus it is important to increase the understanding of the age-related changes of joint structures and their relationship to their impairment to potentially maximize the quality of life of affected individuals.*

## Introduction

The efficiently operating musculoskeletal system is highly dependent on an unimpaired functionality of diarthrodial joints. Generally, joints connect bone-endings with each other and allow a frictionless movement of their surfaces. Different specialized structures are responsible for a smooth joint movement. Muscles, tendons, ligaments, cartilage, synovial membrane, and bone all do their share to ensure a proper joint function.

Joint stability is provided mainly by four factors:

1. The shape of the component parts, which are configured in a way that loading enhances the exactness of their position.
2. Ligaments, as they connect one bone to another and act to constrain and guide joint motion.
3. Muscular stabilization, especially in polyaxial joints.
4. Synovial fluid, as it functions as an adhesive seal between joint surfaces.

The by far more important role of the synovial fluid, which is synthesized by the synovial membrane, is

lubrication of joint members. The synovial fluid can be compared to lube oil and facilitates joint movement.

In active motion, mechanical forces affect all structures of the healthy joint. The greatest share of loading energy is absorbed by the tendons, ligaments, and muscles. Loading stress that is not taken up within the surrounding muscles, tendons, and ligaments is distributed directly on the articular cartilage and the underlying bony structures.

With increasing age, the soft tissues that form the muscles, tendons, ligaments, cartilage, synovial membrane, and joint capsules are subjected to age-related changes. It is well known that the incidence of rheumatoid arthritis, and in particular the development of osteoarthritis, the most prevalent joint disease, are highly linked to increasing age (Creamer *et al.*, 1997; Davis *et al.*, 1991; Felson, 1990).

Joint disorders are one of the most prevalent and symptomatic health problems among middle-aged and elderly people and comprise pain, a decrease in strength, and restriction in the range of motion. These factors impair affected people in their everyday life routines, occupation, and leisure activities. In some individuals these impairments may lead to a decline in mobility, resulting in a loss of independence and finally in a retreat from social life.

Considering population-aging predictions, the percentage of the population age 65 or older will increase significantly during the future decades and will meet the 20% mark in the United States in 2030. In Europe the size of this population is expected to jump from 14.7% in 2000 to more than 23% in 2030 (Kinsella *et al.*, 2005).

The predicted longevity of the population with regard to joint function impairment is seen as a major socio-economic problem and thus makes it extremely important to understand underlying mechanisms in musculoskeletal aging to help prevent and treat these disorders.

## General Aspects of Cellular Senescence

As for all mammalian cells, be they of fibroblastic or epithelial origin, the cells that form the soft tissues of the musculoskeletal system will also undergo senescence. This process starts after an extended period of

proliferation or in response to inadequate growth conditions or physiologic stress. Senescent cells cease to respond to mitogenic stimuli; they undergo changes in the chromatin structure and gene expression and become enlarged and flattened (Serrano *et al.*, 2001; Shelton *et al.*, 1999). Characteristically, such cells show increased adhesion to the extracellular matrix, while losing cell-cell contact. Regarding these alterations, cellular senescence can be seen as a program activated to prevent cell proliferation in various situations of physiologic stress (Ben Porath *et al.*, 2004).

In classical experiments in the 1960s it has been shown that normal human fibroblasts cease to divide following a period of propagation in culture (Hayflick *et al.*, 1961), which was later called Hayflick-limit.

There exist various triggers of senescence of which telomere uncapping has garnered much attention in senescence research. Telomeres are the terminal DNA-proteins of chromosomes. Analysis of telomere length as a function of age, either in cells of people of different age or as a function of cell division number in cultures of human fibroblast, show that mean telomere length gradually decreases with increased age or cell division number (Cooke *et al.*, 1986; Harley *et al.*, 1990). The shortening of the telomeres leads to telomere “uncapping,” which causes disruption of the structure of the protective cap at the end of the telomere (Blackburn, 2001). The uncapped telomere is thought to be recognized as a DNA-break, which activates the DNA damage machinery.

Besides telomere dysfunction, senescence of normal cells can be induced by direct DNA damage, oxidative stress, and oncogene expression.

Oxidative stress plays an important role in the induction of senescence by causing DNA damage and accelerating telomere loss (Forsyth *et al.*, 2003; Parrinello *et al.*, 2003). It has been demonstrated that human fibroblasts undergo premature senescence in high ambient oxygen conditions (Chen *et al.*, 1995). In the condition of internal accumulation of reactive oxygen species, cellular components can be damaged through the oxidation of DNA, proteins, and lipids (Chen *et al.*, 1998).

Reactive oxygen species can be induced by overexpression of the RAS oncogene, promoting cellular senescence (Lee *et al.*, 1999). This response to the RAS activity has been suggested to represent a tumor-suppressor mechanism, by which cells prevent uncontrolled proliferation in response to the aberrant activation of proliferation-driving oncogenes. However, the role of reactive oxygen species in RAS-induced senescence is not fully understood.

Direct DNA damage can be caused by irradiation of cells or by treatment with DNA-damaging agents and may induce cells to undergo senescence. In many cases, the cellular response to such damage is cell death, but also irreversible cell-cycle arrest, depending on the type of agent and/or dosage administered (Wahl *et al.*, 2001).

All these inductors of senescence share a central activating pathway of senescence. P53 and Rb, two tumor suppressor proteins, have been shown to play a critical role in senescence induction, since both are activated upon the entry into senescence. The specific targets of these proteins constitute the majority of the effectors that are necessary for cell-cycle progression.

As a result of aging and cellular senescence, the biological and mechanical behaviors of all musculoskeletal tissues, including skeletal muscle, tendons, ligaments, cartilage, synovial membrane, joint capsule, and bone, undergo specific alterations. These changes follow similar patterns that comprise alterations in the number and function of cells, in their proliferative and synthetic capacity, as well as in the composition of the extracellular matrix. However, since the tissues differ in their composition, structure, and function, age-related changes must be considered individually.

## Age-Related Changes in Joint Structures

### SKELETAL MUSCLE

The normal skeletal muscle consists of multinucleated cells called fibers. Each muscle fiber is an elongated cell surrounded by a plasma membrane called the sarcolemma. Fibers contain myofilaments, contractile proteins that are responsible for muscle contractions. These fibers are grouped in fascicles and surrounded by connective tissue, the perimysium (Bossen, 2000). Skeletal muscles are connected to bone by tendons at each end.

One of the most obvious effects of aging is a decline in muscle strength that is largely related to a loss of muscle mass (sarcopenia). After skeletal maturation the total muscle mass declines at an average of 4% per decade until the age of 50 years. In older individuals the rate of loss increases up to 10% per decade (Buckwalter *et al.*, 1993). Local injury and damage to the innervation of muscle fibers occurs throughout life, but in old age the process of collateral sprouting of the neurons appears to become less effective in repairing innervation, and muscle fibers are lost (Campbell *et al.*, 1973; Lexell *et al.*, 1988).

Normal skeletal muscle has the ability of repair and regeneration following local injury of muscle fibers. This process is thought to be critically dependent on the activation of so-called satellite cells, usually quiescent cells detected outside the sarcolemma but within the basal lamina. Satellite cells, first described in 1961 (Mauro, 1961), are now seen as “spare parts” for postnatal muscle growth and repair.

The recruitment of the satellite cells is governed by a splice variant of the insulin-like growth factor (IGF)-I, termed mechano growth factor (MGF), which is expressed in response to mechanical stimulation (McKoy *et al.*, 1999; Yang *et al.*, 1996). In an animal model, electrical stimuli led to an increase in muscle mass as well as

a concomitant upregulation of MGF mRNA compared to resting control muscles (Goldspink *et al.*, 1992).

The aging organism is much less able to increase MGF levels after high resistance exercise, as compared to muscles of younger individuals (Hameed *et al.*, 2003). Additionally, satellite cell functionality can be decreased by an abnormal accumulation of reactive oxygen species due to a drastic reduction of antioxidant activity in aged satellite cells (Fulle *et al.*, 2005; Short *et al.*, 2005a). This decrease in the antioxidative capacity may cause destabilizing oxidative damage to aging satellite cells, limiting their ability to repair muscle.

Another important factor in the aging process of the skeletal muscle is a decline in mitochondrial function, since the required energy for proper muscle function is generated in mitochondria, which contain their own DNA, called mitochondrial mtDNA (Clayton, 1992). mtDNA abundance and mitochondrial ATP production have been demonstrated to decline with advancing age. The content of several mitochondrial proteins was reduced in older muscles, whereas the level of the oxidative DNA lesion was increased, supporting the oxidative damage theory of aging (Short *et al.*, 2005a).

In contrast, it has been reported that mitochondrial capacities were related to physical activity, but not to age. The mitochondrial theory of aging, which attributes the age-related decline of muscle performance to decreased mitochondrial function, was questioned by these authors (Rasmussen *et al.*, 2003).

Other age-related changes of the skeletal muscle include changes in myosin heavy chain mRNA and protein expression (Short *et al.*, 2005b), myosin heavy chain composition of muscle spindles (Liu *et al.*, 2005), or alterations in the maximal O<sub>2</sub> uptake rate (Conley *et al.*, 2000).

## DENSE FIBROUS TISSUES

Dense fibrous tissues, which include tendons, ligaments, and joint capsules, are also subjected to age-related changes. Although alterations in these tissues received less attention than those in skeletal muscle or articular cartilage, serious impairment can develop in aged individuals as a result of age-dependent changes in fibrous structures.

### *Tendons*

Tendons are tough yet flexible connective tissue bands that attach muscle to skeletal structures. Bundles of collagen that are held together by a layer of loose connective tissue are the main components of tendons. These dense tissue straps are well-suited as transducers, enabling the force of a muscle to be exerted at a distance from the muscle itself. Tendons possess typical tensile properties—the forces applied to a tendon may be more than five times body weight.

It has been proposed that tendons lose their elasticity and slowly become stiffer and more brittle as a result

of age. Moreover, the blood supply that nourishes the tendon was also reported to diminish with age and may cause a decrease in vascular perfusion (Brewer, 1979; Rathbun *et al.*, 1970). These alterations may lead to spontaneous or low-energy ruptures of mostly the rotator cuff of the shoulder, the long head of the biceps brachii, the posterior tibial tendon, patellar tendon, and the Achilles tendon (Brewer, 1979; Burkhead, 1990; Jahss, 1991).

Taking a closer look at structural, mechanical, or cellular age-related changes in tendons, Birch and coworkers reported that there exist differences in structural changes in different tendons. In some tendons aging resulted in a significant increase in collagen-linked fluorescence and a decrease in cellularity, whereas in other tendons high levels of type III collagen were found as a function of age (Birch *et al.*, 1999). These findings are supported by x-ray data on human tendons, demonstrating age-related changes in collagen packing (Naresh *et al.*, 1992). Furthermore, in human supraspinatus tendons there was a significant decrease in total glycosaminoglycan, chondroitin sulphate, and dermatan sulphate concentration with age (Riley *et al.*, 1994). These differences in macromolecular composition and aging may contribute to a tendon specific degeneration.

However, Goodman *et al.* suggested that tenocytes, which become differentiated at an early age, respond to cyclical strain and transforming growth factor- $\beta$  stimulation, and preserve their tendon specific response, but increasing age had only little effect on tenocytes (Goodman *et al.*, 2004). Regarding age-related changes in biomechanical properties, no difference in tensile strength between mature and old tendons was found, suggesting a high compliance of tendons during aging (Nakagawa *et al.*, 1996). Additionally, the tensile and viscoelastic properties of the patellar tendon differed minimally between younger and older ages (Johnson *et al.*, 1994).

Age-related changes in tendon composition may contribute to degeneration of this tissue. Otherwise, the impact of age on mechanical properties seems to be only minimal. This could depend on an above-average physical training status in some individuals, since it has been reported that strength training in old age, at least partly, can reverse the deteriorating effect of aging on tendon properties and function (Maganaris *et al.*, 2004).

### *Ligaments*

Ligaments, which are structurally quite similar to tendons, but appear to have more elastic fibers, attach adjacent bones to one another and maintain them at their correct anatomical positions during movement. They also provide structural support around joint capsules and at sites where bones make contact with other bones. Ligaments have dynamic characteristics, since they respond to exercise or immobilization by altering their tensile strength and are capable of repair after injury.

As seen in tendon tissue, mechanical properties of ligaments may undergo changes with increasing age, such as the deterioration of tensile properties. The structural characteristics of ligament-bone complexes show a progressive decline in tensile stiffness and ultimately lead to failure with increasing age (Woo *et al.*, 1991). Similar results were reported for human lumbar posterior spinal ligaments, where a significant correlation with a decrease in the mechanical strength and increasing age was found (Iida *et al.*, 2002).

A recent light and electron microscopic study revealed ultrastructural differences in the posterior cruciate ligaments, that is, a decrease in collagen fiber diameter and increase in collagen fibril concentration, with aging (Sargon *et al.*, 2004). These data paralleled previously published work on age-related changes of collagen fibrils in human anterior cruciate ligament and Achilles tendon (Strocchi *et al.*, 1991; Strocchi *et al.*, 1996).

When ligament tissue was tested upon alterations in the content of matrix components, an age-dependent decrease in elastin and collagen metabolism was obvious (Osakabe *et al.*, 2001). Moreover, age-related changes of elements were investigated, showing an increase in calcium and magnesium, although iron levels were reduced in the tested ligaments (Tohno *et al.*, 1999; Utsumi *et al.*, 2005).

Given the age-related changes occurring in ligaments affecting mechanical properties, we would expect a quite high incidence of ligament injuries with aging. In particular, since aging ligament cells synthesize lower amounts of elastin and collagen, that may contribute to a decline in mechanical properties and consecutively to an increased risk of injury with advancing age. However, the ability to respond to growth factor stimulation is not lost in aged ligament fibroblasts (Deie *et al.*, 1997), which may uphold matrix remodeling to such a degree to sufficiently withstand mechanical stress even in older individuals. Besides, an overall reduction in physical activity with increasing age may further prevent injuries to this tissue.

#### *Joint capsule*

The joint capsule resembles a sac-like envelope that forms a sleeve around the synovial joint and encloses its cavity. The joint capsule is a dense fibrous connective tissue that is attached to the bones via specialized attachment zones at the end of each involved bone. It seals the joint space, provides passive stability by limiting movements, provides active stability via its proprioceptive nerve endings, and may form articular surfaces for the joint. It varies in thickness according to the stresses to which it is subject, is locally thickened to form capsular ligaments, and may also incorporate tendons.

Nevertheless, some authors doubt the existence of a joint capsule as a defined structure, since it may be regarded as a basketwork of the surrounding ligaments and tendons appearing to form a fibrous capsule.

Little is known about age-related changes in joint capsules. In addition, detailed biomechanical trials of age-dependent alterations in joint capsules have not been reported to the best of our knowledge.

Investigations in knee and finger joint capsules showed that the attachments to bone contain fibrocartilage that is rich in type II collagen and glycosaminoglycans. The attachment changes with age as type II collagen spreads into the capsular ligament or tendon (Benjamin *et al.*, 1991). With mechanical loading parts of the capsule adapt by forming fibrocartilaginous tissue by accumulating cartilage-like glycosaminoglycans and type II collagen. Such regions can be found especially in aged material (Benjamin *et al.*, 1991).

Since the joint capsule contains tendinous and ligamentous structures, the similarity between these tissues suggests that their mechanical properties may also deteriorate with age (Buckwalter *et al.*, 1993).

#### SYNOVIUM

The synovium is the innermost portion of capsular ligament of synovial joints. It is commonly seen as a multilayered complex comprising several layers (intima, subintima, and superficial vascular plexus). Besides its function as immunologic microenvironment, the synovium allows disconnection between adjacent moving structures. Moreover, it is responsible for synovial fluid synthesis, a dialysate of plasma containing high-molecular weighted polysaccharides, known as hyaluronan. The synovial fluid maintains a fluid film between cartilage surfaces under load, which allows hydrodynamic lubrication. Synovial villi, which provide versatile deformability during movement, become more common with age and may compensate for the growing inelasticity and increasingly fibrous character of the subintima.

Investigations of radiohumeral joints showed that the villous pattern changes as a result of aging. Dependent on the location within the joint, the villi even may display a hard plicate pattern in the adult (Isogai *et al.*, 2001).

Morphological studies of the aging synovium revealed an overall loss of synovium lining cells. In detail, synovial intimal fibroblast numbers decreased with advancing age, whereas there was a relative increase in synovial intimal macrophages. Moreover, a fibrosis of the intimal layer caused by collagen accumulation was described, as well as a decreased vascularity (Jilani *et al.*, 1986; Pasquali-Ronchetti *et al.*, 1992).

The composition of the lubricating synovial fluid is also subjected to age-dependent alterations. The concentrations of chondroitin sulfate and hyaluronic acid were measured and were found to vary with age. Their values were highest between 20 and 30 years of age, and thereafter they showed a tendency to decrease (Nakayama *et al.*, 2002). Similar results were described for hydroxyproline and glycosaminoglycan levels, as these macromolecules were reduced with increasing age (van den Boom *et al.*, 2004).

Interestingly, the synovial tissues harbor multipotent mesenchymal stem cells. These cells could be induced to differentiate to the chondrocyte, osteocyte, and adipocyte lineages. The multipotent mesenchymal stem cells showed only limited senescence; neither extensive expansion in monolayer culture, nor donor age or cryopreservation affected their multilineage potential (De Bari *et al.*, 2001). These findings suggest the presence of active synovial mesenchymal stem cells even in elderly individuals. To determine their physiological function, however, further research is needed.

### INTERVERTEBRAL DISC

Intervertebral discs undergo dramatic changes with increasing age. Since stiffness and pain in the back and neck are among the most common physical complaints of the middle-aged and older people, alterations and degenerative changes of the intervertebral disc are of high relevance for clinical routine.

However, the intervertebral disc cannot be compared to a synovial joint, explaining why most of its pathologic features are quite different from those of a joint of the appendicular skeleton (Grignon *et al.*, 2000). Considering this fact, the changes of the intervertebral discs should not be dealt with in detail.

Briefly, with increasing age, fissures and cracks appear in the disc extending from the periphery to the central regions. Morphological studies showed a decrease in proteoglycan and water content as well as a dramatic decline in cell types and cell viability in the central region of the disc (Buckwalter, 1982). Ultrastructurally, disc matrix proteoglycan concentration decreases in the central regions (Buckwalter, 1982; Buckwalter *et al.*, 1985; Buckwalter *et al.*, 1989). In particular a reduction in aggregating proteoglycans and in the size of these aggregates can be observed. A decline in the concentration of a functional link protein, responsible for stabilizing proteoglycan aggregates, may cause changes in proteoglycan structure.

The most critical age-related changes in intervertebral discs are a loss of blood vessels supplying the region of the disc (Hassler, 1969). The consecutive decline in nutrition may lead to a decrease in cell viability and biosynthetic function.

Although the apparent severity of age-dependent changes in the intervertebral discs, regeneration of disc tissue seems to be possible, as shown by *in vitro* studies of enzymatically compromised tissue of the central disc regions (Nitobe *et al.*, 1988).

### ARTICULAR CARTILAGE

Articular cartilage is a connective tissue with a unique structure that provides mechanical resistance to compression and shear forces as well as smooth and frictionless joint movement. Cartilage is not a static structure, but a dynamic functional unit that is in a continuous state of adaption to the changing demands placed upon it.

The tissue is composed of an expanded extracellular matrix, consisting of a collagen network, mainly type II collagen, and proteoglycan molecules, especially aggrecan. A single cell type, the chondrocytes, lies embedded in the cartilage matrix. Chondrocytes account for only 1 to 2% of the tissue volume, but are essential for tissue maintenance since they uphold the physiological steady-state between matrix degradation and tissue replenishment.

Aging of the articular cartilage is highly associated with the development of osteoarthritis, even though degenerative processes seen in osteoarthritis are clearly different from those in aging (Creamer *et al.*, 1997; Davis *et al.*, 1991; Felson, 1990). However, aging processes sooner or later undermine cartilage stability in various ways and are likely to predispose to disease development and/or progression.

Intriguingly, the prevalence and severity of fibrillation of cartilage vary among joints and among different regions of the same joint. Degenerative changes in articular cartilage are not necessarily linked to pain and loss of motion of the joints; not all individuals who suffer from osteoarthritic symptoms have radiographic evidence of it, nor do all degenerative changes progress with age, even in people where osteoarthritis was diagnosed by clinical and radiographic means.

The relationship between aging and changes in the structural and cellular composition of articular cartilage is not fully understood, in particular with regard to its interindividual differences and heterogeneous clinical appearance. Therefore, several theories exist regarding how much aging may affect matrix composition, cell metabolism, and cellularity of articular cartilage.

#### *Wear and tear theory*

One of the first models is based on the repetitive mechanical strains that stress cartilage tissue during aging, also known as the “wear and tear” theory. The cartilage aging process can be viewed as the accumulation of continuous loading over the lifetime of joint use (Radin *et al.*, 1991). Physiologically, mechanical loads between 0–20 MPa strain articular cartilage (Hodge *et al.*, 1986). Forces that exceed these limits may lead to continuous microtraumata of the articular cartilage (Borrelli, Jr. *et al.*, 2004). Ultimately, repetitive damage to the extracellular matrix will culminate in the loss of tissue integrity and function.

A different explanation of the role of mechanical loading in aging is based on remodeled joint geometry in elderly individuals. A change in joint surface congruity and redistribution of load onto formerly unloaded and thus atrophic cartilage areas might result in rapid destruction of these areas of minor load-resistance. The observation that cartilage of the elderly is inadequate to withstand mechanical forces could be explained by the theory of load-distribution.

*Alterations of cartilage matrix components with increasing age*

With advancing age, changes within the extracellular matrix of articular cartilage occur. Although composed of a variety of components, we can roughly discriminate two major components of the cartilage matrix: type II collagen, responsible for resisting shear forces and for the integrity of the extracellular matrix; and aggrecan, a large aggregating proteoglycan providing resistance to compression. Changes in the synthesis rate or structure of these matrix components may contribute to a decrease in mechanical resistance, consequently resulting in structural cartilage damage. However, the mechanical properties of cartilage are not subjected to serious age-related changes in compression properties, but marked age-dependent decrease in tensile stiffness, fatigue resistance, and strength was shown.

**Collagen network.** The collagen network does not display a major loss of collagen bundles with increasing age, since there is only minor collagen remodeling during lifetime. However, the network stiffens and becomes less flexible with advancing age. This process is caused by an increase of covalent cross-linking of the single collagen chains (Verzijl *et al.*, 2002). Thus, the fibrillar network becomes more rigid during physiological deformation by continuous loading. These alterations may be due to the formation of glycation end products (see later).

**Aggrecan monomers.** The large aggregating proteoglycan, known as aggrecan, is subjected to more severe age-related changes. Aggrecan is composed of a core protein to which sugar side chains are attached, forming the proteoglycan structure. This construct binds to hyaluronan via specific binding sites, which are stabilized by a so-called link-protein. During the aging process the major alterations of the aggrecan structure comprises an accumulation of low molecular weight aggrecan monomers, a reduction in size of hyaluronan chains, and fragmented link proteins.

Aggrecan molecules increase in number, but get smaller with age. Their proteoglycan structure alters displaying heterogeneity in the monomer population. The monomers differ in their keratin sulphate, chondroitin sulphate, and protein content and in the size of their core proteins. The age-related changes are characterized by a decrease in the size and number of chondroitin sulphate chains and an increase in the size and number of keratin sulphate chains. Moreover, changes in the amino acid composition of the core protein have been reported, whereas a functional hyaluronan-binding region appears to be present at all ages (Bayliss *et al.*, 1978; Roughley *et al.*, 1980).

These changes, in particular the progressive decrease in the length of chondroitin sulphate-rich regions of proteoglycan monomers, could contribute primarily to an impaired functionality of aged articular cartilage, but generally the fixed charge density, viscoelastic properties,

and the osmotic swelling pressure of the cartilage tissue are thought to be preserved in the aging cartilage, at least in part, by an increase in the concentration of small monomers that are rich in keratin sulphate, compensating for the loss of chondroitin sulphate-rich regions (Bayliss, 1990).

**Hyaluronan chains.** Hyaluronan also undergoes extensive age-related changes. The concentration of hyaluronan increases three- to four-fold during a lifetime, presumably to accommodate the increased number of proteoglycan monomers (Holmes *et al.*, 1988). Interestingly, this change does not arise from a higher rate of hyaluronan synthesis, but from an accumulation of partly degraded hyaluronan, that together with the smaller aggrecan monomers forms lower molecular weight aggregates.

The increase in hyaluronan content maintains the overall aggregation of proteoglycan monomers and consequently keeps the fixed charge and thus the contribution of proteoglycans to the compressive properties of cartilage constant.

**Link protein.** As hyaluronan chains and aggrecan monomers increase in number with advancing age, the concentration of link protein also increases with aging. Its purpose is to stabilize the interaction of the hyaluronan-binding region of aggrecan and hyaluronan. However, at all ages the concentrations of binding region are always in excess of link protein, in particular in aged tissue. As a consequence there is a lack of link protein to stabilize all binding regions. Furthermore, an age-related increase in the molecular heterogeneity and fragmentation of link protein was described (Mort *et al.*, 1985). The binding site stabilities differed at various degrees at all ages due to differences in the concentration of the distinct components and to their functional quality.

**Formation of glycation end products.** The aging components of the extracellular cartilage matrix are also compromised by the formation of glycation end products. These nonenzymatic protein modifications may have consequences for matrix integrity as well as chondrocyte metabolism in the aging cartilage (DeGroot *et al.*, 2001). The accumulation of glycation end products was shown to affect the collagen network by increasing its stiffness (Bank *et al.*, 1998; Verzijl *et al.*, 2002). Moreover an accumulation of these products influences the synthetic activity of chondrocytes down-regulating its metabolic performance. Today it is known that glycation end products may contribute to a reduction in collagen and proteoglycan synthesis, but it is unclear whether the degradative activity of chondrocytes is also affected. This might be of little relevance for the type II collagen network, since there is hardly collagen turnover in adult cartilage. Nevertheless, an age-dependent decrease in the remodeling of proteoglycan and other collagen types, such as type VI or IX, governed by glycation end products could be detrimental for cartilage integrity, since a continuous replacement of these components ensures the integrity of the cartilage matrix.

Finally, aging may influence the extracellular assembly of proteoglycans. Proteoglycan monomers are secreted from the chondrocytes and aggregate with hyaluronan extracellularly. Before the process of bonding is initiated, a conversion of proteoglycan monomers from a form of low hyaluronan affinity to one with a high affinity takes place (Bayliss *et al.*, 1984). In older individuals the rate of conversion of proteoglycan monomers to a high affinity form is conducted much slower compared to younger ones (Bayliss, 1986).

#### *Chondrocytes and aging*

Articular chondrocytes are responsible for a precisely balanced tissue remodeling to uphold tissue homeostasis and integrity. With advancing age, chondrocyte reactions alter; basically, in a way, the cells cease to synthesize proper extracellular matrix components and/or decrease in numbers with advancing age.

Articular cartilage usually is seen as a post-mitotic tissue with insignificant cellular turnover, making articular cartilage very vulnerable to the effects of cell senescence or cell loss. At skeletal maturity, subchondral calcification isolates the tissue from the vascular system so that cartilage is totally cut off from a possibly needed cell supply. Moreover, articular cartilage lacks any sort of germinal cell layer, as epithelial cells can fall back on, in order to compensate for any cell loss.

The cells have further to adapt to a tissue oxygen tension as low as 5% (Scott, 1992) and sustain a low level of metabolic activity necessary to maintain the cartilage matrix. Given physiological mechanical loading, this is in general sufficient to preserve the integrity of the articular surface for many decades. As we can imagine, these rough environments (low oxygen levels, continuous mechanical stress) may contribute to progressive senescence in this limited population of highly differentiated cells, and low levels of metabolic activity make it increasingly difficult to maintain tissue homeostasis.

**Model of a reduced biosynthetic activity.** In the case of a reduced biosynthetic activity, the maintenance of cartilage extracellular matrix could be impaired and may subsequently lead to a disruption of tissue integrity.

A significant decrease in proteoglycan production by articular chondrocytes as a result of aging has been demonstrated (DeGroot *et al.*, 1999; Schafer *et al.*, 1993; Verbruggen *et al.*, 2000), supporting the theory of a reduced biosynthetic activity of articular chondrocytes. However, contrary findings showing a constant rate of proteoglycan biosynthesis in mature articular chondrocytes (Bayliss *et al.*, 1999; Bobacz *et al.*, 2004) compete with the studies just mentioned. A possible explanation for these contradictory data may be the use of different culture techniques, since studies employing explant culture conditions may have to take different mechanisms than failure of chondrocyte metabolism into account.

A possible underlying mechanism for a reduced or maybe altered matrix synthesis in the aging articular

cartilage could be an age-related decline in the responsiveness to growth factors. Such age effects have been described for several molecules in previous studies in animal (Loeser *et al.*, 2000; Martin *et al.*, 1997; Ribault *et al.*, 1998; Schafer *et al.*, 1993) and human (Bobacz *et al.*, 2003; Guerne *et al.*, 1995) cartilage, suggesting a decrease in the responsiveness of articular chondrocytes to various growth factors (platelet-derived growth factors, epidermal growth factor, insulin-like growth factor-I, basic fibroblast growth factor, transforming-growth factor (TGF)- $\beta$  and bone morphogenetic protein-6) with increasing age. A possible explanation for this age-dependent effect may be a change in receptor expression, since growth factor receptors are reported to change with the differentiation status of the chondrocytes (Iwamoto *et al.*, 1991).

**Model of cell number loss.** A second theory of the association between cartilage aging and reduced matrix remodeling is simply based upon a decrease in chondrocyte number.

Several studies suggested that the cell density of the whole thickness of the uncalcified articular cartilage declines sharply during the growth and maturation period of skeletal development, but remains relatively constant in adult life (Huch, 2001; Meachim *et al.*, 1962; Miles *et al.*, 1964; Stockwell, 1967). On the other hand there is evidence that chondrocyte numbers decrease progressively in healthy articular cartilage as a function of age (Mitrovic *et al.*, 1983; Muehleman *et al.*, 1997; Quintero *et al.*, 1984; Vignon *et al.*, 1976). In a more recent report, the latter data have been confirmed (Bobacz *et al.*, 2004).

Merging both theories into one, it can be assumed that it is likely that a reduction in chondrocyte numbers is responsible for a decrease in matrix synthesis rate. An increased biosynthetic activity of the remaining cells to compensate for the overall chondrocyte loss may subsequently culminate in cell exhaustion and premature senescence. This again may lead to the production of inappropriate, noncartilage-specific matrix constituents impairing tissue integrity.

The mechanisms leading to a loss of chondrocytes in aging are still unknown but may be the result of a loss in responsiveness to anabolic growth factors (Guerne *et al.*, 1995), mitotic arrest possibly governed by telomere-dependent senescence (Martin *et al.*, 2002), or programmed cell death (Aigner *et al.*, 2001; Blanco *et al.*, 1998; Hashimoto *et al.*, 1998).

## Conclusion

The unimpaired functionality of diarthrodial joints is essential for an active life. The complex joint system with all its appropriate structures is designed to withstand the changing biomechanical forces that act upon it during lifetime. With increasing age all joint structures are subjected to mechanical, molecular, or cellular alterations that may, depending on their degree, lead to an impairment of the joint operability.

Clearly, a number of events, some of them potentially detrimental, affect the joints during aging, but usually it is a compound of several factors that ultimately results in a deterioration of joint function. Although the knowledge concerning joints and aging has developed considerably during the last years, distinct causes and processes within different joint structures, as well as their interplay, are not fully understood. Regarding joint disorders as a major healthcare problem, it is critical to rapidly increase the understanding of the age-related changes of joint structures and their relationship to its impairment. Progress toward this goal may give us opportunities of intervention that will slow down or even halt age-dependent joint alterations to maximize the quality of life and independence for the increasing number of middle-aged and old people.

# Sleep Quality in the Elderly

Ragnar Asplund

*Sleep is of great importance for health and the quality of life. There is a strong association between sleep disorders on the one hand, and illness and early death on the other. The mortality is higher among elderly persons with sleep disorders than in those who sleep well, and the excess mortality is related to the predominant causes of death, such as heart disease, stroke, cancer, and suicide.*

*The individual prerequisites for a good night's sleep include many things, such as a comfortable bed, fresh air in the bedroom, and a room that is not too cold and not too hot. Another factor with a great impact on sleep is noise.*

*Poor sleep also shows a negative interaction with many somatic and psychiatric diseases and symptoms, as well as causing a deterioration in the quality of life. These diseases and symptoms are more important in explaining sleep deterioration than the age and sex of the patients, although there is a tendency toward an increase in sleep problems with increasing age.*

*There are some evident differences in sleep between men and women. Women report more difficulties in initiating and maintaining sleep than men, whereas men display more sleep disturbances at EEG assessments. Men are also more troubled by sleep-disordered breathing than women.*

*The aim of this chapter is to recapitulate the major causes of sleep disturbances in the elderly, their significance in terms of life expectancy, general health outcome and quality of life, and the principal remedies available.*

## Introduction

Poor sleep is a common complaint in the elderly. In a Swedish questionnaire survey it was found that 10% of elderly men (aged  $74 \pm 6$  years; mean  $\pm$  SD) and 20% of elderly women were troubled by poor sleep. Frequent awakenings were reported by 21% and 27%, respectively, and difficulty in falling asleep after awakening was experienced by 22% and 41%, respectively. Eleven percent of men and 13% of women report frequent nightmares (Asplund and Åberg, 1992). Compared with the younger population, who are often troubled by difficulty in falling asleep at bedtime, elderly persons

more often suffer from frequent awakenings and an increased length of time before falling asleep again. Their total sleep is shortened even though they spend more time in bed, and they have a smaller proportion of slow-wave sleep (SWS) (Morin and Gramling, 1989).

Sleep can be disturbed in several ways. The total amount of sleep can be increased (hypersomnia) or reduced (hyposomnia or insomnia), and it can be fragmented by frequent awakenings. There are also many sleep-disturbing diseases and symptoms, which make getting back to sleep difficult after nocturnal awakenings. Many elderly persons recognize poor sleep as an effect of deterioration of their 24-hour rhythm. They often try to compensate for this by increasing the regularity of their lifestyle, which is probably beneficial not only for their sleep but also for their health in general.

There is a high genetic disposition to develop sleep disorders. In twin studies in humans, good covariation has been demonstrated regarding different qualitative and quantitative sleep variables. Poor sleep is more common in elderly people if their parents have been troubled by sleep complaints (see Figure 71.1) (Asplund, 1995a).

In a study of a large group of elderly men and women, reports on a poor night's sleep were 50% more frequent in men and three times more frequent in women whose parents had sleep problems. Deterioration of sleep from year to year was found to occur three times as often among both men and women whose parents both had sleep problems, compared with those whose parents had been good sleepers (Asplund, 1995a). The total sleep time was shorter in both men and women if either of their parents had sleep problems and was further shortened if both parents had such problems, and the same was true for the length of time up to the first nocturnal awakening. Furthermore, in the corresponding groups, the time taken to get to sleep was prolonged, awakenings were more numerous, and it took longer to fall asleep again after waking up in the night. Sleep problems in childhood occurred four times as often in both men and women whose parents both had such disturbances, compared with those whose parents both had been good sleepers (Asplund, 1995a).

There are some evident differences in sleep between men and women. Women report more difficulties in initiating and maintaining sleep than men, whereas men

**Figure 71.1** Occurrence of difficulty in falling asleep each night among men and women who reported sleep complaints in neither of their parents (N), the father (F), the mother (M), and both parents (B) (Asplund, 1995a).

display more sleep disturbances at electroencephalography (EEG) assessments. Men are also more troubled by sleep-disordered breathing than women (Rediehs *et al.*, 1990). Women have a greater tendency to react to sleep-disturbing factors than men and acquire a lighter sleep during pregnancy. When, in infancy, the child grows old enough to leave the mother undisturbed at night, the mother's sleep remains more fragile than before (Spielman *et al.*, 1996).

## Determinants of Sleep

### THE PHYSIOLOGY OF SLEEP AND ITS AGING

The sleep/wake cycle and the 24-hour rhythm of the body temperature are regulated by a circadian periodicity that originates from the suprachiasmatic nucleus in the hypothalamus. In the morning we wake up, our body temperature increases from the nocturnal level, and we are able to be active throughout the day. In the late evening, when it is dark, we normally go to bed, and after a while we fall asleep.

With reference to the EEG pattern, sleep is divided into five different stages:

- Stage 1: Light or drowsy sleeping representing the transitional stage between being awake and sleeping, lasting 5 to 10 minutes in the late evening. During this stage breathing becomes slow and regular. The heart rate decreases. Episodes of stage 1 sleep occur during the night, with increased frequency and length in the latter part of the night.
- Stage 2: Sleep becomes deeper and the muscle tone decreases. Approximately 40 to 50% of a typical night is spent in stage 2.

- Stages 3 and 4: Referred to as deep sleep, delta sleep, or slow-wave sleep (SWS). Waking from these stages is more difficult than from stages 1 and 2. During SWS, growth hormone is released from the hypothalamus. Many restorative processes, such as healing of injuries and immunological processes necessary for defense against infections or malignancies are most active during SWS (Stanley, 2005).
- Stage 5: During rapid-eye-movement (REM) sleep, dreams are more common than in other sleep stages. REM sleep may occur in four or five periods throughout the night at intervals of 60 to 90 minutes and with increasing length throughout the night. REM sleep has been attributed to emotional well-being and memory (Stanley, 2005).

The longest periods of SWS are seen in children, with a substantial reduction in young adults, and these periods are even shorter or sometimes absent in the elderly. Their total sleep is shortened even though they spend more time in bed. The sleep of the elderly is not only more superficial but also more fragmented than in younger people (Kales *et al.*, 1974).

Sleep and wakefulness are governed by a circadian and a homeostatic mechanism. The sleep/wake cycle is generated by a circadian rhythm that originates from the suprachiasmatic nucleus of the hypothalamus. This cycle makes it easier to fall asleep at the common time of the 24-hour period, most commonly in the evening or at night, whereas falling asleep in the daytime is more difficult or sometimes impossible. The homeostatic mechanism generates increased sleepiness and prolonged sleep after prolonged wakefulness, and consequently the amount of sleep is shorter if sleep takes

## 71. Sleep Quality in the Elderly

place after a shorter time than usual in the waking state (Stanley, 2005).

### AGE-RELATED DEVELOPMENT

The sleep pattern changes in parallel with aging. The time spent in deep sleep (slow-wave sleep) is decreased, and in the very elderly it may be absent. The number of awakenings increases with aging and in many elderly falling asleep after such awakenings becomes increasingly difficult. Elderly persons are therefore more troubled by spending time in the waking state in bed than younger adults. This decline in sleep maintenance is to some extent an expression of the age-related disorganization of the circadian sleep/wake rhythm.

However, sleep quality in the elderly seems to be more attributable to health-related factors than to age *per se*. In a study of the influence of somatic health, mental health and age on sleep in a group of elderly men and women, it was found that in men, more severe sleep disturbances were associated with poorer somatic health, poorer mental health, and increasing age, in that order of importance, and that in women, they were correspondingly associated with poorer somatic health and poorer mental health, but there was no further deterioration of sleep with age (Asplund, 2000).

There is an age-related increase in daytime sleepiness in the elderly, and those with poor night's sleep are more sleepy in the daytime than those with good sleep (see Figure 71.2) (Asplund, 1996).

Severe disruption of the sleep/wake cycle has been observed in very old people suffering from a serious illness, dementia, or both conditions. In a classic study in a nursing home population it was found that most people spent about 40 minutes per hour sleeping at night and about 20 minutes per hour in the daytime.

Correspondingly, they woke up about four to five times every hour at night and three to four times every hour in the daytime. Only six of the subjects experienced even one single hour of consolidated sleep during the 24 recorded hours, and none of them had two or more consecutive hours of sleep (Jacobs *et al.*, 1989).

### SLEEP IN DIFFERENT COUNTRIES

The prevalence rates of sleep disturbances vary considerably between different countries of the world. In a recent review of the literature based on data collected in 50 community-dwelling populations, prevalence rates of insomnia ranging from less than 5% to 40% were reported (Ohayon, 2002). In a cross-sectional survey in 10 countries (Austria, Belgium, Brazil, China, Germany, Japan, Portugal, Slovakia, South Africa, and Spain), answers to a standardized questionnaire were collected from 35,327 men and women with mean age 39 years (7.9% of ages 65 years or older). In the whole study group "not sleeping well" was reported by the least proportion of respondents in Austria (10.4%) and the highest proportion in Belgium (32.2%). Correspondingly, the nocturnal sleep duration varied from  $413 \pm 69$  (mean  $\pm$  standard deviation, SD) minutes in Japan to  $504 \pm 89$  minutes in Portugal, and the time taken to fall asleep varied from  $15.2 \pm 18.4$  minutes in Austria to  $34.4 \pm 42.1$  minutes in South Africa. Regular naps were reported by 12% in Japan and 42.4% in Brazil, and sleepiness during the day by 5.1% in Germany and 20.2% in South Africa (Soldatos *et al.*, 2005).

### ENVIRONMENTAL FACTORS

The individual prerequisites for a good night's sleep include a number of factors, such as a comfortable bed, fresh air in the bedroom, and a room that is not too cold

**Figure 71.2** Affirmative answers (%) to the statement "I am often sleepy in the daytime" in relation to sex, age, and nocturnal sleep. Age (years): <70 (white bars); 70-79 (dotted bars); ≥80 (grey bars) (Asplund, 1996).

and not too hot. A sleep partner also seems to be favorable for sleep. People with a preexisting psychological or psychiatric condition may be more susceptible to the effects of noise, and women are more sensitive to noise than men (Nivison and Endresen, 1993).

Noise is a factor with a great impact on sleep. In a study of adult men and women exposed to road traffic noise during nine nights over a period of two weeks, poorer sleep quality, performance, and mood, and greater tiredness both in the morning and during the day were reported. No habituation of these effects was observed (Öhrström, 2000). Further, in a study of sleep in a residential area of Gothenburg, before and after the opening of a new tunnel for road traffic resulting in reduction of the road traffic from about 25,000 to 2,400 vehicles per 24 hours and from 1,375 to 180 vehicles per night (22–06), the previous adverse effects on sleep were substantially reduced and sleep quality was significantly improved after this extensive noise reduction in residents living near the road (25–67 meters). The subjective sleep improvement experienced by these residents was more pronounced than in those living in a control area (125–405 meters from the road). The improvement was recorded in all four sleep quality measures: “difficulty in falling asleep,” “awakenings,” “sleep quality,” and “tiredness in the morning” (see Figure 71.3) (Öhrström, 2004).

Sleep disturbances are particularly common in nursing homes. Nursing routines need to be performed at all hours and a certain amount of noise and light at night cannot be avoided. Sleep is also deteriorated by large amounts of time spent in bed during the daytime and consequent inability to sleep at night. Some patients have a poorly functioning sleep/wake rhythm, resulting in daytime sleep and also night wandering, which disturbs other residents. The little access to outdoor activities, for medical and nursing-related reasons, may partly explain the increased occurrence of sleep complaints among elderly people living in nursing homes. The rhythmic change of light during the 24-hour period, which plays an important role in the sleep-wake timing,

is difficult to maintain. Bright light in the daytime has proven effective in the treatment of sleep maintenance insomnia in the elderly (Hajak *et al.*, 1995).

Many healthy elderly people try to compensate for disruption of the sleep/wake rhythm by increasing the regularity of their lifestyle, which is probably beneficial not only for their sleep but also for their health in general (Reynolds *et al.*, 1991; Monk *et al.*, 1997). Lifestyle intervention is also desirable for improvement of sleep in the nursing home setting (Alessi *et al.*, 2000).

## Health Impairment and Sleep

### SOMATIC DISEASES AND SYMPTOMS

#### Heart diseases

Heart diseases and sleep disturbances interact with one another in a reciprocal and complicated way. In a classic study of Finnish adult men, Partinen and coworkers found a higher prevalence of coronary heart diseases in men who slept less than six hours per night after adjustment for age, sleep quality, use of sleeping pills and tranquilizers, smoking, alcohol use, Type A score, neuroticism, use of cardiovascular drugs, and history of hypertension. Difficulty in falling asleep at bedtime has been found to be associated with a two-fold increase in the risk of myocardial infarction during a follow-up period of 4.2 years (Appels and Schoultens, 1991). Further, among patients with myocardial infarction in another study, almost half had had sleep disorders during the six months immediately preceding the onset, which is a higher proportion than in a comparable population without myocardial infarction (Carney *et al.*, 1990).

Waking up in the night precedes more often than follows an angina pectoris attack. Most of these nocturnal awakenings are accompanied by getting up for visits to the toilet, and angina pectoris at night often occurs in connection with getting out of bed for micturition (Asplund, 2004).

**Figure 71.3** Residents' own comparison of sleep after the change in road traffic. Exposed (grey bars); controls (white bars) (Öhrström *et al.*, 2004).

## 71. Sleep Quality in the Elderly

In a questionnaire survey in northern Sweden among men and women aged 65 years or older, strong correlations were found between, on the one hand, affirmative answers to questions concerning two cardiac symptoms, namely "I am troubled by spasmodic pains in the chest" and "I am troubled by a sensation of irregular heart beats," and on the other hand, sleep complaints. The validity of the answers to the questions on heart diseases was supported by the fact that almost 90% of the subjects who stated that they suffered from spasmodic chest pain also reported the use of antianginal drugs, and that persons with subjective cardiac arrhythmia were also high consumers of drugs for heart diseases (Asplund, 1994). In both genders, the occurrence of either of these symptoms was associated with difficulty in falling asleep and those who reported both symptoms were troubled with difficulty in falling asleep at least twice as often as among those without cardiac symptoms. Difficulty in falling asleep within one hour after going to bed, nocturnal awakenings, and difficulty in getting to sleep after such awakenings were also increased in subjects with cardiac symptoms. Both men and women who stated that they woke up in the morning with a feeling of anxiety reported angina pectoris twice as often as those who woke up without anxiety. Also, the frequency of angina pectoris was twice as high in men and four times as high in women who reported that their final awakening was too early every morning, compared with those who woke up too early less than once a month. Cardiac arrhythmia was more than three times as common among men and more than twice as common among women who stated that they woke up too early every morning, compared with less than once a month (Asplund, 1994).

Only very few studies regarding the relation between sleep and cardiac diseases have been conducted in persons older than 65 years. In a study of sleep complaints and incident fatal and nonfatal first myocardial infarction over three years in 2,960 North Carolina adults aged 65 years or older, Schwartz *et al.* (1998) reported that the occurrence of myocardial infarction during the study period was increased in association with reports on restless sleep (incidence density ratio (IDR) 1.58, 95% confidence interval 1.11–2.24) and trouble falling asleep (1.68, 1.09–2.60) after adjustment for age, gender, and race. IDR was not substantially influenced by reports on smoking, blood pressure, diabetes, or obesity. Self-rated health and depression were strong independent correlates for myocardial infarction. Both of these conditions are also very closely linked to sleep impairment in the elderly and poor sleep is one of the diagnostic criteria in the diagnosis of major depression (DSM-IV).

Patients with coronary artery diseases who suffer from sleep apnea show poor cardiac function and have a high incidence of cardiac events, and frequent apnea episodes are a common finding in patients with congestive heart failure. Nocturnal arterial oxyhemoglobin desaturation

caused by sleep-disordered breathing may be partly responsible for the excess morbidity and mortality in association with sleep disorders in the elderly (Javaheri, 1996).

### *Stroke*

Stroke and the sleep/wake cycle show a reciprocal relationship. Several studies have shown that the onset of ischemic stroke more often occurs in the early morning than in other parts of the 24-hour period, independently of well-known risk factors and of clinical stroke subtypes (Casetta *et al.*, 2002). Both the increase in blood pressure in the morning and the circadian variability in the coagulation system may explain this increased risk of stroke.

Ischemic stroke often is followed by sleep impairment. In a study of insomnia, defined as at least one affirmative answer to a set of three items of the Hamilton Depression Scale, in patients with acute ischemic stroke complaints, insomnia occurred in 68% of patients on admission and had decreased to 49% at 18 months. From two months, symptoms of insomnia were associated independently with depression (Palomäki *et al.*, 2003). Other studies have also shown that depression is a common finding in association with stroke and sleep impairment is an early symptom of depression.

In patients who have suffered a cerebrovascular lesion, sleep is often disturbed by breathing impairment. Stroke patients have wider fluctuations in upper airway resistance than control subjects, resulting in frequent apneic episodes, and thereby run an increased risk of arterial oxyhemoglobin desaturation during post-stroke rehabilitation. This sleep apnea syndrome is associated with a poorer functional outcome and increased mortality. The diffuse cerebral symptoms such as cognitive deficits, depression, and fatigue are often explained by sleep apnea, and patients with stroke and diffuse cerebral symptoms should therefore be investigated for sleep-disordered breathing (Mohsenin and Valor, 1995).

### *Parkinson's disease*

Sleep disorders occur in 74 to 98% of patients with idiopathic Parkinson's disease, and have serious effects on their quality of life. Accordingly, sleep and quality of life of spousal caregivers is also often affected. These patients suffer from a wide variety of somatic symptoms with an impact on sleep, such as stiffness, pain, muscle cramps, inability to turn over in bed, inability to get out of bed without aid, and polyuria. Vivid dreams, nightmares, and night terrors are also increased (Pal *et al.*, 2004). Their sleep becomes fragmented by an increased number of nocturnal awakenings and difficulty in getting back to sleep, resulting in daytime sleepiness. Sleep disturbances increase with the severity of the disease (Partinen *et al.*, 1997).

In a recent report it has been suggested that patients with Parkinson's disease with severe sleep disorders may

represent a subset of patients with early, progressive degeneration of sleep centers, rather than with an enhanced aging process. They are more susceptible to mood disturbances, which correlate with the severity of the sleep dysfunction (Pal *et al.*, 2004).

In Parkinson's disease, treatment of the disease itself is the most important way of reducing the sleep disturbances. Controlled-release levodopa less often causes nocturnal symptoms compared to standard levodopa. Hypnotics or antidepressants may be added for further symptom relief (Partinen *et al.*, 1997).

Excessive daytime sleepiness and sudden sleep attacks are common complaints in Parkinson's disease. An increase in these symptoms in association with dopamine agonist treatment has been suggested, but other studies have not confirmed such a relationship. Patients with Parkinson's disease and excessive daytime sleepiness have a longer duration of disease, longer treatment with dopamine agonists, and more pronounced parkinsonian motor symptoms than those without excessive daytime sleepiness (Pal *et al.*, 2004).

#### *Musculoskeletal pain*

Pain is a common complaint in people who are troubled by poor sleep, and poor sleepers experience not only greater pain intensity but also more pain discomfort than good sleepers (Asplund, 1996). The total sleep time is shorter, sleep efficiency is lower, and sleep onset latency is longer in persons with very severe pain than in those with pain of low severity. Sleep impairment and musculoskeletal pain seem to interact in a reciprocal manner. In a recent study in adult men and women suffering from musculoskeletal pain in the neck, shoulder(s), and/or the lumbar region who were treated with acupuncture on 10 occasions over a period of four weeks it was found that during a six-month follow-up period after cessation of treatment, only the patient group whose pain improved in the evening showed a favorable development of night sleep, and correspondingly, only the group who experienced improved sleep felt pain relief in the morning (Hansson and Asplund, 2005). A detrimental influence of nocturnal sleep impairment on pain the following day has also been reported in patients with fibromyalgia. There are some experimental data supporting the hypothesis that sleep deterioration may contribute to the lowering of the pain threshold. Onen and colleagues reported that healthy men after 40 hours of total sleep deprivation showed hyperalgesia in response to mechanical stimulation and that subsequent SWS was associated with an analgesic effect (Onen *et al.*, 2001).

In the elderly, the occurrence and severity of pain increase in parallel with increasing age and are strongly correlated to sleep impairment. One disease related to a high frequency of sleep disorders is rheumatoid arthritis.

Accordingly, attempts should always be made to achieve the best possible pain relief (Asplund, 1999).

#### *Sleep apnea syndrome*

Apneic episodes during sleep are common, and can be caused by a disturbance in the breathing control mechanism in the central nervous system (central sleep apnea) or by narrowing of the pharyngeal airway and loss of dilator tone during sleep (obstructive sleep apnea). Sleep apnea syndrome (SAS) causes sleep fragmentation and results in a variety of somatic diseases and symptoms, such as hypertension and coronary artery disease (Olsson *et al.*, 1995). Daytime sleepiness is increased in association with SAS and more so in the elderly than in young adults.

Sleep apnea is very common in elderly people. There is a reciprocal relationship between sleep apnea and dementia. Sleep apnea is more common in elderly patients suffering from dementia, and the frequency of breathing disturbances during the night is related to the severity of the dementia. Dementia, on the other hand, is increased by sleep apnea. Among community-dwelling elderly persons over the age of 70 years, 24% show an apnea index (AI) of more than five apneas per hour of sleep, and a study of 80-year-old patients severely affected by dementia and living in nursing homes revealed an AI of five per hour in 42% of patients (Asplund, 1999).

Increased mortality, particularly at night, has been reported among patients with sleep apnea. Sleep apnea represents heavy costs for healthcare services prior to treatment for the apnea. Successful treatment results in a lower mortality risk and normalization of somatic and psychological symptoms, and improves the patient's quality of life and safety in traffic.

*Central sleep apnea* is characterized by the occurrence of apneic events during sleep with no associated ventilatory effort. Many neurological diseases affecting the brain, such as cerebral arteriosclerosis, infarctions, tumors, hemorrhage, encephalitis, poliomyelitis, and other infectious diseases are able to produce breathing pattern disorders in sleep. Nocturnal central apneic episodes resulting in a decrease in nocturnal arterial oxygen-hemoglobin desaturation contribute to the progressive impairment in cardiac function in patients with heart failure (Asplund, 1999).

In certain patients, the history and physical examination may arouse suspicion of obstructive sleep apnea (OSA), a condition characterized by frequent disturbances of the night's sleep due to apneic episodes, daytime sleepiness, and a general lack of well-being. Nocturia due to nocturnal polyuria is a pathognomonic finding in OSA. In stroke patients, OSA is more common than central sleep apnea, and sleep apnea precedes the stroke in many cases. Polysomnography is helpful in the assessment of OSA. Treatment may improve the patient's

well-being, reduce daytime sleepiness, lower the blood pressure, and reduce the risk of ongoing cardiovascular damage (Silverberg *et al.*, 1997).

OSA is a common finding in persons who are troubled by loud snoring, although snoring *per se* is not necessarily associated with OSA. OSA is more common in men than in women. After the menopausal transition, however, the prevalence of sleep apnea is steeply increased in women and approaches that in men. The respiratory symptoms are aggravated by overweight, cigarette smoking, alcohol, and hypnotics, and are improved by elimination of these factors (Asplund, 1999).

#### *Asthma*

Asthma is a condition with a profound negative influence on sleep. Asthmatic patients spend more time awake at night, they have a longer sleep onset latency and a shorter period of deep sleep. They have less refreshing sleep, and the occurrence of respiratory symptoms is dependent on the sleep structure. These patients suffer from bronchoconstriction more often during REM sleep than during other periods of sleep, and they also run an excess risk of oxygen desaturation during REM sleep. Because of their breathing difficulties, they often use bronchodilator inhalations at night. Such drugs are stimulants *per se*, and hence are detrimental to sleep. Nocturnal airway obstruction is associated with excess mortality. In patients with nocturnal asthma, daytime cognitive performance is impaired to a degree related to the severity of their disease (Asplund, 1999).

#### *Nocturia and nocturnal polyuria*

Nocturia is such a common condition in the older population that it is often considered to be a normal consequence of aging and therefore is very often disregarded and consequently left untreated. However, nocturia has a profoundly negative impact on health, sleep, and quality of life in many elderly persons. The sleep disruption associated with frequent nocturnal awakenings may induce excessive daytime fatigue, cognitive impairment, mood alterations, and increased susceptibility to disease. Nocturia is also associated with an increased risk of depression and an elevated mortality rate. Nocturnal voiding episodes increase the risk of falls and fractures during the visits to the toilet and back, especially in older, frail people with a decreased cognitive and motoric functioning. Nocturia not only imposes a significant burden on many nocturic persons and their partners, but may also entail considerable cost to the society. The fatigue due to sleep deprivation further augments the risk of accidents on the road and at work. Hence, nocturia is a serious disorder, which, if not treated appropriately, may have far-reaching consequences, both for the patient and society (Asplund, 1995b).

In three out of four cases of nocturia, nocturnal polyuria is present. The nocturnal polyuria syndrome (NPS) is characterized by increased nocturnal diuresis and a consequent increase in nocturnal micturition episodes, increased thirst and fluid intake, especially at night, and sleep disturbances. The prevalence of NPS has been estimated to be 3% in an elderly population, with no gender difference. People with polyuria at night wake up more frequently with a need to visit the toilet and have more difficulty in falling asleep after being out of bed. They often suffer from poor health and an impaired quality of life (Asplund, 1995b).

Even though many symptoms in NPS are similar to those in diabetes insipidus, there are important differences; in NPS, the 24-hour diuresis is normal or only moderately increased. The rhythm of the diuresis, on the other hand, is altered. There is an increase in the nocturnal part of the 24-hour diuresis, caused by a lack of diurnal rhythm in the antidiuretic hormone (ADH) system, and often the plasma ADH level is not detectable at all in the night (Asplund, 1995b).

In NPS, sleep is disturbed by the increased number of nocturnal voiding episodes and often also by a need for nocturnal drinking. The percentage of persons who report a poor night's sleep is more than twice as high among both men and women with three or more nocturnal voiding episodes than among those with none. This increase in sleep impairment includes an increased number of nocturnal awakenings, difficulty in falling asleep after such awakenings, sleepiness in the morning, and daytime sleepiness. Nightmares are also more numerous in parallel with increased numbers of nocturnal micturition episodes (Asplund, 1995b).

Nocturia is associated with a significant increase in the occurrence of dry eyes and dry mouth among the elderly, and dryness of the mucous membranes is highly sleep-disturbing. There is also a negative fluid balance, which needs to be corrected by drinking throughout the whole 24-hour period, but especially at night. The dryness of the eyes and mouth seem to be consequences of this negative fluid balance (Asplund, 2004).

NPS also is associated with poor balance, which implies an increased risk of falls in the night, and hypnotic treatment in elderly persons with NPS may increase this risk. During recent years, treatment of increased nocturnal urine output with desmopressin, a vasopressin analogue, has been used in the elderly and found successful in many cases (Asplund, 2004). This implies a possibility of reducing the use of sleeping pills in NPS patients.

#### *Restless legs and other nocturnal symptoms from the lower extremities*

Restless legs syndrome (RLS) is a common sensorimotor disorder characterized by an urge to move the extremities,

caused or accompanied by unpleasant sensations in the affected limbs. The prevalence of RLS is 9 to 20% in the elderly, with twice as high prevalence figures in women as in men. The symptoms are absent during activity but appear at rest and become more pronounced in the evening or at night. Sleep impairment is the most common reason why patients seek medical aid (Hornyak *et al.*, 2004).

The most effective relief is obtained by getting out of bed and walking around, but this results in deterioration of sleep. Most of the patients with restless legs syndrome also have periodic leg movements, characterized by repetitive flexions of the extremities, during sleep and relaxed wakefulness. Periodic leg movement syndrome may sometimes be present in patients who are not troubled by restless legs in the awake state, and may be suspected in patients with severely disturbed sleep. Neuroleptics often are associated with the occurrence or worsening of RLS, and their use should therefore be avoided. Dopaminergic agents are considered to be the treatment of choice. Opioids, anticonvulsants, or hypnotics also are used frequently and are well tolerated in most elderly sufferers. Interaction with other medications and the possibility of sedation due to slower metabolism in the elderly should be considered (Hornyak *et al.*, 2004).

Leg muscle cramps are common, especially in the older age groups. They often occur in the evening and prevent sleep. The etiology of leg cramps is not clear. Cardiovascular diseases as well as peripheral vascular and neurological disorders are more common in patients with nocturnal leg cramps than in those without. The treatments include stretching exercises, quinine sulfate, and vitamin E, but no treatment has proved to be effective for all patients. Quinine sulfate often is prescribed to avoid muscle cramps in the elderly, although it has some important side effects. Serious hypersensitivity reactions and thrombocytopenia have been reported after its use.

#### *Sensory organ dysfunctions*

In many elderly persons, poor sleep may be attributed to a deterioration of their 24-hour rhythm. Such a disturbance is especially profound in blind persons, in whom severe sleep disturbances are prevalent. However, some blind persons have a normal sleep history despite a lack of subjective light perception, if they have an intact retino-hypothalamic photic pathway (Czeisler *et al.*, 1995).

Reports on poor sleep, frequent awakenings, and difficulties in falling asleep after waking at night are also more common in men and women with visual impairment than in those without impaired vision after adjustment for age, general health, circulatory organ disease and diabetes (Asplund, 2000). Further, in elderly persons with cataracts sleep is improved one month after cataract extraction and further improvement may be experienced during the first nine months (Asplund and Ejdervik-Lindblad, 2004). There may be lifestyle factors in the

background of sleep deterioration in relation to visual impairment. Impaired vision often leads to difficulties in outdoor activities and hence to reduced exposure to bright daylight. Bright light has been proven effective in the treatment of sleep maintenance insomnia in the elderly. It is also possible that difficulty in being physically active and a lack of intellectual stimulation as a result of visual impairment can cause increased sleep deterioration (Asplund, 2000).

Among persons with impaired hearing, poor sleep is more common in both sexes, whereas frequent awakenings and difficulty in falling asleep after waking at night are more common in women (Asplund, 2005). Hearing loss influences psychological well-being and reduces the opportunities for mental stimulation, which may have a negative impact on alertness and daytime activity. Poor hearing is also associated with increased daytime sleepiness independent of health, sleep status, and age.

Hearing impairment as well as other otological disorders often is associated with tinnitus. One common consequence of tinnitus is a disturbance of sleep, and from different studies prevalence figures of sleep disturbance of 25 to 71% have been reported (Asplund, 2005). Many patients are annoyed by their tinnitus during substantial parts of their time, which makes them tired and impairs their quality of life. As elderly tinnitus sufferers are more inclined to have sleep problems than elderly persons in general, tinnitus seems to cause daytime sleepiness both directly and through its detrimental effect on sleep (Asplund, 2005).

## PSYCHIATRIC DISEASES AND SYMPTOMS

### *Alzheimer's disease and other dementias*

Senile dementia of the Alzheimer's type (AD) is often associated with sleep impairment, and several kinds of disturbances have been described, such as reduction of sleep efficiency and of the total length of sleep. There is also a relationship between the severity of the sleep disturbance and the severity of the dementia. Patients with AD have an increased number and duration of awakenings, an increased percentage of stage 1 sleep, reduced slow-wave ("deep") sleep, and reduced REM sleep (Petit *et al.*, 2004).

As a consequence of the continuing sleep disorganization in parallel with progression of the AD, night-wandering and disturbing behavior are common problems both for the patient and for his or her spouse and caregivers. This problem may be alleviated at least to some extent, by attempting to give the patient daytime activity, avoidance of daytime sleeping, and use of hypnotics during periods of pronounced disturbances of the sleep/wake rhythm.

Depressive symptoms are common in patients with AD, and in elderly persons with depression it is often difficult to distinguish this from AD. The sleep pattern

in AD differs from that of depression in showing a greater reduction of REM sleep and a lower REM density. The intellectual ability and the daytime performance may also be impaired by central sleep apnea, which is present in 33 to 53% of patients with AD (Asplund, 1999).

#### *Depression*

Sleep problems are common in elderly persons with depressive disorders, and in the Diagnostic Statistical Manual (DSM-IV) of Mental Disorders, sleep deterioration is included as one of the nine criteria for the diagnosis of major depression (American Psychiatric Association 2000). Depression is a fairly common condition. In a recent questionnaire survey in northern Sweden among men and women of ages 18 years and older, the prevalence of major depression was found to be 4.8% in men and 6.3% in women with only minor difference with respect to age (Asplund *et al.*, 2004).

In persons with depression, sleep problems occur most frequently during acute depressive episodes, but the disturbed sleep often persists during remission. The sleep symptoms consist mainly of an increase in sleep latency, a reduced total sleep time, and a decrease in sleep efficiency, and the disturbed sleep structure may result in intense dreams or nightmares. Early morning awakening is one of the most significant biological markers of depression. Treatment of the depressive disease is necessary for relief from sleep symptoms. The newer, selective serotonin reuptake inhibitors (SSRI) have no sedative or sleep-inducing effect, and aggravated insomnia may occur in connection with such treatment. Tricyclic antidepressants often have sleep-promoting effects when administered in the evening. However, because of their side effects, they are not as well tolerated as SSRI drugs. Adjuvant hypnotic medication therefore can be a good choice for sleep improvement during the acute depressive episode (Asplund *et al.*, 2004).

A probably often-overlooked cause of sleep disturbances in elderly persons with depression is nocturia. In a recent study it was found that nocturia was increased six-fold in men and three-fold in women in association with major depression after age and somatic health had been taken into consideration (Asplund *et al.*, 2004). Treatment with SSRI has been mentioned in association with different urological symptoms, but accounted for only a minor part of the increase in nocturia. The cause of the increase in the number of nocturnal voiding episodes in association with depression is not clear, but there is support for the assumption that the nocturnal diuresis may be increased and also that the micturition mechanism is altered, resulting in a reduced bladder capacity. The sleep impairment *per se*, which is part of the depressive symptomatology, can also partly explain the increase in nocturnal voiding, as an effect of inhibition of the normal nocturnal reduction of the urine output.

## **Treatment**

The treatment of sleep complaints in the elderly must first of all be focused on diagnostic and therapeutic measures in order to alleviate treatable somatic and mental sleep-disturbing diseases and symptoms as far as possible. However, this is not easy, and many elderly persons will continue to suffer from different kinds of sleep disturbances even after a thorough exploration and treatment of their problems.

Specific treatment of insomnia may involve pharmacologic and/or nonpharmacologic approaches. Benzodiazepines are the most commonly prescribed medications for insomnia. Their use in short-term treatment has been shown to be effective, whereas treatment over a longer period, months or even years on a regular basis, has been questioned (Moller *et al.*, 2004). Side-effects have been described in association with the use of benzodiazepine hypnotics, such as agitation, daytime sedation, cognitive impairment, and an increased risk of falls. Both sleep impairment itself and the use of benzodiazepines are associated with an increased risk of cognitive and psychomotor impairments, but sometimes sleep medication may be associated with less disturbances of daytime functioning than severe sleep impairment (Asplund, 1996).

Sleep medication for longer periods loses its favorable influence on sleep, but its side-effects may remain. If a period of treatment with hypnotics longer than three to four weeks can be anticipated, intermittent treatment, every two or three nights, can be appropriate.

Alternatives to the benzodiazepines are the more modern, selective benzodiazepine receptor agonists zopiclone, zolpidem, and zaleplon. These are believed to cause less daytime sleepiness and to produce less impairment in slow-wave sleep, which is already diminished in old age. Zopiclone has also been shown to increase SWS. Their efficacy and safety for short-term use have been demonstrated in geriatric populations, although studies of their long-term use are still lacking (Moller *et al.*, 2004).

Disorders of the circadian sleep/wake rhythm are fairly common in the elderly. Melatonin treatment has been tried in various doses as a hypnotic drug in order to restore a regular 24-hour sleep/wake rhythm, which is disrupted in some elderly people, as a result of age-related deterioration of the function of the circadian clock in the suprachiasmatic nucleus in the brain. Treatment with melatonin seems to be of no clinical value in the management of psychophysiological insomnia in general, but may be beneficial in the initiation and maintenance of sleep in melatonin-deficient elderly insomniacs. Melatonin has a short half-life, and good results are reported in elderly persons given controlled-release melatonin preparations (Asplund, 1999). A number of melatonin agonists have been developed with (hopefully) improved properties in comparison to melatonin. Some of these agents are now in clinical trials for treatment of insomnia

in people with circadian rhythm sleep disorders (Turek *et al.*, 2004).

Bright light has proven effective in the treatment of sleep maintenance insomnia in the elderly. However, the design of the treatment, especially the timing of exposure to light, is important. Murphy and Campbell (1996) studied the effect of bright light on performance and sleep in a group of elderly persons suffering from sleep maintenance insomnia. The patients received treatment with bright light (>4,000 lux from 9 p.m. to 11 p.m.) every night during a 12-day period and maintenance treatment with bright light twice weekly (>4,000 lux from 9 p.m. to 11 p.m. or >4,000 lux from 3 p.m. to 5 p.m.) for a three-month period. The former treatment resulted in significant improvement not only in the quality of sleep but also in daytime cognitive functioning (Murphy and Campbell, 1996).

Nonpharmacologic approaches to insomnia also include a wide range of cognitive, behavioral, and educational techniques. The most commonly used techniques include bed-restriction, stimulus control, sleep hygiene education, and cognitive strategies. In some studies the use of such techniques in elderly populations have shown results comparable to and better sustained than those of hypnotics (Moller, 2004). Cognitive-behavioral treatments for sleep problems in people aged 60 and over are mildly effective for some aspects of sleep. The durability of the effect of these treatments remains unproven (Montgomery and Dennis, 2004).

In a Netherlandic study, educational radio was used for treatment of sleep disorders in the population. The researchers report that the training (eight radio programs) produced an estimated decrease in sleep latency of 25 minutes and an increase in the duration of sleep by nearly 40 minutes, and of the people using hypnotic drugs, 40% ceased their use after the course (Oosterhuis and Klip, 1997).

## Conclusion

Many elderly people suffer from poor sleep. Although sleep impairment is more prevalent in women, its negative consequences for life expectancy, health, and quality of life are more pronounced in men. Many common diseases and symptoms cause insomnia such as musculoskeletal pain, angina pectoris, difficulty in breathing, depression, and dementia. Insomnia can be precipitated or exacerbated particularly by conditions that may worsen at night, for example, gastroesophageal reflux, congestive heart failure, restless legs, periodic leg movement disorder, or asthma. When the resulting insomnia becomes chronic, psychiatric disturbances such as impaired concentration and memory, irritability, depressed mood, or anxiety may develop. There is an overlap in symptomatology between insomnia secondary to medical conditions, circadian disturbances, sleep

disorders, and actual psychiatric disorders (Moller *et al.*, 2004).

The occurrence of sleep problems in the elderly more often is related to poor somatic health than to poor mental health. Many studies have shown that sleep problems in the elderly increase in parallel with increasing age, but when the influence of somatic and mental health has been taken into account, age *per se* has very little impact on sleep.

The use of sleep medication shows a pattern parallel with that of sleep, namely, a stronger relationship to somatic than to mental health (Asplund, 2000). This may reflect the fact that sleep difficulties often serve as a proxy for medical conditions that should have been treated otherwise than by sleep medication. Some elderly men and women are treated with hypnotics even though they do not experience any real sleep problem. Such medication is observed particularly among persons with very poor somatic health (Asplund, 1995). In most cases they need some relief from their nocturnal symptoms in order to get some rest. This observation may support the view that sleep medication in the elderly can be reduced if pain and discomfort due to somatic and mental diseases and symptoms are alleviated.

# Atherogenesis and Aging

Cam Patterson

*The prevalence of coronary artery disease increases with age (2002), and age itself is an independent risk factor for atherogenesis (Kannel and Gordon, 1980), suggesting that the biological milieu in aging populations is conducive to atheromatous lesion formation. Increased susceptibility to cellular stress and accrual of damage to vascular tissues are likely factors in the atherogenic milieu attributable to aging, yet the precise molecular processes underlying the age-associated events culminating in atherosclerotic lesion formation remain to be determined. Given the difficulties in understanding these mechanisms in humans, a variety of animal models have been developed that represent various aspects of vascular injury and atherosclerosis. In this chapter, we will provide a concise overview of the etiology of atherosclerotic arterial disease and the contributions of aging in this process. We will also review the methods for manipulating blood vessels via mechanical and humoral factors to induce vascular injury, and we will consider the application of these methods in specific animal models that are particularly conducive for understanding the prevalence and enormous burden of cardiovascular disease in the course of aging.*

## Introduction

Vascular diseases—coronary artery disease, peripheral vascular disease, and cerebrovascular disease—are extremely debilitating, and are by far the most common causes of stroke, myocardial infarction, and heart failure in the United States (2002). The vast majority of vascular disease occurs due to atherosclerosis of the affected vessels, yet our understanding of the mechanisms by which atherosclerosis develops is limited. Clinicians therefore have few tools at their disposal to prevent or reverse the atherosclerotic process in patients at risk for the consequences of atherosclerosis.

Blood vessels invade and nourish every organ in the body, so the consequences of vascular disease are diverse and reflect dysfunction of the organ system(s) targeted by the affected vessels. Atherosclerotic disease of coronary vessels threatens myocardial viability and can lead to myocardial infarction and its sequelae, and disease of the medium and small vessels of the cerebral vessels can lead to stroke. Although these are the

most common manifestations of vascular disease, other vessels are also frequently affected. Abdominal aortic aneurysms are a relatively common affliction in elderly populations; the vascular disease leading to these aneurysms bears both similarities and differences with typical atheromatous disease typically seen in coronary and other vascular beds. These aneurysms may rupture catastrophically or cause thrombotic occlusions of the distal extremities. Vascular disease also affects the renal and mesenteric vasculature, and contributes to the complications of diabetes.

According to the most recent statistics reported by the National Center for Health Statistics, cardiovascular diseases remain the leading cause of death in the United States (2002). In 2001, 41% of all deaths were due to cardiovascular disease, and of these, nearly three quarters were atherosclerosis-related. The good news is that death rates due to cardiovascular diseases declined 36% over the preceding 20 years. The bad news is that the burden of cardiovascular diseases falls disproportionately among the elderly, who are the fastest growing segment of our population. Adults over age 70 are almost four times more likely to suffer cardiovascular diseases than are those in the 40- to 49-year age group. In fact, some cardiovascular diseases, such as abdominal aortic aneurysms, are almost unknown in individuals under age 65, yet may be found in up to 5% of males over age 65 (Salo *et al.*, 1999). Unless reductions occur in the incidence of cardiovascular diseases in the elderly, it is probable that the increasing numbers of older individuals will provide resistance against the long-term trends toward decreasing overall cardiovascular mortality.

## Mechanisms of Atherosclerosis

Atheromatous lesions develop over decades and occur principally within the intima, the innermost layer of the arterial wall. Several paradigms exist for classification of atherosclerotic lesions based primarily on morphologic considerations. The earliest identifiable lesion, the *fatty streak*, is a flat, yellowish, nonobstructive accumulation of neointimal lipid that can be found in the aorta and coronary arteries of most individuals beginning in the second decade of life. The *fibrous plaque* is a more advanced whitish lesion containing proliferative smooth muscle cells, infiltrating macrophages and other

inflammatory cells, and extracellular matrix components. Whether fibrous plaques inevitably arise from fatty streaks rather than appearing *de novo* is not clear. Often, a necrotic *lipid core* resides deep within the fibrous plaque, which contains macrophage-derived foam cells and extracellular lipids. Fibrous plaques may protrude eccentrically into the lumen, resulting in obstruction of blood flow and symptoms such as angina pectoris and claudication. However, defects of the lesion surface and accompanying thrombosis are not present, and therefore unstable coronary syndromes typically are not associated with these lesions.

Progression of fibrous plaques leads to *advanced or complicated lesions*, which may contain increased amounts of connective tissue around the necrotic core (fibroatheromas) and/or calcifications of the necrotic core. These components may alter the compliance of the vessel and thus have a destabilizing tendency. Neovascularization of the plaque by the process of angiogenesis may occur (O'Brien *et al.*, 1994), and the presence of these vessels may lead to intraplaque hemorrhage, which is an important source of plaque instability and intraplaque hematoma formation. The intimal surface of advanced lesions may have minor disruptions (*fissures*) or suffer gross denudation (the *ulcerative plaque*), which can serve as a nidus for acute thrombosis directly. Surface disruption may also lead to *plaque rupture* with extrusion of lipid core components and activation of the coagulation cascade within the intraluminal compartment. Advanced lesions encompass a variety of pathologic components in varying mixtures, but they share two ominous characteristics: They may progress rapidly, owing to features such as intraplaque hemorrhage, leading to rapid progression of obstructive symptoms such as angina. By virtue of their tendency to rupture and thrombus formation, they may also cause acute occlusion of coronary and cerebral vessels, resulting in myocardial infarction and stroke, the most deadly consequences of atherosclerotic disease.

The framework for understanding how atherosclerotic lesions form and progress was provided by Russell Ross (Ross, 1993). Dr. Ross proposed the “response-to-injury” hypothesis, which argues that the initiating event in lesion formation is some form of “injury” to the endothelium, the cell layer that forms the luminal barrier of all blood vessels. Although modifications of this initial hypothesis have been made to incorporate subsequent observations, it still provides a useful framework for understanding how lesions form. Endothelial injury in this model may take the form of *mechanical forces* such as high blood pressure or changes in shear stress and cyclic strain that can occur at vessel bifurcations; *metabolic conditions* such as diabetes mellitus, hyperhomocysteinemia, or hyperlipidemia that produce substances that directly injure the endothelium; or *environmental agents* such as the products of tobacco smoke or even infectious agents that also impair endothelial cell function. It is

important to note the close correlation between the factors that may cause endothelial injury and the known risk factors for atherosclerosis.

Regardless of the cause, injured endothelium has several proatherogenic properties. Normal adaptive vascular responses, such as the release of endothelium-derived nitric oxide, are impaired. Endothelial denudation or activation leads to adhesion of platelets and inflammatory cells that can release proatherogenic growth factors. Adherent monocytes and lymphocytes may also directly invade the vessel wall, where they participate directly in lesion formation. Low-density lipoprotein cholesterol may be taken up by macrophages and other vascular cells after injury, leading to foam cell formation and lipid accumulation in necrotic areas. Intraplaque macrophages may be particularly destabilizing within advanced plaques by releasing factors such as matrix metalloproteinases that degrade the extracellular matrix and impair the integrity of the atherosclerotic lesion. Lesion stability can also be triggered by apoptosis of the endothelium, which removes the vessel barrier to thrombus formation, and also by apoptosis of intraplaque smooth muscle cells, which may serve as a stabilizing function in complicated lesions (Ferguson and Patterson, 2003). It is clear that the evolution of atherosclerotic lesions is incredibly complex, involving a large number of events and many cell types, some of which participate in both detrimental and protective processes within the lesion, depending on the stage of the lesion and the location of the cell. This enormous complexity explains in part why the genetics of atherosclerosis is still so poorly understood at the present time.

## Atherosclerosis and Aging

There are two explanations for the increased prevalence of vascular disease in the elderly: (1) the increased risk represents a longer duration of exposure to conditions that promote atherosclerosis (i.e., the time-dose product of the risk factors); and (2) atherosclerosis is a specific aging-associated process. It is important to note that these possibilities are not mutually exclusive and that from the perspective of a given elderly individual at risk for vascular disease, this distinction may not matter much. However, discrimination between these hypotheses has important implications for prevention of vascular disease, particularly at the population level. In the former case, preventive therapies should focus on early interventions on established risk factors such as hypercholesterolemia, hypertension, diabetes, obesity, and smoking; in the latter case, specific therapies may be required to target the aging-associated mechanisms that accelerate atherosclerosis in the elderly.

The possibility that atherosclerosis has a specific aging-associated pathogenesis can be explored at the epidemiologic and pathophysiologic levels. The Framingham study still provides the best data for understanding the

*epidemiologic* impact of aging on cardiovascular disease. One way that this data set can be used to address the role of aging *per se* as a risk factor for atherosclerosis is to examine the age-dependence of established cardiovascular risk factors. Indeed, the combined effect of all cardiovascular risk factors together, or of each risk factor individually (with the exception of hypertension), decreases with age, in spite of the age-associated increase in prevalence of cardiovascular disease, suggesting that aging itself is the critical factor (Kannel and Gordon, 1980). More to the point, multivariate analysis demonstrates that aging is a risk factor for atherosclerosis independent of cholesterol level, blood pressure, diabetes, or smoking.

Well-described *physiologic* changes in the cardiovascular system occur with aging that may predispose the vasculature to accelerate the development of atherosclerosis. A variety of studies have shown that older animals have an increased susceptibility and responsiveness to vascular insults (Weingand *et al.*, 1986; Spagnoli *et al.*, 1991; McCaffrey and Falcone, 1993). With aging, there is progressive dilation of large vessels with associated intimal thickening (Michel *et al.*, 1994). Collagen content is increased but elastin content is decreased, resulting in decreased compliance of large arteries (Fornieri *et al.*, 1992). In fact, the change in matrix composition is the primary determinant of intimal thickening associated with aging, as total cellularity remains constant or even decreases (Fornieri *et al.*, 1992; Michel *et al.*, 1994; Lopez-Candales *et al.*, 1997). Bilato and Crow term these aging-associated vascular changes “the vasculopathy of aging,” and argue that they provide the soil for atherosclerosis in elderly individuals (Bilato and Crow, 1996). Strongly supporting the hypothesis that atherogenesis is an intrinsically age-related process, accelerated atherosclerosis is seen in diseases associated with premature senescence, such as Werner’s syndrome and progeria (Cohen *et al.*, 1987).

At present, we know in significant detail the molecular and cellular events that link important cardiovascular risk factors (increased cholesterol, hypertension, diabetes, and smoking) with atherosclerotic lesion progression, and in many cases we have effective therapies that have been extensively documented to modify the risk of cardiovascular events. In comparison with these other risk factors, we know almost nothing about the molecular events that link aging and atherosclerosis, and consequently we have no therapies aimed at modulating the cardiovascular risk inherent to aging. This gap in our knowledge provides the fundamental rationale for the application of animal models of atherosclerosis to delineate the age-associated pathogenetic mechanisms of this disease.

### Animal Models of Atherosclerosis

A variety of animal models have been used to study atherosclerosis since the first description of atherosclerosis

in rabbits in the early years of the twentieth century (Anitschkow, 1914). Each model differs with respect to variables such as the length of time to development of lesions, similarity to human pathology, and the requirements for supplementation to induce atherosclerosis, and as such it is clear that a single ideal model for analyzing atherosclerosis does not exist. At the present time, a number of animal models of atherosclerosis, such as canines and pigeons, are primarily of historical interest and are not discussed here.

### PRIMATES

Both New World and Old World monkeys have been extensively evaluated for their ability to develop atherosclerotic lesions. Nonhuman primates develop atherosclerotic lesions that bear remarkable similarities to those of humans, including the ability to mineralize and undergo plaque rupture. Atheromatous formation in monkeys is modified by many of the same factors that influence human vascular disease—diet, gender, age, blood pressure, and genetics. Thus, nonhuman primates have many ideal characteristics for developing animal models of atherosclerosis. However, these advantages are mitigated by three major factors: regulatory issues that make it difficult to acquire and obtain monkeys for research; requirements for specialized housing and veterinary services; and the relatively long time-intervals required for atherosclerotic lesion development.

In spite of these challenges, nonhuman primates exhibit a number of remarkable features that favor their use for understanding the mechanisms of human vascular disease. For example, cynomolgus macaques have lipid profiles similar to humans, and exhibit sex differences in lesion formation that mimic what is observed in humans (Rudel *et al.*, 1977). In addition, both cynomolgus and rhesus monkeys develop myocardial infarctions (Bond *et al.*, 1980), which is otherwise a rare occurrence within the animal kingdom outside *Homo sapiens*. Localization of atherosclerotic lesions in monkeys is generally similar to that in humans, allowing analysis of disease in coronary, iliac, aortic, and intracranial vessels, all of which are major sources of disease in humans.

Arguably the best data linking diet and lifestyle changes with modulation of the risk of atherosclerosis have derived from nonhuman primate studies. Regression of atherosclerosis has been amply demonstrated to occur in conjunction with reductions in plasma cholesterol concentrations (Clarkson *et al.*, 1984). This remains one of the few models in which true plaque regression can be observed, and given that therapeutic interventions to elicit plaque regression in humans are limited, this is a powerful advantage. In addition, monkeys are arguably the only model organisms in which human-type psychosocial stresses can be tested. A number of studies have now shown clearly that high levels of psychosocial stress associated with activation of the autonomic nervous system and neuroendocrine reactions to stress in monkeys

result in acceleration of atherosclerotic lesion formation that at least in some cases can be modulated pharmacologically (Kaplan *et al.*, 1987). Thus, it is unfortunate that logistical and practical reasons limit the utility of these models, which are becoming increasingly limited to a few specialized centers.

## SWINE

Atherosclerosis occurs spontaneously in swine and is easily induced by proatherogenic diets. It occurs in distributions similar to that observed in humans, and the common circulatory mechanisms and large caliber of porcine arteries facilitates their analysis. The pathogenesis and histology of lesions in swine closely parallels that observed in humans: focal intimal thickening, fatty streaks, inflammatory cell infiltration, lipid deposits, and fibrous plaque formation are all observed in lesions in pigs (see Figure 72.1).

In spite of these features, swine have been used only infrequently for pharmacologic studies of atherosclerosis. Pigs are extremely expensive and require special handling, and their dietary requirements can be formidable. Because pigs grow quickly, changes in weight can make pharmacologic dosing studies nontrivial. Miniature swine, such as the Yucatan, have been developed to circumvent some of these issues, but microswine remain expensive to purchase and maintain. The recent development of a pig model with features of metabolic syndrome (Nichols *et al.*, 1992) may reinvigorate the use of this model to study cardiovascular disease, given the increasing appreciation of a tight link between this syndrome and atherosclerosis in humans.

## RABBITS

The rabbit has the distinction of being the first species recognized to develop diet-induced atheromatous lesions, in the landmark report by Anitschkow in 1914 (Anitschkow, 1914). New Zealand white rabbits develop

lesions primarily in the aorta, and their development is associated with extraordinarily high plasma cholesterol levels (in the 1000–3000 mg/dl range), which can compromise other organ systems in ways that affect the experimental utility of this model. Disease of epicardial coronary vessels is rarely described, and though some features of human atheroma are present in the aortic lesions in rabbits, the prominent human concern of plaque instability is not a feature.

The use of rabbits as models of atherosclerosis has been enhanced significantly by development of genetic models, including the Watanabe heritable hyperlipidemic rabbit, which carries a spontaneous mutation in the LDL receptor (Watanabe, 1980). These rabbits develop aortic lesions spontaneously, and thus they serve as a particularly useful model to test mechanical and pharmacological interventions in atherosclerosis-related conditions. However, even in these genetically defined rabbits, intervals of at least a year are required for the development and progression of advanced lesions, and therefore time and cost issues factor into the choice of this model.

## MICE

Rodents do not naturally develop atherosclerosis and have small-caliber arteries that develop primarily medial lesions under extraordinary dietary conditions that are distinct morphologically from human atheromatous disease. Each of these factors has contributed to an historical consideration that rodents were poor models of atherosclerosis. Hypercholesterolemic hamsters were briefly popular (and are still used occasionally) owing to their ability to develop lesions within the aortic arch that mimic subendothelial foam cell accumulation and that can be studied by *en face* preparations for quantitative analysis (Nistor *et al.*, 1987). However, the road to the now nearly ubiquitous use of the mouse as the primary model for studying atherosclerosis was paved by the

**Figure 72.1** Swine model of atherosclerosis. Histologic samples from normal and atherosclerotic pig arteries demonstrate the hallmark characteristics of atherosclerosis, including cholesterol deposition, calcification, foam cell accumulation, and development of a fibrous cap.

development of mouse strains genetically modified by homologous recombination to develop accelerated atherosclerotic lesions, and was further cemented by the mouse genome project, which anointed the mouse as the primary model for genetic analyses in most laboratories today.

Although previous studies of strain-specific differences in medial thickening led to the supposition that mice are resistant to atherosclerosis, the development of hypercholesterolemic mice by deletion of the gene for apolipoprotein E indicated that this is not the case (Plump *et al.*, 1992; Zhang *et al.*, 1992). These mice become spontaneously hypercholesterolemic and develop atherosclerotic lesions in the aorta, along the aortic valves, and within the great vessels. The development of these lesions occurs spontaneously but can be markedly accelerated by feeding the mice a high-fat (“Western”) diet. Acceleration of lesion formation with a high-fat diet can reduce the time needed for lesions to fully invest the large vessels in ApoE<sup>-/-</sup> mice to three months or less, which is one of the most rapid intervals among experimental models of atherosclerosis. Lesions form with many of the morphological characteristics of human atherosclerosis, and usually are quantified by serial sectioning at the level of the aortic valve or by Oil Red O staining of the aorta *en face* to define the extent of lesion formation throughout the aorta. Unfortunately, the distribution of lesions does not extend to the coronary circulation and advanced features such as plaque rupture are observed only under extraordinary circumstances.

ApoE<sup>-/-</sup> mice and the somewhat less frequently used but phenotypically similar LDL receptor-deficient mice are now the most common animal models of atherosclerosis by far. It is noteworthy that, to date, modulation of cholesterol metabolism has been the only mechanism that results in atheroma development in mice. The development of ApoE<sup>-/-</sup> mice has made possible an extraordinary analysis of modifiable factors such as diet, exercise, drug effects, and others that determine the extent of atherosclerotic lesion formation. In addition, the widespread availability, low cost, and rapid time to disease formation have made ApoE<sup>-/-</sup> mice an ideal model for drug screening and validation experiments.

In addition to these virtues, the availability of a broad variety of genetically modified mouse strains has allowed the molecular dissection of events that influence the pathogenesis of atherosclerosis that is virtually impossible in other models of this disease. The usual strategy has been to cross ApoE<sup>-/-</sup> mice with mice deficient in other proteins that are required for specific pathways or cellular events to determine the effects of this second molecule on the ApoE<sup>-/-</sup> phenotype. As an example of this approach, ApoE<sup>-/-</sup> mice also deficient in activity of the NADPH oxidase (by deletion of the essential component p47<sup>phox</sup>) have reduced levels of atherosclerosis, which indicates a necessary role for oxidative stress in atherosclerotic lesion formation (Barry-Lane *et al.*, 2001).

This approach can be further augmented by bone marrow transplantation to dissect out the relative contributions of different cell types (circulating versus mural cells) to any phenotype that is observed. Finally, mice are perhaps the only animal model available in which it is feasible to perform advanced genetic crosses to search for new atherosclerosis-related genes and genetic modifiers that regulate the disease process through the awesome power of genetics.

Many of these features would suggest that ApoE<sup>-/-</sup> or similar mice are the ideal animal models for studying atherosclerosis, and in many respects they are. As indicated earlier, the availability, rapid time to disease onset, and genetic features are unique to this model, and no other model is as cost-effective on an animal-by-animal basis. Nevertheless, the limited distribution of lesions within the circulatory tree in this model and the failure to replicate many key steps in atherosclerotic vascular disease are important limitations. Thus, it is unlikely that mouse models alone will suffice in all circumstances for thorough evaluations of atherosclerotic disease.

## Endovascular Injury

Although atherosclerotic disease is the major cause of morbidity and mortality in advanced civilizations, other diseases of the vasculature are common and have been modeled in animals.

With the development of interventional techniques to treat cardiovascular disease, especially in the coronary circulation, it has become apparent that the maladaptive response to endovascular injury (clinically referred to as restenosis) is mechanistically distinct from atherosclerosis, although a few features (such as smooth muscle proliferation) are common in both processes. Endovascular injury originally was used experimentally as a means to induce vascular responses, but the widespread use of balloon angioplasty and endovascular stenting has made the modeling of endovascular injury a greater experimental imperative.

Attempts to induce endovascular injury have been made in virtually every laboratory animal. In animals with large-caliber arteries, such as monkeys, pigs, and dogs, the same approaches that are used clinically (balloon injury and stent implantation) are used experimentally. In most cases, the time course and the extent of injury induced are similar to those seen in humans, especially when these techniques are accompanied by high-fat diets or are performed on pre-injured arterial segments. The initial phases of the response to endovascular injury consist of endothelial denudation, platelet adhesion, and intravascular thrombosis. The acute phase is followed by medial hyperplasia of smooth muscle cells, with resultant migration and further proliferation within the intima that occurs one to four weeks after injury. During the latter phase of the injury response,

matrix deposition and further intimal thickening occur, leading to an eventual return to quiescence, albeit with an obstructive endovascular lesion at the site of injury (Patterson, 2002).

The response to endovascular injury, both in humans and in animal models, is further complicated because arterial remodeling provides an additional influence on the ultimate vascular response. This remodeling, which involves changes in the elastic laminae and adventitia that can either be favorable (outward) or unfavorable (inward) can modulate the extent to which lesions induced by endovascular injury become obstructive. Unfortunately, the mechanisms that regulate this remodeling phase are poorly understood, which emphasizes the need to study and understand this process in animal models.

Owing to the mechanical requirements for endovascular injury, large animal models produce more favorable responses that closely mimic the human condition. Injury to nonhuman primates using standard balloon catheter techniques results in a vascular response almost identical to that observed in humans, with early thrombosis and a late remodeling phase. Unfortunately, few centers have access to this approach. Balloon-mediated injury to the Yucatan minipig provides a consistent high-grade lesion, especially when combined with a high-fat diet, and these lesions can themselves be used as further targets for stent implantation (Gal *et al.*, 1990). These characteristics have made the swine model attractive both for studying the pathogenesis of endovascular injury and as a tool for the development of interventional techniques.

One major disadvantage of the aforementioned approaches is the time and expense necessary for large animal studies, not only with respect to the cost of the animals themselves but also attendant costs of instrumentation and anesthesia costs, none of which are trivial. Attempts to create appropriate small animal models of endovascular injury have, therefore, been a high priority. The caliber of blood vessels in New Zealand white rabbits has limited the usefulness of these animals for such approaches, but the larger Giant Flemish rabbits overcome this limitation and have seen some use for this purpose (LeVeen *et al.*, 1982). The rat carotid injury model, in which a balloon is used to damage the endothelium of the carotid artery, produces a characteristic lesion that has been extensively characterized (for example, see Ruef *et al.* (1999)). Unfortunately, the lesion in these animals is limited predominantly to smooth muscle proliferation, and for this reason translation of studies using this approach should be limited to understanding mechanisms for activation of smooth muscle cells. Thrombotic, inflammatory, and remodeling components are largely lacking in this model, which explains why observations of drug effects based on rat carotid injury have not been reproducible in early phase drug development studies in humans.

In spite of the limitations of the rat approach to endovascular injury, there have now been numerous attempts

to simulate this injury response in mice. The impetus for these efforts stems in part from the ease of use of mice as an animal model from a logistical perspective, but probably even more from the widespread availability of genetically modified mouse strains that allow specific characterization of pathophysiologic mechanisms. The approaches that have been used in mice are varied, and include endoluminal injury with wires to denude endothelium, arterial ligation (particularly of the carotid artery) to induce flow-dependent proliferation and remodeling, and a wide variety of direct arterial injury approaches. These models have been enormously fruitful in eliciting mechanisms of the injury response, particularly with regard to proliferative responses. However, it is essential to keep in mind that the response to injury in these mouse models is limited almost exclusively to medial smooth muscle cell proliferation, which is only one among many components of the endovascular injury response in humans. Thus, these studies must be carefully interpreted. At present, mouse models have limited utility for testing pharmacologic interventions.

## Conclusion

Given the enormous burden of cardiovascular disease, especially among elderly individuals, it is not surprising that so many approaches have been developed to model these disease processes in animals. The approaches available vary, in part because atherosclerosis and related diseases are such complicated cellular events. With shorter life spans and responses to vascular insults enhanced by dietary influences, these animal models are in some cases particularly well suited for exploring why vascular disease is such a burden within aging populations and why it is so closely associated with accelerated aging processes.

# Managing Menopausal Symptoms

Mary Ellen Rousseau

*This chapter deals with menopause-associated symptoms including hot flashes, night sweats, sleep disturbances, and vaginal symptoms. Other symptoms that accompany the perimenopause transition but are related to other life events or aging, including sexual dysfunction and mood disturbances, are discussed. The options for managing these changes include menopause hormone therapy, both systemic and local, as well as complementary therapies and nonhormonal therapies for each of the symptoms.*

## Introduction

Symptom perception, whether during menopause or otherwise, is comprised of sensations that differ from the ordinary. The main symptoms associated with menopause are hot flashes, night sweats, and vaginal symptoms including dyspareunia, dryness, and itching. For many decades other maladies have also been attributed to menopause including depression, mood swings, loss of youthfulness, sleep problems, and memory and cognitive dysfunction. Until the 1990s most research on menopausal women was derived from data from convenience samples of treatment-seeking white middle-class women (Avis *et al.*, 1993) and expert opinion. Whether these symptoms can be attributed to a menopause syndrome and the changing hormonal milieu that occurs in midlife or whether they exist on a continuum that proceeds along with aging is a major question at the heart of the menopause construct itself.

The cross-sectional portion of the Study of Women's Health Across the Nation (S.W.A.N.), a multiethnic sample of women (Avis *et al.*, 2001) has shown that vasomotor symptoms (VMS) consistently relate to the time just before and just after menopause. Across all racial and ethnic groups, other symptoms including difficulty sleeping, forgetfulness, stiffness/soreness, feeling tense, feeling depressed, and irritability have not shown a corresponding pattern of clustering around the menopause event. Rather, some symptoms increased over the long run, and the occurrence of some remained consistent throughout the time period from premenopause to postmenopause. This data suggests that there is no universal menopause syndrome in the general population as had been commonly accepted. However, that is not to say

that there is not a subgroup of women who do suffer menopause symptoms that can be more inclusive than just vasomotor symptoms. Some women may have a propensity toward depression that is related to hormone changes, for example, postpartum depression. Such women may develop depression at the time of menopause. It is theorized that some women have a lower threshold for symptoms because of specific personal factors that accompany the menopause transition. During perimenopause, women may experience difficult socioeconomic pressures such as job loss, loss of parents or partners, declining personal health status, and difficult physical or cosmetic changes. When these occur at a time of considerable hormonal flux, the woman's threshold for coping may be met and she may become symptomatic to an extent that causes distress. On the other hand, many women by midlife have built a life's worth of coping mechanisms and resiliency that menopause does not rock.

## Symptoms

### BLEEDING

Bleeding pattern is the first change a woman will experience as she approaches the perimenopause transition. The reproductive-age-cycling woman will have predictable menses after ovulation because the cascade of hormonal events leads to a menstrual bleed after 14 days in the luteal phase of the cycle. When a woman reaches the perimenopause period, her supply of follicles secreting estradiol is decreased to a point that not every cycle is ovulatory. Circulating inhibin-B levels drop in response to the decreased number of follicles present in the ovary, leading to a rise in follicle stimulating hormone (FSH) levels. The increased FSH helps the ovary to produce near normal (premenopause levels) estradiol levels until just before the actual menopause. However, ovulation does not always occur under such circumstances, causing longer or shorter intervals between menses. When ovulation fails to occur, these cycles are characterized by absence of progesterone production, further contributing to cycle irregularity and skipped cycles characteristic of the late perimenopause period.

Irregular bleeding patterns are very common in the perimenopause period and can be linked to hormonal

changes. Cycle irregularity is defined as cycles less than 21 days or greater than 35 days. It is less clear whether or not menorrhagia (heavy bleeding at regular intervals) is also associated with normal perimenopause changes (Van Voorhis, 2005). Longitudinal data from the S.W.A.N. study will give us a greater understanding of the hormonal underpinnings of the menopause change and perhaps clear up various questions about bleeding patterns during perimenopause. At the present time, however, menorrhagia is not considered a predictor of menopause (Van Voorhis, 2005) but is a common clinical finding associated with fibroids and polyps of the lining of the uterus. The prevalence of both polyps and fibroids peaks between the ages of 40 to 50, further confusing the diagnosis because of the hormonal changes taking place at the same time. Diagnostic evaluation of bleeding can be accomplished by transvaginal ultrasound, hysteroscopy, endometrial sampling, or a combination of diagnostic tools.

Often exogenous hormones are used to regulate menstrual bleeding during this time period in women screened for contraindications (heart disease risk, thromboembolic events, and smoking). Both estrogen and progestins are implicated in the increased risk of heart disease, stroke, and other thromboembolic events, as evidenced in the data from the Women's Health Initiative (WHI) (Rossouw *et al.*, 2002). Hormonal contraception such as patches (Ortho Evra™) and oral contraceptive pills are used to cause more predictable bleeding patterns. Other options include cyclic progestins: medroxyprogesterone acetate—Provera™, Cycrin™; micronized progesterone—Prometrium™; norethindrone acetate—Aygestin™, each of which is prescribed for 14 days every calendar month. Alternative treatment options for perimenopause bleeding include depo Provera™ and progesterone IUDs (Mirena™). Giving cyclic progestins offers the same predictable bleeding pattern as when OCPs are used but offers no contraception. Use of depo Provera™ leads to an atrophic endometrial uterine lining leading to amenorrhea. Women using depo Provera run the risk of decreasing bone loss, which is of particular importance in the perimenopausal woman. Use of the progestin IUD offers local progesterone effect, usually leading to an atrophic endometrial lining but with less theoretical chance of decreasing bone loss or increased theoretical risk of thromboembolic events.

### VASOMOTOR SYMPTOMS (VMS)

Quality of life in menopause encompasses more than just absence of symptoms. It includes enjoyment of life, participation in meaningful relationships, work, and play (Matthews and Bromberger, 2005). Although most women in Western societies report hot flashes and night sweats, for most of these women such symptoms do not affect quality of life. In fact, data

from the Melbourne Women's Mid-life Project show that well-being increases across the menopause transition (Dennerstein *et al.*, 2003). Lifestyle changes are recommended first for vasomotor symptoms. These include weight reduction for women who are significantly overweight; it has long been considered that women who were obese had fewer vasomotor symptoms because of elevated estrone levels from aromatization of adipose tissue to androgens than to estrone. However, new evidence shows that the occurrence of VMS in obese perimenopausal women may be due to the increased heat insulation afforded by greater adiposity, leading to more hot flashes (Freedman, 2002; Glickman-Weiss *et al.*, 1999). Smoking is associated with hot flashes, so the patient is encouraged to quit or reduce smoking to decrease the incidence of hot flashes (Whiteman *et al.*, 2003). The data on alcohol use and hot flashes is mixed (Gold *et al.*, 2004). Observational studies of physical activity and VMS do not show a relationship with hot flashes (Li *et al.*, 2003; Li *et al.*, 1999; Sternfeld *et al.*, 1999).

Menopause hormone therapy (MHT), however, is very effective for treatment of hot flashes and night sweats and by secondary gain can be useful for treating sleep disturbances that result from waking related to hot flashes. Prior to 2002 when the Women's Health Initiative (WHI) was halted because of increased risk for women taking estrogen and progestin therapy for breast cancer (anticipated) and for increased risk for heart disease, stroke, and other thromboembolic events (unanticipated), MHT was recommended for all postmenopausal women to protect against osteoporosis and heart disease as well as for treatment of symptoms including hot flashes, vaginal dryness, mood changes, sleep disturbances, and sexual dysfunction. Subsequently, the estrogen-only arm of the WHI was discontinued as well, because of the increased risk of stroke (RR 1.4 for women on estrogen alone). In addition, data from the WHI demonstrated increased risk of dementia and urinary incontinence with use of MHT (Hendrix *et al.*, 2005; Shumaker *et al.*, 2004).

Presently, the Federal Drug Administration (FDA) indicates use of MHT for moderate (with sweating) to severe (limits activities) hot flashes with a frequency of 80 to 100 per week. The FDA recommends use of the smallest dose MHT to alleviate symptoms for the shortest amount of time possible. Prior to 2002, the oral dose of conjugated equine estrogen (CEE) recommended to protect from heart disease and osteoporosis and to alleviate all symptoms was 0.625 mg daily. There was aggressive marketing to women's health professionals that this or an equivalent dose in another preparation was the standard of care to control symptoms. The side effects usually encountered at this dose included breast tenderness and breakthrough bleeding. In the recent past there has been development of lower dose products that are half to one-quarter the CEE 0.625 mg dose in patch and oral

forms and to use of local therapy for vaginal symptoms has been recommended.

MHT is an excellent treatment for distressing hot flashes. The side effect profile has been extensively studied, in fact more so than nearly all other drugs on the market. If a woman chooses to use MHT, a starting dose of CEE 0.3 mg or a 25 mcg transdermal patch is recommended. If vaginal symptoms are problematic, then MHT options include vaginal estrogen creams (Premarin<sup>TM</sup> (CEE), Estrace<sup>TM</sup> (estradiol), rings (Estring<sup>TM</sup>, Femring<sup>TM</sup>), or tablets (Vagifem<sup>TM</sup>). New products are coming on the market all the time. Menostar is a 14 mcg transdermal patch that came on the market in 2004. It has FDA approval for the treatment of osteopenia (prevention of osteoporosis). However, it can be used for treatment of hot flashes when choosing a low dose estrogen product.

One caveat to keep in mind is that for women with an intact uterus (one who has not had a hysterectomy), a prescription for a progestin must accompany the use of estrogen products. This protects the lining of the uterus from unopposed estrogen effect (over stimulation), which can lead to a proliferative endometrium, hyperplasia, or endometrial cancer.

Stopping use of MHT as soon as no longer necessary is a reasonable goal. It is not easy to identify when that time might be. Stopping when symptoms are no longer problematic is important because individual risk to a woman using MHT accumulates with length of time used. The recommendation by the FDA to use MHT for the shortest time possible, however, is not a clear or well-defined concept. Grady recommends stopping MHT every 6 to 12 months to establish whether the MHT is still needed (Grady, 2005). The woman can expect a return of hot flashes for a period of time when stopping the hormones, and these usually peak at about four weeks. Seventy percent of women reported mild hot flashes upon stopping MHT, with 30% reporting troubling flashes (Ettinger, Grady, Tosteson, Pressman, and Macer, 2003). Of the latter group, 25% resumed treatment in six months. It is recommended to taper the MHT by day in order to avoid writing multiple prescriptions for varying doses. This means use of MHT every other day for two weeks, to three times a week, to twice weekly, and so on, taking longer than a month to finish with the goal of reducing discomfort from hot flashes.

Complementary and alternative therapies (CAM) are used by up to 50% of the population of the United States (Eisenberg *et al.*, 1998), and menopause-aged women are targeted daily on television with products that are purported to help with all symptoms of menopause. Most CAM trials suffer serious design flaws, including most do not have a placebo arm, they are short duration, and they have few subjects. In addition, trials of dietary supplements often fail to adequately describe which part of the plant is used, how the herb is prepared, what solvents are used, and so on.

Black cohosh is probably the most extensively studied herb for hot flashes but findings vary across studies. The mechanism of action of this herb was long thought to be that of a weak phytoestrogen (plant estrogen) but research now suggests a nonhormonal effect (Low Dog, 2005). Black cohosh is available as a standardized extract in the commercial preparation Remifemin<sup>TM</sup>. Evening primrose oil has been studied, and though it is a rich source of gamma linolenic and linolenic acid, its efficacy for hot flashes is unproven. Ginseng is used in Asian cultures as a tonic and has no usefulness for hot flashes (Low Dog, 2005). Kava has been shown to be an effective anxiolytic in Cochrane reviews but concerns for hepatotoxicity need to be addressed (Pittler, 2000; Pittler *et al.*, 2002).

Although there has been a great deal of interest in the use of soy for menopause symptoms, soy products are difficult to characterize because it makes a difference whether food products or extracts are being considered. Soy in food generally is considered safe when used as part of a balanced diet. Whether or not dietary soy conveys health benefits is unproven. Studies show conflicting results with regard to hot flashes (Faure *et al.*, 2002; Han *et al.*, 2002; Nikander *et al.*, 2003; Penotti *et al.*, 2003). Supplements of soy have unknown effects because most studies do not show percent of isoflavones (plant estrogen) included in the extract. Estroven is one herbal supplement that contains 55 mg of isoflavones from non-GMO soya, Japanese arrowroot, calcium, and vitamins E, B6, and folic acid.

Most clinical trials of red clover, Trifolium pretense L. (Promensil<sup>TM</sup>), have failed to show any benefit over placebo (Baber *et al.*, 1999; Knight *et al.*, 1999; Tice *et al.*, 2003). However, in a randomized, placebo control study of 30 women for 12 weeks, Promensil<sup>TM</sup> use resulted in a significant reduction in hot flashes from baseline (van de Weijer and R., 2002).

Other modalities have been investigated for relief of hot flashes in menopausal women, including acupuncture, magnetic therapy, reflexology, and homeopathy. An electronic search of relevant studies was reported at the NIH State-of-the-Science Consensus Conference on Management of Menopause-Related Symptoms found 11 intervention studies, including seven on acupuncture, one on magnets, one on reflexology and two on homeopathy (Carpenter and Neal, 2005). All the studies examined suffered from design flaws—most were uncontrolled, with small sample sizes making conclusions far from firm. And most have inconsistent results regarding improvement in hot flashes.

In the past, centrally active agents Bellergal<sup>TM</sup> and Clonidine<sup>TM</sup> have been used to control hot flashes. Bellergal<sup>TM</sup> was popular two decades ago and has limited efficacy for decreasing hot flash frequency or severity (Bergmans, Merkus, Corbey, Schellekens, and Ubachs, 1987; Lebherz and French, 1969). Clonidine<sup>TM</sup>,

an older hypertensive preparation, has been demonstrated to reduce hot flashes with only moderate efficacy, but toxicity limits its use (Loprinzi, 2005). In the 1990s selective serotonin reuptake inhibitors (SSRIs) were found to reduce hot flashes in women using them for other reasons. It appeared that the SSRIs were not only efficacious but also well tolerated (Stearns, 2000; Loprinzi, 1998). Subsequent placebo-controlled double blind studies of venlafaxine (Effexor™) and paroxetine (Paxil™) have shown reduction in hot flashes (Loprinzi 2000; Stearns, 2003). Pilot studies are ongoing for other, newer antidepressants, which also look promising. Gabapentin (Neurontin™) has been anecdotally noted to decrease hot flashes, and ongoing trials promise new interest in its use. Gabapentin is relatively well tolerated by most women and may be one of the most efficacious and clinically appropriate agents for use along with the newer antidepressants (Loprinzi, 2005).

### VAGINAL SYMPTOMS

During the menopause transition, women may experience vaginal symptoms including vaginal dryness, itching, and dyspareunia (painful intercourse). These vaginal changes result from changes in the serum estradiol levels that drop precipitously just before the last period. The end organ response to this drop in estradiol results in less estrogen effect on the mucus membranes that line the vaginal wall. During the reproductive years the vaginal wall is composed of a highly estrogenized superficial layer beneath which is the intermediate layer, and beneath that is the basal layer. This bottom-most layer is exposed when estradiol levels drop at menopause. When this happens the vagina loses elasticity and moisture, blood vessels are closer to the surface, and with time atrophy occurs. It is hypothesized that for some women who maintain an active sex life, blood flow to the pelvis keeps the vaginal supple and can prevent symptoms. Many women, though, experience itching and pain, and are unable to have comfortable intercourse, especially in the postmenopause period.

Vaginal complaints can be dealt with effectively by use of local MHT in the forms of estrogen rings (Estring™, Femring™), creams (Premarin™ cream, Estrace™ cream), and tablets (Vagifem™), which have local vaginal effects and in theory have reduced systemic effects compared to oral or transdermal estrogens. Package inserts recommend that progestins be used to offset the estrogen effect on the uterine lining. A postmenopausal woman who uses the local estrogen for a short time may not develop a proliferative or hyperplasia of the uterine lining but if any postmenopause bleeding does occur with use of local estrogen products, investigation of the cause of the bleeding must be conducted.

Alternately, for women who wish to avoid use of MHT for vaginal symptoms, water-based lubricants such as KY Jelly™, KY Warming Liquid™, Astroglide™,

Liquid Silk™, or Eros™ (silicone based) can offer more comfortable vaginal penetration without side effects. Water-based lubricants are safe to use with all sex toys and condoms, whereas oil-based lubricants can react with rubber and cause it to disintegrate. Oil-based products such as Vaseline™ can irritate the mucous membranes of the vagina and is difficult to wash away. Many water-based lubricants contain glycerin, which may lead to vaginal infections or allergic reactions in some women. To avoid this, it is recommended that women wash thoroughly after using a lubricant, or find a water-based product that does not contain glycerin as an ingredient. Women should avoid lubricants with flavoring in them because they often contain sugar, which can also contribute to yeast infections.

Burning, itching, painful intercourse, and discomfort during everyday activities are the most common symptoms of vaginal dryness. Vaginal moisturizers are yet another alternative to help with vaginal symptoms. Replens™, a vaginal moisturizer, helps sustain vaginal moisture with a comfortable coating, and helps maintain vaginal epithelial integrity and vaginal elasticity.

### MOOD DISTURBANCES

The majority of studies from large literature searches indicate no associations between the menopause stage and mood symptoms, development of mental disorders, or general mental health (Haney, 2005). Two cohort studies report increased incidence of depressive symptoms among peri- and postmenopausal women (Freeman *et al.*, 2004; Maartens, Knottnerus, and Pop, 2002). Data from studies of prevalence rates for mood symptoms have wide ranges and are similar across the menopausal stages (Haney, 2005).

Periods of reproductive hormonal change (premenstrual, postpartum, and perimenopause) may constitute times of particular risk to women with regard to depressive illness. Since perimenopause is a time of great change for women in many arenas including important hormone changes, some women will be at risk for affective disorders during this period. Treatment of mood disturbances that accompany the transition through the menopausal stages is important given the morbidity associated with untreated affective disorders. The efficacy of antidepressants to treat depression is widely supported. SSRIs and dual-action antidepressants, serotonin and norepinephrine reuptake inhibitors (SNRIs) (venlafaxine—Effexor™, and duloxetine—Cymbalta™), are generally very effective, yet side effects, which include weight gain, insomnia, and sexual dysfunction, may be problematic for many women and can contribute to nonadherence.

### Sexual Dysfunction

Unlike hot flashes and night sweats, which mirror the menopausal stage that a woman undergoes sexual

changes in both women and men decline on a steady slope with age. For women, a further incremental decline is related to falling estradiol levels probably more so than declines in testosterone levels (Dennerstein, Randolph, Taffe, Dudley, and Burger, 2002). The factors that affect a woman's sexuality include first and foremost aging, the length of her sexual relationship with her partner, her own or her partner's health problems, loss of a partner, and psychosocial stressors (Dennerstein, 2005). Moreover, sexual function or dysfunction in women is multidimensional. The problem may rest with desire, arousal, and inorgasmia. It is also nonlinear—a woman can have responsive desire vs. innate desire (arousal before desire). Her sexual functioning at menopause or at any time along the lifespan is highly related to her previous behavior or level of interest, her feelings toward her partner, and her partner's status. Not surprisingly, a new partner puts a new set of variables in play for a woman's sexual interests and behavior. Mood disorders also need to be taken into account with regard to women's sexuality because they can affect interest in sex and responsiveness. And finally, not all women are distressed with having a low level of sexual function.

That being said, problems with vaginal dryness or atrophy can be remedied with local vaginal use of MHT, vaginal lubricants, or moisturizers as discussed in the previous section. Some women respond to estrogen or progestin therapy, which may improve receptivity to sexual play.

Testosterone has been used with estrogen to improve sexual function. The decline in circulating testosterone levels is gradual with levels generally lower than in younger women (Judd, Judd, Lucas, and Yen, 1974). However, in women who have undergone either a surgical or medical castration, there is a 50% decline in testosterone levels (Judd *et al.*, 1974). Nearly all data on use of testosterone in women for sexual dysfunction has been done in combination therapy with estrogen. Data suggest that women receiving either estrogen alone or an estrogen–testosterone combination had significant improvements over baseline in well-being, sexual function, and energy levels (Sherwin, 1998, 2002; Simon *et al.*, 1999). In the United States, only the combination of methyltestosterone in combination with esterified estrogen (Estratest™) is available as an FDA-approved treatment modality. Methyltestosterone (Halotestin™) is available alone as a 2 mg dose, which may be used as an adjunct to estrogen therapy if estrogen therapy alone does not improve sexual function, but this is off-label use. Currently, testosterone patches and gels are being tested in phase III trials. For clinicians who are using testosterone preparations, laboratory monitoring of bioavailable or free testosterone levels, serum hormone binding globulin (SHBG) and lipids should be considered. Blood pressure should be monitored as well. There is no long-term safety data for testosterone

therapy, so long-term use cannot be recommended (Liu, 2005).

## Conclusion

Most women in Western societies report some symptoms of menopause. Women at the same time employ a range of symptom management options including self-care strategies with over-the-counter products, complementary therapies, lifestyle modifications, as well as prescription hormones. So the perimenopause period offers an opportunity to women and health providers to consider strategies for self-care, disease screening, and promotion of healthy aging. Yet menopause needs a conceptual framework that bridges genetic, molecular, and physiologic factors hypothesized to cause symptoms and the social and cultural context in which women experience them. The Women's Health Initiative has given untold insights into the risks of menopause hormone therapy, despite its shortcomings (mean age 67); and the prospective longitudinal investigation of 3302 multiethnic women in the S.W.A.N study to track changes in women as they age and experience menopause will give insight into a whole array of questions. The S.W.A.N study has already pointed out the fact that vasomotor symptoms apart from other symptoms are the only symptoms that occur in synchrony with the perimenopause transition. There is a great deal of work yet to do regarding menopause and the symptoms that sometimes accompany the transition. In the end the best information will come from perimenopause-age women from all walks of life.

# Psychological Aging: A Contextual View

Hans-Werner Wahl and Frieder R. Lang

*In this chapter we review theories on the psychological dynamics of person–environment relations as people age. The chapter begins with an introduction to the issue of aging in context by contrasting perspectives of the biology of aging, the social sciences, and psychological gerontology. We also consider the historical background important for the understanding of a contextual view of aging in the evolution of gerontology, as well as introduce core theory elements of life-span developmental psychology such as the concept of developmental tasks. In the main body of the chapter, contextual aging will be approached by following three lines of thinking, as well as empirical research in aging research. First, person–environment dynamics are strongly driven in old age by interchange with the social environment, and respective theories addressing this fundamental dynamic of person–environment regulation in social aging will find intense discussion. Second, the area of environmental gerontology, sometimes also coined the ecology of aging, has offered much in terms of theories and empirical findings, when it comes to person–environment relations in old and very old age. As the argument goes, getting older coincides with a substantial increase of vulnerability for “press” in the physical-spatial environment. Third, we will provide our view on how an integrative view of the social and physical environment can be achieved. The chapter ends with a prospective outlook on how the obvious separated treatment of physical and social environment in aging theories can be overcome, thus allowing research to address new and innovative issues on aging.*

## Introduction

The assumption that aging occurs in context probably is an implicit or explicit core feature of all major models of aging, in biology, in the social sciences, as well as in psychological science. How such context is defined and what kind of impact is attributed to context strongly depends on the disciplinary perspective taken on aging. For example, Cowdry (1939), a pioneer in biogerontology, suggested distinguishing between endogenous and exogenous processes of aging. According to the endogenous view, aging is an involuntary process operating cumulatively over time and resulting in adverse

modifications of cells. In the exogenous view, aging is seen as the consequence of infections, accidents, or environmental poisons. In most current theories in biogerontology, aging, or what is sometimes coined *senescence* in the biology of aging, is viewed primarily as an internal decline process related to the flow of chronological age and ending in the event of death (Cristofalo, Tresini, Francis, and Volker, 1999). Environmental conditions, however, shape the survival time of aging organisms, because it is generally acknowledged in models of longevity that genetic factors explain less than 30% of variability in survival time (Vaupel, Carey, and Christensen, 2003). The understanding of context in biological models of aging tends nevertheless to remain rather general, referring mostly to basic physical properties such as temperature, kind of nutrition, or environmental stress level, for instance, when young and old organisms are confronted with uncontrollable negative experiences in an age-comparative experimental design. It is worth mentioning that in the rapidly growing field of behavioral genetics in aging research, most recently a series of articles has underlined the still widely unmet need for a well-defined conception of the environment in order to better understand the operation of gene expression (or depression) in the flow of aging (Johnson and Crow, 2005).

At the other extreme, a social science concept of aging puts major emphasis on the operation of social, cultural, historical, and societal contexts, and how such influences are shaping aging processes. As was argued, different societal expectations and norms structure the sequence of the life course. Temporal inconsistencies between the individual and societal demands or norms may cause negative societal reactions and/or psychological stress on the individual level (Hagestad and Neugarten, 1985). Think of becoming pregnant at the age of 13 years, being unmarried still at the age of 50, or learning to drive a car at the age of 80 years. Additionally, historical context is changing dramatically over time, and this leads to changes of the flow of individual lives and person–society interrelations. A classic example is Elder’s (1974) research on *Children of the Great Depression*, which serves as an impressive illustration of the long-term influences of early childhood and adolescent experiences with the socioeconomic and family consequences of the Great

Depression on the individuals' life course trajectories across adulthood and later life.

Psychological models of human aging have also put strong emphasis on the contextual component of life span and adult life development (Baltes, 1987; Carp, 1967; Dannefer, 1992; Kleemeier, 1959; Lawton, 1999; Rebok and Hoyer, 1977). Similarly to social science perspectives, the term *context* as used in psychological models of aging implies that the interaction between the aging individual and his or her environment is crucial for the understanding of the course and outcome of aging. According to psychological models of aging framed in a strong contextual view, a fundamental psychological challenge of aging individuals is to adjust or readjust their relation with the environment in which they live. Accordingly, a major research task of psychological gerontology is to describe and explain stability and change of person–environment dynamics as people age. As Dannefer (1992) has pointed out, the term *context* as also used in most psychological models of aging is predominantly composed of two large-scale entities, the social environment and the physical environment. The social environment refers to the totality of the diverse range of phenomena, events, and forces that exist outside the developing individual and are directly linked to other persons. This includes research issues such as social networks, social support, or the regulation of social relationships in later adulthood (Antonucci, 2001; Lang, 2001). The physical environment refers to the totality of the diverse range of phenomena, events, and forces that exist outside the developing individual and are directly linked to the material and spatial sphere. This covers research issues such as the impact of the physical-spatial home environment on aging, the role of neighborhoods and infrastructural characteristics, long-term institutions, as well as the challenge and outcome of residential decisions in later phases of the life span (Lawton, 1999; Wahl, 2001; Wahl and Gitlin, In press).

Moreover, emphasizing the context of aging in psychological aging research necessarily implies the need to consider natural settings, which are difficult to capture reliably and validly with experimental approaches in the laboratory. Furthermore, psychological models of aging strive to go beyond survival time as a major outcome of aging, as is often the case in biological models of aging. Instead, psychology focuses on outcomes such as subjective well-being, autonomy, or meaning of life, to name just a few, as products of the person–environment interactions across adulthood.

## HISTORICAL CONSIDERATIONS

In historical perspective, aging has long been regarded as a purely biological and degenerative process. For example, Metchnikoff (1903), frequently cited as the creator of the term *gerontology*, made the argument in his Macrophage Theory that aging can be seen predominantly as an infectious disease, and, as a consequence,

he believed that possible means to counteract such an infection (e.g., yogurt) would be helpful to delay aging. Given the strong biological and medical orientation of early gerontology, the explicit consideration of the socio-physical environment was an important step in its historical development toward a strong interdisciplinary research field. This paradigm shift was mainly driven by the growing role of a social and behavioral science perspective within gerontology and life course research, which began evolving since the late 1920s. For instance, Hall (1922) and Hollingsworth (1927) in the United States provided early contributions to aging research from a developmental psychologist's view, promoting the idea that improved understanding of life-span development is possible only when considering the social situations of aging individuals. Similarly, developmental psychologist Charlotte Bühler (1933) argued in her key work, *The Human Life Course as a Psychological Problem*, that the social world is a driving force not only of child and adolescent development, but also of development in adulthood and late life.

In the 1930s and 1940s, a social science perspective (sometimes also coined social gerontology) began to evolve in American gerontology, mainly nurtured by the creation of the Committee of Human Development at the University of Chicago and its key members, such as Bernice Neugarten and Robert Havighurst. Still more explicit, the interplay between the aging individual and his or her social world was treated for the first time in the *Handbook of Social Gerontology*, edited by Tibbitts in 1960, and the now classic gerontological monograph, *Growing Old: The Process of Disengagement*, by Cumming and Henry (1961). Around the same time period, the basic role of physical, spatial, and infrastructural environments in the aging process found increased attention, as manifested in pioneering handbook chapters such as Kleemeier's (1959) *Behavior and the Organization of the Bodily and External Environment* and Vivrett's (1960) *Housing and Community Settings for Older People*. Since then, addressing the role of context for the course and direction of aging processes has become an essential element of life course theory as well as life-span perspectives in social and behavioral gerontology (Baltes, 1987; Dannefer, 1992; Rebok and Hoyer, 1977). Reference to resources (or constraints) in the person and her or his environment, when the process and outcome of aging is the target of analysis, has even reached the status of a research paradigm in social and behavioral gerontology.

## ESSENTIALS OF A LIFE-SPAN VIEW ON AGING

Life-span contextualism has advanced and elaborated the idea that contexts affect the course, direction, and outcomes of development (Baltes, Reese, and Lipsitt, 1980; Lerner and Kaufman, 1985). Throughout the life course, individuals are confronted with new and changing contexts that structure and sequence the course and

direction of their development. However, not all changes in an individual's environment are developmentally meaningful and effective to the same extent. Life-span theory, in this vein, has contributed importantly to a more sophisticated understanding of how contexts influence and shape the individual's life-long development (Baltes, 1997). For example, life-span perspectives emphasized the interplay of contextual influences on developmental change. This has led to a differentiation of three systems of influence that coconstruct and coregulate life-span development:

1. History-graded influences on aging pertain to such influences that affect most individuals at a given time in history; for example, technological advancement, sociopolitical or economic changes, or natural disasters.
2. Nonnormative or idiosyncratic influences are a result of specific life-course paths and events that few individuals experience.
3. Age-graded systems of influence are a result of biological and cultural processes that are closely associated with chronological age, for example, the age-stratification in most modern societies (Riley, 1985) or age-dependent normative expectations (Heckhausen, 1999).

Similarly and consistent with these assumptions is Havighurst's (1948/1972) already mentioned notion of *developmental tasks* that result from three different sources: biology, society, and internal experience of the individual. Developmental tasks are helpful in determining the course and sequence of how and when individuals are expected to make specific developmental progress or at what time in life they should engage in or disengage from developmental goals (Freund, 2004; Heckhausen, 1999). With this, life-span perspectives on the person–environment dynamics helped overcoming dualistic perspectives on developmental contexts such as nature versus nurture (Lerner, 1998). Consequently, nature and nurture are seen as interwoven systems of influence, leading to a greater focus on the (shared and nonshared) environmental determinants of individual development. Perhaps even more importantly, in life-span contextualism the interplay of person and environment is conceived of as a dynamic involving the agentic individual as producer of his or her own developmental context (Baltes, 1987; Lerner and Busch-Rossnagel, 1981; Lang and Heckhausen, 2006). This implies that the context of aging is seen as one that evolves from the individual's ontogeny, and as a result of life course patterns of behavior. As individuals develop and acquire new strategies of how to exert influence in their environments, they continuously mold their physical and social environments. Thus, the developmental role of context is two-fold. On the one hand, individuals acquire and learn about developmental opportunities and frames of

reference for age-specific norms and action (Heckhausen, 1999; Settersten, 1999). On the other hand, developmental contexts, both social and physical, represent outcomes of individuals' life-course decisions, planning, and management (Brandtstädter and Lerner, 1999; Lang, 2001; Wahl and Gitlin, In press). One central assumption in this line of reasoning is that the extent to which individuals successfully manage to adapt their physical and social environments in accordance with their need states and their psychological resources contributes importantly to an enhanced life quality, a prolonged life expectancy, and increased quality in the exertion of the life expectancy.

Person–environment dynamics are part and parcel of many, now classic, theoretical approaches and models of aging and life-span development, such as Erikson's theory of psychosocial development (1959) and Thomaes's cognitive theory of aging (1970), to name only two (see Wahl and Kruse (2005) for a rather comprehensive overview on developmental stage models of human aging). All these theoretical approaches played an important role in advancing the idea that aging is embedded in social, historical, and cultural processes over the entire life course, which cannot be understood without fully acknowledging the dynamics of person–environment interaction. However, with the exception of the work of Lawton (Lawton and Nahemow, 1973; Lawton, 1989), most of these psychological models have predominantly focused on issues related to social environments rather than on the joint interplay of technical, physical, geographical, social, and biological environments that coregulate and determine the individual's process of aging. In the next section of the chapter, we discuss contextual models that have focused the social and societal environments separately from models that predominantly considered the physical-geographical environments, before presenting an integrative perspective on the socio-physical contexts of aging. It should be emphasized that although we concentrate our discussion of person–environment models of psychological aging on the micro- and meso-level of analysis, the broader socio-cultural or societal context and the interaction of social and physical elements therein, for example, cohort differences and the historical embeddedness of development and aging, provide a major background for the lower levels of contextual analysis (Baltes, Reese, and Lipsitt, 1980; Baltes, 1987; Elder, 1974; Hagestad and Dannefer, 2001). Consequently, we conceive of the developmental context as a multilevel and multidimensional structure of systems that are interwoven in their impact on individual behavior. Contextualistic thinking traditionally aims at identifying the structures and functions in the resulting matrix of developmental contexts that are most relevant for improved understanding of the individual's potentials and possibilities to adaptively master the many challenges of the aging experience. Although most theories have predominantly

focused exclusively on either social or physical contexts, only few attempts exist to more entirely capture the physical and social nature of contextual influences on aging.

### **Psychological Aging in Context: Focusing the Social and the Physical Environment, and the Need for an Integrative Perspective**

#### **ROLE OF THE SOCIAL ENVIRONMENT AS PEOPLE AGE**

Gerontological research on social environments is seeking to identify in what ways qualitative as well as quantitative features of an individual's social contacts and social network contribute to the individual's functioning and life quality (Lang and Carstensen, 1998; Pinguart and Sörenson, 2000; Rook, 2000). The theoretical conceptions about the role of social environments across adulthood are manifold and range from macro-theoretical approaches such as the age stratification theory (Riley, 1985) to micro-theoretical conceptions such as social exchange theory (Bengtson, Burgess, and Parrott, 1997) and the socio-emotional selectivity theory (Carstensen, Isaacowitz, and Charles, 1999).

Theories about the social environments in later life typically have viewed the individual as a recipient or adaptive user of social resources rather than as an active person that engages him- or herself in the construal or even the production of the social environment (Lang 2001; Steverink, Lindenberg, and Ormel, 1998). Recent life-span approaches on the development of social relationships in later life have more explicitly addressed processes that influence and gear the individual's motivations, attitudes, and behaviors toward other people throughout the life course. Most prominently among these are the social convoy model (Antonucci, Langfahl, and Akiyama, 2004), the socio-emotional selectivity theory (Carstensen *et al.*, 1999) and resource-oriented models of social behavior (Lang, 2004). Also, research on parent-child relationships has a long tradition in research on social relations as people age (Frankel and DeWit, 1989; Rosenmayr and Köckeis, 1965; Tartler, 1961). In the following, we first analyze some of the more classical theories of social aging and then elaborate on the implications of more recent theories on aging in the social domain.

#### *Classic approaches to aging in social contexts*

Interestingly, theoretical conceptions of the social environment in later adulthood often relied on metaphors derived from features of the physical world when referring to social experiences in later adulthood. This includes concepts such as social strata, social convoy, social network, support bank, closeness, distance, or life space as metaphoric descriptions of specific aspects of an

individual's social world. Such metaphors serve to keep in mind that all social relationships occur in time as well as in space. Even the now "classic" theories of social aging such as disengagement theory and activity theory have, at least implicitly, acknowledged that aspects of the physical world are relevant for better understanding of social functioning in later life.

According to *disengagement theory* (Cumming and Henry, 1961), older individuals are seen as limiting their social life spaces in response to societal pressures and in order to prepare for the final phase of their lives. Cumming and Henry (1961) explicitly referred to Lewin's (1936) notion of a psychological life space when they introduced their concept of *social lifespace* as reflecting the individual's decreasing social opportunities during the aging process. *Activity theory* emphasized that being socially engaged in a variety of social roles both within and outside the family contributes to better functioning and better life quality (Havighurst, Neugarten, and Tobin, 1968; Lemon, Bengtson, and Peterson, 1972). Keeping a physical or geographical distance from members of younger generations is seen as protecting the older individual from stressful social demands and ensuring maximal freedom to develop age-adequate and adaptive patterns of social activity that contribute to increased well-being. Tartler (1961) introduced the idea of "feeling close at a physical distance" as one adaptive feature of parent-child relationships related to a better quality of the relationship. Empirical findings could support the notion of "intimacy at a distance" (Rosenmayr and Köckeis, 1965) as an adaptive regulatory mechanism of intergenerational relationships (Frankel and DeWit, 1989; Wagner, Schütze, and Lang, 1999). For example, in a study with 454 older parents, Frankel and DeWit (1989) found that greater geographical distance was a strong predictor of reduced contact with adult children but was significantly less strongly associated with the experience of important conversations with children. This indicates that the parent-child tie appears to remain emotionally meaningful irrespective of the physical distance. Emotional closeness in relationships may thus be an important compensation mechanism for overcoming seemingly insurmountable geographic distance.

In his *social integration theory*, Rosow (1974) argued that loss of social roles in later life requires that individuals develop new age-specific and age-adequate social roles. According to the theory, older people, who live in age-segregated environments, are more likely to identify themselves with their age group and their neighborhood. Consequently, they are more likely to engage in community activities when there is no interference with the interests of the younger generation. Empirical findings are not quite consistent, though. For example, older people living in age-segregated neighborhoods were more satisfied with their living circumstances than those who lived in nonsegregated quarters (Messer, 1967; Sherman, 1975). However, it was

shown that the positive effect of age segregation is mostly related to differences in socio-economic wealth. Vaskovics (1990) reported that in regions with good infrastructure and a high-quality living standard, age concentration in the neighborhood was unrelated to living satisfaction. Despite the lack of empirical evidence, social integration theory has made a significant contribution in linking facets of the social and the physical environment in the aging process.

#### *Recent theories of aging in social contexts*

One of the most prominent theories of social aging and life-span development of social relationships in recent time is the *social convoy model* (Antonucci, 1990; Antonucci and Akiyama, 1995; Antonucci, Langfahl, and Akiyama, 2004). According to this model, an individual's social world is structured hierarchically. The metaphor of a social convoy is viewed as illustrating the life-long dynamic of social ties over the life course. As an individual grows old, his or her relationships and relationship partners change synchronously while he or she moves along the time continuum of his or her life course. At times, relationships drop out of the convoy, while new relationship partners join the social convoy, and some partners, who were lost at times, join the social convoy again. Furthermore, the social convoy is not only moving in time and space, there is also structural change within an individual's convoy. Sometimes individuals feel close to some relationship partners, while other network partners become less important, and vice versa. The composition and functions of social convoys change depending on an individual's age, gender, culture, physical or emotional needs, as well as depending on the specific relationship histories.

There is no doubt that the social convoy has become one of the most powerful metaphors in the field of aging by elegantly capturing many of the complex and dynamic characteristics of the life-long development of social relationships. More importantly, the social convoy model has broadened the perspective on social relationships as being both outcomes of, as well as contexts for, developmental processes (Antonucci *et al.*, 2004; Carstensen and Lang, 1997). The importance of this notion comes into mind when considering specific environments and behavior settings such as nursing homes (Baltes, 1996); quality of living standard or public places in urban cities provide or constrain opportunities for social contact in later life. For example, in a review of research on intergenerational contacts in urban regions, Lang (1998) suggested that there exist distinct age-graded zones for children, families, and older adults in the city that do not have much overlap due to the architecture, laying out, and installation of equipment in most modern urban cities. It is an open question whether social relationships follow the constraints of the physical environment, or whether physical environments reflect the evolution

of an ontogeny of social needs and motivations over the centuries.

In her *socio-emotional selectivity theory*, Laura Carstensen and collaborators (Carstensen *et al.*, 1999; Carstensen and Lang, 1997; Lang and Carstensen, 2002) argued that over the course of life, individuals become increasingly aware that time is a precious resource that is limited. As a consequence, when people perceive time as limited, they are more eager to make the most efficient use of their time by focusing on aspects in their present lives that promise to entail meaningful experiences. According to the theory, such experience is expected to be associated with seeking emotional meaning rather than with seeking new information that will be useful in the more distant future. This central tenet of socio-emotional selectivity theory was empirically shown to operate across different domains of cognitive, emotional, and social aging. For example, in memory tasks, the proportion of recalled emotional materials from all recalled materials was largest among older adults as compared to young adults (Carstensen and Turk-Charles, 1994; Fung and Carstensen, 2003). Adults of different ages, who perceived their time as limited, reported priority of goals related to control of affect and generativity than adults, who perceived no time limitations in their future (Lang and Carstensen, 2002).

Finally, it is important to note that emotional meaning may not only be derived from those partners to whom one feels close but also from the familiarity and security of everyday routines and living circumstances. In this case, even peripheral social contacts with people known for many years or even decades may provide meaningful experience to the older individual (Fingerman, 2004). Going further, it can be asked whether the adaptive processes leading to changes in social motivation are not only depending on perceived time limitations but also on the individual's personal and environmental resources in general. There are great individual differences with respect to what types of social situations provide meaning to an individual. Consequently, some individuals may prefer to focus on indoor activities, whereas others prefer social outdoor activities, again a hint for considering social and physical environmental phenomena in a simultaneous manner.

#### ROLE OF THE PHYSICAL ENVIRONMENT AS PEOPLE AGE

Environmental gerontology or, as it may be labeled, the ecology of aging, typically is identified with the description, explanation, and modification/optimization of the relation between the elderly person and his or her physical environment (Wahl, 2001; Wahl and Gitlin, In press). Furthermore, by drawing from German psychologist Kurt Lewin's (1936) basic insight that behavior has to be seen as a function of the person and his or her environment, American psychologist M. Powell Lawton (1982) has suggested the *ecological equation* as

most essential for the ecology of aging. That is, the consideration of the impact of the interaction between the aging person (P) and the environment (E) on a variety of behavioral outcomes such as well-being and functioning has been added to the isolated consideration of the person and his or her environment (Behavior = P, E, P X E). Environmental gerontology primarily considers the relevance of the full range of physical components of the environment for aging processes, but also acknowledged is the strong, integrated role of the social dimension. For example, the home environment is not only a physical structure, but also a place punctuated by pronounced intimacy with one's partner, social interactions, and the symbolization of attachment, normalcy, and loss (Rubinstein and Parmelee, 1992).

The mission of environmental gerontology within gerontology can be seen in its contributions to the understanding of prototypical environment-related tasks of the aging individual, such as preserving independence in the face of physical and mental impairments by use of environmental resources within and outside the home environment ("aging in place"), initiating processes of relocation if desired or necessary, and adapting to new living environment settings (e.g., a nursing home) after relocation.

#### *Classic theories of aging in physical contexts*

The most widely acknowledged theory to be considered is the *competence-press model* introduced by Lawton and Nahemow (1973). Lawton and Nahemow (1973) have argued that variation in adaptational outcomes in old age are, in comparison to younger age groups (with the notable exception of early childhood), more strongly influenced by environmental conditions (Environmental Docility Hypothesis). Moreover, older adults with lower competence are expected to be particularly prone to what has been coined by Lawton and Nahemow as *environmental press*. In other words, the older an aging organism, the more environmental characteristics are able to contribute to the explanation of adaptational outcomes such as everyday competence or well-being. The competence-press model provides a broad, overarching framework, allowing different types and levels of competence such as sensory loss, physical mobility loss, or cognitive decline and environmental factors including housing standards, neighborhood conditions, or public transport to be considered. Perhaps the most important element of the competence press model is its fundamental assumption that for each aging person there is an optimal combination of (still) available competence and environmental circumstances leading to the relative highest possible behavioral and emotional functioning for that person. The model also suggests that it is at the lower levels of competence that older people become the most susceptible to their environment, such that low competence in conjunction with high "environmental press" is most detrimental for the individual's

autonomy and well-being. A related argument in this concept is that as competence declines in later life, the zone of adaptation narrows such that environmental choices that can promote well-being and autonomy become increasingly constrained.

The competence-environmental press framework as suggested by Lawton and Nahemow (1973) continues to provide the basic mechanism of person-environment relations as people age and has been supported by a considerable body of empirical research. For example, research on the impact of physical distances on social interaction patterns of elders in institutional settings shows that longer distances undermine social relations, thus highlighting the "environmental docility" as people age (Lawton and Simon, 1968). As was also found, based on a large study with elderly Germans from East and West Germany, substandard housing conditions were significantly associated with performance deficits in the so-called activities of daily living, and higher care needs among elders in East Germany could be partly explained by the stronger prevalence of substandard housing (Olbrich and Diegritz, 1995). As has also been found, there is a substantial link between housing quality and well-being (Evans, Kantrowitz, and Eshelman, 2002).

Another family of ecology of aging approaches relevant for the present work's discussion has centered on the concept of *person-environment fit*. Both Kahana's (1982) as well as Carp's (1987; Carp and Carp, 1984) work is closely affiliated with this concept. According to the person-environment-fit model, misfits between an older person's objective competencies or subjective needs and the potential of the environment to support or fulfill these objective or subjective personal characteristics is detrimental to using one's full developmental potential. Inversely, person-environment fit is seen as a necessary, albeit not sufficient, precondition for such development. For example, Wahl, Oswald, and Zimprich (1999) examined the role of fit between remaining competencies of visually impaired elders and the given physical home setting, and found that lower functional ability was significantly related with lower person-environment fit. In addition, mismatches between the needs of nursing home residents and the willingness or capacity of staff to fulfill these needs have been found to be related to their general well-being—the greater the mismatch, the lower was the observed well-being (Kahana, Liang, and Felton, 1980).

In addition to the empirical findings, the competence-press model as well as the person-environment-fit model have become major drivers in the practical world of designing and optimizing environments for older people. A scope of dimensions has been suggested as particularly important to qualify the "right" balance between competence and the environment such as safety, orientation, privacy, accessibility, stimulation, and control (Lawton, 2001).

*Recent theories of aging in physical contexts*

Besides classic ecology of aging approaches, additional and parallel research streams appearing since the 1980s in environmental gerontology subsumable under the headings of *meaning of home* deserve mentioning. Work in the tradition of the subjective aging in place concept emphasizes the simultaneous consideration of ties inside of the aging person to his or her physical and social environment. A typical approach in this line of research is the more qualitative work of Rowles (1983) and of Rubinstein (1989). Rowles' widely acknowledged approach focuses on the many facets of what he has coined *insideness*. According to Rowles, different types of insideness, all speaking to the transition of "spaces into places," can be found as the result of empirical analysis. Whereas social insideness arises from everyday social exchange over long periods of time, physical insideness is characterized by familiarities and routines within given settings such as the home environment. A third element of insideness has been labeled autobiographical insideness; that is, places are carrying a rich collection of memories and thus support the aging individual's sense of place identity. Empirical research also has shown that physical insideness is particularly important for aging individuals with chronically disabling conditions.

Rubinstein's (1989) conception of the meaning of home relies on the assumption that the active management of the environment in itself represents a major source of well-being as people age, especially for those who are frail or living alone. Rubinstein identifies three classes of psychosocial processes that give meaning to the home environment, namely, social-centered (ordering of the home environment based on a person's version of socio-cultural rules for domestic order), person-centered (expression of one's life course in features of the home), and body-centered (the ongoing relationship of the body to the environmental features that surround it) processes. Oswald and Wahl's (2005) analysis sheds further light on these processes by identifying how chronic conditions (in this case, ongoing mobility impairment) affect representations of the home environment. When subjects were asked what "being at home" means, mobility-impaired elders reported significantly more aspects of familiarity and accustomization compared to unimpaired elders.

Adding to this from another point of view, the concept of *place attachment* has been introduced and defined as reflecting feelings about a geographic location and emotional binding of a person to places (Rubinstein and Parmelee, 1992). As has been empirically found, place attachment seems to steadily grow across the life course, reaching its culminating point in very old age (Oswald and Wahl, 2003). This underlines the notion that forced relocation to a nursing home in very old age due to a chronically disabling condition is a critical life event and

a profound challenge for maintaining well-being and a sense of identity.

The role of subjective person-place relations in aging has long been neglected in the practical field due to an overemphasis on objective characteristics such as environmental barriers or physical distances. However, it is now clearly acknowledged that objective and subjective dimensions of person-place relations are interacting in many ways. An example is a situation of objectively diagnosed need for improvement of housing quality according to standards of barrier-free environments, which might not fit well with a decade-long developed personal priority for continuity and stability of the home environment.

#### ON THE INTERTWINED ROLE OF THE SOCIAL AND PHYSICAL ENVIRONMENT AS PEOPLE AGE: AN INTEGRATIVE PERSPECTIVE

##### *Interlinkages between the social and physical environment*

It generally appears that the bodies of knowledge related to the social context and to the physical context of aging have grown widely apart and independent of each other (Wahl and Lang, 2004). And it is indeed tempting to accept and acknowledge the separateness of the social and physical surroundings and their different role in aging. On a surface level, we might view the social environment as one that is apparently alive and actively shaping the aging individual, whereas the physical environment appears to be dead and a no-response context. However, as has been shown already at different locations in the foregoing sections, this would entail a limited and basically wrong understanding of both of these environmental spheres.

The social and the physical worlds are equally dynamic, malleable, and responsive contexts of aging individuals. In fact, the structural similarities between the social and the physical environments as seen from an older person-environment interaction point of view are striking: On the one hand, both the social and the physical environment provide major resources or constraints for the individual's action potentials and quality of life. On the other hand, individuals appear to actively regulate the quality, structure, and function of their social and physical environments, thereby enhancing their social and physical resources. This includes, for example, the choices individuals make with respect to social partners, their living arrangements, and the physical adaptation of their home environments. Furthermore and most important for social and behavioral gerontology perspectives is that the social and physical environment contributes in a closely interwoven manner to what has been coined person-environment-fit processes (Carp, 1987; Kahana, 1982).

To support this line of thought, first it must be acknowledged that social relations are always framed

within physical-spatial conditions (e.g., social contacts within institutions are shaped by physical-spatial dimensions; see Lawton and Simon (1968), Docility Hypothesis). For example, many social relationships such as neighborhood relations or casual ties in everyday life evolve from affordances and opportunities of specific physical environments (Fingerman, 2004; Lang, 1998). Inversely, physical environments are not lifeless entities; they symbolize, for example, most influential social experiences of one's biography. For example, objects in the home environment may serve as powerful reminders of a lost loved one (Oswald and Wahl, 2005; Rubinstein, 1989). Second, the social and the physical environments interact in complex and dynamic ways with respect to the proactive striving of aging individuals toward maintaining adaptation. For example, losing one's care-providing spouse in a remote area can produce severe person-environment misfit. The decision to relocate to an assisted living facility located in a town far away from the former place of living as a consequence of this critical event might lead to a barrier-free physical environment and new developmental opportunities in terms of social interchange with other residents. However, the compensation and optimization associated with this relocation decision may not come without losses such as interruptions of former important social and physical ties to neighbors and landscapes.

To conclude, by ignoring either the social or the physical components in contextual approaches to aging, a one-sided, if not wrong, understanding of the fundamental processes of aging may be the consequence. That is, knowing about the geographical, technical, and physical features together with their social-relational implications, as well as knowing about the social contexts within the opportunities and constraints of the physical world, are both needed to develop an understanding of how aging is associated with contextual processes.

*The Social-Physical Place Over Time model as a driver of integration*

We propose an integrative theoretical framework intended to merge the social with the physical, namely, the model of *Social-Physical Place Over Time* (SPOT; see Wahl and Lang (2004)). The SPOT concept combines three major elements of an aging person's everyday life world: First, a central element of SPOT, namely, Place, underscores the fact that every aging person's day-to-day behavior is embedded within a given physical and spatial surrounding. Place is meaningful for one specific aging individual in a variety of regards such as long-term living at this location, long-term developed place attachments, ties to neighborhoods, the specifics of the physical layout of this location, and its near and farther surroundings in the community (Oswald, and Wahl, 2005). With the concept of Place, we rely on the ideas and work of gerontology scholars such as Rowles and Watkins (2003) or Weisman, Chaudhury, and Diaz Moore (2000), but

also on general assumptions of a more classic environmental psychology (Proshansky, Fabian, and Kaminoff, 1983). It was pointed out in this work that Places necessarily combine both a physical-spatial and a social-cultural dimension. Second, and as a consequence of our first point, we should always think of Places as socially constructed, socially filled-out, and socially shaped physical environments. The term *Social-Physical Place* explicitly emphasizes our focus on the multilevel and multidimensional character of living places of individuals. This is not to say that places are merely social and physical, but we believe that the interplay of social and physical contexts is critical for the understanding of contextual aging processes. Third, the SPOT concept implies a developmental perspective when highlighting that Places are dynamic and show both change and stability "Over Time," as people age. Our central assumption is that negotiating SPOT reveals quite different dynamics across the adult life span, which are highly relevant for the course and outcomes of aging. We will address this in the next section.

Going further, Lang (2004) proposed a goal-resource-congruence model of proactive regulation of social relationships across the life span. According to this model, resource changes determine changes in the individual's social motivation over the life course depending on age-specific opportunity structures. The model contends that an individual's proactive regulation of social relationships consists of two basic motivations: one aims at maximizing a sense of agency in social contexts, and one aims at a sense of belonging in one's social relationships. As people experience resource loss, as is typically the case in the course from middle adulthood to old and very old age, seeking to belong in one's social world (e.g., helping other people, experience positive social contact) is expected to obtain greater priority, whereas individuals prioritize social agency goals such as autonomy or social acceptance when many resources are available. This conceptual model is consistent with recent empirical findings on age differences in social functioning (Lang, 2001; Lang and Carstensen, 2002; Lang, Rieckmann, and Baltes, 2002).

We assume that the goal-resource-congruence model also applies to the regulation of physical environments that entail both meanings of belonging (e.g. familiarity of home environment) and agency (e.g., autonomy, keeping routines, approaching residential decisions). For example, it is a well-known fact that frail older people are often reluctant to leave their community dwellings even when it is difficult for them to manage household chores mostly because their familiar home environment provides a strong sense of meaning and belonging for them. Losing personal resources in later life is a threatening event. Declines in physical health may lead to the heightened importance of experiencing continuity and belongingness in one's immediate environment. These considerations are also consistent with socio-emotional selectivity

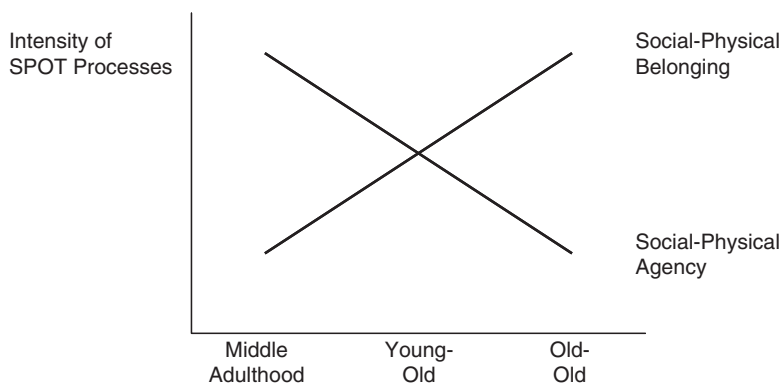

## 74. Psychological Aging: A Contextual View

theory (Carstensen *et al.*, 1999), which posits that as individuals perceive their future time as being limited, they are more likely to seek stimulation of positive emotions (Mather and Carstensen, 2003) and positive memories (Carstensen and Turk-Charles, 1994).

As a consequence, we argue that two fundamental motivations are major forces in SPOT, maximizing *social-physical agency* and maximizing *social-physical belonging*. In addition, we argue that a similar adaptive dynamic, both regarding agency and belonging in the social and physical environmental spheres, is at work from middle adulthood through early “young” age to the oldest old, driven by the co-occurrence of decreasing competence (i.e., a lowered action potential of the individual) and the perception that future time becomes more and more limited. That is, the salience and impact of social-physical agency is expected to decrease, while the salience and impact of social-physical belonging is assumed to increase as people pass from middle adulthood to very old age (see Figure 74.1).

Changes in the dynamism of belonging and agency strivings are related to demands and challenges of age-specific contexts. Although we concur with Neugarten (1974) that much caution is needed in defining middle adulthood, we use the labels of middle adulthood (50–64 years), young old (65–79 years) and old old (above 80 years) in order to exemplify the role of age-related changes on the illustrated SPOT processes of agency or belongingness. The combined dynamism of agency and belonging lies at the heart of understanding of how social-physical contexts influence the construal of person–environment fit across adulthood. We contend that such a perspective provides a theoretically and empirically strong avenue, which substantively adds to viewing aging in context either exclusively in terms of social relations or in terms of physical environment. In particular, considering both the social and the physical environment as simultaneously contributing resources of the aging process adds to a more comprehensive and integrative understanding of the potential of these resources in aging in objective and subjective terms.

A telling example to illustrate these expected person–environment dynamics as people age is provided by relocation research, because relocation probably is the most radical process, in which the physical and frequently major elements of the social environment are changed at the same time. Having lived in a specific place implies an enormous amount of implicit knowledge related to everyday routines, to geographical distances inside and outside the home, to distinguishing neighbors from strangers, to seasonal changes of the sunlight, and to community services. Seeking to enhance one’s sense of belongingness refers to the meaning and memories that individuals associate with their immediate home environment and that creates a sense of place identity. Not surprisingly, therefore, relocation in later adulthood may not be a question of just finding technically more easy-going, age-adequate, comfortable and supportive new living places, but rather it is a question of resolving the nearly impossible puzzle of keeping the meaning, while adjusting the environmental demands (Oswald, Schilling, Wahl, and Gäng, 2002). These challenges probably reveal a quite different dynamic at different stages of later life, most directly addressed in the relocation literature by the suggestion to distinguish between first, second, and third moves (Litwak and Longino, 1987). Though first moves are expected to predominantly appear in the early years after retirement, mainly reflecting a desire to improve social-physical agency (e.g., a more comfortable home, better living conditions, shorter walks, etc.), second moves are expected to appear later in the course of old age and are motivated by the supportive function of the environment in terms of reducing risks or ensuring against potential needs. Relocating to be closer to one’s children is a typical example. In terms of SPOT, the dynamics behind these moves are echoed in a tentative balance between social-physical agency and belongingness needs. Finally, third moves predominantly target the supportive function of the environment and are best exemplified by moves to nursing homes or assisted living facilities quite late in life. In this situation, the need of social-physical belongingness, even though frequently

**Figure 74.1** Expected trajectories of intensity of agency and belonging in the Social-Physical Places Over Time Model (SPOT).

major competence losses have occurred and future time has become quite limited, is particularly challenged, and finding a new person–environment–fit pattern in order to keep the meaning frequently is a very difficult enterprise.

*Additional considerations in terms of person–environment fit*

As we argued in detail elsewhere (Wahl and Lang, 2004), a focus on person–environment dynamics in aging necessarily leads to the question of whether there is a fit (or misfit) between the older person and his or her environment. Generally speaking, agency and belonging are predominantly representing adaptational processes on the level of person–environment dynamics, whereas person–environment fit is seen predominantly as the outcome of such processes. It deserves noting that such conceptions should be understood as an attempt to accentuate what is operating in the complex person–environment dynamic as people age rather than an always clear-cut differentiation. Going further, outcomes on the level of person–environment fit are probably drivers of more global outcomes on the person level such as autonomy, well-being, and identity.

Specifically, we propose three interrelated pairs of criteria for the evaluation of the person–environment fit in SPOT processes. First, the criteria of safety and familiarity represent a major dimension of the person–social environment transaction. For example, strong and close relations with children who are not living far from one’s own dwelling may strengthen the safety feelings of an aging person, even if the physical environment is demanding. Another important issue of discussing safety and familiarity with implications for person–environment fit evaluations is what Parmelee and Lawton (1990) have called the security-autonomy dialectics. For example, social partners may enhance feelings of safety, but this might become detrimental in situations, when they have a tendency toward overprotection (Baltes and Wahl, 1992). Similarly, technology in the home environment (Wahl and Mollenkopf, 2003) can provide a major tool to feel more secure, but technology might also run the risk of provoking new dependencies and questioning the full use of still-remaining competencies of an aging individual.

Second, stimulation and activation as criteria of person–environment fit often have been disregarded due to a tendency in the literature to put emphasis predominantly on frail older adults. Physical-spatial arrangements can facilitate or hinder social contacts. Some environments are more prone to encourage or initiate social contact than others. The recreational functions of environments such as park areas or of spatial-related behaviors outside the home such as traveling, meanwhile, are widely recognized as major resources for aging individuals (Wahl, 2001). The interlinkages of stimulation to social contact and relations are obvious.

Social relations serve major stimulative functions for aging adults such as securing ongoing personal interchange and making new interpersonal experiences. Furthermore, physical constellations can stipulate new social contacts; physical-spatial behaviors outside of the home frequently are associated with seeking or caring for social contacts.

Third, continuity and keeping the meaning are also closely affiliated with the physical as well as the social environment. On the one hand, settings such as the home environment and the residential area surrounding one’s home become major “landscapes of memories” (Rowles, 1983; Sebba, 1991) and ecological extensions of the self (Rubinstein, 1989), and thus important material keepers of meaning. As recent research has revealed, older adults experience a whole scope of meanings associated with their home environment (Oswald and Wahl, *In press*). The intensity of this attachment to place becomes most obvious when the aging, and particularly the very old, person is challenged by a new residential decision. On the other hand, it is equally clear that continuity and meaning are also strongly bound to one’s social ties, and it is an important insight of the more recent research on social relations that even very old individuals are proactively able to preserve this social relations quality.

In a final step of integration, we suggest considering, a developmental perspective on criteria of socio-physical person–environment fit in accordance with our assumptions on age-related trajectories of social-physical agency and belonging (see Figure 74.2).

We assume that person–environment fit in terms of stimulation and activation has its relative highest importance in middle adulthood, which is changing toward safety and familiarity as people approach extreme age. Or to put it the other way around: Misfits regarding stimulation and activation will unfold their strongest negative impact on outcomes such as global well-being in middle adulthood and early age, while in extreme age, misfits in the domains of safety and familiarity will provide a major threat to psychological health. The basic human tendency of seeking continuity and keeping the meaning is expected to operate in between the two other fit criteria. However, we also assume that continuity and keeping the meaning become more and more important, while navigating from middle adulthood and young-old age to the stadium of being old-old or oldest-old. This is because one of the major human strivings, namely, the search for meaning, is forced to operate in very high age within the highest constraints of all the human life span.

## Conclusion

According to life-span perspectives, an individual’s context determines the course, direction, and outcomes of development from birth to death. Moreover, life-span

## 74. Psychological Aging: A Contextual View

**Figure 74.2** Expected trajectories of importance of person–environment–fit criteria in the Social-Physical Places Over Time Model (SPOT).

contextualism has contributed importantly to understanding of the specific role that contexts play in the process of aging (Baltes, Reese, and Lipsitt, 1980; Lerner and Kaufman, 1985). One assumption is that psychological aging is mainly driven throughout the life course by the ongoing need to negotiate between new and changing contexts in the light of new and changing person competencies as well as the ever-increasing nearness to the finality of life and death. Social as well as physical-spatial environmental spheres have been identified as major drivers of human development and aging. More recent theories on social relationships such as the social convoy model and socio-emotional selectivity theory have led to a rich set of new and robust and empirical insights on how social relationships contribute to psychological well-being (besides other outcomes) and to proactive shaping of social environments (Antonucci, 2001; Antonucci *et al.*, 2004; Lang, 2001; Lang and Carstensen, 2002; Lansford *et al.*, 2001). Although it appears that the emotional quality of relationships is more relevant to most relevant aging outcomes than structural characteristics of social relationships, the mechanisms underlying the links between relationship quality and outcomes such as well-being, life quality, and health are not yet fully understood. Similarly, the role of physical environments has been addressed by a rich collection of theories and findings, perhaps less controversial than models related to the social environment, but also not without major differences. For example, pointing to the importance of the observable physical environment versus assuming that the predominant issue is the perceived physical environment for human aging has remained an open question (Wahl and Gitlin, In press). Given the extensive treatment of the social as well as the physical environment as major contexts for human aging, the central argument of the chapter was that an intertwined consideration of both of these environmental spheres still is not spelled out well. This is a surprising observation given that links between the social and physical environment are strongly demanded since early psychological theorizing related to the process and outcome of human aging.

In order to address this missing link in the psychological aging literature, we have proposed the Social-Physical Places Over Time (SPOT) concept as a meta-theoretical perspective that addresses both the physical and social environment of aging individuals, as well as makes predictions in terms of the developmental dynamics inherent in person-social-physical-environment relations in the adult life span. There still is a clear need to address such links between the social and physical environment in forthcoming empirical research. For example, one hypothesis to be tested would be that the predicted dynamics of SPOT in terms of a tendency to switch from a sense of social-physical agency toward a sense of social-physical belongingness can actually be observed in aging persons (refer back to Figure 74.1). A related hypothesis would be that the age-related change in importance of different person–environment–fit criteria predicted in SPOT, namely, from stimulation and activation to safety and familiarity in conjunction with an increasing importance of continuity and meaning, is actually observable (refer back to Figure 74.2). Seen on a more general level, the assumed trajectories of agency and belonging on the one hand and person–environment–fit criteria on the other hand also mean that the life period of being young-old is the prime time in later life imposing the need for “changing tracks.” Still, much of middle adulthood is possible; the limits of this action potential also appear more and more clearly at the horizon of what one’s future aging will bring in terms of being old-old. Such historically new developmental dynamics in the adult phase of life putting much transformation pressure on those being young-old is the consequence of the rapid increase in life expectancy and the increase of distant life expectancy in particular (Wahl and Kruse, 2005). In this respect, the SPOT related developmental assumptions in terms of late-life trajectories in the human life course also question to some extent the widely held belief that being young-old is a time of activism and health, without much sorrow.

Additionally, an important prediction deviating from SPOT would be that older adults who focus on belonging,

although there is a need to actively change their social-physical places, may show more rapid declines and may miss important occasions to maintain quality of life. This would be a new psychological variation of the “use it or lose it” case not considered so far in empirical research, which mostly concentrated on cognitive and physical functioning in this regard (Schaie and Willis, 2002). In contrast, frail older adults, who are no longer capable of exerting much socio-physical agency in their environments, but continue to do so, may be at high risk of suffering from the too-many demands, and eventually from depression in the longer run. This would be a new psychological variation of the “lose it after overusing it” case also not considered so far in empirical research.

Obviously, many questions related to person–environment dynamics in general, as well as the SPOT model in particular, have remained unanswered in this chapter. For instance, the role of gender deserves serious consideration, because aging men and women may reveal different dynamics in regulating socio-physical agency and belonging; it could well be that women are able to exert “new” agency in becoming old and very old (e.g., as “minister of the interior,” caring for good relations beneath the generations in family systems; Baltes and Silverberg, 1994), whereas men may become more eager to “let things go” and “practice” variations of belonging instead of agency (e.g., by developing interest in gardening or a hobby exerted in the home area). In addition, cognitive competence impacts heavily on person–environment dynamics, and the question of what the right mix of agency and belonging might be for a person developing dementia still is an intriguing challenge for applied psychological and psychiatric research. In terms of another major transition of our societies, future person–environment dynamics in aging will be driven more strongly by technology such as intelligent houses, the Internet, and virtual realities at large. It remains to be seen how these new contextual forces will shape processes and outcomes of psychological aging in the decades to come.

# Nutrients and Aging

Lawrence J. Whalley

*This chapter provides a brief outline of some research methods now widely used in nutritional gerontology. First, the topic is placed in an historical perspective stressing major influences of the last century on public and professional thinking about nutritional health. These socio-cultural aspects of the discipline are shown to be relevant to contemporary research sampling from populations drawn from heterogeneous nutritional backgrounds. The five main types of study (ecological, cross-sectional, case-control, cohort, and experimental) in nutritional gerontology are specified. Issues in measurement are addressed in terms of the need to establish measures of reliability and validity of intake of specific nutrients, the purpose of energy adjustment, and the advantages of dietary pattern recognition over intake of single nutrients. The use of biomarkers is mentioned in the context of a lack of gold standards—including anthropometrics—of measurement of food consumption. Research methods in gene-nutrient interaction are considered in terms of nutrient regulation of gene transcription, nutrient damage to DNA, nutrient protection of DNA, and interactions between specific nutrients, energy regulation, and aging genes. The chapter concludes with a brief note about the role of nutrients as environmental cues of specific steps in developmental programming (including aging).*

## Introduction

The study of nutrients and aging is based on those same research methods that are the foundation of all nutritional science. These methods are well established in nutritional studies, and their application to aging research is certainly productive. However, many pitfalls are the lot of the unwary newcomer. Not least is that expert knowledge accrued from over a century of nutritional research does not yet inform popular views about the nutritional requirements of old people. This is of increasing importance as the food industry seeks to maximize profits through increased consumption of processed (added value) foods and use of food supplements often marketed for the older consumer. The industry has shown itself very capable of presenting views in favor of consumption of specific food products as scientific facts when the research evidence is often absent or even contradictory.

This chapter aims to provide a brief introduction to those new to nutritional research in the elderly. By way of introduction, it is necessary, however, to summarize briefly the recent history of nutritional research and to comment on research questions that seem most pressing on public perceptions of the value of nutritional studies in the elderly. The aim is to help those who are just starting out to navigate their route around obstacles, avoid time-consuming pointless detours (or even wandering!), and to complete their studies as efficiently and rewardingly as possible. Familiarity is assumed with one or more of the excellent general accounts of research methods. Furthermore, no attempt is made to set out what the best nutritional advice might be concerning consumption of particular foodstuffs in aging and age-related diseases. However, important social changes of the last 150 years may not be widely known. These are major influences on research in nutritional gerontology and are briefly summarized as follows.

## Historical Perspective

In the developed world, nutritional research has its roots in recognition of the role of environmental factors in the origins of disease and the need for measures to improve the health of the public. Early emphasis was placed on the role of governments in public health matters, largely by removing the threats of foul air, poor hygiene in food preparation, and inadequate sanitation. Only much later, for reasons of food safety, did government interest turn to food. By 1900, a consensus had emerged that public health matters were the responsibility of government, whereas doctors were responsible for the health of the individual patient. Recruitment of poorly nourished conscripts into the army during the Great War (1914–1918) became a national concern when it was recognized that many young men were malnourished and that, without remedial steps, the war might be lost. Victory brought its own problems as advocates of the eugenics movement argued that the upper classes would be overwhelmed by the more fecund lower classes, whose gene pool was weakened through loss of the “cream of the generation” in the war. This view was once widely held but soon countered in the United Kingdom (but not Germany) through research that showed the ill

health and short stature of poor people to be caused not by genetics but by the malnourishment of poverty. Nutritional research energized many social reformers who ensured that by 1933, U.K. school children could receive free meals and milk. Cod liver oil was soon added to prevent rickets. The discovery of vitamins by then had made a huge impact in clinical medicine and reinforced the view that public action to improve diet should be aimed at meeting minimal requirements for promoting growth through addition of meat, milk, fruit, and vegetables to a poor diet.

These issues were at the fore in the United Kingdom during the Second World War (1939–1945) when fear of “starvation into submission” was high: over 50% of U.K. food came from the United States and Canada at a time when German submarines sank huge numbers of Allied ships. This threat produced a food strategy informed by nutritional research. For the first time in U.K. history, a generation of children were able to consume a diet sufficient not only in energy but in necessary proteins and vitamins. These policies met with international acclaim after the war when it was recognized that scientific advice had produced an effective system of rationing, governments had devised efficient distribution and pricing policies, and nutritional education was well directed. Thereafter, the same policies shaped U.S. food aid to a devastated Europe only to be slowly replaced, as Europe recovered, by policies of self-reliance and commercial investment in the industrialization of food supply. These successful policies have produced the enormous food surpluses of today. Sadly, these policies have also destabilized food supply in underdeveloped countries and caused massive, and not necessarily healthy, changes in Western dietary habits. Monocultural farming systems have reduced the cost of raising cattle, pigs, and chickens so much that the usual diets in Western Europe and urban United States now comprise a great deal of what was once regarded as luxury food. These changes are now being extended as former Eastern bloc countries reflect their growing affluence and perception that freedom of choice should include choice of food as well as democracy.

In post-war Europe, the notion became widespread that the days of malnutrition were over and that the role of governments should be to regulate food safety rather than its nutrient value which, it was felt, could be confidently assumed and, anyway, was a matter of personal choice in a free society. The nutritional content of foodstuffs was inspected from the standpoint of minimum content to protect the consumer against the adulteration of foods but not to ensure nutrient value. The present situation is now hugely complex, with many more new food products widely available through the growth of supermarkets to replace traditional distribution systems of local foods. Returns on these massive investments can be assured only by adding advertising and other overhead to the costs of food.

In these circumstances, it is unsurprising that processed foods now comprise over 70% of the modern Western diet: more potatoes are eaten in processed form than in their freshly cooked state. Likewise, sugar is added widely to foods, as is salt, to enhance taste, so much so that most of the salt consumed in the Western diet is now derived from processed foods over which the consumer has no control. Many commentators are aware of the health risks associated with modern energy-dense but nutrient-poor diets and advocate change. Too often, these remedies repeat the lessons of nutritional education that had been so effective in the early part of the last century but are no longer appropriate. Modern consumers are encouraged to believe that their diets are deficient in specific ways much as those earlier diets were deficient in energy, protein, or vitamins. Addition of missing ingredients to modern diets is the most often proposed remedy when there is a much better case to adopt radical changes in eating patterns. Healthy eating provides less energy, less sugar and salt, and more fruit and vegetables. Nutritional gerontology is thus faced with a complex set of problems. Probably to a greater extent than at any other point in human history, there is greater diversity in diet within and between populations. In some older individuals, dietary preferences established in youth can persist into late life: meals are prepared following traditional routines. In others, greater reliance on prepared foods has been acquired, sometimes with regular supplementation with specific foods, complementary or alternative medicines. Younger individuals, in contrast, may have insufficient interest (and often little time) to prepare foods and rely heavily on convenience foods.

Research designs in nutritional gerontology are influenced by these historical considerations. At the simplest level, sampling subjects for studies in nutritional gerontology takes account of the problem that between birth cohorts (say, 1915–1919 and 1935–1939) there are often very large differences in early life dietary histories. These may be sufficient to account for differences that might otherwise be attributed to aging. At a more complex level (set out later in the final sections on gene–nutrient programming of developmental plasticity), there is good evidence that maternal/fetal exposures to different nutritional environments can modify the risk of late-onset diseases. Inclusion of historical dietary data in studies of this type requires some knowledge of prevailing dietary exposures during relevant epochs. Carpenter (2003a, b, c, d) has provided an excellent overview of the history of nutritional science.

## Nutritional Gerontology

At the outset, it is useful to state the broad objectives of studies in nutritional gerontology:

1. To describe the contribution of nutrition to individual differences in aging processes, variation

of incidence of age-related diseases, and the acquisition of age-related disabilities.

2. To elucidate the specific contributions of nutrients to age-dependent mechanisms underlying age-related diseases.
3. To inform the provision of services, to improve advice for old people, and where possible, to use the results of nutrient-based research to prevent, control, and treat age-related disease.

In clinical nutrition, the older patient represents an important challenge. Often, the contribution of poor nutrition can be overlooked; clinical outcomes become suboptimal, and dietary factors in common age-related diseases are acknowledged, though hardly ever acted upon. To summarize, older persons have the same nutritional requirements as younger subjects but their energy needs are less. Absorption of foods is altered by changes in the gastric mucosa and intestines. To accommodate this, older people should eat less but seek to maintain intakes of essential micronutrients by eating nutrient-dense foods that are low in fat (like lean meat and fish) and include eggs, low-fat milk, vegetables, and fruit in a varied and balanced diet. Together, these provide the protein, vitamins, and minerals needed but with fewer calories. Some old people take food supplements, believing these can do no harm. Generally, when supplements do not exceed the recommended daily allowance, this is the case. Supraphysiologic doses of food supplements should be avoided, however, as should the assumption that a poor diet can be made good by consumption of supplements. The greatest hazard of food supplement use arises when this use is preferred to clinical investigation of current clinical symptoms. Self-treatment with food supplements of nonnutritional disease poses a very real danger to the health of old people.

The research base to inform advice on intake of nutrients in old age is now substantial and continues its gradual development so that dietary advice often needs to be updated. The principles that guide new research are major determinants of the quality of this advice. Nutritional studies are influenced by the complexity of the nutritional environment in which individuals seek to optimize their quality of life, minimize disease risks, and make best use of that part of their income available for food. These complexities are multilayered and involve community factors that affect the food supply for old people, its quality and balance; interpersonal issues that relate eating to a communal activity that is modified by the exclusion or marginalization of old people in some contemporary societies; impairments of food preparation linked to sensory loss, motor disabilities, and poor health; the impact on appetite of intercurrent illnesses or loss in old age of a long-term partner; individual preferences for specific types of food; and individual patterns in the absorption and metabolism of foodstuffs.

## Research Questions in Nutritional Gerontology

It is in this many-sided setting that research questions on nutrients and aging must first be formulated. Research methods that are not informed by these issues can become pointless exercises in data gathering of little use across the information spectrum that extends from those who must devise public health policies on nutrition in aging to those seeking to interpret the results of laboratory investigations of old people. For example, in the study of cancer (often an age-related disease) there are at least four major constraints on nutritional epidemiological methods (Riboli *et al.*, 2002). These constraints are relevant to a wide range of studies in nutritional gerontology:

1. Measurements of diet lack precision and specificity, particularly for estimates of food consumption.
2. Nutrient intakes are highly correlated, and attribution of causation to one nutrient acting on its own may be misleading.
3. Biological measures of nutrients in tissues may not accurately and reliably reflect dietary intake because the biological regulation of these measures is complex and may be influenced by levels of other nutrients.
4. Most studies undertaken to date have not considered the effects of the physical characteristics of food (an orange as a whole fruit or as a juice, the way the food is prepared, water content, and so on) on the metabolic activity of the constituents of food.

Studies on nutrients and aging, therefore, require prudently framed research questions, thoughtful research designs, careful planning, execution, and interpretation. Although not inherently intellectually challenging, these issues are often so intricate that the best studies are completed within strong collaborations. The nature and scope of these collaborations will influence the type of research questions posed, the measures available to address these questions, the choice of statistical methods, and their interpretation (Ryan, 2003). Obviously, a clear statement of hypotheses is a necessary first step, but often this will be modified in collaboration with others who are perhaps more familiar with issues concerning choice of measures and advise a specific approach to measurement and to issues of validity and reliability. In this preliminary setting, a research group, often in a spirit of flexibility and compromise, will agree on the research model to be tested. Will this be an ecological, observational, or an experimental study? How well controlled will be the variables of most interest? What are the characteristics of the population to be studied? Within a nutritional context, are there specific factors that seem likely to confound interpretation of results? These questions require forward planning chiefly in the

design of studies in nutritional gerontology. The following sections consider aging research problems in nutritional studies that arise in sampling (including the problem of refusals), variable measurement, fieldwork, statistical analyses, and interpretation. Because this author's principal interest is in cognitive aspects of the associations between nutrients and aging, certain cognitive issues will be alluded to (Kohlmeier *et al.*, 1993). Animal studies are not considered in this chapter, though much of great relevance to human aging has been learned from carefully conducted studies. The topic of animal studies on nutrients and aging is simply too extensive to be dealt with even in summary form in this section. This issue is especially relevant to current studies of the possible benefits that might accrue for general health and longevity through the practice of caloric restriction. Whereas the database from human ecological and animal studies to support the adoption of low caloric eating patterns seems adequate, data from other types of well-designed human studies remain sparse. This topic is addressed in Chapter 31.

### Sampling in Aging Research

As an example, take a seemingly simple research question. Suppose a researcher aims to detect the contribution of aging and diet to body mass index (BMI). One approach might be to measure height and weight in a sample of subjects believed to be representative of the general population at different ages, and then to test the association between age and BMI and report the result, seeking to explain the proposed association using age differences in dietary data. These three measures (age, diet, and BMI) are open to confounding by quite distinct processes. First, as set out earlier, the structure of a general population (from which the sample is drawn) is made up of cohorts, each from successive birth epochs, each exposed over time to changes in food quality and availability. Younger subjects may have preferences for, and easy access to, energy-dense foods, rich in saturated fats but nutrient-poor, being depleted in fruit or vegetable vitamins and fiber. The older cohorts may have had quite different dietary experiences, never as young people eating to excess but sometimes undergoing extreme dietary privations. During the twentieth century, these experiences were not uncommon, even during the U.S. Depression or wartime Europe. These types of nutritional deprivation impact variously on aging samples collected cross-sectionally. To this can be added the effects of illnesses and death on sample content, so that—because of censoring by premature death—samples are often under-representative of subjects in whom the associations of interest may be strongest. This is above all true of the relationship between low socioeconomic status and recruitment and retention in studies of nutrition and health (see later).

Cross-cohort comparisons are also susceptible to the influences of factors that produce changes in nutritional behaviors in late adulthood and old age. These susceptibilities may vary by education, by strong continuities in eating habits in one generation that are not detected in another, and, most importantly, by the effects of health or disability status within an aging sample. For instance, there were major changes in the acquisition of physical and possibly mental disabilities in old age in the last quarter of the twentieth century (Vita *et al.*, 1998). Chronic disability prevalence declined in the U.S. population aged over 65 years from 1982 to 1989, and this trend accelerated through 1999 (Manton and Gu, 2001; Fries, 2002, 2003). It is unreasonable, therefore, to assume that within a sample of old people, cohorts drawn from different birth epochs, subjects will exhibit the same illness profiles. These differences between samples may reflect major changes in lifestyle that include differences in eating behavior. The example of reductions in incidence of coronary heart disease in men (1955–1995) is the most repeatedly cited example (Rosamund *et al.*, 1998), to which can be added differences between age-cohorts of women in their use of estrogen replacement therapy (1970–1995) and the growth of sales of prepared, convenience foods (often sugar/salt-rich) aimed at older consumers living alone. Competent accounts of research strategies that aim to reduce the prevalence of chronic disabilities are available (Prentice *et al.*, 2004).

To overcome these sampling problems in cross-cohort comparisons between different age groups and within old age, greater investments are required. First, follow up studies are possible, often of individuals ascertained at some earlier point in the life cycle when nutritional data of variable quality may have been acquired. Second, a longitudinal study may be planned with considerable implications for the resources and commitments of participants and researchers alike. The first example is often opportunistic; the researchers, hearing of a dataset captured for a purpose unrelated to aging—say maternal health in pregnancy—next locate surviving participants and begin energetically to recruit the compliant among them to an aging study. Not until data are analyzed do the researchers begin critically to examine the validity and reliability of the original nutritional data collected perhaps 40 or more years ago. Nutritional measurement instruments have undergone steady improvement, and it is often unsafe to assume that datasets will be as informative as initially assumed. The best advice is to examine contemporary criteria now used to assess scientific reports submitted to current academic journals in the field of nutrition. Then ask the same questions of the historical dataset. How does it compare? Based on the historical record, is the original study reproducible? Are the descriptions of the population sampled available and satisfactory in quite simple terms: demographic, anthropometric, and (if relevant) cognitive parameters? Do the subject identifiers allow exact matching with

possible survivors? Will they agree to take part; does their initial participation support the assumption that they agree to be contacted at this later date? If these cannot be satisfactorily established in the first stage of data examination, it is best to treat the dataset—even the most appealing—with circumspection.

### **Role of Institutional Review Boards and Ethics of Research Committees**

Comparable ethical issues arise with prospective longitudinal studies, except that the researcher is required to anticipate the demands at reassessment as if subjects were to be approached for the first time. Here, the importance of advance permissions to track subjects as they migrate geographically and socially cannot be overstated. In this context, it is useful to anticipate difficulties, retaining in longitudinal studies those who may be or become most disadvantaged or whose health may fail. Discussions with experienced ethicists are often helpful. Sometimes guidance can improve the research design and compliance because the changes in research procedures sought to obtain ethical approval are so often well focused. In aging research, when community-dwelling populations are to be sampled, there is a particular problem with refusals, and this will raise specific ethical issues. First, on recruitment there is a bias toward under-representation of the disadvantaged in society. Individuals unable or unwilling to take part for reasons of mental illness or impairment are a major cause for concern as these may be those same individuals for whom the research findings may be most relevant. Individuals who are aware of the health risks posed by their lifestyle are also less likely to volunteer to take part and, when they do, may fail to return for follow-up assessments. Solutions to these problems are imperfect, and most researchers seek to identify the source and size of the errors accrued. Good research practice goes a long way to overcoming subject resistance. So, if a personal approach is taken with each volunteer and, for a group that is anticipated to have problems with research, extra steps are introduced. These are often labor-intensive and demand continuing personal contact with a named person, familiar with the reservations expressed by the volunteer and careful to explain all procedures.

The approach taken to resolve these issues can be coercive or rely on inducements. Ethicists may vary in where a boundary can be set between encouragement to participate and a subject being disadvantaged in some way if they refuse or withdraw consent. Among subjects who find great difficulty responding helpfully to requests from professional people, there are sometimes those who can see why, as individuals, they should take part. Where appropriate, these individuals can be encouraged to seek the involvement of their peers. The success of this snow balling approach is tempered by the need

to explain—sometimes repeatedly—the purpose of the research, its possible benefits to the wider public, and the nature and inconvenience their taking part might lead to.

Noncompliance causes huge heartaches and headaches. Carefully judged continuity of personal contacts between the volunteer subject and single named research worker can achieve high levels of compliance, but often this is detected only upon study completion. Some measures of reliability and validity need to be part of the study design. In self-reports of food intake, for example, at least three elements of reliability are built into the measurement instruments. These are basically estimates of consistency: Does the subject respond in the same direction when the same or similar question is posed? From test occasion to occasion, is the same question answered in the same way? Is there evidence of inconsistency attributable to some confounder (e.g., poor memory)? Validity is much more problematical and is addressed in a later section.

### **Types of Study**

Sampling procedures offer five types of study: ecological, cross-sectional, case-control, cohort, and experimental.

#### **ECOLOGICAL STUDIES**

Ecological studies are most often based on existing data and rely on units of measurement that are groups of subjects rather than individuals. An example would be a study of the incidence rates of a disease where nutritional deficiencies are thought to be causally important in countries that vary in exposure to that nutritional deficiency. Grouping can be on the basis of any characteristic (e.g., geography, year of birth, etc.) but is usually socio-demographic. Migrant studies fall into this category (Marmot, 1989) but are more informative when conducted as case-control studies. Ecological studies are a useful starting point in preliminary analyses of research questions, often generating many testable hypotheses (Armstrong and Doll, 1975). Power calculations for ecological studies determine the number of groups required in each arm of the comparison, not the number of subjects.

#### **CROSS-SECTIONAL STUDIES**

Cross-sectional studies examine variables at a single point in time. Without the possibility of establishing temporal precedence, typically cross-sectional studies cannot establish causality. Three sorts of analysis are available here: (1) tests of the strength of association between variables; (2) significance of differences between groups in the quantity of a variable; and (3) difference in the rate of occurrence of an event (commonly an outcome of interest). In nutritional gerontology, it is important not only to estimate the number of subjects required to test the study hypothesis, but also to decide

upon the optimum type of dietary assessment. Within an individual old person there may be considerable variation over time, possibly reflecting the vagaries of social opportunities to share a meal. Longer periods of dietary intake may be required to take account of this yet; in some old people this is prone to faulty recall. To allow for this, it is usual to rely on old people for relatively brief periods of recall and to compensate for this by increasing the size of the sample. It is, however, not an easy task to decide on the best combination of observation period and sample size. The choice is influenced by the purpose served by the data. If it is necessary to relate dietary intake of each individual to some other characteristic of the same individual, then the most accurate measures of dietary intake are required (usually, seven days or more of weighed intake less food waste). However, this labor-intensive method is not required if it is more important to identify subjects at the extremes of a food-intake distribution or to make comparisons between mean values of each group. There are many comprehensive accounts of cross-sectional study designs that are well summarized by Cade (1997).

#### CASE-CONTROL STUDIES

Case-control studies are an efficient way to examine possible causal mechanisms, and the background, conduct, and interpretation of these study designs is well summarized (Schesselmann, 1982). In nutritional gerontology, it would be usual first to specify criteria for the presence/absence of a condition and then to identify a group with a condition (cases) and a group without that condition (control subjects). The prior exposures of the cases and controls to a putative causal agent or process could then be compared. There is wide discussion on the need to match cases and controls, and when this is done, how exactly matching should take place. It will seem obvious that the best solution is to match cases and controls as closely as possible. However, this sometimes can remove important differences between groups in particular where exposure and matching variables are linked (positively or negatively), as is the case within a wide range of socio-demographic variables. Concerns about measurement errors ensure that case-control studies are not the design of choice in nutritional gerontology. This is largely because it is necessary in nutritional research to obtain estimates of measurement error while evaluating the diet-disease relationship. This is difficult to achieve in case-control studies that rely on historical data. Instead, it is better to undertake a prospective longitudinal study with repeated measurements of diet and even better to employ several methods to measure diet. The cohort study design can meet these requirements.

#### COHORT STUDIES

Cohort studies differ from case-control studies in that the cohort moves forward in step, whereas the case-control study is a retrospective, historical analysis of

prevalent cases. Longitudinal study designs sometimes seek to detect and then adjust for contributions to measurement error made by previous exposure to the same measurement. This arises in many settings but is most problematic when mental performance is measured. It may surprise the investigator that even after intervals, each of several years, some old people—mainly the better educated—maintain consistent improvements, whereas the less able or educated may underperform on first testing, improve on the first re-testing, and thereafter show expected age-related decline. These problems may be detected in study designs where several consecutive cohorts (say, now aged 60–64; 65–69; 70–74 years, etc.) are recruited, and at each reassessment these cohorts are added to by subjects of the same age but who did not take part in the earlier assessment (Schaie, 1994). Obviously, these sampling processes are demanding of time and effort and should be envisaged only when the research questions demand it; most often simple methods can provide useful results commensurate with many issues involved. A key advantage of cohort studies is that these provide estimates of relative risk, whereas cross-sectional studies permit calculation of the odds ratio. In practice, the odds ratio provides an acceptable estimate of relative risk. There are many good accounts of cohort study design in nutritional epidemiology (e.g., Willett and Colditz, 1998; Day *et al.*, 1999), and methods to combine data from several studies are also available (Mannisto *et al.*, 2004).

#### EXPERIMENTAL STUDIES

Experimental studies rely on the detection of the effects on an intervention. The design is a special application of the case-control study where the exposure is planned and the design prospective. The assumption is that random allocation of subjects to the active intervention or the placebo arms of a study will provide a balanced design, with potential confounders arising by chance with about equal frequency in the study arms. An experimental study is the preferred means of hypothesis testing in most laboratory settings, and relevant methods are subject to continuing improvements (Murray *et al.*, 2004). In human nutrition, the experimental study is most often a randomized, placebo-controlled trial of the possible benefits of dietary manipulation or supplementation. There are numerous good accounts of experimental designs suitable for testing intervention hypotheses in old people; most frequent concerns arise over sample size and statistical power in studies with old people. Latterly, there are many informative commentaries on the quality and generalizability of clinical trial data (e.g., Khaw *et al.*, 2004) that address the recurring problem of the failure of apparent benefits observed in a clinical trial to translate into clinical practice. In nutritional gerontology there are several age-specific problems, not least that dropout rates may be much higher than in younger

samples, and sample size calculations need to be set conservatively (Lazovitch *et al.*, 2002).

### Variable Measurement

The correct estimation of the relationships between exposure and the presence of a condition (usually a disease) relies upon the probability distribution of measurement errors and the distribution of exposures and confounders in the whole population from which the sample is drawn. These requirements pose several problems in nutritional gerontology. Their resolution should entail good quality validation studies, at least in subsamples of the population of old people. However, as is set out later, there is no gold-standard measurement of nutritional intake, and the best that can be attained is the inclusion of several different measures of dietary intake that are used on several occasions. These would then give an estimate of the error incurred with the study instrument. However, caution is required even before using this when the study period greatly exceeds the time interval between first and last measure of reliability.

### Food Consumption by Old People

This is used to estimate the adequacy of dietary intake by old people, to relate dietary habits to nutritional status and then to health parameters, and to detect change in dietary habit following intervention (e.g., a nutritional education program). The nutritional literature is replete with studies of this type undertaken to meet a wide range of needs, from simple description of trends over time (e.g., Volkert *et al.*, 2004) to the need to detect specific subgroups of old people at most risk for poor nutrition (e.g., Sharkey *et al.*, 2002). The bare bones of this approach is to record what subjects recall they have eaten during a recent period (over the previous day, week, or some such), and then to convert this to intake of nutrients (Wahlqvist, 2002). This is done by either conducting laboratory analysis of samples of the food taken or by looking at food composition tables and estimating nutrient intake from these. Obviously, studies that analyze foods directly are thought more accurate than recall methods in old people where food intake is to be related to nutrient status. Food tables should not be accepted uncritically: the values they contain represent the average for what is often a small number of samples and are prone to error, for example, when mixed dishes are reported or when water content varies substantially. The consensus view is that food tables are acceptable for observational studies for the purpose of classification of subjects or providing group mean values. They are less useful in intervention studies. A critique of methodologies is presented by Maggi *et al.* (1993).

### WEIGHED RECORDS

To obtain a weighed record, laboratory methods are quite well established. It is feasible sometimes to obtain a duplicate portion of the food consumed by the subject and, after adjustment for waste, analyze that or an aliquot drawn from it (Bingham *et al.*, 1995). When using food composition tables, several alternates are available. In a direct observation study, the portions would be weighed precisely, waste subtracted from this, and the composition estimated by reference to food composition tables. If reliance was placed on dietary interview data, subjects would recall their food intake and thus provide a recent dietary history, which (as earlier) could be converted into typical intakes of nutrients using food composition tables. Comparable, sometimes supplementary, methods involve the subject keeping a food diary. Some care is required when using food composition tables, however, since these may vary from country to country and from time to time within one country. For these reasons, it remains necessary to include food analyses in many studies. These methods are expensive, and for reasons of feasibility and economy, most individual surveys rely on either prospective or retrospective methods of dietary assessment (Longnecker *et al.*, 1995). Retrospective surveys rely on memory, the ability to conceptualize what is required, accuracy of estimation of portion sizes, and are open to bias toward reporting a healthier pattern of eating than is in fact the case. Nevertheless, compliance is usually high among old people with surveys (often postal) of this type, and the results are quite reproducible among those with regular eating habits. Food Frequency Questionnaires (FFQ) or Food Frequency and Amount Questionnaires (FAQ) are the most often used of all methods of dietary assessment. Importantly, so far, no FFQ or FAQ has been designed specifically for use with old people. Typically, a FFQ is designed to test a specific hypothesis concerning intake of a specific nutrient or group of nutrients often taking the number of respondents into account. Some sensory impairments that are common in old people will confound eating behaviors. These include visual and olfactory losses (Griep *et al.*, 1996). An account of common methodological and interpretative errors is provided by Beaton *et al.* (1997). Comparisons between Food Frequency Questionnaires and diet records are also available (Margetts *et al.*, 1989; Bingham *et al.*, 1994, 1997).

### ENERGY ADJUSTMENT

The method used to express the nutrient content of diet merits some consideration (Willett *et al.*, 1997). The general principle is that the expression of content should make nutritional sense and should take account of influences on bioavailability and loss of nutrients in food preparation. Energy adjustment is perhaps the most frequently used method. The greater the consumption

of all foods, so consumption of specific nutrients is also likely to be greater. Bigger, more active subjects will eat more than the sedentary. Improvements in comparisons between subjects and between studies can be achieved through energy adjustment. This is particularly useful when individuals seek to minimize their intake at the level of macronutrients (as with some obese individuals). Differences between under-reporters and those who make valid returns are much reduced after energy adjustment. Energy adjustment is unhelpful when there is no relationship between energy consumption and the relevant nutrient.

#### VALIDATION STUDIES IN OLD PEOPLE

The newcomer to nutritional gerontology might feel overwhelmed by the prospect of obtaining valid and reliable measures of dietary intake. There appears to be a huge potential for confounding by impaired cognition, sensory loss, appetite changes, acquired poverty, impaired mobility, access to fresh food, and failure to complete cooking (Jorissen and Riedel, 2002). As individuals mature and establish personal independence, each is expected to take more responsibility for their own basic needs, such as warmth, shelter, food, and companionship. With aging, many require support to maintain this independence, and the reasons for this are extraordinarily varied. Take, for example, a woman living alone who rarely leaves the house and for whom food shopping has become hugely effortful. Her circumstances may have arisen because she has suffered sensory loss (above all, of sight or hearing), or she has problems with mobility and fears falling, or her bladder control is unsure and she is anxious about incontinence. To these can be added a plethora of mental symptoms and impairments that confound any attempts to anticipate all sources of error in measurement of eating habits and nutritional status in old people. To accommodate these adaptations to old age, over-reliance on preserved or dry foodstuffs may develop with understandable lack of variety and later, little interest in consuming unappetizing food.

There is, therefore, a particular need in studies of old people to establish the validity of food intake estimates at the individual or group level. The first step in a validation study is to set the key reference measures. From the outset it is important to accept that biomarkers of nutrient intake derived from concentrations of nutrients in blood or other tissues do not provide an absolute measure of intake. Clearly, these will be related in some way to intake, but it will not be a simple direct relationship. Other factors—absorption, metabolism, binding, excretion—will influence the measure, which in turn may not reflect the availability of the nutrient in the tissue of interest (e.g., a blood test as a guide to intra-neuronal concentration). When designing studies, the commitment to validation should not be treated lightly.

#### Biomarkers of Healthy Eating

Biomarkers are used to assess nutritional intakes and nutritional status because they are believed to provide more accurate estimates of intake/bioavailability of specific nutrients, especially where these are combined (as in most meals) or cooked to variable extent. There are also concerns about the validity of food composition tables when foods are known to vary over time (as with industrialized food processing) or cultivated in different soils or climatic conditions.

Although some researchers think of biomarkers as potential gold standards of dietary intake, there are good reasons to accept such a view only with thoughtful reservations (Weinstein *et al.*, 2004). Subjects are well known to vary in metabolic pathways for reasons of sex, genetics, and previous nutrient exposures (Arab *et al.*, 2003). These differences include age-related variations in absorption, the impact of coingestion of foods that may inhibit the absorption of others (e.g., green vegetables contain oxalic acid, which impairs the absorption of calcium). Likewise, renal excretion is subject to tight controls designed to remove unwanted metabolic products and excess nutrients but to retain needed nutrients. Urinary analyses, for these reasons, can be misleading as they indicate the net outcome of these diverse processes (including saturation) and are not directly correlated with intakes.

Biomarkers may be measured in a wide range of tissues that include plasma, serum, red blood cells, white blood cells, feces, urine, hair, nail, buccal cells, and a number of measures specifically designed to assess overall antioxidant capacity (Polidori *et al.*, 2001), metabolic state (e.g., exhaled air), or the extent of DNA damage (Potischman, 2003a, 2003b). Some tissues seem especially relevant to aging studies (e.g., lipid content of red blood cell membranes; Hulbert *et al.*, 2004), but it is best to plan to collect diverse types of samples before drawing any general conclusions. This is true in most biomarker studies; whenever possible, ensure that the chosen marker is examined or tested in at least two biological systems (Ilich *et al.*, 2003). Before deciding upon any biomarker, it is always useful to discuss the choice with the laboratory where the tests will be conducted. This advice often includes appraisal of recent analytical developments, the competing interests of high reliability/validity of a specific measure when set against convenience and compliance. There are also helpful critiques of specific biomarkers, the principles of which can easily be applied to another biomarker (e.g., Ness *et al.*, 1999). It is also essential to discuss all aspects of sampling, separation, labeling, storage, and how laboratory data are to be linked to the research database. Decisions on these and related matters should be recorded and circulated as a clear written statement of protocol.

Body composition studies in old people provide useful measures that discriminate between health and disease

states (Fuller *et al.*, 1996). This is a highly specialized research technique, requiring great care in its application and interpretation. Available methods include bioelectric impedance studies (Baumgartner, 2000; Aghdassi *et al.*, 2001).

In nutritional gerontology, the issue of differences in cognitive ability in the assessment of dietary history/nutritional status is rarely investigated. Studies are needed that investigate the advantages of biomarkers over retrospective recall in the presence/absence of cognitive impairment (Morris *et al.*, 2002). Likewise, in the investigation of the role of nutrients in aging and age-related diseases, it is useful to place firmly among the aims of a project the needs of clinicians who might make use of the findings. For example, in clinical practice, it is commonplace to identify the concentration of vitamin B12/folate as being suboptimal and predictive of disease. It is uncommon for these values to be considered in the context of a relevant metabolite such as homocysteine, largely because uncertainties remain about the value of such measures and their availability. Nevertheless, these matters do interest clinicians, and the value of measuring a number of parameters linked to a pathophysiologic process is appealing and worth bearing in mind when choosing what might be measured.

Resources available include a series of papers published in 2003 as a supplement to *The Journal of Nutrition* ("Biomarkers of Nutritional Exposures and Nutritional Status").

### Dietary Patterns

People eat mixes of foods, not isolated nutrients. Within individuals there are strong correlations between the consumption of individual nutrients so that it is often very difficult to separate the contribution to health or disease of one nutrient from a group of nutrients. Therefore, interest has grown in the identification of patterns of food consumption and the extent to which particular patterns can be linked to health outcomes (dietary pattern analysis). This interest represents an understandable expansion of awareness of the importance of particular food combinations and the role of nutrient-nutrient interactions (Hu *et al.*, 1999; Millen *et al.*, 2004). In large part, the interest is based on ecological comparisons between communities who differ in risk of specific diseases that can be plausibly linked to dietary habits. Where the aim is to understand an overall picture of the relationships between diet and disease, dietary patterns may be more informative than study of single nutrients in isolation (Balder *et al.*, 2003).

The main techniques used to determine eating patterns are (a) principal components factor analysis, (b) cluster analysis, and (c) dietary indices (Newby *et al.*, 2004a, b). The first two methods are useful in the reduction or grouping of data, whereas the third is valuable in the prospective study of dietary contributions to disease

prevention. In factor analysis, dietary data are obtained by recall methods, and foods are sorted into major nutrient groups. These nutrient groups are then factor-analyzed using principal component methods (with or without rotation). The major factors produced are inspected for content validity and named accordingly, such that a factor that comprises high energy intake, saturated fats, and alcohol might be labeled high risk, where another factor comprising low energy, fruit and vegetables, unprocessed oily fish, and so on might be labeled prudent (Montonen *et al.*, 2005). These factors are consistently derived in samples from diverse Western populations and have proven to be useful in understanding the contributions of diet rather than specific nutrients to risks of disease.

### Anthropometrics

Historically, understanding the associations between nutrients and development (of which aging processes comprise a major component) has been based on recognition that anthropometric measures are useful proxies of health status that vary from detection of the impact on health of the public attributable to improved feeding (as in the growth of infants) to selection of military recruits and to the progress of chronic disease. For most populations, detailed reference data are available, and these can be used for purposes as diverse as demonstration that a study sample is typical of the population from which it was drawn to surveillance of the general nutritional status of large populations (e.g., Hughes *et al.*, 2004). However, caution is advised when applying such simple methods to underdeveloped countries where there may be many malnourished subjects, frequent recurrent disease (e.g., malaria), and other stressors. Exposure to these confounders may vary within a country from place to place and over time.

At first glance, anthropometric data appear robust and simple to use. Certainly, most reports in nutritional gerontology do not provide detailed methods for anthropometric data collection, yet caveats abound. First, it is important to include anthropometric data in descriptions of samples. Second, in old people, great care must be exercised to ensure that these data are reproducible, so some training will always be required to achieve this. It is also useful in old people, in addition to height, to record the demispan between outstretched fingers and the midpoint of the sternum. This measure agrees closely with maximum height achieved and can be used to allow for shrinkage in stature with age in old people. As in much nutrition research, many measures are not normally distributed, and transformations to approximate normality should be made by systematically reviewing which of the following yields the best result (by increasing adjustment): square root ( $\sqrt{x}$ ), logarithmic, inverse square root ( $1/\sqrt{x}$ ), and inverse ( $1/x$ ).

Studies on reliability of measures of height and weight suggest that *a priori* maximum acceptable values should be set for differences between observers. This becomes more important as more measures are added to a study (e.g., arm circumference, triceps skin fold, subscapular skin fold). Here, it is useful to provide an estimate of measurement error such as the technical error of measurement (TEM) from one or more observers.

Anthropometric indices are derived from two or more raw anthropometric measures. Examples include the body mass index (BMI), arm muscle area (AMA) and arm fat area (AFA), and waist-hip ratio. Together, these measures and composite indices provide a guide to under- and overnutrition in a sample. The extent of underweight is gauged by applying a criterion value (usually 16, 17, or 18.5) to BMI scores. So far, it is uncertain how BMI varies within samples of old people. A greater proportion of under- and overweight individuals die before or soon after entering old age, but subsequently, overweight individuals enjoy some advantages, with a better chance of surviving some illnesses, yet with a greater risk of falls and such (Ledikwe *et al.*, 2003).

## Gene-Nutrient Interactions

The molecular dissection of environment-gene interactions has the potential to overturn accepted ideas concerning the role of nutrients in aging and age-related diseases (Paoloni-Giacobino *et al.*, 2003; Gluckman and Hansom, 2004). Many novel methods of study have been developed. Following is a brief summary of the main mechanisms of gene-nutrient interaction and research methods available to study them.

### MECHANISMS

There is evidence of accumulation of DNA damage in aging. For some, this evidence is the foundation of the “the DNA damage hypothesis of aging.” This predicts that with aging, DNA damage exceeds DNA repair capacity and that the rate of aging will be directly related to the rate of accumulation of damage to DNA. Dietary habits and the intake of specific nutrients can be related to this hypothesis in four main ways: (a) nutrients can up-regulate or down-regulate gene transcription; (b) nutrients can damage DNA; (c) nutrients can protect DNA from damage; and (d) exposure to specific nutrients may slow or hasten aging processes through interaction with aging genes.

#### *Nutrient and gene transcription*

Specific nutrients could interact with a cellular recognition site and trigger the release of the second messenger followed by a DNA-binding protein. This is required to move from the cytoplasm into the nucleus and bind with the regulatory portion of a gene. Gene transcription is thereby stimulated or inhibited with production of

greater or lesser amounts of product. Nutrients known to modify gene transcription include some polyunsaturated fatty acids (e.g., eicosodocosohexaenoic acid, [EPA]), certain amino acids, and fat-soluble vitamins (vitamins A, D, and their metabolites). Methods to study these processes in specific cell types and metabolic pathways in aging humans are currently under development. One basic approach is to load a biological system with the substrate of enzyme believed to be regulated by a specific nutrient. Up- or down- regulation of a gene is inferred by quantification of the metabolites of the substrate before and after exposure to the nutrient load or its comparator. From the perspective of studies on human health and disease, early nutrient exposure during critical developmental periods may modify genes involved in related metabolic processes. (Waterland and Jirtle, 2004). These studies are in their infancy, but so far more than 20 genes have been found to be modified in this way, usually through hypomethylation. In addition, some genetic polymorphisms are associated with individual differences in response to nutrient intake. This is best understood for lipid metabolism (Masson *et al.*, 2003), but other physiological systems are certain to be modified in this way.

#### *Nutrient damage to DNA*

Nutrient damage to DNA is studied extensively in cancer biology. It is known that dietary components (including the products of cooking) and some contaminants of food may cause DNA damage. Although there are many examples from cancer (often an age-related disease), none have so far been confidently linked to differences in rates of aging.

#### *DNA-protective nutrients*

DNA-protective nutrients are present in diet. This is best regarded as a mixture of compounds, some of which are potentially harmful to DNA, whereas others are protective. The overall effect of diet on the accumulation of damaged DNA reflects the sum of their opposing actions. Nutrients that protect DNA include the antioxidants vitamin C and vitamin E, and the carotenoids, probably by stabilizing free radicals. All plant leaves contain chlorophyll, which forms a water-soluble salt, chlorophyllin, that can protect DNA from damage. This last mechanism is an example of those many biological processes (open to genetic influence) that may activate or inhibit conversion of dietary compounds to potent DNA-damaging agents. So far, none of these processes are studied extensively in aging populations, so their general importance, though recognized, remains unknown. The underlying biology, though complex, suggests pathways that may modify the rate of progression in aging and on to age-related diseases.

*Nutrients and aging genes*

If genes that convey longevity could be discovered, then these will be relevant to aging. This possibility rests on the likelihood that (1) especially in extreme old age, these genes may reduce rates of aging, and (2) these genes may modify cellular and biochemical pathways involved in gene–nutrient determined mechanisms of aging and age-related disease. The best-known example of such a gene is the  $\epsilon 4$  allele of the apolipoprotein E gene that decreases markedly in frequency with advancing age, whereas the much rarer  $\epsilon 2$  allele becomes more frequent. These findings are attributed to increased mortality in Alzheimer's and cardiovascular diseases associated with the  $\epsilon 4$  allele and the slight protection afforded by the  $\epsilon 2$  allele. The siblings and children of centenarians show reduced rates of age-related cardiovascular diseases, hypertension, diabetes, and stroke but not osteoporosis, cancers, and thyroid disease, suggesting that genetic effects are greater in the former disease group than the latter, in whom environmental, including nutritional, effects may predominate (Perls *et al.*, 2002, 2004). The exact identity of longevity genes is unknown; much current thinking concerns genes regulating inflammatory processes and energy production. The first proposition is supported by repeated observations that age-related diseases (like AD, PD, atherosclerosis, and type 2 diabetes) are sometimes initiated or exacerbated by systemic inflammation. This has supported the idea that an anti-inflammatory genotype is linked to longevity. In turn, certain nutrients are believed to be anti-inflammatory; these include the n-3 polyunsaturated fatty acids, eicosapentaenoic and docosahexaenoic acids. Regulation of energy metabolism, insulin resistance, and longevity are discussed in the next section.

**Nutritional Programming**

This topic is most often raised in response to the question: “What—if any—are the fetal origins of individual differences in aging and the incidence of age-related diseases?” During pregnancy, dietary requirements change because a mother must consume or synthesize all that is required for the growth and development of her baby. Factors like poverty, moral or religious taboos, or poor education are major influences on dietary habits in pregnancy. If, for reason of poor diet or placental insufficiency, a fetus fails to receive necessary calories and nutrients required for development, the risks increase of several age-related diseases. The importance of maternal nutrition and the consequences of low birth weight are now widely recognized in studies of aging and age-related disease.

Fetal nutritional programming is defined as “a stimulus (nutrient) or insult (absence of essential nutrient) to the fetus at a critical or sensitive period in intrauterine life with lasting effects on body structure, physiology

and metabolism” (Godfrey and Barker, 2001). This concept underpins the “fetal origins of adult disease hypothesis.” The hypothesis rests on the facts that, although genes determine optimum growth potential, the intrauterine environment and nutrient availability determine the extent of fetal growth attained.

Neonatal body weights, sizes, and proportions are gauges of the intrauterine growth and nutritional status. These provide useful proxies in population-based studies of nutritional status and growth. But these are less than ideal. Research methods to improve on this are in development and are likely to derive from the following. Fetal nutrition depends on the concentration of nutrients in the maternal circulation, on uteroplacental blood flow, and on the efficiency of transfer of nutrients across the placenta. Nutrient concentration in maternal blood essentially is determined by the mother's body composition, activity, metabolism, and diet. Recent studies have developed noninvasive techniques to measure relevant parameters (e.g., functional magnetic resonance imaging of placental function). Although these are certainly feasible in population-based studies, at present it is not possible to obtain large-scale normative data on the healthy fetus.

The general hypothesis that fetal growth is an important influence on late-onset diseases has been developed further. The Barker Hypothesis proposes that the fetal nutritional environment programs offspring for the likely availability of calories/nutrients during later development. Infants who have experienced a poor nutritional environment *in utero* are programmed to anticipate poor nutritional conditions in later life. Consequently, their metabolism is primed to conserve calories and nutrients as these become available. Their phenotype is small, and in poor conditions their health remains good. Conversely, infants whose intrauterine nutritional supplies were good will develop an optimal phenotype and enjoy corresponding good health. Problems for health and aging arise when intrauterine nutrition is mismatched with the adult nutritional environment (McMillen and Robinson, 2005). When the poorly nourished fetus encounters abundant foods in adulthood, programs to retain calories/nutrients are inappropriate; obesity, hyperlipidemia, hypertension, and abnormal glucose metabolism arise. Research methods to analyze the mechanisms initially relied on human ecological studies that exploit historical databases with high standards of clinical follow-up (in survivors born during the Dutch famine of 1944/1945; Roseboom *et al.*, 2001) and, increasingly, on animal models. The term *metabolic imprinting* was recently introduced to promote studies to unravel associations between early nutrition and increased susceptibility to late-onset diseases. This term implies the persistence of an adaptive genomic change in response to a nutritional stimulus that occurs during a critical period of development. The phenomenon of imprinting describes the effect on the single allele of a gene, which

is expressed in a parent-of-origin dependent manner. Genetic mechanisms to explain these processes are now described. These do not involve alterations to DNA sequences, but rather to epigenetic gene regulation (Waterland and Jirtle, 2004). DNA methylation is highly dependent on the availability of dietary methyl donors (e.g., methionine) and cofactors (e.g., vitamin B12). Early in embryogenesis, continuous cycles of cytosine methylation are established. Under- or overavailability of methyl donors can cause lasting effects on specific genes. It is now a subject of great interest in the study of the role of nutrients in aging and susceptibility to age-related diseases to identify the classes of genes that may be involved. Imprinted genes might be one such class of gene, and studies are now underway to determine if one or more of these genes is associated with individual differences in rates of aging and disease incidence.

## Conclusion

Research into aging will remain a priority for the foreseeable future. Whatever is achieved seems likely always to fall short of a human craving for a long and healthy life. The key outcome variable from a public perspective is a decrease in age-dependent mortality with the hope that for most, these added years will be comfortable and productive. There are without doubt major genetic and environmental contributions to aging and, of these, the environmental contribution seems most open to effective intervention. In broad terms, there is a popular view that lifestyle issues are the most important and the one over which an individual can exercise most control. When this rather imprecise term is analyzed, the spotlight falls on nutrition holding center stage in aging research.

This chapter has set out some of the pitfalls—and more than one elephant trap—for the researcher new to this field. The scene was set by looking first from an historical perspective and seeing that aging populations comprise diverse groups of people so much so that differences between the young-old and the old-old attributed to aging might sometimes be better understood in terms of major differences in dietary histories. This point recurred in the final sections on gene-nutrient interactions and the importance of nutritional programming. Here, full knowledge of the maternal, neonatal, and adult nutritional histories of people is necessary to unravel the basic biology in human studies. More likely, promising animal models will be developed to explore the ways aging processes are influenced by the early nutritional environment.

Although this chapter has emphasized the role of nutritional studies in aging human populations, there is an important place for animal studies. Much of this is outside the competence of this reviewer, being found in journals concerning animal husbandry and in nutritional biochemistry. Although the case is strong to focus on

human studies, when there is little commercial interest in old animals, this should not be understood as making light of the possible contributions to human health such animal studies might make.

Emphasis was placed on the need in nutritional studies to devise and implement effective methods to estimate the validity and reliability of nutritional intake methods. None of those summarized earlier are perfect, and there is great scope for novel improvements. In step with this, there are also opportunities to introduce advanced statistical models into studies on nutrients and human aging. The exponential growth witnessed in the molecular epidemiology of nutrition and the huge interest shown in understanding the role of specific genes makes this one of the most stimulating areas in which to start research. These are exciting times.

# Methods for Studying Hearing Impairment and Auditory Problems of the Aged

Robert D. Frisina and D. Robert Frisina

*Age-related hearing loss—presbycusis—is the foremost communication disorder of our elderly, and one of their top three chronic medical conditions. Currently, there are no cures for the sensorineural hearing loss and auditory processing problems that affect the majority of persons over age 60. We hope that increased basic research with animal models coupled with human clinical studies will lead to breakthrough translational studies aimed at prevention and eventual biomedical cure. The present chapter reviews a variety of effective procedures for measuring hearing loss as a function of age, including both classical and experimental paradigms. A theme of this exposition is that by utilizing key testing procedures, we can gain an understanding about how age and age-related ototoxic insults and conditions can affect either the cochlea (portion of the inner ear used for hearing) or the central auditory system (portions of the brain used for hearing).*

## Human Investigations

### AUDITORY SENSITIVITY: AUDIOGRAMS, NOISE THRESHOLDS, SPEECH DISCRIMINATION

A classic sign and symptom of age-related hearing loss in human listeners and patients is a gradual decline of hearing sensitivity in the higher frequencies, oftentimes beginning in the middle-age years. The classic manner in which hearing sensitivity is measured results in a *pure-tone audiogram*, and is the basic measurement of hearing sensitivity performed by all audiologists. In producing the audiogram, thresholds to single tones are measured by asking the subject or listener to respond when a tone of a certain frequency is detected. In a standard audiogram, measurements are made at discrete frequencies from 250 Hz up to 4 kHz. For research purposes, or early diagnosis of presbycusis, ultra-high frequency audiograms can be measured. In such cases the test frequencies can go as high as 20 kHz and require special audiometer calibration and headphones. Audiometric frequencies at 6 and 8 kHz are particularly useful for early diagnosis

and research (Tadros *et al.*, 2005), and frequencies up to 14 kHz can be useful for experimental studies of age-related hearing loss in humans.

Overall sensitivity of the ear can be measured using wideband signals such as white noise, speech-weighted noise, and speech sounds themselves, to determine threshold sensitivity. The most commonly used speech measure is called the *speech reception threshold* (SRT). Audiologists use two-syllable words with equal stress, called spondees, to determine one's speech reception threshold. The SRT correlates highly with speech-frequency pure tone audiogram averages. Speech discrimination tests, as contrasted with SRT, are suprathreshold measures that test the capacity of the cochlea to resolve speech sounds in quiet conditions. A commonly used standardized test is the Northwestern University (NU-6), consisting of 50 words in each of several lists. Each word contains three phonemes in a consonant–vowel–consonant format. The phoneme distribution in each word list approximates the frequency of occurrence of each phoneme in everyday speech. This test is routinely administered in quiet at an intensity level of 30 dB greater than the SRT level, a condition that is characteristic of conversational speech in quiet environments. Old adults with mild or moderate degrees of sensorineural hearing loss are expected to do well on this measure; thus it is a valuable screening tool used to detect unique aberrations that might occur in a given case. Performance in noisy environments involves more than the cochlea and cannot be predicted from this measure in quiet; therefore, additional tests are designed to measure more closely the ability to communicate in everyday noise environments.

### OUTER HAIR CELL SYSTEM: OTOACOUSTIC EMISSIONS—TRANSIENT, DISTORTION PRODUCT

There are two types of hair cells in the auditory portion of the mammalian inner ear. There is one row of *inner hair cells* that spiral from the cochlear base to the apex, and generally three rows of *outer hair cells* in the cochlear

**Figure 76.1** In the 1–6 kHz frequency range, DPOAE amplitudes decline with age, particularly from middle age to old age. For all three age groups, the greatest amplitudes are in the 4–5 kHz region, which is the region showing the greatest decline in DPOAE amplitudes from middle to old age. The values on the right side of the graph are the mean values for the three age groups, across all of the frequencies tested. Error bars represent standard errors of the mean (S.E.M.). From Kim *et al.* (2002), with permission.

spiral. Inner hair cells provide the main channels through which we hear; that is, they carry sound information from the cochlea to those portions of the brain used for hearing. About 95% of the auditory nerve fibers in the eighth cranial nerve form synapses with inner hair cells. In contrast, outer hair cells provide nonlinear electrohydro-mechanical inputs to the inner hair cells that make the latter much more sensitive to quiet sounds and neuroethologically-relevant complex vocalizations such as speech, and allow them to participate more fully in neural feedback loops from the brain to the ear.

*Otoacoustic emissions* are faint sounds originating from the outer hair cells of the cochlea that can be recorded from the external ear canal (Kemp, 1978). They are sometimes produced spontaneously, but the most common recording procedure is when sounds are put into the ear, and then on a msec time scale, otoacoustic emissions are produced by the outer hair cells in response to the input sounds. When acoustic clicks are used to elicit the otoacoustic emissions, these physiological responses are referred to as *transient-evoked otoacoustic emissions*—TEOAEs. When two tones are presented at the same time, the nonlinear properties of the outer hair cell system produce distortion product frequencies, such as cubic or quadratic distortion products, that are not present in the original acoustic stimulus. The most commonly used *distortion-product otoacoustic emission* (DPOAE) is the 2F1-F2 component, where F1 and F2 are two frequencies at an optimal frequency ratio. Otoacoustic emissions are quite advantageous for measuring the

**Figure 76.2** In a study of otoacoustic emissions in aged subjects with and without a sloping, presbycusis audiogram, a significant difference in DPOAE amplitudes was found between the normal hearing group relative to the presbycusis group. In the subjects with the high-frequency sloping hearing loss, the right ear DPOAE amplitude declines more than the left ear decline re the normal hearing aged controls, especially in the  $f_2 = 2\text{--}5$  kHz region. From Tadros *et al.* (2005), with permission.

health and well-being of the outer hair cell system because they are unbiased neurophysiological measurements that can be obtained rapidly in a noninvasive manner (no surgery required), relatively easily in human subjects (no anesthetic required) or animal models, including rodents and higher mammals (short-acting light anesthetic required). It is well established that otoacoustic emission amplitudes decline with age, as outer hair cells are lost in the aging process prior to the loss of inner hair cells, as shown in Figures 76.1 and 76.2

(Lonsbury-Martin *et al.*, 1990, 1991; Stover and Norton, 1993; Tadros *et al.*, 2005).

#### EFFERENT FEEDBACK SYSTEM: CONTRALATERAL SUPPRESSION OF OTOACOUSTIC EMISSIONS

The *ascending* auditory system (afferent) processes information from the cochlea as this information travels from the inner ear to the brainstem, and then to the higher centers of the brain including the medial geniculate body of the thalamus, and on to the auditory cortex where perception of sounds takes place. Along with this ascending portion of the system, there are nerve cells in the brain that can also send information from the brain *back to the inner ear*. This *descending* part of the auditory system, sometimes referred to as the *efferent system*, can modulate the auditory information processed in the cochlea. For example, in the presence of loud sounds or background noise, the outputs of the cochlea can be reduced when the nerve cells of the efferent system become active.

We can measure the strength of the auditory efferent system by recording the amplitudes of otoacoustic emissions, both in the presence or absence of sounds or noise presented to the opposite (contralateral) ear. When the amplitudes of otoacoustic emissions are reduced in one ear (ipsilateral ear) due to the presence of sound stimulation in the other ear (contralateral ear), the efferent system has been activated. The greater the decrease in the amplitude of these emissions, the greater the strength and health of the descending auditory

efferent system. Since the health and abilities of the cochlea for processing important sounds such as speech depend partly on the efficacy of the auditory efferent system, measuring the operation of this system with age is useful and important. For example, for human subjects, Kim *et al.* (2002) discovered that the auditory efferent system begins to lose its capabilities in middle age, and is almost completely inoperative in most old subjects (see Figure 76.3).

They discovered this by testing human subjects (young adult, middle age, and old) who had audiometric thresholds in the normal hearing range on standard hearing tests as well as DPOAEs in quiet and in the presence of contralateral noise. This is a case where the inner ears of these subjects had normal sensitivity (audiograms in the normal range), but there was clearly an age-related problem in the central auditory system, at least for those portions of the brain associated with the efferent system. Taken together, otoacoustic emissions along with the *contralateral suppression* (CS) of otoacoustic emissions provide information on the operating status of the ear-peripheral auditory system, and the brain-auditory feedback system, respectively.

#### TIMING (TEMPORAL) AND FREQUENCY (SPECTRAL) PROCESSING: GAP DETECTION, AMPLITUDE MODULATION

For human subjects, auditory psychophysics (psychoacoustics) can provide perceptual information about the system as a whole. Psychoacousticians make careful

**Figure 76.3** Mean magnitude of contralateral suppression (CS) as a function of  $f_2$  frequency (Hz) in three age groups. CS of DPOAEs, mediated by the medial olivocochlear system, declined with age. The most dramatic age-related decline occurred in middle age, with further declines occurring in old age. Note that greater amounts of CS are indicated by negative values. Notice that the least suppression occurs in the 4–6 kHz region for the young and old groups, where the DPOAEs have maximal magnitudes for all three age groups (see Figure 76.1). The values on the right side of the graph are the mean values for the three age groups across all of the test frequencies. From Kim *et al.* (2002), with permission.

measurements of fine acoustic features under different listening conditions, and for the present purposes, in subjects of different ages. A standard stimulus for auditory studies of temporal processing is a silent gap between two sounds, with the task referred to as *gap detection*. Here the subject or listener will usually listen to a standard sound without a gap, followed (or preceded) rapidly with two sounds separated by a short temporal gap. From trial-to-trial, the task can be made easier by lengthening the gap, or more difficult by shortening the gap. The subject's task is to identify which sound stimulus contains the temporal gap. Threshold is attained when the subject achieves a specified correct percentage of responses. Depending on the frequencies of the sounds composing the gap, young adult subjects with normal hearing can detect gaps as short as about one msec. It has been found that with age, gap detection thresholds become larger; that is, a longer gap is required by older subjects for correct identification than by young adults with normal hearing (Snell and Frisina, 2000; Snell *et al.*, 2002). Declines in auditory temporal processing are worsened by the extent of hearing loss as measured in a subject's audiogram (Gordon-Salant and Fitzgibbons, 1993; Fitzgibbons and Gordon-Salant, 1996). Very little is known about how processing of rapid changes in sound amplitude–amplitude modulation, or how frequency selectivity changes with age alone in human listeners, although these measures have been used extensively to document temporal and spectral processing deficits associated with hearing loss in young adults.

#### SPEECH PROCESSING IN NOISE: SPEECH IN NOISE (SPIN), HEARING IN NOISE TEST (HINT)

Psychoacousticians and research audiologists interested in the capabilities of the auditory system in more natural, realistic acoustic situations employ hearing measurement tests that assess the ability of the listener to understand speech in background noise. Two of the most useful, commonly used rigorous procedures for measuring speech comprehension in background noise are the SPIN test and HINT.

These tests involve the presentation of speech signals in different levels of background noise. In the SPIN test, the background noise is a calibrated recording of multi-talker babble—the simultaneous speaking of a group of male and female adult voices, where the voice of any one particular person is not discernible. The SPIN test, administered under headphones, measures each ear independently, whereas the HINT is administered in the free field and utilizes both ears simultaneously. In the HINT, the background noise is a speech-weighted noise devoid of any semantic content. The initial test conditions for the HINT involve having the speech signal and background noise come from the same position, N0, which is directly in front of the subject. The effect of spatial separation of speech and noise is measured in the

HINT. Both tests have been useful measures of the aging auditory system where speech comprehension in background noise was being investigated. For example, Frisina and Frisina (1997), by utilizing the SPIN with human subjects whose audiograms were in the normal hearing range, discovered that aged subjects performed worse in background noise than younger adult subjects. In addition, the effect of sensorineural hearing loss was revealed when age-matched old subjects with different degrees of hearing loss were compared with old subjects within the normal range of hearing. This important study demonstrated that (1) age alone could negatively influence speech recognition in a noise background, and (2) hearing loss itself could result in a decline in speech recognition when measured in a noise background.

#### SPATIAL PROCESSING: HEARING IN NOISE TEST (HINT)

In addition to testing a subject's ability to understand speech in background noise, the HINT also has spatial processing components to it. Specifically, three main spatial processing conditions typically are utilized: N0, where the speech and noise come from the same position directly in front of the listener; N90, where the speech comes from in front, but the background noise emanates from a location to the right, 90° from center; and N270, where the noise comes from 90° left of center. If responses to speech differ between these locations, it implicates properties or problems due to the brainstem portion of the central auditory system where *binaural processing* occurs; that is, at the level of the superior olivary complex or auditory midbrain.

#### EAR AND BRAINSTEM PHYSIOLOGICAL PROCESSING: AUDITORY BRAINSTEM RESPONSE

The most commonly used neurophysiological measure of both peripheral and central (brainstem) auditory processing is the *auditory brainstem response (ABR)*. This noninvasive auditory-evoked potential procedure reflects the integrity of the inner ear and brainstem auditory system extending from the auditory nerve to the level of the lateral lemniscus, just posterior or ventral to the auditory midbrain–inferior colliculus. Scalp electrodes record a series of early neuroelectrical potentials that follow auditory stimulation. The human ABR consists of five waves or peaks, with Waves I and V being the most prominent and useful for clinical purposes or research experiments. This procedure has gained widespread use in neonates, infants, and children who do not respond successfully to behavioral auditory threshold measurement procedures. Its limited use with the old subjects is directed to those whose standard test results suggest the possibility of brainstem tumors or eighth-nerve anomalies. If Wave I of the ABR is sufficiently large for analysis, cochlear sensitivity can be isolated and assessed independently of the brainstem activity for study of the

aging auditory system. Generally, ABR latencies, such as Wave V, increase with age for both women and men (Jerger and Hall, 1980; Jerger and Johnson, 1988).

Brainstem auditory temporal processing disorders during aging have been identified in human subjects using forward masking of Wave V (Walton *et al.*, 1999). Here, the intensity of a first (masking) tone is varied to measure the time delay between the masking tone and a probe tone that follows with a variable time delay. Specifically, in humans, age will lengthen the time delay needed for a tone to recover its level due to the presence of the masking tone, thus reducing temporal resolution of the brainstem auditory system.

#### AUDITORY LATE AND EVENT-RELATED POTENTIALS—CEREBRAL CORTEX

Several late auditory evoked potentials can be measured with scalp recording electrodes in mammals, including humans, including N1, P2, and P3. The latter is sometimes referred to as the *P300 endogenous event-related potential* and can be elicited by an unusual (target or oddball) stimulus that is presented in the context of a standard stimulus usually being repeated many times. These cortical potentials are of higher amplitudes than ABRs, thus requiring fewer repetitions to be recorded faithfully above the electrical noise floor. There have been a number of studies of the aging auditory system employing the P300 and other auditory cortical potentials, and they generally show an increased latency and decreased amplitude with age (Swartz *et al.*, 1992, 1994).

### Animal Model Techniques

#### AUDITORY SENSITIVITY: ABR AUDIOGRAMS, NOISE THRESHOLDS

These threshold sensitivity measures using pure tones or wideband noise bursts are similar to the ABR neurophysiological measures as described earlier for humans. Their major advantage for animal applications is that the basic sensitivity of the peripheral and brainstem auditory systems can be measured relatively easily and quickly, especially as compared to classical behavioral paradigms such as operant conditioning techniques. However, unlike human adults, but similar to infants or some young children, the animal needs to be anesthetized for a period of 30 to 60 minutes to assess the full frequency range of hearing in most mammals. So, although this procedure utilizes surface electrodes and is noninvasive, the animal will require a short-acting anesthetic, either inhalation or intraperitoneal injection, to reduce muscle-related electrical activity to the level where the small neural brain signals can be picked up above the electrical background noise (noise floor). Since anesthetics reduce homeostatic body temperature control, mammals undergoing ABR recordings must be kept on a heating pad, oftentimes used in conjunction with a thermometer for servo-control

feedback. Age-related changes in peripheral and brainstem auditory sensitivity have been well-documented utilizing ABRs. For example, different inbred strains of mice lose their hearing at different rates, which has been measured using the mammalian ABR audiogram (Hunter and Willott, 1987; Jacobson *et al.*, 2003). An example of this age-related loss in ABR sensitivity is shown in Figure 76.4, highlighting sex differences for the CBA strain of mouse that loses its hearing slowly, like most human cases of presbycusis (Guimaraes *et al.*, 2004).

Suprathreshold ABR amplitudes also decline with age in strains of mice that have been frequently employed in studies on the neural bases of presbycusis—CBA, C57 (Henry and Lepkowski, 1978; Walton *et al.*, 1995).

#### OUTER HAIR CELL SYSTEM: OTOACOUSTIC EMISSIONS—TRANSIENT, DISTORTION PRODUCT

As in human subjects, the presentation of two simultaneous tones with a specific frequency ratio (DPOAE) or the presentation of a train of clicks (TEOAE) can be employed to obtain an objective neurophysiological assessment of the cochlear outer hair cell system as a function of animal age. Also like ABRs, adult human subjects can have their otoacoustic emissions measured by relaxing in a comfortable chair, whereas mammals need to receive a short-acting anesthetic to achieve the level of reduced muscle activity and twitching (sleep) necessary to obtain good ear canal recordings for the otoacoustic emissions waveforms. Like humans, the amplitudes of otoacoustic emissions decline in aging mammals, in a manner proportionate to the loss of cochlear outer hair cells with age, usually starting at the cochlear base that corresponds to the place that codes higher frequencies (Spongr *et al.*, 1997; Jacobson *et al.*, 2003). An example of DPOAE amplitude that declines as a function of age for female and male CBA mice is provided in Figure 76.5 (Guimaraes *et al.*, 2004).

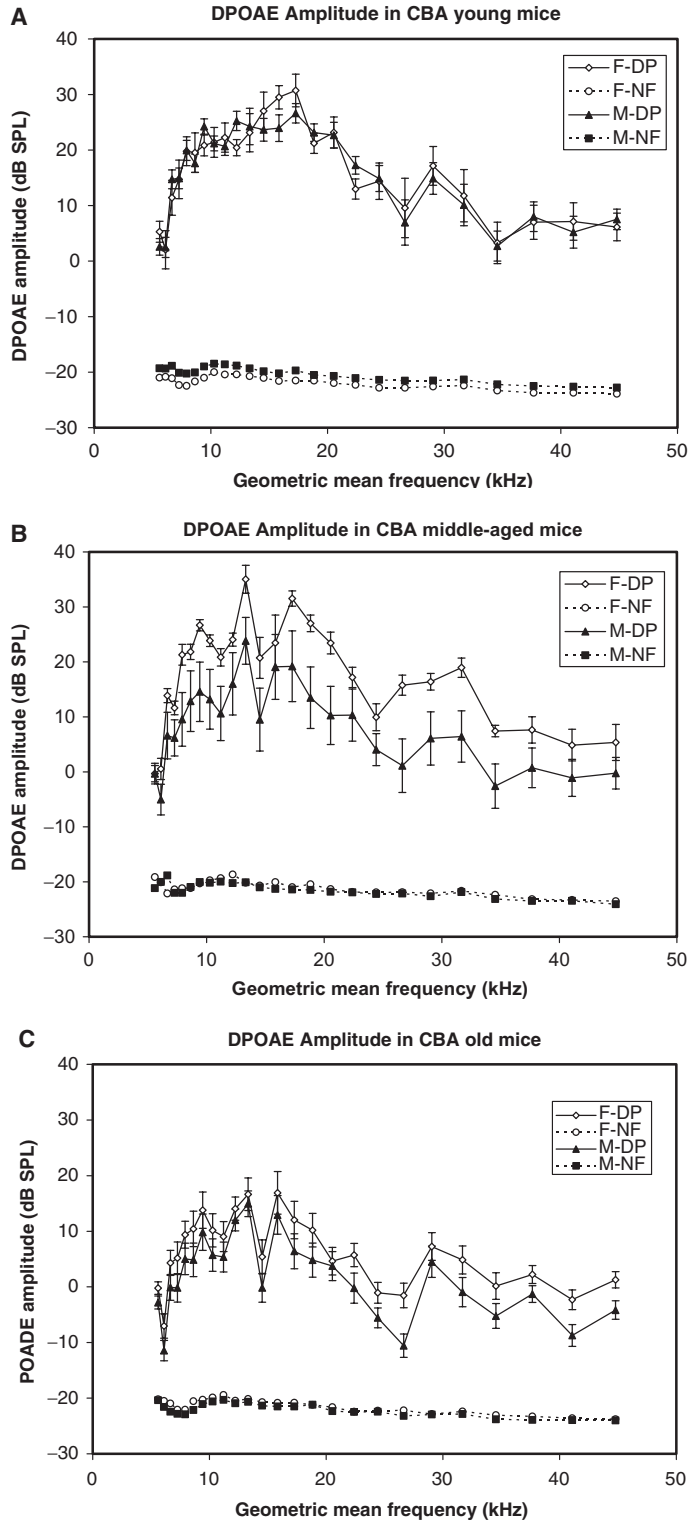

#### EFFERENT FEEDBACK SYSTEM: CONTRALATERAL SUPPRESSION OF OTOACOUSTIC EMISSIONS

As described earlier in the section on contralateral suppression (CS) in human subjects, presentation of an acoustic stimulus to the contralateral ear can suppress the amplitude of the ipsilateral otoacoustic emissions via the physiological effects of the auditory efferent feedback system whose nerve cell bodies originate in the superior olivary complex of the brainstem auditory system. Jacobson *et al.* (2003) performed the analogous experiment in CBA mice that Kim *et al.* (2002) conducted in human subjects and made a similar discovery: Significant age-related declines in CS magnitudes occur in middle-aged mice, prior to the onset of major declines in the amplitudes of otoacoustic emissions and elevations in ABR audiogram tone thresholds that are characteristic of old age.

**Figure 76.4** ABR recordings were made from CBA mice. ABR thresholds were measured for frequencies of 3, 6, 12, 24, 32, and 48 kHz. Young adult mice have good sensitivity up to 48 kHz, with the best sensitivity in the 5–30 kHz range, and no male/female differences. As mice age, sensitivity declines, and CBA mice tend to have relatively good hearing sensitivity even in old age. **A.** Young adult thresholds. **B.** Middle-aged data show few differences between the sexes. **C.** Old recordings show lower thresholds for females, but this difference was not statistically significant. From Guimaraes *et al.* (2004), with permission.

76. Methods for Studying Hearing Impairment of the Aged

**Figure 76.5** Relationships between DPOAE amplitude (dB SPL) and geometric mean frequencies (5.6–44.8 kHz) in three age groups of CBA mice, including the mean noise floor across the testing frequencies. **A.** Young adult group—similar amplitudes for both sexes. **B.** Middle-aged group—the females presented with higher DPOAE amplitude than males. The findings were confirmed with a two-way ANOVA ( $F=11.9$ ,  $P < 0.001$ ). **C.** Old group—the DPOAE amplitudes for females were also higher than those for males with confirmation by the two-way ANOVA ( $F= 5.91$ ,  $P < 0.05$ ). Note that the sex difference was smaller than for the middle-aged group (1B). F-DP = Female DPOAE; F-NF= Female noise floor; M-DP= Male DPOAE; and M-NF= Male noise floor. From Guimaraes *et al.* (2004), with permission.

#### COCHLEAR PHYSIOLOGICAL POTENTIALS

The *endocochlear potential* measures the voltage potential in *scala media*, which contains the K<sup>+</sup> rich endolymph in the cochlea. This fluid bathes the tops of the cochlear inner and outer hair cells, and plays an important role in hair cell transduction of acoustic sound waves in the inner ear into the code of the nervous system that gets sent to the brain via the nerve fibers of the auditory division of the eighth cranial nerve. R.A. Schmiedt and coworkers have measured this potential *in vivo*, in animal models of different ages (e.g., gerbils), and found that the magnitude of this electrical potential declines with normal aging (Schmiedt and Schulte, 1992; Schulte and Schmiedt, 1992; Schmiedt, 1993). This decline is analogous to a car battery slowly going dead over time. As this battery-like voltage declines with age, the sensitivity of the inner ear decreases as measured by cochlear compound action potentials and the thresholds of auditory-nerve fibers, and the overall sensitivity of the auditory system becomes impaired (Schmiedt *et al.*, 1990; Hellstrom and Schmiedt, 1990, 1991).

#### TIMING (TEMPORAL) PROCESSING: INHIBITION OF ACOUSTIC STARTLE RESPONSE BEHAVIORAL GAP DETECTION

J.R. Ison and colleagues have pioneered the use of the behavioral psychology paradigm, known as the *inhibition of the startle reflex*, as a fast and reliable measure of the hearing capabilities in animals, especially for studies of the aging auditory system and determination of its neural bases (Hoffman and Ison, 1980; Ison, 1982; Ison and Hoffman, 1983; Young and Fechter, 1983; Ison and Bowen, 2000). This procedure is carried out by taking advantage of the fact that mammals will respond quickly and in an unbiased way when presented with a loud click, via a jump in the case of rodents, or with an eye blink in larger mammals including humans. The click would be akin to snapping your fingers near your ear. Ison and coworkers have demonstrated that when a warning sound is presented just before the startle stimulus (loud click), the amplitude of the rodent jump or human eye blink will be attenuated proportionately to the effectiveness or detectability of the warning sound (prepulse). This reliable, efficient measure of auditory processing is called *prepulse inhibition*. Ison's team has utilized this effectively to evaluate the temporal processing capabilities of the aging auditory system using gaps or decrements in ongoing sounds, including tones or wideband noise, as prepulse inhibition stimuli (Walton *et al.*, 1997; Ison *et al.*, 1997, 1998, 2001; Barsz *et al.*, 2002; Allen *et al.*, 2003). For example, in CBA mice the gap detection threshold significantly declines with age, and these temporal processing deficits mirror neurophysiological gap threshold changes recorded at the level of the auditory midbrain–inferior colliculus, described in more detail later.

#### SPATIAL PROCESSING: INHIBITION OF ACOUSTIC STARTLE RESPONSE BEHAVIORAL TESTING

Ison's research group has more recently developed a variation on the inhibition of startle research paradigm for measuring spatial processing in mice as a function of age (Allen *et al.*, 2004). Here, a mouse assumes a standard spatial position and orientation in the inhibition of startle measurement cage. When in the calibrated place, a prepulse inhibition auditory stimulus is presented from one of several possible spatial positions. By varying the location of the prepulse inhibition sound in a calibrated manner from trial to trial, auditory spatial processing capabilities of mice can be measured as a function of age and stimulus type. Indeed, the ability to correctly localize sounds in space, particularly the azimuth, declines significantly in the aging mouse.

#### BRAINSTEM PHYSIOLOGICAL PROCESSING: SINGLE NERVE CELL AND EVOKED POTENTIAL RECORDINGS

As presented earlier in the human sections, presbycusis involves a loss of sensitivity to sound, temporal processing deficits, and spatial tuning degradations, all of which can contribute to a difficulty understanding speech by the elderly, particularly in noisy situations. Behavioral and evoked potential work in animal models, such as mice and other rodents, confirms that most mammals develop age-related hearing problems with many similarities to the human condition, such as spatial and temporal processing deficits, that are confounded by complex acoustic environments such as those containing background noise. Physiological recordings in the auditory brainstem give insights to the neural mechanisms that may underlie these perceptual and behavioral findings.

Willott and coworkers were the first to systematically investigate changes in *tonotopic* or *cochleotopic* organizations of brainstem auditory nuclei as the high-frequency hearing loss characteristic of presbycusis progresses in mice (Willott *et al.*, 1985, 1988a, b; Willott, 1986, 1991). Tonotopic or cochleotopic organization refers to the fact that the major cell groups, or nuclei, of the brainstem auditory system have frequency organizations that originate in the cochlear spiral, where high frequency nerve cells are in one location, then middle frequency, then low frequency nerve cells in another, much like the keys on a piano. Tonotopically organized nerve cell pathways connect the cochlea to the cochlear nucleus, the first major nucleus of the central auditory system, and these pathways continue in an organized manner up through the auditory cortex, with sound information being processed at each step along the way. In aging, when the basal portions of the cochlea lose a significant number of hair cells with age, there is a concomitant loss of high frequency pathways and nerve cells in the central auditory system. Willott and colleagues discovered that

**Figure 76.6** Single nerve cells in the auditory midbrain–inferior colliculus of unanaesthetized CBA mice have longer gap thresholds in old age, compared to young adults. The proportion of single nerve cells possessing minimum gap thresholds (MGTs) ranging from 1 to >11 msec are shown for young adult mice, hatched bars (N=78 cells), and for old mice, solid bars (N=108 cells). Note that the data in this histogram indicate a distribution of single-nerve cell gap thresholds to longer gaps in old age. From Walton *et al.* (1998), with permission.

when there is a loss of high frequency pathways to the auditory midbrain–inferior colliculus, the ventral portions of this region start responding to lower frequencies in the absence of the normal high frequency inputs.

Walton and coworkers have made extensive single nerve cell recordings in the inferior colliculus of old CBA mice, who still have reasonably good auditory sensitivity in old age. They have discovered that at suprathreshold sound levels where single nerve cells still give good responses, temporal processing problems can occur during aging that increase gap detection thresholds and distort responses to the onset and waveforms of biologically relevant sounds (Walton *et al.*, 1997, 1998, 2002; Simon *et al.*, 2004). Examples of some of these changes in the responses of single nerve cells are provided in Figures 76.6 and 76.7.

#### NEURAL BASES OF PRESBYCUSIS: NEUROANATOMY, IMMUNOCYTOCHEMISTRY, TRACT TRACING

Not surprisingly, there are neuroanatomical and neurochemical changes occurring in the auditory system with age that correlate and may underlie the behavioral and functional declines that have been discussed so far. A variety of anatomical and biochemical methodologies have been employed to examine these aspects of age-related hearing loss, and in most cases, animal models have been effectively employed.

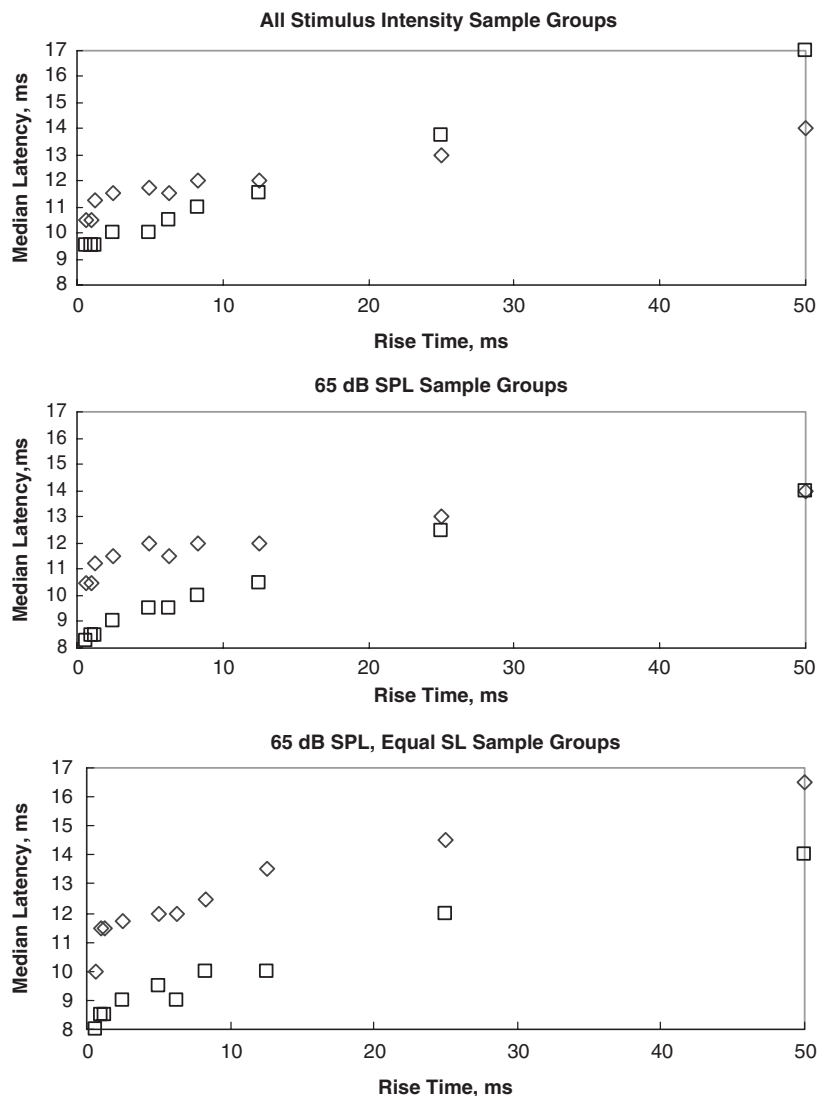

D.M. Caspary and his colleagues conducted a comprehensive series of anatomical and biochemical experiments on the GABA system in the auditory midbrain. GABA is one of the two most prominent inhibitory neurotransmitters in the central auditory system. Caspary's group put forth some convincing evidence that there is an *age-related down-regulation* of the main GABA

neurotransmitter system of the auditory midbrain (Caspary *et al.*, 1990, 1995, 1999; Helfert *et al.*, 1999). This loss of inhibition is consistent with some of the neurophysiological functional data concerning the disruption of complex sound processing in quiet and background noise characteristic of presbycusis.

Frisina and coworkers have studied certain anatomical aspects that accompany the age-related temporal processing deficits discovered by Walton's team as presented earlier. For instance, the same regions of the auditory midbrain that manifest the age-dependent temporal processing disorders also show changes in intracellular calcium regulation as investigated using immunocytochemical antibody labeling methodologies (Zettel *et al.*, 1997, 2001). *Calbindin* and *calretinin* are two of the most important calcium-binding proteins in the brain involved in intracellular calcium regulation critical for neurotransmitter synthesis and release. Calbindin was found to decline with age in the inferior colliculus, and calretinin increased with age, but only in mice with good hearing in old age. Mice deafened as young adults did not show this upregulation, indicating that it was dependent on the sound-evoked activity being present. Frisina's group also found that certain neural input pathways from the contralateral cochlear nucleus and superior olivary complex in the brainstem auditory system to the inferior colliculus showed an age-related decline using neural tract-tracing techniques (Frisina and Walton, 2001).

#### Conclusion

It is evident that a variety of methodologies have been effectively utilized to investigate age-related hearing loss in human listeners and for animal models. Exciting future possibilities include assessing hearing improvements using

**Figure 76.7** Graphs showing the relationship between median latency and sound stimulus rise time for young-adult (diamond) and old (square) single nerve cell groups containing: (A) all nerve cells analyzed; (B) nerve cells stimulated at 65 dB SPL; and (C) matched young-adult and old nerve cells stimulated at 65 dB SPL and equal sensation levels above each cell's threshold. In all cases, the nerve cells in the old animals show shorter latencies than the young adult cells. This is consistent with a loss of inhibition with age in the auditory midbrain and has implications for disruptions of complex sound coding with age. From Simon *et al.* (2004), with permission.

the most effective hearing measurement methods, first in animal rehabilitation experiments aimed at preventing or curing hearing loss and deafness with gene therapy approaches or stem cell transplantation. If in the not-so-far future this is achieved reliably in mammals, and eventually primates, then hearing assessment in human clinical trials will hopefully follow soon after that.

# A Model for Understanding the Pathomechanics of Osteoarthritis in Aging

Thomas P. Andriacchi and Annegret Mündermann

*Osteoarthritis occurs in the majority of adults and is often described as “wear and tear” arthritis, or a disease of aging resulting from the structural and biochemical breakdown of articular cartilage in synovial joints. The causes of degenerative osteoarthritis with aging are complex and involve interrelated biological, mechanical, and structural pathways. This chapter examines the interrelationship or coupling of these pathways that converges at an in vivo systems level in humans. Using the knee as an example, an integrated in vivo framework for understanding the various factors that influence the initiation and progression of osteoarthritis is described. This framework provides a basis for explaining the role of kinematics and load on the progression of osteoarthritis. The framework helps to explain the integrated effect of biological, morphological, and neuromuscular changes to the musculoskeletal system during aging or during menopause on the increased rate of idiopathic osteoarthritis with aging.*

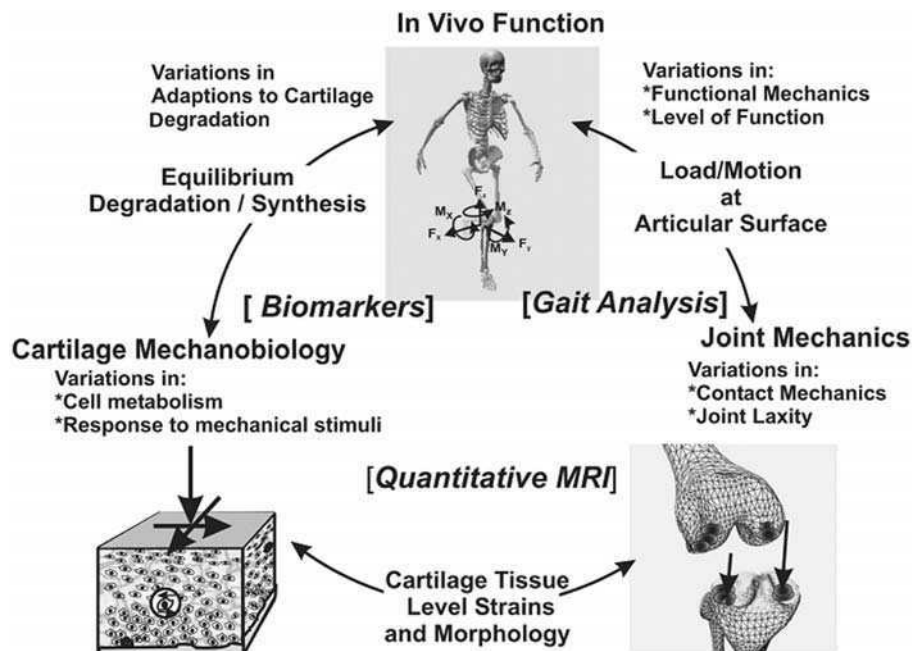

## Introduction

Arthritis is the most common type of joint disease and comprises a heterogeneous group of conditions that cause common histopathological and radiological changes. Osteoarthritis, often described as wear-and-tear arthritis, occurs in the majority of adults. It is a disease of aging resulting from the structural and biochemical breakdown of articular cartilage in synovial joints. The “itis” in osteoarthritis implies inflammation; however, most people with this condition do not have inflamed joints. Osteoarthrosis, defining a condition where the joints are affected by degeneration without inflammation, is probably a more accurate overall description of the condition. Nevertheless, as most people refer to the condition as osteoarthritis, this is the term used here. Osteoarthrosis and osteoarthritis are terms that are used virtually interchangeably.

The causes of degenerative osteoarthritis with aging are complex and involve interrelated biological

(Lohmander *et al.*, 1999; Maniwa *et al.*, 2001; Otterness *et al.*, 2001), mechanical (Beaupré *et al.*, 2000; Carter *et al.*, 1998; Grodzinsky *et al.*, 2000; Mow and Guo, 2002; Mow and Wang, 1999), and structural (Eckstein *et al.*, 2002; Koff *et al.*, 2003; Peterfy *et al.*, 1994) pathways. The interrelationship or coupling of these pathways converges at an *in vivo* systems level in humans (see Figure 77.1).

*In vivo* function influences the mechanical environment of articular cartilage and the mechanobiology (Arokoski *et al.*, 2000; Sweet *et al.*, 1992; Thonar *et al.*, 1985) of the tissue. Thus, *in vivo* function is coupled to the structure and health of the joint. Patients can functionally adapt to pathological joint changes such as ligament injury or degeneration of the articular cartilage. For example, it has been observed from *in vivo* studies (Mündermann *et al.*, 2004; Prodromos *et al.*, 1985; Wang *et al.*, 1990) that some patients with knee osteoarthritis can adopt patterns of locomotion that lower the load at the knee and reduce the rate at which osteoarthritis progresses. Variations in the soft tissue properties or structure (Ateshian *et al.*, 1991; Cicuttini *et al.*, 2002) of the joint can influence the congruency and laxity of the joint and produce substantial variations in contact stress and joint motion that impact the mechanical environment of the cartilage. Cartilage adapts to mechanical stimuli (Smith *et al.*, 1995) and ultimately becomes dependent on the maintenance of that mechanical stimulus for normal tissue function (Carter and Wong, 2003). *In vitro* studies (Smith *et al.*, 1995) have shown that isolated cartilage cells (chondrocytes) can adapt to changes in their mechanical environment by changing metabolic activity in response to increased levels of certain types of stress (Beaupré *et al.*, 2000; Carter *et al.*, 1998; Grodzinsky *et al.*, 2000; Guilak and Mow, 2000). Cartilage health depends on the body's ability to maintain the equilibrium between degeneration and synthesis of cartilage constituents including collagen fibrils and proteoglycans. Chondrocytes, the cells of cartilage, retain this equilibrium by controlling enzymatic processes.

**Figure 77.1** Understanding the *in vivo* response of articular cartilage to its physical environment requires an integrated view of the problem that considers functional, anatomical, and biological interactions. Gait analysis, quantitative MRI, and assays of biomarkers provide a basis for understanding the interaction between the various pathways that lead to the initiation and progression of osteoarthritis (from Andriacchi *et al.*, 2004).

## DEFINITION AND TYPES OF OSTEOARTHRITIS

Any analysis of the pathomechanics of osteoarthritis must consider the various forms of the disease. In general, osteoarthritis can be categorized as idiopathic, post traumatic, and other forms of joint degeneration.

### *Idiopathic osteoarthritis*

Idiopathic osteoarthritis occurs in previously intact joints with no apparent initiating factor or event and is related primarily to the natural aging process. Risk factors for idiopathic osteoarthritis include obesity, hormone levels, or genetics (Flores and Hochberg, 2003). Idiopathic osteoarthritis is the most common form of arthritis associated with aging. However, the rate of progression of osteoarthritis can vary substantially among different individuals with similar risk factors. The reason for variable rates of the progression of the disease with aging among seemingly similar patients has been the subject of numerous studies and will be addressed from a pathomechanical viewpoint in this chapter.

### *Post traumatic osteoarthritis*

Post traumatic osteoarthritis is the accelerated degeneration that occurs in a joint as the direct and indirect result of injury. Following an injury to a joint, such as the rupture of the anterior cruciate ligament or a tear of a meniscus, a patient is susceptible to developing

osteoarthritic changes to the joint earlier in life (Daniel *et al.*, 1994; Englund *et al.*, 2003; Roos *et al.*, 2001; Roos *et al.*, 1995; von Porat *et al.*, 2004). It is not clear whether the change in the mechanical environment or biological changes associated with the injury to the joint are the primary cause for the earlier onset of osteoarthritis, and it has been suggested (Andriacchi *et al.*, 2004) that these factors are interrelated.

### *Others forms of osteoarthritis*

Osteoarthritis can also be caused by other conditions including gout (crystal formation in the joints), lupus (the body's defense system can harm the joints, the heart, the skin, the kidneys, and other organs), and viral hepatitis (an infection of the liver).

## DEMOGRAPHICS OF OSTEOARTHRITIS

Currently, about 20 million Americans are affected by osteoarthritis, and the prevalence of osteoarthritis is two-and-a-half times that of heart disease and six times that of cancer. It is projected that by 2030, 20% of Americans—about 70 million people—will have passed their sixty-fifth birthday and will be at risk for osteoarthritis (National Institute of Arthritis, 2003). Similar percentages of most Western populations suffer from osteoarthritis (Statistisches Bundesamt Germany, 2003; Statistics Canada, 2003). The risk of developing osteoarthritis is higher in African-Americans, Hispanics, and

Asians compared to Caucasians (Escalante and del Rincón, 2001; Jordan *et al.*, 2003; Xu *et al.*, 2003).

#### *Aging*

The incidence of clinically symptomatic osteoarthritis increases with increasing age, independent of site, and for both female and male populations (Felson *et al.*, 1987; Oliveria *et al.*, 1995; Verbrugge, 1995). Biological tissues undergo significant changes during the aging process including biological changes and associated changes in mechanical properties.

#### *Gender*

Although the incidence of osteoarthritis at the knee and hip is similar in male and female populations under the age of 60 years, the incidence in females over the age of 60 years increases at a faster rate than in males over the age of 60 years (Oliveria *et al.*, 1995; Peyron *et al.*, 1993). Differences or changes in hormone levels, in part, may account for these differences, although this association is still under debate (Richette *et al.*, 2003). Estrogen, the female sex hormone, has been shown to affect biological tissue properties and turnover. For instance, in cartilage, increased estrogen levels have been related to increased matrix protein turnover (for review, see Richette *et al.* (2003)). In comparison, lower estrogen levels during adolescence may lead to increased femoral cartilage thickness and stiffness. In certain ligaments, higher estrogen levels are associated with greater stiffness (Romani *et al.*, 2003), and the maximum voluntary force per cross-sectional area in skeletal muscle dramatically declines in post-menopausal women (Phillips *et al.*, 1993). During menopause, estrogen levels decrease drastically. These reports suggest that lower estrogen levels during and after menopause may lead to lower matrix protein turnover in cartilage, greater cartilage stiffness, greater joint laxity, and lower muscle forces. These changes occur in addition to age-related physiological and morphological changes in biological tissues (see later) and may be, in part, responsible for higher incidence of idiopathic osteoarthritis in women after menopause.

#### *Site specificity*

Although osteoarthritis can affect most synovial joints of the upper and lower extremities and trunk (hand, wrist, ankle, knee, hip, neck, back), it is observed most frequently at the knee and rarely at the wrist and ankle (Neame *et al.*, 2004; Oliveria *et al.*, 1995). Potential reasons for the site specificity of osteoarthritis include structural and metabolic differences of biological tissues between joints, for instance the higher content of proteoglycans and water in cartilage and decreased catabolic and increased anabolic activity of chondrocytes at the ankle compared to the knee (Kuettner and Cole, 2005). However, co-occurrence of hand and knee osteoarthritis

in the same patient (Englund *et al.*, 2004) suggests that not only local joint-specific biological and mechanical factors, but also global factors such as hereditary and environmental factors affecting the entire organism, may play a role in the development of osteoarthritis.

#### *Cost to society*

Costs to the American society associated with osteoarthritis currently exceed 80 billion dollars per year (National Institute of Arthritis, 2003). This number will increase with the increase in life expectancy and with the rapid aging of the population, especially as the baby-boomers will reach the age of 60 years within the next two decades and thus will be at greater risk of developing osteoarthritis. Currently, osteoarthritis is the sixth fastest growing disease in the United States (Forbers, 2005). Approximately two-thirds of the costs associated with osteoarthritis are indirect costs due to work loss and work disability payments (for review see Dunlop *et al.* (2003)).

### THE COMPLEXITY OF OSTEOARTHRITIS

The complexity of understanding osteoarthritis is well illustrated by considering the conflicting conclusions that can be drawn from clinical and laboratory reports on the relative influence of mechanical factors on the progression of degenerative changes to the articular cartilage at the knee. For example, experimental and theoretical studies suggest that load can produce an adaptive response (thickening, enhanced mechanical properties, etc.) (Carter *et al.*, 1998; Carter and Wong, 2003) of cartilage. In contrast, clinical studies report that patients with knee osteoarthritis and higher loads at the knee during walking have a more rapid rate of cartilage breakdown than patients with lower loads (Miyazaki *et al.*, 2002; Prodromos *et al.*, 1985). Clearly, the conclusion that cartilage responds positively to increased load is in conflict with clinical observations that increased load stimulates more rapid breakdown of articular cartilage. As will be discussed later, it appears that the cartilage response to load is dependent on the health of the cartilage.

*In vivo* studies can provide an integrated approach that consolidates the multiple pathways associated with the cause and progression of osteoarthritis. Gait analysis, quantitative magnetic resonance imaging (MRI), and assays of biomarkers provide methods to evaluate a framework for understanding the interrelationship between the factors that influence the progression of osteoarthritis (see Figure 77.1).

The purpose of this chapter is to describe an integrated view of the *in vivo* pathomechanics of osteoarthritis associated with aging. The material is based on studies of assays of biomarkers, cartilage morphology (quantitative MRI), and human function (gait analysis).

## Cartilage Mechanobiology, Osteoarthritis, and Aging

The structure and function of articular cartilage are maintained by the metabolic activity of chondrocytes, the cells in cartilage. The chondrocytes are embedded in a highly structured avascular extracellular matrix. The extracellular matrix is made up of structural proteins including collagen, proteoglycans, other proteins, peptides, and water.

Type II collagen fibrils form a network within the tissue with different primary fiber orientation in the deep zone (closest to bone), transitional zone, middle zone, and superficial zone (closest to cartilage surface) (see Figure 77.2). The zones contain different collagen organization as well as different amounts of proteoglycans. The collagen fibers are responsible for the tensile strength of cartilage and are surrounded by the matrix that primarily consists of water. Proteoglycans are responsible for the compressive strength, are arranged within the collagen network, and attract water. Other proteins and peptides, including growth

factors, cytokines, and metalloproteinases, are responsible for tissue growth, communication between chondrocytes, and regulation of anabolic and catabolic processes.

The early stages of osteoarthritis are associated with fraying and fibrillation of the superficial layer of cartilage (see Figure 77.3) and there is a reduction of chondrocytes in superficial zones. The cartilage matrix loses proteoglycans, and in the later stages capillary buds penetrate the layer of calcified cartilage. The pain associated with osteoarthritis is associated with synovial hypertrophy creating increased intra-articular pressure and producing joint pain.

### CELL METABOLISM

Biological tissues undergo significant changes during the aging process. The metabolic response of chondrocytes changes with aging. For instance, with increasing age, articular cartilage chondrocytes become less responsive to anabolic cytokines (Martin and Buckwalter, 2000) presumably leading to reduced synthetic capacity (DeGroot *et al.*, 1999) and activity (Bolton *et al.*, 1999) of chondrocytes. Due to these changes in cell metabolism, the size of water-attracting proteoglycan aggregates decreases (Buckwalter *et al.*, 1994), and consequently the water content also decreases with age (Venn, 1978). In contrast, collagen molecules have an extremely long half-life (>200 years; Maroudas *et al.* (1992)), and the total amount of collagen in cartilage does not decrease with age (Venn, 1978). However, with age, increasing numbers of cross-links between molecules form by nonenzymatic glycation (Bank *et al.*, 1998).

The biological changes in cartilage with aging may be the cause for the overall altered mechanical properties of the tissue such as decreased tensile stiffness and strength (Kempson, 1982). Articular cartilage aging does not cause osteoarthritis, but the age-related metabolic and phenotypic decline of the chondrocytes increases the risk of articular cartilage degeneration and limits the ability of the cell to repair the tissue once degenerative changes occur (Martin and Buckwalter, 2002). Similar changes have been observed in menisci (McAlinden *et al.*, 2001) and ligaments (Noyes and Grood, 1976; Woo *et al.*, 1991).

In contrast to the natural aging process, osteoarthritis is associated with a prominent regenerative and reparative activity. More specifically, osteoarthritis is characterized by increased cell activity and cell proliferation, but also by hypertrophy and erosion of the tissue, focal defects, pericellular degradation and interterritorial matrix degradation, nonreversible proteoglycan depletion, mild focal superficial inflammation of the synovium, and subchondral remodeling. Cartilage changes in early osteoarthritis include chondrocyte proliferation, surface fibrillation, and perichondral collagen condensation. In advanced osteoarthritis, fissures extend to the midzone,

**Figure 77.2** Cartilage can be organized into four zones from a functional viewpoint.

The **Superficial Tangential Zone** is the thinnest layer, with the highest content of collagen and the lowest concentration of proteoglycans; contains flat chondrocytes and collagen fibers arranged tangentially to the articular surface; has greatest ability to resist shear stresses and serves as a gliding surface for the joint; limits passage of large molecules between synovial fluid and cartilage; *the first to show changes of osteoarthritis.*

The **Transition Zone** is composed almost entirely of proteoglycans and spherical chondrocytes; this zone involves the transition between the shearing forces of the surface layer to compression forces in the deeper cartilage layers.

The **Deep Zone** is the largest part of the articular cartilage. It contains elongated chondrocytes and collagen fibers aligned perpendicular to the subchondral plate; this zone distributes loads and resists compression.

The **Calcified Cartilage Zone** separates hyaline cartilage from subchondral bone; contains mainly type X collagen in the calcified cartilage layer and in hypertrophic zone of the growth plate; *capillary buds penetrate the layer of calcified cartilage as osteoarthritis progresses.*

## 77. A Model for Understanding the Pathomechanics of Osteoarthritis in Aging

**Figure 77.3** Illustration of the changes to the superficial zone of cartilage during the progression of osteoarthritis (OA). **A.** Normal cartilage shows a smooth surface; the early stage of OA is characterized by **B.** flaking of the surface; **C.** fibrillation; and **D.** the formation of a blister. The mechanical surface changes will increase the coefficient of friction at the surface. From Gannon and Sokoloff (1999).

the matrix delaminates and erodes, fibrosis can be observed, and fibrocartilage is formed as a repair response (Pritzker, 2003).

### BIOMARKERS FOR OSTEOARTHRITIS

*In vivo* assessment of degenerative biological changes to cartilage can be evaluated by assays of enzymes, enzyme-inhibitors, and protein fragments, generically termed biological markers or biomarkers. Biomarkers have the potential to become indicators of normal biological processes, pathogenic processes, or pharmacologic response to a therapeutic intervention.

The *in vivo* physical and biological environment must be considered together when evaluating biomarkers (see Figure 77.1). Cartilage oligomeric matrix protein (COMP), a prominent constituent of articular cartilage, is up-regulated following cyclical compression *in situ* and may play an important role in transducing mechanical forces in the extracellular matrix to the cell (Wong *et al.*, 1999). For example, competing marathon runners whose joints are exposed to repetitive loading during frequent running training and competition have elevated serum COMP concentrations compared to healthy control subjects (Neidhart *et al.*, 2000). In another study (Mündermann *et al.*, 2005; Mündermann *et al.*, 2004), reduced COMP levels were associated with the adduction moment at the knee, suggesting that mechanical variations in the way individuals perform the same activity are related to the differences in the cartilage COMP levels. In contrast, keratan sulfate, a biomarker reflecting the rate of cartilage catabolism (Thonar *et al.*, 1985), did not significantly change in 15 marathon runners before, immediately after, and 48 hours after the completion of a training marathon (Sweet *et al.*, 1992). Thus, these

data suggest that with careful and regular training, running a marathon appears not to increase the rate of degradation of articular cartilage. Changes in COMP and keratan sulfate concentrations suggest that although exercise may not lead to an acute degenerative response of major cartilage constituents including chondrocytes, proteoglycans, and collagen, other constituents such as COMP may be adversely affected.

In osteoarthritic cartilage, the sensitive equilibrium between tissue degeneration and synthesis is disrupted and degenerative processes preponderate. Fragments of proteoglycans or proteins (glucosaminoglycan and COMP) and catabolic and other enzymes, as well as their inhibitors (metalloproteinases, interleukin-1, interleukin-1 receptor antagonist) found in body fluids, may reflect net cartilage degeneration or increased metabolic activity (Otterness *et al.*, 2001).

Quantifying blood serum concentrations of biomarkers is a promising yet minimally invasive tool to investigate the tissue's response to mechanical load *in vivo*. To date, very little is known about changes in biomarker concentrations that occur in relation to loads placed upon the joint during everyday activities (Mündermann *et al.*, 2005; Mündermann *et al.*, 2004). Similar physical activities may promote tissue synthesis in the healthy joint while accelerating degenerative processes in the osteoarthritic joint.

There are still substantial gaps in our ability to interpret the relationships between changes in biomarkers and the loading environment of cartilage. Specificity of the marker to cartilage and the joint of interest always remains a question in studies where markers are extracted from serum. In addition, controlling for the influence of chronic versus transient loads also is an important consideration. Thus, there is a need for

further research in this area to define and identify the role of biomarkers in the evaluation of knee osteoarthritis.

### Joint Structure, Osteoarthritis, and Aging

The normal function of diarthrodial joints such as the knee involves providing a wide range of mobility while sustaining large forces that are multiples of the body's weight. For example, normal function of the knee during stair climbing requires the knee to flex in the range between 0 and 90 degrees while sustaining compressive forces on the articular surface that can exceed four times body weight. As previously discussed, the biology of cartilage is influenced by the mechanical environment of the joint. Thus, the intrinsic mechanical environment (force and motion) is an important consideration in the context of understanding the factors that influence the initiation and progression of osteoarthritis. The intrinsic forces and motions at the joint are dependent on complex interactions between the shape of the articulating surfaces, passive soft tissue properties surrounding the joints, and active muscle contraction. Thus, individual anatomical variations in joint anatomy that influence joint movement or the forces on the joint can influence the mechanobiology of the articular cartilage and ultimately play a role in the factors associated with the progression of osteoarthritis. For example, the association of joint laxity with osteoarthritis at the knee will be discussed in the next sections of this chapter.

#### JOINT LAXITY AND OSTEOARTHRITIS

Passive (no muscle contraction) joint laxity is dependent on the conformity of the articular geometry, the properties of the ligaments, menisci (at the knee), and the

capsule at the joint. Any changes in the mechanical properties of these structures, whether they occur with aging, disease, or following a joint injury, will have an effect on this mechanical environment. For instance, joint laxity appears to be critically important for the health of a joint (Sharma *et al.*, 1999). Joint laxity can produce large displacements of the articular surfaces, alter congruity and contact sites, and increase local shear and compressive stresses. Joint laxity depends on several factors including the mechanical properties of ligaments and muscle strength and coordination (see Figure 77.4).

The knee, a common site of osteoarthritis, provides a good illustration of the primary components of the joint that maintain joint stability and thus influence joint laxity. The major ligaments stabilizing the knee in translation and rotation are the anterior (ACL) and posterior (PCL) cruciate ligaments. The stiffness and elastic modulus of these ligaments decrease with age (Noyes and Grood, 1976; Woo *et al.*, 1991). The major changes in muscle with age include reduced muscle activation (Stackhouse *et al.*, 2001; Stevens *et al.*, 2003), cross-sectional area (Frontera *et al.*, 2000; Jubrias *et al.*, 1997; Kent-Braun and Alexander, 1999), force per cross-sectional area (Jubrias *et al.*, 1997), and maximum muscle strength (Frontera *et al.*, 2000; Jubrias *et al.*, 1997; Lindle *et al.*, 1997). These age-associated changes in the properties of ligaments and muscle can cause increased joint laxity with age.

Active muscle contraction plays an important role in the dynamic stability of the joint during functional activities such as walking. As illustrated in Figure 77.4, the lateral stability (resistance to lateral joint opening) is dependent on the tension in passive soft tissue (lateral collateral ligament) and active muscle force producing a moment (tendency of a force to produce a rotation) resisting the extrinsic moment tending to adduct the

**Figure 77.4** This diagram of the knee illustrates how stability of the joint is maintained by passive ligament forces and active muscle contraction. In this example, the passive ligament force in the lateral collateral ligament and the active force generated by the quadriceps muscle resist a moment tending to create lateral joint opening (A). Loss of passive stiffness of the ligament and/or a reduction in muscle force can result in a pathological condition where the joint opens laterally, transferring the entire load to a single compartment of the knee (B). Both ligament stiffness and muscle control of the joint decline with aging.

tibia. If the passive soft tissue and muscle forces do not balance the extrinsic moment tending to adduct the knee, then the lateral side of the knee will open and all the force at the knee will be transferred across the medial side of the knee. This condition will potentially overload the medial compartment of the knee and is likely one of the reasons that patients with increased laxity are at higher risk for knee osteoarthritis. As will be discussed later in this chapter, there is a large extrinsic moment that tends to adduct the knee during the stance phase of gait.

The importance of muscle force in the development of osteoarthritis during aging is illustrated by the fact that muscle function and strength decline with aging. Patients with knee osteoarthritis experience changes in their muscle strength and coordination that are independent of the aging process. For instance, activity of the vastus lateralis muscle relative to maximal vastus lateralis muscle activity is much greater in patients with knee osteoarthritis compared to age-matched controls and young adults (Hortobagyi *et al.*, 2005). Decreased quadriceps muscle strength per muscle mass suggests that osteoarthritis patients experience muscle inhibition due to altered afferent input from the diseased joint and consequent reduction in efferent motor neuron stimulation of the quadriceps muscle (Slemenda *et al.*, 1997). In addition, medial compartment knee osteoarthritis is associated with a greater loss of cartilage in the medial compared to the lateral compartment of the knee, and leads to increasing varus alignment with increasing severity (Mündermann *et al.*, 2004). These age-independent changes in muscle properties and cartilage morphology likely contribute to a further increase in joint laxity in patients with knee osteoarthritis.

Menopause may accelerate the loss of muscle mass and result in decreased muscle performance and functional capacity (Sipila, 2003). Although differences in ligament properties between men and women are unknown, ACL stiffness does correlate with estrogen and progesterone levels (Romani *et al.*, 2003), and estrogen levels are lower in postmenopausal women. Probably resulting from these differences in ligament and muscle properties, even healthy women have greater varus-valgus laxity than healthy men (Sharma *et al.*, 1999), potentially contributing to the higher incidence of osteoarthritis in women after menopause. Thus the increased incidence of osteoarthritis in postmenopausal women is likely related to increased passive and dynamic laxity of the joint.

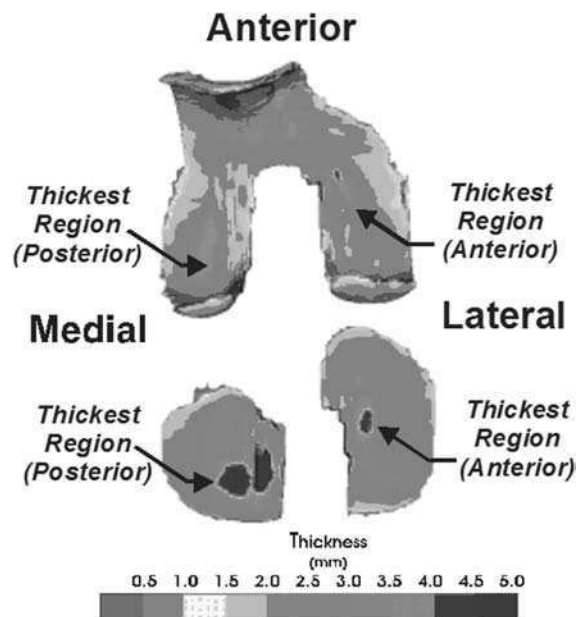

### CARTILAGE MORPHOLOGY

Cartilage will structurally adapt to joint loading (Arokoski *et al.*, 2000). As previously noted, cartilage adaptation to loading has been well studied from an experimental and theoretical viewpoint. However, *in vivo* assessment of cartilage adaptation to joint loading has

been limited by the availability of methods to evaluate *in vivo* changes in cartilage. MRI-based techniques are useful for evaluating *in vivo* quantitative morphological characteristics of articular cartilage. Typically, three-dimensional models of articular cartilage are assembled from a set of two-dimensional images requiring segmentation of the cartilage. Methods for cartilage segmentation have been extensively studied (Pham *et al.*, 2000; Stammberger *et al.*, 1999).

MR images can be used to examine the thickness variation of cartilage at the knee relative to the type of loads that occur during dynamic activities such as walking. For example, the highest loads at the knee occur at heel strike with the knee near full extension (Schipplein and Andriacchi, 1991). Typically, the thickest regions of the femoral and tibial load-bearing articular cartilage are aligned when the knee is at full extension, suggesting an adaptation to the high loads at heel strike on mating surfaces of the tibiofemoral articulation (see Figure 77.5).

There are several typical qualitative features (Andriacchi *et al.*, 2004) in the variation of tibial and femoral cartilage thickness common to most healthy knees (see Figure 77.5). The tibial cartilage was thicker in the posterior weight-bearing region in the lateral compartment. The femoral condyle cartilage was thicker in the posterior region of the lateral femoral condyle. The tibial cartilage was thicker in the anterior weight-bearing region in the medial compartment. The femoral condyle cartilage was thicker in the anterior region of the medial

**Figure 77.5** The features (proximal viewpoint) of the regional thickness variations of femoral and tibial cartilage (segmented from MRI and color-coded for thickness) were common to all normal subjects. From Andriacchi *et al.* (2004).

femoral condyle. The thickness variation on the tibia mirrored the thickness variation on the femoral condyles in each compartment. For example, thicker posterior cartilage on the lateral femoral condyle was mirrored by thicker cartilage in the posterior region of the tibial cartilage in the lateral compartment.

### ***In vivo* Function, Osteoarthritis, and Aging**

As noted earlier, the mechanical environment of the cartilage is influenced by the intrinsic anatomy of the joint. The extrinsic loading (e.g., weight and inertia) during dynamic activities such as walking can also have a profound influence on the health of articular cartilage. For example, it has been shown (Schipplein and Andriacchi, 1991) that individual variations in the way people walk can influence the distribution of load between the medial and lateral compartments of the knee. Specifically the adduction moment at the knee during walking (*adduction moment*—the tendency of the external forces acting on the lower limb to produce adduction of the knee) causes higher forces to be transmitted to the medial side of the knee (see Figure 77.6).

#### **Knee Adduction Moment during Gait and Medial-Lateral Joint Loading**

**Figure 77.6** The knee adduction moment during walking could be related to the distribution of medial and lateral loads across the knee.

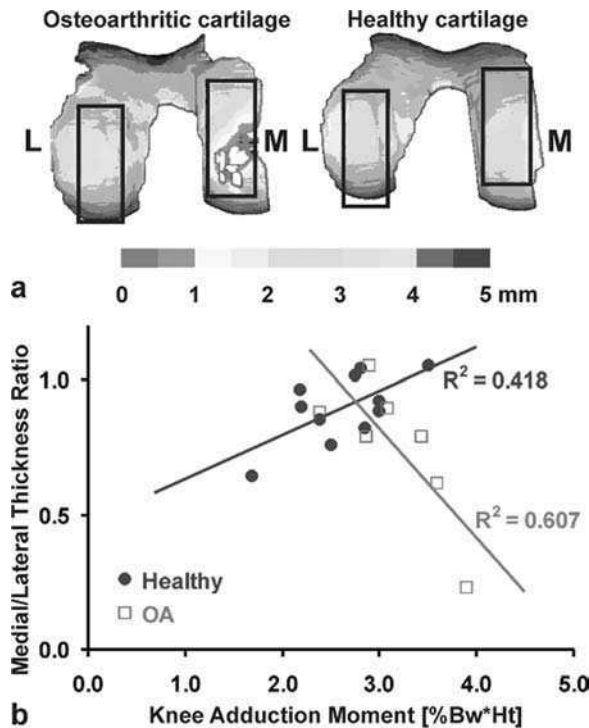

It has been shown (Hurwitz *et al.*, 1998) that the knee adduction moment during gait is positively correlated with the distribution of medial and lateral bone mineral content and is the best single predictor of the medial-to-lateral ratio of proximal bone mineral content. Thus, the higher the knee adduction moment, the greater the load on the medial plateau relative to that of the lateral plateau and the higher the bone mineral content in the proximal tibia under the medial plateau as compared to that under the lateral plateau. Consequently, variation in walking mechanics can influence the load sustained by cartilage *in vivo* and has the potential to influence the health and pathomechanics of articular cartilage.

#### **LOAD INFLUENCES HEALTHY CARTILAGE AND CARTILAGE WITH OSTEOARTHRITIS DIFFERENTLY**

A recent study (Andriacchi *et al.*, 2004) examined the relationship between loading and motion at the knee during walking and the response in healthy cartilage relative to cartilage with osteoarthritis. Healthy cartilage thickness increased on the medial condyle in subjects with a higher adduction moment based on a significant ( $P < 0.05$ ) positive correlation between the ratio of medial to lateral condyle thickness and adduction moment (see Figure 77.7). In contrast, for osteoarthritic cartilage, the medial to lateral condyle thickness ratio decreased with an increase in the adduction moment.

In patients with knee osteoarthritis, it has been shown that individual variations in the mechanics of walking can influence the rate of progression of knee osteoarthritis (Miyazaki *et al.*, 2002) and the outcome of treatment for medial compartment osteoarthritis at the knee (Prodromos *et al.*, 1985; Wang *et al.*, 1990). For example, varus alignment of the knee has been related to the presence and progression of medial compartment knee osteoarthritis. This type of alignment theoretically would place higher load on the medial side of the knee. A surgical procedure, the high tibial osteotomy (HTO), involves realigning the tibial plateau to reduce the load on the medial compartment of the knee. Patients who adopt a gait pattern with a low adduction moment following surgery and patients with less severe disease have a better outcome with an HTO and a slower rate of disease progression (Prodromos *et al.*, 1985; Wang *et al.*, 1990).

Patients with knee osteoarthritis typically walk with greater knee adduction moments than age-matched control subjects (Mündermann *et al.*, 2004), which is also a strong predictor for the presence (Baliunas *et al.*, 2002; Gök *et al.*, 2002; Schnitzer *et al.*, 1993), severity (Mündermann *et al.*, 2004; Sharma *et al.*, 1998), and rate of progression (Miyazaki *et al.*, 2002) of medial compartment knee osteoarthritis. In addition, patients with knee osteoarthritis seem to experience a smaller range of knee flexion during the stance phase of walking (Childs *et al.*, 2004; Kaufman *et al.*, 2001; Messier *et al.*,

**Figure 77.7** Femoral cartilage thickness increases with load for healthy cartilage and decreases with load for cartilage with osteoarthritis (OA). **a.** The load bearing regions of interest (ROI) are indicated by the rectangular areas shown on the color thickness map of the femoral cartilage. **b.** The medial-to-lateral ratio of the average ROI thickness was correlated to the adduction moment normalized as percentage body weight times height (%Bw\*Ht) for an osteoarthritic group and a healthy group.

1992) that is associated with a smaller net quadriceps moment (Kaufman *et al.*, 2001).

As previously noted, the adduction moment at the knee has been related to the progression and treatment outcome for medial compartment osteoarthritis at the knee. In a recent study (Mündermann *et al.*, 2004) of 44 patients (88 knees) with osteoarthritis of the medial compartment of the knee, it was shown that the adduction moment at the knee during walking was significantly lower in patients with less severe disease. Severity of the disease was assessed by a clinical rating system reported by Kellgren and Lawrence (K-L) (Kellgren and Lawrence, 1963). Patients were diagnosed to have knee osteoarthritis in one or both knee joints based on clinical, radiographic data, and K-L grades ranged from 1 to 4 (most severe) for both knees. A statistically significant increase in knee adduction moment was found for knees with K-L grade 3 or 4 compared to asymptomatic matched control knees ( $P = 0.039$ ) and for knees with K-L grade 3 or 4 compared to knees with K-L grade equal to or smaller than 2. In addition, the mechanical axis varus alignment was significantly greater in patients with more severe osteoarthritis.

These results suggest that differences in the adduction moment are less likely the initial cause for osteoarthritis, but rather the effect of morphological changes in the pathological joint such as medial compartment joint space narrowing. This increase in adduction moment at later stages of osteoarthritis may lead to an accelerated rate of disease progression. Some patients may be able to alter their walking mechanics to reduce their maximum knee adduction moment at very early stages of the disease and reduce the rate of progression. This explanation is supported by the fact that patients with less severe knee osteoarthritis appear to have different gait mechanics than asymptomatic control subjects and are able to reduce the adduction moment by walking slower during everyday activities.

The primary changes in gait that occur with increasing age are slower walking speeds, reduced step length, and increased double support time (Kerrigan *et al.*, 1998; Riley *et al.*, 2001; Winter *et al.*, 1990). It has been suggested (DeVita and Hortobágyi, 2000) that age causes a redistribution of joint torques and powers, with the elderly using their hip extensors more and their knee extensors and ankle plantar flexors less than young adults when walking at the same speed. This shift in power generation could be caused by the physiological changes in muscle (Frontera *et al.*, 2000; Jubrias *et al.*, 1997; Kent-Braun and Alexander, 1999; Lindle *et al.*, 1997; Stackhouse *et al.*, 2001; Stevens *et al.*, 2003), where the knee extensor muscles in the elderly are simply not capable of producing similar forces than in young adults.

## FUNCTIONAL KINEMATICS DURING WALKING AND OSTEOARTHRITIS

As previously discussed, functional joint loading can influence the health of articular cartilage and is ultimately associated with the progression of degenerative changes to cartilage. In addition, joint motion (kinematics) can influence the initiation of osteoarthritis (Andriacchi *et al.*, 2004). For example, the anterior cruciate ligament (ACL) of the knee, one of the four major ligaments of the knee, provides translational and rotational stability to the joint. The ACL frequently is injured during sporting activity and is the most frequently reconstructed soft-tissue structure at the knee. The ACL-deficient knee provides a basis for examining the influence of abnormal kinematics on the initiation of knee osteoarthritis. There are numerous clinical studies (Buckland-Wright *et al.*, 2000; Daniel *et al.*, 1994; Lohmander and Roos, 1994; Roos *et al.*, 1995) that report premature knee osteoarthritis in chronic ACL-deficient knees and even in knees following reconstruction. Even though ACL reconstruction does restore anterior-posterior stability (Daniel *et al.*, 1994), it has not been documented that ACL reconstruction restores normal rotational alignment and motion to the knee, suggesting the possibility that rotational changes following ACL injury could be a

factor in the initiation of knee osteoarthritis following ACL injury (Kanamori *et al.*, 2002; Ma *et al.*, 2000).

Studies of patient function (Andriacchi and Dyrby, 2005; Georgoulis *et al.*, 2003; Vergis and Gillquist, 1998) following ACL injury support the observation that rotational changes following ACL injury are a major factor in the progression of knee osteoarthritis. In particular, a recent study (Andriacchi and Dyrby, 2005) demonstrated that ACL-deficient patients did not have an increased range of AP motion relative to the contralateral side. However, there was an offset in internal-external (IE) rotation position relative to the contralateral limb. The offset was determined from the temporal average of all IE values over the entire walking cycle. The tibia was more internally rotated throughout stance phase than in healthy control subjects. The fact that the rotational offset was also present at the end of swing phase where the tibia normally externally rotates with knee extension (screw-home movement) suggests that the loss of the ACL causes a reduction of the internal rotation of the tibia at the end of swing phase. This rotational offset is maintained through the stance phase of the walking cycle.

A positional offset shifts the load bearing contact areas of the knee away from normal locations. The change in the rotational characteristics at the knee could cause specific regions of the cartilage to be loaded that were not loaded prior to the ACL injury. It has been suggested (Bullough *et al.*, 1992; Yao and Seedhom, 1993) that the altered contact mechanics in the newly loaded regions could produce local degenerative changes to the articular cartilage. As previously reported (Bullough *et al.*, 1992; Wong *et al.*, 1999), cartilage in highly loaded areas has mechanically adapted relative to underused areas where signs of fibrillation can be observed in healthy knees in relatively young subjects. It has been suggested (Andriacchi *et al.*, 2004) that a spatial shift in the contact region could place loads on a region of cartilage that may not adapt to the rapidly increased load initiating degenerative changes (Wu *et al.*, 2000). It is important to note that other studies (Kvist and Gillquist, 2001) have demonstrated a shift in the anterior-posterior position of the tibial femoral contact during walking after loss of the ACL. Thus, it is likely that ACL injury causes a shift in the load bearing location through a combination of rotational and translational changes in the normal kinematics of the joint.

Clinical and laboratory studies (Cicuttini *et al.*, 2002; Wu *et al.*, 2000) have suggested that changes in contact position could be a factor in the degenerative changes, even in knees with an intact ACL. In particular, rotational malalignment has been related to an increased incidence of knee osteoarthritis (Nagao *et al.*, 1998; Yagi, 1994). A shift in the load bearing area to an infrequently loaded region would cause articular surface damage and increase fibrillation of the collagen network and lead to the degenerative changes that have been associated with increased clinical laxity.

The preceding observation for the ACL-deficient knee can be related to the changes to the musculoskeletal system that occur with aging. In particular, ligament stiffness (Noyes and Grood, 1976; Woo *et al.*, 1991), muscle strength (Jubrias *et al.*, 1997), and muscle activation (Stackhouse *et al.*, 2001) decline with aging. The decline in passive joint stability derived from ligament restraint and dynamic stability derived from muscle forces can cause abnormal kinematics that increase with age. These kinematic changes will lead to a shift in the normal load bearing regions in a manner similar to the kinematic changes following ACL injury. Hormonal changes that occur with menopause produce similar changes (Phillips *et al.*, 1993; Rasanen and Messner, 1999; Richette *et al.*, 2003) to those described for aging and could explain the increased incidence of knee osteoarthritis reported in women over the age of 50 (Oliveria *et al.*, 1995). In addition, aging (Buckwalter *et al.*, 1994) and hormonal (Rasanen and Messner, 1999) changes can limit the ability of cartilage to adapt and repair (Martin and Buckwalter, 2000) cartilage damage associated with changes in load bearing regions. Chronic kinematic changes with aging and menopause can cause degenerative changes to cartilage, since older cartilage might not have the capacity to adapt to load bearing changes in contrast to younger cartilage.

## Conclusion

The progression of osteoarthritis with aging is best understood by considering the interrelated biological, morphological, and neuromuscular pathways associated with the disease. The interrelationship or coupling of these pathways converges at an *in vivo* systems level in humans. Each of these pathways changes with aging in ways that increase the risk of osteoarthritis.

The material presented in this chapter provides an integrated *in vivo* framework for understanding the various factors that influence the initiation and progression of osteoarthritis that is consistent with theoretical, laboratory, and clinical observations of the pathomechanics of osteoarthritis. This framework provides a basis for explaining the role of kinematics and load on the progression of knee osteoarthritis. Although this framework was developed from an analysis of *in vivo* pathomechanics, it also explains how the convergence of biological, morphological, and neuromuscular changes to the musculoskeletal system during aging or during menopause leads to the increased rate of idiopathic osteoarthritis with aging.

The *in vivo* framework presented should be helpful for the interpretation of laboratory experiments, the identification of risk factors for knee osteoarthritis, and the development of methods for the evaluation of osteoarthritis at the knee.

# Aging and Cardiovascular Angiogenesis Models

Andrew Chin, Jacquelyne M. Holm, Inga J. Duignan, and Jay M. Edelberg

*The development of new strategies to reduce the impact of heart disease in the aging population is an increasingly important public health issue. Indeed, although present clinical therapies have reduced the overall prevalence of cardiovascular disease (Hansson et al., 1999; Yusuf et al., 2000; Volpe et al., 2005), myocardial infarction and congestive heart failure remain the most significant cause of morbidity and mortality in older individuals (Black, 2003; Oxenham et al., 2003; Stewart et al., 2003). To this end, recent studies, primarily in rodent models, suggest that impairment in cardiac angiogenesis may predispose the aging heart to more severe pathophysiology and lead to the worst clinical outcomes observed in the geriatric population. This chapter aims to review integrated methodological approaches to aid in the investigation of senescent cardiac angiogenesis in order to facilitate further studies into the basic biological changes underlying the age-associated alterations in cardiac angiogenic regulation and potentially enhance the preclinical testing of novel therapeutic approaches based on such discoveries.*

## Introduction

Previous studies have identified age-associated changes in the heart that may serve as potential targets to reverse the geriatric predisposition to more severe cardiovascular pathology. Specifically, age-associated changes in cardiac growth factor expression, vascular wall composition, free radical production, and shifts in apoptotic pathways may contribute to increased cardiac damage after coronary artery occlusion in the older heart. Indeed, experimental strategies based on these findings may offer potential therapeutic approaches to diminish the overall impact of cardiovascular disease in the aging population.

To fully understand the impact of the age-related changes in cardiac angiogenesis, *in vivo* models are required. It is essential that preclinical development of therapies based on these biological changes with aging be fully tested in age-appropriate models of cardiovascular disease in order to increase the translational potential of treatment of older persons. Based on the

importance of rodent models in the basic investigation of the biology of aging in the cardiovascular system, as well as the utility of mice and, to a lesser extent, rats in models of human pathophysiology, this review will aim to summarize *in vivo* models of cardiac angiogenesis, including models of cardiovascular disease and interventional protocols.

## Cardiac Angiogenesis: Identification of Biological Changes

Aging is associated with significant alterations at multiple levels of cell regulation, including growth factor expression, receptor signaling, and cell migration. Previous studies employing a spectrum of molecular, cellular, and physiological approaches have demonstrated that alterations in vascular growth factor pathways (Edelberg *et al.*, 2002b; Xaymardan *et al.*, 2004b) result in endothelial cellular dysfunction (Rivard *et al.*, 1999; Cai *et al.*, 2003) and impaired angiogenesis (Nakae *et al.*, 2000; Shimada *et al.*, 2004), which may underlie the senescent predisposition to increased vascular disease in the aging heart. To this end, endothelial dysfunction is one of the most important risk factors for cardiovascular disease in the general population (Widlansky *et al.*, 2003), and its impact is heightened with age. Physiologically, vascular endothelial growth factor–nitric oxide (NO) pathways, which play a central role in endothelial-mediated vasodilation, are impaired with aging (Berkowitz *et al.*, 2003) and may result in increased myocardial injury after coronary occlusion compared to younger hearts. In the heart episodes of cardiac tissue hypoxia caused by transient coronary occlusion induce vasodilatory actions that result in cardioprotection in the young rodent heart (Rochetaing *et al.*, 2003). In the aged heart, this ischemic preconditioning can be significantly depressed (Abete *et al.*, 1997; Tani *et al.*, 1999; Fenton *et al.*, 2000). Beyond changes in vascular endothelial growth factor (VEGF) (Rivard *et al.*, 1999), experimental models have demonstrated impairments in the expression and function of angiogenic factors including basic fibroblast growth factor (b-FGF) (Augustin-Voss *et al.*, 1993;

Garfinkel *et al.*, 1996), transforming growth factor beta (TGF- $\beta$ ) (Reed *et al.*, 1998), and platelet-derived growth factor (PDGF) (Sarzani *et al.*, 1991; Edelberg *et al.*, 2002b; Cai *et al.*, 2003) with aging, suggesting that strategies directed at these and other senescent changes may restore angiogenic pathways in the aging heart and may have clinical utility in conjunction with present reperfusion therapies.

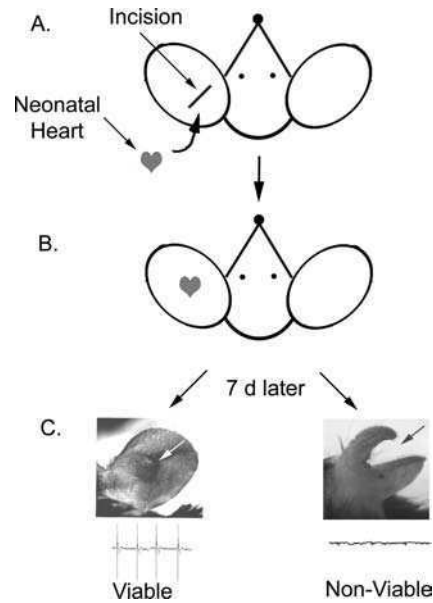

## Candidate Testing

Angiogenesis is a dynamic process that requires inductive models to investigate the biological significance of potential regulatory mechanisms. Hence, although characterization of age-related differences in angiogenic components can facilitate the discovery of the potential mechanisms underlying the senescent impairment in cardiac angiogenesis, the *in vivo* significance of these findings can only be elucidated through interventions to modulate angiogenic induction. To this end, models testing angiogenic growth factors such as VEGF (Ferrara, 2001), bFGF (Yanagisawa-Miwa *et al.*, 1992; Harada *et al.*, 1994), and PDGF (Edelberg *et al.*, 2002b) have been shown to induce angiogenesis in the aging vasculature. In the heart, molecular and protein, as well as cell-based approaches, have been studied in models aimed at determining the significance of different pathways in senescent cardiac angiogenic impairment.

As investigations continue to develop the understanding of the biological basis of the changes in senescent cardiac angiogenic impairment, studies that employ established *in vivo* approaches to assess the functional impact of age-associated changes in elements and pathways will continue to be required. Unfortunately, the modern tools of genetic engineering do not readily lend themselves to high throughput investigations of aging and cardiac angiogenesis. Indeed, the potential combination of allele targeting and colony aging negates the power of knockout mice as an initial tool to investigate the significance of genes associated with the senescent impairment in cardiac angiogenesis. Thus *in vivo* models employing wild type aged animals can allow the best initial assessment of the potential contribution to candidate genes, proteins, and pathways associated with the biological changes of angiogenesis in the aging heart.

## Cardiac Allograft Assay

In order to more rapidly screen the functional significance of age-associated changes in cardiac angiogenic pathways without the requirement of direct cardiac targeting, a cardiac allograft model of angiogenesis is employed (see Figure 78.1). This model, in which neonatal cardiac tissue is engrafted into the pinnal tissue of various age syngeneic mice, allows for the isolation of age on the angiogenic vasculature (Edelberg *et al.*, 2002b; Edelberg

**Figure 78.1** This cartoon illustrates the neonatal cardiac allograft protocol to understand changes in cardiac angiogenic pathways. **A.** A 3 mm incision is created on the dorsum of the pinna, and a subcutaneous pocket is created 0–24 h after injection of molecular, protein, or cellular treatments. **B.** An explanted neonatal (~24 h) heart is placed into the pocket and excess air is expressed from the pocket to facilitate adherence. **C.** Cardiac allografts are examined 7d post transplantation for visual viability and electrical activity.

*et al.*, 2002) while controlling the age of the myocardium. Indeed, in the transplants, allograft neovascularization is mediated by host endothelial cells recruited into the donor hearts that recapitulate the cardiac myocyte-endothelial cell communication *in vivo* (Edelberg *et al.*, 2002b; Aird *et al.*, 1997), thus allowing the direct comparison of cardiac angiogenic potential in different age groups. Moreover, this model supports the testing of both molecular and cell-based interventions to modulate or restore functional cardiac angiogenesis *in vivo*. Indeed, the result of these studies are highly predictive of the functional role of different strategies in more clinically relevant models, including myocardial infarction studies (see Table 78.1), and thus provides a reasonable throughput screening approach in the investigation of cardiac angiogenesis in the aging rodent.

## PINNAL ALLOGRAFT TRANSPLANT

A 3 mm incision is made on the dorsum of the pinna in senescent murine hosts, and curved forceps are delicately used to create a subcutaneous pocket (5 × 3 mm). Neonatal hearts are explanted from decapitated 1 d old pups and transplanted into the dorsum of the pinna of an isogenic adult murine host as previously described (Edelberg *et al.*, 2002; Xaymardan *et al.*, 2004b). The donor cardiac tissue is prepared by harvesting the heart without the pericardial sac from syngeneic neonatal (1 d)

## 78. Aging and Cardiovascular Angiogenic Models

TABLE 78.1  
Predictive value of cardiac allograft model in cardioprotection

Age	Treatment	Cardiac Allograft	Cardioprotection in the Endogenous Heart	Reference
	Pretreatment			
Young	PDGF-AB	Enhance Blood Flow	+++	Edelberg <i>et al.</i> (2002a and b)
Old	PDGF-AB	Restoration of Engraftment	++	Edelberg <i>et al.</i> (2002b); Cai <i>et al.</i> (2003)
Young	TNF- $\alpha$	Lipid Peroxidation	+++	Cai <i>et al.</i> (2003); Edelberg <i>et al.</i> (2004)
Old	TNF- $\alpha$	Significant Lipid Peroxidation	↑ Mortality	Cai <i>et al.</i> (2003); Edelberg <i>et al.</i> (2004)
	Acute Treatment			
Old	PDGF-AB	Failure to Restore	↑ Myocardial Infarction/Apoptosis	Edelberg <i>et al.</i> (2002)
Old	PDGF-AB, VEGF, and Ang-2	Restoration of Engraftment	+++	Xaymardan <i>et al.</i> (2004b)

mice. This tissue is engrafted into the 5 × 3 mm subcutaneous pocket, and gentle pressure is applied with the tips of the forceps to express air from the pocket and facilitate the adherence between donor and recipient tissues. Engraftment viability is scored 7 d post transplantation via tissue integrity, electrocardiographic (ECG) activity, and blood flow.

To measure the effects of specific angiogenic pathways, the host transplantation site can be treated with molecular, protein, or cellular combinations. Specifically, the murine pinnae can be treated with up to 20  $\mu$ l of injective either before or at the time of allograft transplantation (through a 30 G × 8 mm needle injected subdermally). In addition, the effects of remote treatments such as contralateral injections or systematic manipulations, including bone marrow transplantation, can be tested in this model.

### Assessment protocols

The host ears are grossly analyzed 7 d post transplantation for viability. One qualitative method used to assess viability is transplant integrity. Ears that exhibit intact, healthy tissue are scored as viable, whereas any signs of tissue degradation, inflammation, or necrosis are scored as nonviable (see Figure 78.1).

Local ECGs can be employed to confirm cardiac allograft viability. Specifically, ECGs are acquired via pinnal electrodes to measure allograft activity with 500 Hz sampling, band pass filtered between 3.0 and 100 Hz, and notch filtered at 60.0 Hz, amplified 1000 $\times$ . Limb electrodes are placed to record the endogenous heart simultaneously to control for field effect.

Functional blood flow to the transplanted cardiac tissue can also be assessed by laser Doppler with an

Advance Laser Flowmeter ALF21/2D (Advance, Tokyo) as previously described (Edelberg *et al.*, 2002a). Blood flow measurements are taken at baseline (day 0) and 7 d post transplantation to assess angiogenic activity.

## Endogenous Cardiac Interventions

The physiological significance of these findings in the cardiac allograft model requires confirmation in the endogenous heart. To directly assess the role of various genes/pathways in angiogenesis in the intact heart, murine and rat models provide select advantages and limitations. Specifically, for strategies targeting the wild-type heart, studies employing rats, which have less variability in coronary anatomy as compared with mice, provide a more quantitative model for subsequent myocardial infarction studies. Murine models can provide a more qualitative model in myocardial infarction studies by allowing the use of transgenic animals. Notably, the hearts of both species can be targeted selectively in open interventions to assess the impact of molecular and cellular approaches to alter cardiac angiogenesis.

## SURGICAL APPROACH

### Cardiac access

Both mice and rats can be anesthetized for open cardiac interventions with a cocktail of ketamine (mice, 100 mg/kg; rats, 95 mg/kg) and xylazine (mice, 10 mg/kg; rats, 4 mg/kg). This method of anesthesia requires artificial ventilation with room air (mice, 120–140 breaths/min with a weight adjusted tidal volume of 0.2ml/breath; rats, 90–100 breaths/min with a weight adjusted tidal volume of 1.5–2.0 ml/breath) after endotracheal intubation. Upon performing a left thoracotomy (~4 cm), the

heart can be accessed through a 1 cm incision of the intercostal muscle between the fourth and fifth ribs using rib retractors (mice, 3 cm; rats, 5 cm). The LAD artery is identified as the coronary system branching from the left circumflex just below the left atrial appendage.

#### Cardiac injection

Cardiac angiogenesis can be modulated in different vascular beds of the cardiac myocardium, but the direct access approach facilitates interventions targeted at the anterior wall of the heart. To this end, a strategy based on the positive identification of the LAD is employed to direct the two 25  $\mu$ l injections (30 G  $\times$  8 mm syringe) of treatment (e.g., growth factor, cells, etc.) or vehicle alone is administered 2mm apart on the mid-left anterior ventricular wall (see Figure 78.2). After treatment the lungs are inflated, and the chest wall is closed with a three-layer closure. Sets of animals can then be sacrificed at different time points to histologically quantify cardiac angiogenesis, or be potentially imaged with noninvasive approaches currently being developed as measures of cardiac perfusion.

#### Assessment approach

In the aging heart, both morphometric and immunohistology protocols have been employed in the quantification of angiogenesis. Morphometric studies of perfusion fixed tissue can provide accurate assessment about cardiac capillary density as well as the macrovasculature in the heart (Anversa *et al.*, 1991; Anversa *et al.*, 1994). Immunohistology can differentiate the heterogeneous endothelial cell subpopulations that contribute to cardiac angiogenesis (Edelberg *et al.*, 2002b; Cai *et al.*, 2003;

Xaymardan *et al.*, 2004b). Studies directed at the mid-papillary level in cross sections of the left ventricle provide a direct assessment of the potential actions of local injections directed at the level of the mid LAD.

#### Morphometric studies

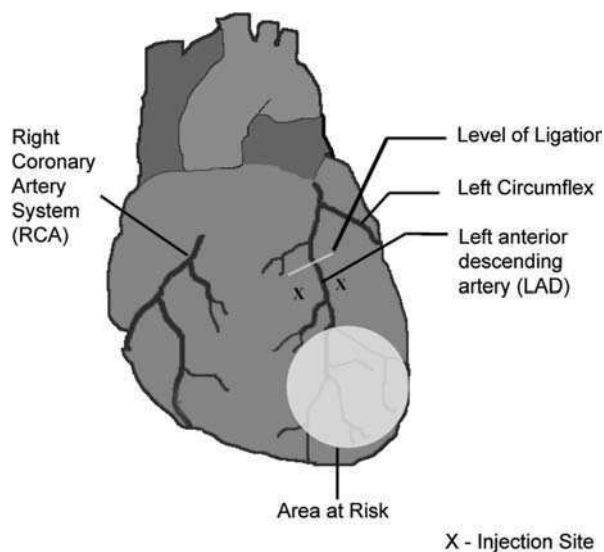

Morphometric analysis employs hearts that are arrested in diastole with cadmium-Cl and cannulation-based perfusion formalin fixation (Li *et al.*, 1997) and allows for the direct assessment of capillary profiles (Anversa *et al.*, 1994). In addition to providing a quantification of capillary density, this approach facilitates the direct analysis of myocyte-capillary ratios and quantification of the left coronary arterial tree.

#### Immunohistology—Vascular histology

The characterization of cardiac angiogenesis by immunohistology can be performed on perfusion fixed or embedded tissue. Immunostains with antibodies directed against platelet endothelial cell adhesion molecule (PECAM; CD31), as well as VE cadherin, can provide an overall assessment of vascular density in the hearts. In addition, studies of von Willebrand factor, VEGF receptors, including Flk-1 and Flt-1, Ang receptors, Tie-2 and PDGF receptors  $\alpha$  and  $\beta$  can provide important insight into the kinetics and potential mechanisms governing alterations in angiogenic pathways in the aging heart. The analysis of capillary density can be determined by automated image analysis such as CapiShape (Hu *et al.*, 1999) or directly through manual quantification of all stained luminal structures in high-power fields (40–100  $\times$  magnification) in a blinded approach.

#### In vivo anatomical/functional imaging

Recent advances in noninvasive approaches employing vascular contrast with both echocardiography (ultrasound-based) and magnetic resonance imaging (NMR-based) offer the potential to provide important information about cardiac microvascular anatomy and blood flow after angiogenic induction (Pearlman *et al.*, 1995; Wilke *et al.*, 2000) as well as after myocardial infarction (Gladish, 2005; Kaandorp *et al.*, 2005).

**Figure 78.2** This diagram of the heart illustrates the area at risk in the left ventricle resulting from the occlusion of the left anterior descending artery (LAD) in the rat myocardial infarction model. Note the site of injection and level of ligation.

## Myocardial Infarction Model

The significance of cardiac angiogenesis can be functionally measured in the cardioprotection provided in myocardial infarction models. Indeed, the ability to induce myocardial injury (ischemia, infarction, etc.) provides an important model of clinical cardiovascular disease and is a useful technique in studying cardiac-specific angiogenesis. Specifically, acute coronary occlusion models have been used to observe angiogenesis after the administration of growth factors (Edelberg *et al.*, 2002b; Chachques *et al.*, 2004; Xaymardan *et al.*, 2004b), stem cells (Nagaya *et al.*, 2004; Xaymardan *et al.*, 2004a),

and genes that encode for growth factors (Schwarz *et al.*, 2000; Su *et al.*, 2002; Hao *et al.*, 2004; Hao *et al.*, 2004; Su *et al.*, 2004).

## Surgical Approach

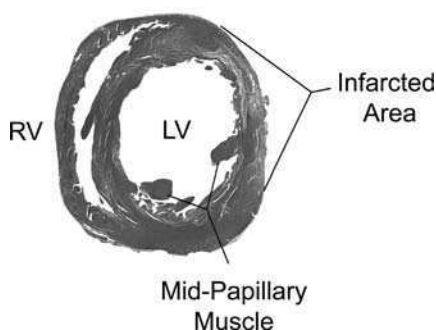

A left ventricular myocardial infarction can be induced via the occlusion of the LAD artery by physical ligation using an 8-0 nylon suture (Ethilon, Ethicon, NJ) or by photothrombosis (see Figure 78.2), which involves a systemic injection of a photosensitizing dye (e.g., Rose Bengal) and excitation of the interested artery with a laser ion light source as Rosen (2001) and Eichenbaum (2002) have displayed in mice. This procedure can be used in concert with the molecular injection procedure where administration of the treatments can be given prior to or after the occlusion. Moreover, the duration of the occlusion can be varied from periods of ischemia and reperfusion to permanent coronary ligation, modeling acute coronary syndrome and acute myocardial infarction, respectively. In addition, the functional significance of various interventions can be assessed at a range of time points after myocardial infarction to investigate the potential role of angiogenic pathways in the aging rodent heart.

## ANALYSIS

### *Area at risk*

Acutely, an increase in cardiac angiogenesis can reduce the area at risk in the treated heart. The area at risk in hearts can be quantified via histological approaches. In order to view the extent of area at risk (as an inverse correlate of cardiac angiogenesis), Masson's trichrome staining can be performed on cardiac sections at the mid papillary muscle (see Figure 78.3).

Alternatively, triphenyltetrazolium (TTC) is another method utilized to quantify infarction size (Birnbaum *et al.*, 2003). Similarly, the extent of myocardial cell death can be quantified at early time points by staining for apoptotic cells by terminal deoxynucleotidyltransferase-mediated dUTP nick end labeling (TUNEL) staining (Xaymardan *et al.*, 2004b).

**Figure 78.3** Masson's trichrome staining 14 d after a left anterior descending artery occlusion, at the mid-papillary level. Smooth muscle cells are stained red, and areas of fibrosis are stained blue.

### *Area of myocardial infarction*

A more chronic measure of the role of cardiac angiogenesis is the Masson's trichrome stain of the area of cardiac injury. Specifically, Masson's trichrome utilizes three stains to selectively identify muscle, collagen fibers, and fibrin. As illustrated in Figure 78.3, the fibrotic area is stained blue, indicating the area at risk. (Note: red = intact myocardium.) Histological quantification of the left ventricular myocardial infarct percentage at the mid-papillary level can be obtained from Masson's trichrome stained sections by imaging software developed at the National Institute of Health (ImageJ v1.28) and Eq. 1:

$$\frac{\text{Myocardial infarction area}}{(\text{Left ventricle total area} - \text{Chamber area})} \times 100\% \quad (1)$$

Indeed, previous studies have demonstrated the inverse association between preinfarction cardiac angiogenesis and extent of myocardial infarction based on Masson's trichrome stain in the aging rat heart (Edelberg *et al.*, 2002b; Cai *et al.*, 2003; Xaymardan *et al.*, 2004b).

### *Functional assessment*

Measures of cardiac function after myocardial injury provide an important correlation with histological measures of myocardial injury in the study of cardiac angiogenesis. Moreover, through the use of noninvasive functional testing the impact of various interventions can be measured in live animals, providing important clinical insights in the testing strategies targeted at angiogenesis in the aging heart.

## Exercise Physiology

Recently the utility of maximum sprinting speed in predicting the extent of myocardial injury after an acute infarction in the young heart has been demonstrated (Zheng *et al.*, 2004) based on the protocols originally developed by Barbato (1998). In order to assess cardiac function in rodent models, the inverse association between postinfarction maximum exercise speed and extent of myocardial injury has been demonstrated (Zheng *et al.*, 2004), suggesting that exercise speed may be a direct correlate of preinfarction cardiac angiogenesis.

Two days after coronary ligation, the rats can be trained using a motor-driven treadmill. Animals are acclimated to the treadmill (10° inclination) 2 min/d, 5 d/week for two weeks, with the stimulus intensity of the shock grid being 2mA. During the first week, the animals train at 10 m/min; during the second week, the animals are trained at 15 m/min. After the acclimation period, the maximal sprinting speed is measured in each rat (Zheng *et al.*, 2004), beginning at a speed of 10 m/min. The speed is increased 5 m/min every 30 s until the rat

becomes exhausted. “Exhausted” is defined as the inability to keep up with the belt for 5 s. Each rat is tested once daily on three consecutive days (12–14 d post-ligation).

Notably, however, impaired function in the older peripheral vasculature and diminished overall reserve in aging animals may reduce the utility of this assessment approach in models of myocardial infarction in the older heart.

## Echocardiography

In order to assess cardiac function in rodent models, wall motion can be directly imaged by echocardiography before and/or after myocardial infarction. Specifically, the inverse association between postinfarction left ventricular fractional shortening and extent of myocardial injury has been shown (see Figure 78.4), suggesting that echocardiography may be a direct correlate of preinfarction cardiac angiogenesis (Zheng *et al.*, 2004).

## Echocardiography Protocols

Cardiac function can be studied on unanesthetized animals by restraining them in the left lateral decubitus position using a 15 MHz frequency linear phased array

transducer, or alternatively, can be imaged under anesthesia via a 10 MHz transesophageal probe. Long-axis and short-axis parasternal views of the left ventricle will be obtained with M-mode echocardiograms taken at the mid-papillary muscle level (see Figure 78.5).

Cardiac wall motion can be scored by dividing the ventricle into six equal radial segments (see Figure 78.6).

**Figure 78.4** Inverse association between MI Size and FS. Graph depicting the trend of cardiac function as measured by fractional shortening to myocardial infarction size.

**Figure 78.5** M-mode echocardiography. Representative rat transesophageal echocardiograms depicting left ventricular myocardial function at baseline and 14 d after myocardial infarction. Note the depressed anterior wall motion postinfarction (AW = Anterior Wall; PW = Posterior Wall).

**Figure 78.6** Regional systolic ventricular wall thickening in control rats and rats with anterior wall myocardial infarctions. Negative values indicate pathological systolic wall thinning.

The mean wall thickness of each segment can be determined using measurements from three to five cardiac cycles. Systolic wall thickening in each segment is defined as the mean systolic wall thickness minus the mean diastolic wall thickness that can be utilized to measure the functional preservation of the cardiac myocardium following coronary artery occlusion. Specifically, fractional shortening is measured as the difference in left ventricular end-diastolic diameter (LVEDD) and left ventricular end-systolic diameter (LVESD), divided by LVEDD and taken as a percent:

$$FS(\%) = ((LVEDD) - LVESD)/LVEDD * 100\% \quad (II)$$

## Conclusion

Overall, these *in vivo* models provide us with valuable insight into the process of age-associated changes in cardiac angiogenesis. By employing the cardiac allograft assay in concert with the myocardial infarction model, molecular and cellular interventions can be tested to restore functional cardiac angiogenesis. Indeed, cardiac angiogenic growth can directly be measured quantitatively via laser Doppler, or qualitatively upon gross examination for engraftment. Based on the results from these study models in the endogenous myocardium the action of specific pathways has been characterized and quantified with regard to angiogenesis in the aging heart. In time, these models will advance, enabling us to better understand the age-associated dynamics of angiogenesis.

# Models for the Study of Stroke

Thiruma V. Arumugam and Mark P. Mattson

*Stroke is a devastating disease that represents the third leading cause of death in the United States. Vessel occlusions account for 85% of all strokes, and primary intracerebral bleeding accounts for about 15%. There are several different risk factors for ischemic stroke including genetic factors, aging, hypertension, hypercholesterolemia, diabetes mellitus, atrial fibrillation, coagulation disorders, and smoking. The pathophysiological processes in stroke are complex and involve disruption of the blood-brain barrier, energy failure, loss of cell ion homeostasis, acidosis, increased intracellular calcium levels, excitotoxicity, free radical-mediated toxicity, generation of arachidonic acid products, cytokine mediated cytotoxicity, complement activation, activation of glial cells, and infiltration of leukocytes. Animal models have been developed that closely resemble stroke injury seen in human patients. Many experimental models are used to study stroke injury. Mechanisms of cell damage are determined by testing effects of different manipulations on the extent of cell death in a model. The three main classes of in vivo animal models are global ischemia, focal ischemia, and hypoxia/ischemia. Technological advances and experimental discoveries have begun to define the cellular and molecular mechanisms involved in stroke injury, and exploration of these targets led to the development of numerous agents that target various injury pathways. Despite numerous agents that can prevent the cascade of events leading to ischemic neuronal death in animal models, there is no neuroprotective agent that has been shown to conclusively improve stroke outcome in humans. Novel interventions will be required to overcome hurdles associated with bench-to-bedside translation.*

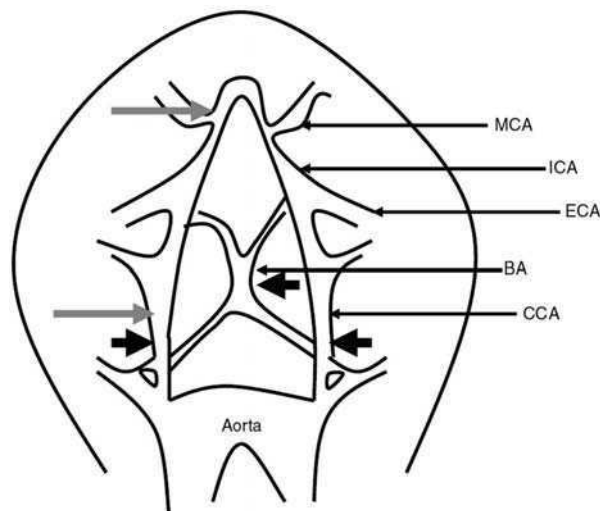

## Introduction

Stroke is a devastating disease that represents the third leading cause of death in the United States ([www.strokeassociation.org](http://www.strokeassociation.org)). Each year, more than half a million Americans fall victim to stroke, which costs approximately 70 billion dollars. It is estimated that the lifetime risk for stroke is between 8 and 10%. Pathogenetically, stroke involves a heterogeneous group of processes. Vessel occlusions (ischemic stroke) account

for 85% of all strokes; primary intracerebral bleeding (hemorrhagic stroke) accounts for about 15%. Embolisms cause approximately 75% of all cerebral vessel occlusions and are the most frequent cause of focally impeded blood flow within the brain. Microangiopathical causes, namely, *in situ* thromboses and hyalinoses of the arterioles, occur in about 20% of all cases. Hemodynamic infarctions as a result of high-grade stenoses of the cerebral arteries are rare and account for less than 5% (Mergenthaler *et al.*, 2004).

Ischemia is defined as a reduction in blood flow sufficient to alter cellular function. Brain tissue is exquisitely sensitive to ischemia such that even brief ischemia to neurons can initiate a complex sequence of events that ultimately culminates in cellular death. Different brain regions have different thresholds for ischemic cell damage, with white matter being more resilient than gray matter. In addition, certain populations of neurons are selectively vulnerable to ischemia; for example, in the hippocampus, CA1 pyramidal neurons are vulnerable to ischemia, whereas dentate granule neurons are resistant. Ischemia of cerebral tissue and death of neurons and glial cells underlie all forms of stroke and intraparenchymal hemorrhage. The cellular and biochemical abnormalities in stroke overlap with those that occur in closed head injury and subarachnoid hemorrhage. There are two major categories of experimental ischemia, namely, global and focal ischemia models. In global ischemia models, typically two or four cervical vessels are temporarily interrupted, and circulation is restored after some delay (see Figure 79.1).

In focal ischemia models, the middle cerebral artery typically is occluded either permanently or temporarily to allow reperfusion (McBean and Kelly, 1998). Animal hemorrhagic stroke models are able to reproduce the key pathophysiologic events documented in human hemorrhagic stroke. Thus, hemorrhagic stroke models serve as an important tool for understanding the mechanisms underlying brain injury after an intracerebral bleed. However, future efforts should be directed toward the development of a model that mimics the pathophysiologic processes that lead to spontaneous intracerebral hemorrhage, progression of hemorrhage, and recurrence of bleeding in humans (Andaluz *et al.*, 2002).

**Figure 79.1** Surgical technique for inducing global or focal cerebral ischemia in mouse. Schematic illustration of arteries demonstrating the three points of occlusion (short arrows) for global ischemia (3-VO) and long arrows for focal ischemia. MCA: middle cerebral artery; ICA: internal carotid artery; ECA: external carotid artery; BA: basilar artery; CCA: common carotid artery.

Early restoration of blood flow remains the treatment of choice for limiting brain injury following stroke. Improved educational efforts that emphasize the early signs and symptoms of stroke, coupled with the widespread application of thrombolytic therapy to patients with acute ischemic stroke, have decreased morbidity and mortality. Although reperfusion of the ischemic brain is desirable, tissue damage often results from both the transient ischemic insult and the reperfusion, the latter process inducing an inflammatory response that causes additional injury to the cerebral microcirculation and adjacent brain tissue. Hence, a rapidly evolving area of emphasis in stroke research involves defining the molecular and cellular basis for the augmented tissue injury and inflammation associated with transient cerebral ischemia. Experimental evidence suggests that the majority of stroke patients exhibit a slow evolution of brain injury that occurs over a period of hours to days. This window of opportunity provides a realistic target for therapeutic intervention, with the goal of inhibiting the progression of tissue damage that normally results from both ischemia and reperfusion. Attenuating and/or delaying this time-dependent brain injury may improve neurological outcome and facilitate brain recovery from injury (Legos and Barone, 2003).

This chapter considers the etiology and pathogenesis of stroke. Risk factors and pathophysiology of injury are explained. Experimental animal models of global, focal, and hemorrhagic strokes are described in detail, and different experimental strategies to analyze the injury are also explained. Finally, we describe preclinical studies using different strategies in experimental models, the results of human neuroprotection and revascularization

trials, and emerging approaches for the prevention and treatment of stroke.

## Etiologies and Pathogenesis

### RISK FACTORS

There are several different risk factors for ischemic stroke including genetic factors, aging, hypertension, hypercholesterolemia, diabetes mellitus, atrial fibrillation, coagulation disorders, and smoking.

#### *Genetic factors*

Single-gene defects can lead to stroke through specific pathophysiological mechanisms including large artery disease, coagulation disorders, small vessel disease, cardiac embolism, mitochondrial disorders, and ion channel disorders (Hassan and Markus, 2000). Single gene alterations can be responsible for stroke, but their prevalence is low. Considerable effort is being made to identify stroke-related genes in different human populations through the candidate gene approach. Due to the large number of candidate genes, many studies have been reported in the literature. They have investigated components of the haemostatic system, vasoconstrictor and vasodilator substances, and enzymes involved in homocysteine and lipid metabolism (Hassan and Markus, 2000). The large variation in ethnic groups that have been studied, the variable sample size, and the dissimilar criteria in the selection of patients and controls have led to variable results, with few consistent findings. The angiotensin converting enzyme (ACE) gene has been an extensively investigated candidate gene in ischemic stroke. However, both positive and negative associations have been reported for the ACE gene in different samples (Markus *et al.*, 1995). Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a monogenic syndrome associated with lacunar stroke and vascular dementia (Dichgans, 2002). It is caused by mutations of the *Notch3* gene that encodes a membrane receptor (Artavanis-Tsakonas *et al.*, 1999). Several mutations of this same gene have been discovered in different affected families (Joutel *et al.*, 2000). As for other monogenic stroke syndromes, information obtained on the genetic basis of CADASIL were extended to the general population by a systematic screening in the attempt to discover a role for *Notch3* in common forms of stroke; however, the results to date have been negative.

#### *Hypertension*

Epidemiological studies have shown a positive and linear relationship between both systolic and diastolic blood pressure (BP) and the incidence of any subtype of ischemic or hemorrhagic stroke, at any age, and in both sexes. However, no threshold distinguishes patients who will have a vascular event from those who will not.

In individuals with normal BP, the vascular risk, including stroke, is higher in those who have the highest levels of normal BP (Vasan *et al.*, 2001). The risk of stroke doubles for every 7.5 mm Hg increase in diastolic BP (Leys *et al.*, 2002). Isolated systolic arterial hypertension, defined as systolic BP greater than 160 mm Hg with diastolic BP lower than 90 mm Hg, is also an important risk factor for stroke in the elderly (Leys *et al.*, 2002). Although the primary prevention of stroke through the treatment of hypertension is well established, the issue of lowering BP after a cerebrovascular event has been uncertain, particularly since this might worsen cerebral perfusion if autoregulation remains chronically damaged or if severe carotid artery stenosis is present. In contrast to primary prevention studies in which hypertensive patients were studied, the majority of secondary prevention studies recruited patients irrespective of their BP (Rashid *et al.*, 2003). Overall, lowering BP was associated with significant reductions in stroke; a nonsignificant benefit was also seen for severe stroke, but overall mortality was not altered (Rashid *et al.*, 2003).

#### *Hypercholesterolemia*

Whether hypercholesterolemia, a major risk factor for coronary heart disease, is associated with stroke is controversial and remains a matter of debate. Elevated levels of circulating cholesterol cause deposits to form inside blood vessels. When the deposits become sufficiently large, they block blood vessels and decrease the flow of blood. These deposits are part of a disease process called atherosclerosis, which can cause blood clots to form that will ultimately stop blood flow. Data from a clinical study, which enrolled healthy men without vascular disease, suggest that patients in the highest quartile of total cholesterol to high-density lipoprotein ratio have an increased risk of stroke (Bowman *et al.*, 2003). There was no evidence of increased risk in patients with elevated total cholesterol, high-density lipoprotein, or triglycerides. Further studies are needed to determine if lowering cholesterol levels in healthy individuals reduces the incidence of stroke. Other studies in an elderly population suggested a protective effect of a higher high-density lipoprotein cholesterol level (Sacco *et al.*, 2001).

#### *Diabetes*

The risk of mortality and morbidity from stroke in subjects with diabetes is increased by more than two-fold; diabetes is an independent risk factor for stroke (Mankovsky and Ziegler, 2004). Chronic hyperglycemia, insulin resistance, and their associated cellular and molecular alterations may contribute to an elevated stroke risk either by amplification of the harmful effect of existing risk factors or by acting independently. The pathophysiological and biochemical ischemic cerebral impairments in patients with diabetes are not fully characterized; however, as the risk of morbidity and mortality associated with stroke in patients with diabetes

is high, the existing preventive measures could significantly reduce prevalence of stroke.

#### *Aging*

Age is an important risk factor for the frequency and the occurrence of stroke as well as for its outcome. In a clinical study of stroke patients, age was one of the most significant prognostic factors (Brown *et al.*, 1996). Age also was found to be associated with poor prognosis in a study of patients with transient ischemic attacks (Howard *et al.*, 1987). In healthy volunteers, basal cerebral blood flow was shown to decrease with age, and this age-dependent effect was even more pronounced in cases of cerebral atherosclerotic disease (Ewing *et al.*, 1989). Although stroke is mostly a disease of the elderly, the majority of experimental models use healthy young animals. Although hypertension, an important risk factor in stroke, was repeatedly tested by using spontaneously hypertensive rats, age as a risk factor for ischemic or hemorrhagic stroke has not been thoroughly addressed in animal models. However, some of the recent studies have addressed the effect of age in stroke pathology and prognosis (Davis *et al.*, 1995). Of the available animal species to model stroke, large mammals such as dogs have displayed inconsistent lesions (Garcia, 1984), whereas the inter-animal variability is low in inbred strains of rats and mice.

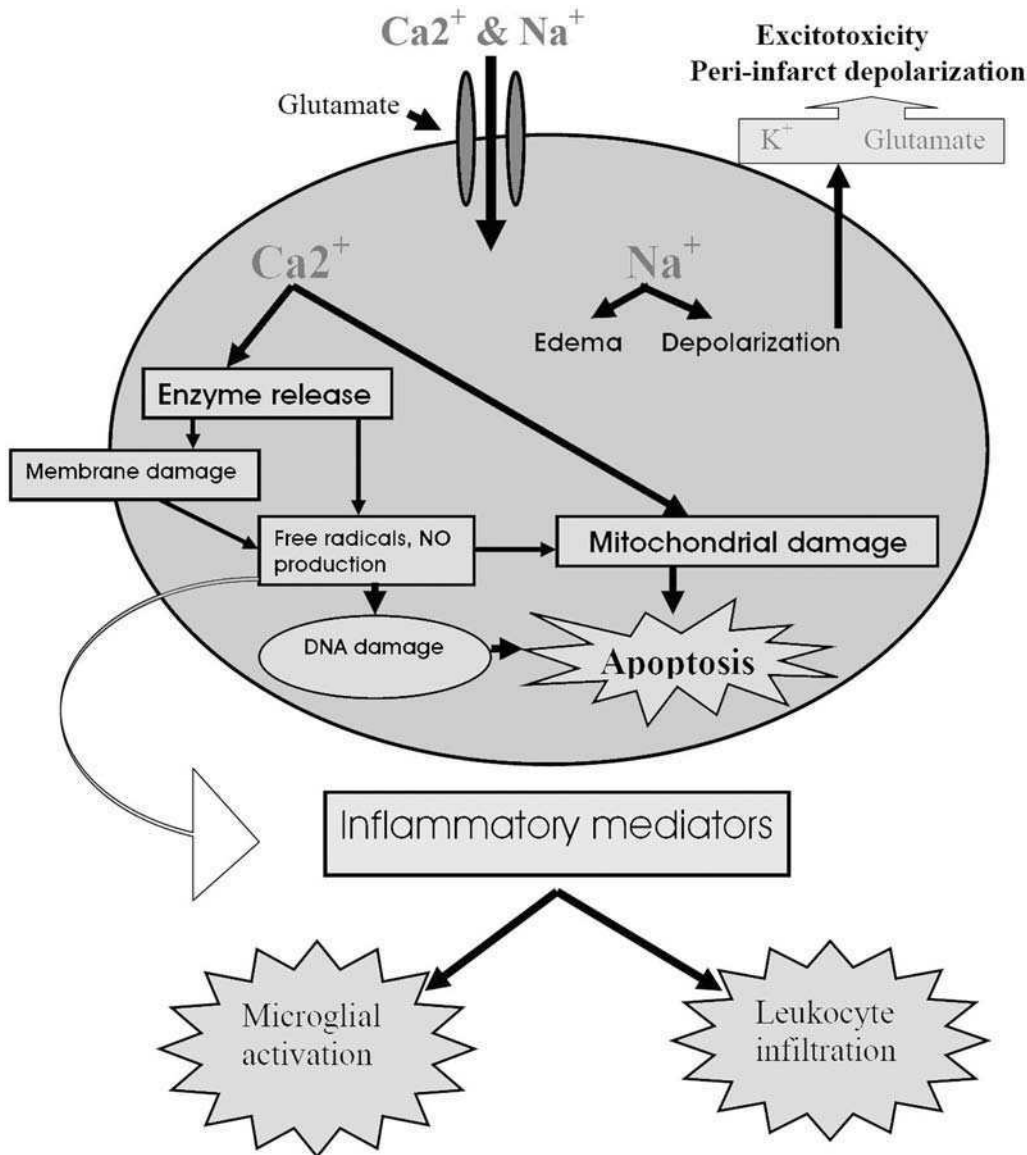

#### *Lifestyle*

Overeating, a sedentary lifestyle, smoking, and diets high in saturated and trans-fats and cholesterol and low in whole grains and vegetables increase the risk of stroke ([www.strokeassociation.org](http://www.strokeassociation.org)). Conversely, diets low in calories and “bad” fats and high in vegetables and whole grains, regular exercise, and abstinence from smoking reduce the risk of stroke. These factors may promote or inhibit the pathological processes involved in atherosclerosis. In addition, dietary restriction and physical exercise may protect neurons against ischemic damage, enhance neurogenesis, and improve functional outcome by stimulating the production of neurotrophic factors in brain cells (Mattson *et al.*, 2002).

### PATHOPHYSIOLOGY

The pathophysiological processes in stroke are complex and involve disruption of the blood-brain barrier (BBB), energy failure, loss of cell ion homeostasis, acidosis, increased intracellular calcium levels, excitotoxicity, free radical-mediated toxicity, generation of arachidonic acid products, cytokine mediated cytotoxicity, complement activation, activation of glial cells, and infiltration of leukocytes (see Figure 79.2).

These events can lead to ischemic necrosis, which occurs in the severely ischemic core regions. Necrosis is morphologically characterized by initial cellular and organelle swelling; subsequent disruption of nuclear, organelle, and plasma membranes; disintegration of

**Figure 79.2** Pathophysiological mechanisms of ischemic stroke. Ischemia-induced energy failure leads to the depolarization of neurons. Activation of specific glutamate receptors dramatically increases intracellular  $\text{Ca}^{2+}$  and  $\text{Na}^{+}$  concentrations, and  $\text{K}^{+}$  is released into the extracellular space. Edema result when cells swell as water moves into the cells. Increased level of intracellular messenger  $\text{Ca}^{2+}$  activates proteases, lipases, and endonucleases. Free radicals are generated and damage membranes, mitochondria, and DNA, in turn triggering cell death and inducing the formation of inflammatory mediators, which activate microglia and lead to the invasion of leukocytes via up-regulation of endothelial adhesion molecules.

nuclear structure and cytoplasmic organelles; and disintegration with extrusion of cell contents into the extracellular space (Manjo and Joris, 1995). Less severe ischemia, as occurs in the penumbra region of a focal ischemic infarct, evolves more slowly and depends on the activation of genes (Dirnagl *et al.*, 1999; Lipton, 1999; Zheng and Yenari, 2004).

A significant portion of ischemia-induced neuronal damage is mediated by excessive accumulation of excitatory amino acids, leading to toxic increases in intracellular calcium. This increase in calcium activates

various signaling pathways, ultimately leading to cell death. Soon after cessation of cerebral blood flow, energy-dependent pumps fail, resulting in the flow of ions down their concentration gradients. This results in cellular swelling and depolarization. Calcium ions enter the cell through voltage-dependent and ligand-gated ion channels, resulting in activation of a number of proteases, kinases, lipases, and endonucleases, ending in cell death (Lipton, 1999; Mattson *et al.*, 2000). Glutamate, which is the major excitatory neurotransmitter in the brain, accumulates in the extracellular space and activates its receptors.

Glutamate receptor activation induces alterations in the concentration of intracellular ions, especially  $\text{Ca}^{2+}$  and  $\text{Na}^+$  (see Figure 79.2). Elevations of intracellular  $\text{Na}^+$  can be damaging to neuronal survival at earlier time points after ischemia. However, experimental studies by different groups suggested that glutamate toxicity is primarily dependent on  $\text{Ca}^{2+}$  influx (Arundine and Tymianski, 2004; Mattson, 1997).

Neurons normally are exposed to a baseline level of oxidative stress from both exogenous and endogenous sources. Free radicals are highly reactive molecules with one or more unpaired electrons. Free radicals can react with DNA, proteins, and lipids causing varying degrees of damage and dysfunction. Several experimental and clinical observations showed increased free radical formation during all forms of stroke injury. Free radicals involved in stroke-induced brain injury include superoxide anion radical, hydroxyl radical, and nitric oxide (NO). The damaging effects of free radicals normally are prevented or reduced by mechanisms such as antioxidant enzymes and free radical scavengers (Love, 1999; Neumar, 2000). The primary source of oxygen free radicals during ischemic or hemorrhagic stroke injury is the mitochondria that produce superoxide anion radical during the electron transport process. Another potentially important source of superoxide in postischemic neurons is the metabolism of arachidonic acid through the cyclooxygenase and lipoxygenase pathways (Hall, 1995).

Oxygen free radicals can also be generated by activated microglia and infiltrating peripheral leukocytes via the NADPH oxidase system following reperfusion of ischemic injury (Stoll *et al.*, 1998). NO is generated from L-arginine through one of several nitric oxide synthase (NOS) isoforms. The neuronal form (nNOS), which requires calcium/calmodulin for activation, is produced by subpopulations of neurons throughout the brain (Dawson and Dawson, 1998). Inducible NOS (iNOS) is produced by inflammatory cells such as microglia and monocytes. These two isoforms, for the most part, are damaging to the brain under ischemic conditions. A third isoform found in endothelial cells (eNOS) is believed to have vasodilatory properties and may play a beneficial role, as it may ultimately improve local blood flow. NO diffuses freely across membranes and reacts with superoxide to produce peroxynitrite ( $\text{ONOO}^-$ ), another highly reactive free radical (Love, 1999). Both oxygen free radicals and reactive nitrogen species are involved in activating several pathways involved in cell death following stroke, such as apoptosis and inflammation. A reduction of oxygen supply also leads to the accumulation of lactate via anaerobic glycolysis and thus to acidosis. Besides the production of different species of oxygen radicals, acidosis also interferes with intracellular protein synthesis. Lipid peroxidation also appears to play a prominent role in the pathogenesis of stroke. The mechanism whereby membrane lipid peroxidation induces neuronal apoptosis appears to involve generation of

an aldehyde called 4-hydroxynonenal, which covalently modifies membrane transporters such as  $\text{Na}^+/\text{K}^+$  ATPase, glucose transporter, and glutamate transporter, thereby impairing their function (Mattson *et al.*, 2000).

Though potentially damaging,  $\text{Ca}^{2+}$  and free radicals can activate neuroprotective transcription factors, including nuclear factor- $\kappa$ B (NF- $\kappa$ B), hypoxia inducible factor 1, and interferon regulatory factor 1 (Dirnagl *et al.*, 1999). On the other hand, some of these transcription factors induce the expression of inflammatory cytokines (for example, IL-1, IL-6, and TNF- $\alpha$ ) and chemokines (e.g., IL-8 and MCP-1), endothelial cell adhesion molecules (e.g., selectins, ICAM-1, and VCAM-1), and other proinflammatory genes (e.g., interferon-inducible protein-10) (Dirnagl *et al.*, 1999; Ishikawa *et al.*, 2004). There are several resident cell populations within brain tissue that are able to secrete proinflammatory mediators after an ischemic insult, including endothelial cells, astrocytes, microglia, and neurons. This gene activation results in increased protein levels for cytokines and increased expression of endothelial cell adhesion molecules (CAMs) in post-stroke brain tissue. A major role in brain inflammation following stroke is ascribed to microglia, especially in the penumbra. Similar to leukocytes, activated microglia produce several proinflammatory cytokines as well as toxic metabolites and enzymes. In addition to microglia, astrocytes have an important part in stroke-induced brain inflammation. They can produce both proinflammatory cytokines and neuroprotective factors such as erythropoietin, TGF- $\beta$ 1, and metallothionein-2 (Mergenthaler *et al.*, 2004). Because of the mixed nature of microglial and astrocyte products (both destructive and protective factors), the overall role of microglia may differ at different time points following stroke insult, with protective or regenerative activities occurring days to weeks after the onset of ischemia. Brain endothelium is distinctive compared with other organs, as evidenced by the BBB. However, it responds to stroke injury with increased permeability and diminished barrier function, along with degradation of the basal lamina of the vessel wall that occurs as in other organs after ischemic injury (del Zoppo and Hallenbeck, 2000). Similarly, there is evidence that acute ischemic stroke enhances the interactions of brain endothelium with extravascular (astrocytes, microglia, neurons) and intravascular (platelets, leukocytes) cells and that these interactions contribute to the injury process (Ishikawa *et al.*, 2004). The net result of all these responses to stroke is that the cerebral vasculature assumes the following phenotype: (1) poor capillary perfusion of brain tissue, (2) pro-adhesive for circulating cells, (3) pro-inflammatory, (4) pro-thrombogenic, and (5) diminished endothelial barrier function.

There is a large body of evidence that implicates leukocytes in the pathogenesis of stroke injury. The contention that leukocytes mediate reperfusion-induced tissue injury and microvascular dysfunction is supported

by three major lines of evidence: (1) leukocytes (primarily neutrophils) accumulate in postischemic tissues prior to the onset of tissue injury; (2) animals rendered neutropenic exhibit a diminished injury response to ischemic stroke and (3) prevention of leukocyte-endothelial cell adhesion with monoclonal antibodies (mAbs) directed against specific leukocyte or endothelial CAMs also affords substantial protection against stroke injury (Ishikawa *et al.*, 2004). The pathophysiological significance of the lymphocyte recruitment into the brain after ischemic stroke remains unclear. However, our recent studies (T.V. Arumugam, unpublished data) showed important roles for T-lymphocytes in mediating reperfusion injury in postischemic brain tissue.

## Animal Models of Stroke

Animal models have been developed that closely resemble stroke injury seen in human patients. Many experimental models are used to study stroke injury. Mechanisms of cell damage are determined by testing effects of different manipulations on the extent of cell death in a model. The three main classes of *in vivo* animal models are global ischemia, focal ischemia, and hypoxia/ischemia. The latter method in which vessel occlusion is combined with breathing a hypoxic mixture is almost exclusively used in young animals. Global ischemic insults are most commonly produced by vessel occlusions, and less commonly by complete brain circulatory arrest. Although the former are not actually global, a large portion of the forebrain is quite uniformly affected. In focal ischemic stroke models, the middle cerebral artery (MCA) is the most commonly occluded vessel; the vessel can be occluded either permanently or transiently. Damage results from both ischemia and reperfusion. Collateral blood flow may also play a role in reducing the initial impact of the occlusion. Intracerebral hemorrhage frequently accompanies ischemic stroke, mainly because of disruptions of the BBB.

There are many advantages to using small animals such as rats and mice in stroke models. Rats and mice are relatively inexpensive animals, and their cranial circulatory anatomy is similar to humans. It is also possible to control the severity, duration, and location of the vessel occlusion. Physiological factors can be controlled, and histopathology allows for assessment of ischemic pathogenesis and tissue infarction.

## GLOBAL STROKE MODEL

It has been stated that the focal stroke models are of greater relevance to the human condition of stroke. However, global ischemia is of clear relevance to cardiac arrest and asphyxia in humans. In addition, it should be noted that the physiological, biochemical, and functional measurements made during recovery from a global model of reversible ischemia may be important in identifying the molecular and cellular mechanism and action of

potential neuroprotective agents. Global models of cerebral ischemia may thus be as useful as focal models, provided that care is taken in the interpretation of the data. The three most widely used animal models of global ischemia are: (1) four-vessel occlusion (4-VO) and two-vessel occlusion (2-VO) combined with hypotension in the rat, (2) 2-VO occlusion in the gerbil, and (3) 2-VO in the mouse. A 2-VO mouse model was developed recently to study transgenic mice and is now being systematically studied (Kitagawa *et al.*, 1998).

### *Rat models of global stroke*

**4-VO.** This model has several advantages, including ease of preparation, a high incidence of predictable ischemic neuronal damage, a low incidence of seizures, and the absence of anesthesia (i.e., at the time of carotid occlusion). This particular model has been, and still is, widely used to investigate the effectiveness of potential therapeutic agents. The rat 4-VO model involves permanent coagulation of the vertebral arteries, which alone has no deleterious effects, and temporary ligation of the two common carotid arteries. Experimental results show loss of righting reflex within 15 s, and a blood flow decrease to 3% of control values in hippocampus, striatum, and neocortex (McBean and Kelly, 1998).

**2-VO.** This model is carried out under a general anesthetic and requires the administration of a muscle relaxant. It has been well documented that a bilateral occlusion of the common carotid arteries alone is not sufficient either to bring the cerebral blood flow down below the ischemic threshold or to upset the energy state of the brain tissue to an extent sufficient to produce detectable cell death. To produce a damaging ischemic insult, the brain blood flow has to be reduced at the same time as the carotid arteries are occluded. The hypotension normally is produced in one of three ways: (1) controlled exsanguinations, (2) adjunctive administration of peripheral vasodilators, or (3) a combination of both approaches. The ligation of both common carotid arteries along with a BP reduction to 50 mm Hg causes as much or more damage than 4-VO. Blood flows fall to 3 to 5% in hippocampus, neocortex, and striatum. However, in some cases blood flow is reduced to 15% of control levels (McBean and Kelly, 1998; Swan *et al.*, 1988).

### *Gerbil model of global stroke*

This is induced by temporarily ligating the carotid arteries, with no reduction in BP. Because there are no posterior communicating arteries in gerbils, this produces profound forebrain ischemia. Changes are similar to those in the rat models: blood flow in cortex is 1% and in hippocampus is 4% of control values (Herrmann *et al.*, 2004).

### *Mouse model of global stroke*

Mouse models of global stroke are similar to rat 2-VO models using bilateral occlusion of the common carotid

arteries. Several studies showed mouse global ischemia models with quantitatively uniform injury to CA1 neurons, using techniques including two-vessel occlusion and two-vessel occlusion with hypotension (Yonekura *et al.*, 2004). However, because of the variability of collateral flow via the posterior communicating artery, it has been difficult to obtain uniform injury in CA1 while retaining high survival and success rates. One model combines basilar artery occlusion with bilateral common carotid artery occlusion (three-vessel occlusion; Panahian *et al.*, 1996). However, in this model the animal survival rate was low and CA1 neuronal injury was inconsistent. Because the basilar artery of mice runs through a narrow groove in the brain stem and is attached to the pia mater and arachnoid membrane with arachnoid trabeculae, it is difficult to isolate and occlude.

#### *Complete global ischemia*

Finally, there is complete global ischemia, generally achieved by neck-cuff, cardiac arrest, or by ligating or compressing all arteries from the heart (Bottiger *et al.*, 1999). Blood flow to the whole brain is zero or <1% in these models. Due to high mortality associated with this model, it is not widely used.

### FOCAL ISCHEMIC STROKE MODELS

Focal ischemic stroke models, whether in larger mammals such as cats, dogs, or nonhuman primates, or in small mammals such as rodents, usually involve occlusion of one MCA (Lipton 1999). Focal ischemia is differentiated from global ischemia in two ways. First, even at the core of the lesion, the blood flow is almost always higher than during global ischemia so that longer insults are required to cause damage. Second, there is a significant gradation of ischemia from the core of the lesion to its outermost boundary, and hence there are different metabolic conditions within the affected site. Because of its duration and heterogeneity, the insult is much more complex than global ischemia, but it is an invaluable model for stroke and is thus widely studied. There are two models of focal ischemic stroke: transient focal ischemia and permanent focal ischemia. In transient focal ischemia models, vessels are blocked for up to 3 h, followed by prolonged reperfusion, whereas in permanent focal ischemia, the arterial blockage is maintained throughout an experiment, usually for one or more days.

#### *Transient middle cerebral artery occlusion*

There are two principal occlusion sites in this model (see Figure 79.1). In proximal occlusion, the MCA is occluded close to its branching from the internal carotid artery, before the origin of the lenticulostriate arteries. A newer and now widely used approach to proximal MCA occlusion is the insertion of a nylon suture into the carotid artery, past the point at which the MCA branches so that the latter is occluded at its origin.

The procedure is as follows. After a midline neck incision, the left external carotid and pterigoparotine arteries are isolated and ligated with silk thread. The internal carotid artery is occluded at the peripheral site of the bifurcation of the internal carotid artery (ICA) and the pterigoparotine artery with a small clip, and the common carotid artery (CCA) is ligated with silk thread. The external carotid artery (ECA) is cut, and a nylon monofilament, whose tip is blunted (0.20–0.22 mm for a mouse) with a coagulator, is inserted into the ECA. The ECA and the inserted nylon thread are tightened with a silk suture, which prevents bleeding during advancement of the nylon thread and during its removal at the time of reperfusion, and rotated for its advancement into the ICA. After removal of the clip at the ICA, the nylon thread is advanced until light resistance is felt and the distance from the nylon thread tip to the internal carotid artery-ptyergophalantine artery bifurcation is slightly more than 6 mm (mouse), and the distance to the ICA-ECA bifurcation is slightly less than 9 mm. During MCAO, the parietal bone becomes pale on the occluded side and laser Doppler flowmetry reveals that blood flow in this area falls to less than 20% of baseline. The nylon thread and the CCA ligature are removed after an occlusion period and reperfusion occurs with release of blood flow from the internal carotid artery. There are some potentially important artifacts with this widely used method. Blood flow following temporary ischemia is somewhat compromised by the partial occlusion of the carotid arteries with the filament and there is quite extensive damage to small arteries in the ischemic field, with damage to endothelial and smooth muscle cells. It has been suggested that this damage may affect subsequent neuronal cell death by exacerbating the leukocyte response in the reperfusion period (Ishikawa *et al.*, 2004).

#### *Permanent middle cerebral artery occlusion*

The commonly used permanent focal ischemia model involves occlusion of one or more branches of the MCA. The MCA is exposed via a transtemporal approach. After the temporalis muscle is retracted, a 2- to 3-mm burr hole is drilled 2 to 3 mm rostral to the fusion of the zygoma and squamosal bones. The MCA is exposed after opening and retracting the dura matter. Using a steel hook maneuvered via a micromanipulator, the MCA is elevated and electrocoagulated (McAuley, 1995).

#### *Embolic model of focal ischemia*

The procedure for this model is similar to the transient focal ischemic model (Zhang *et al.*, 2003). Briefly, a longitudinal incision is made in the midline of the ventral cervical skin. The CCA, ICA, and ECA are exposed. The distal portion of the ECA is ligated with two sutures and the ECA is cut between these two sutures. A silk suture is tied loosely around the origin of the ECA. The CCA and ICA are clamped temporarily using microvascular clips. A small puncture is made on the wall of the

ECA with a pair of spring scissors. A modified PE-10 catheter connected with a PE-50 tubing (40 mm in length for 10 ml thrombus and 20 mm for 5 ml) filled with bovine thrombin is introduced into the lumen of the ECA via the puncture. The suture around the origin of the ECA is tightened and the clip on the ICA is removed. After the blood is withdrawn, the catheter is advanced up in the ICA until its tip is 1 to 2 mm away from the origin of the MCA. The catheter is retained there for 15 minutes to allow formation of a clot. Once the clot has formed, it is then gently injected into the MCA. The catheter in the ICA is removed five minutes after the clot injection and the ECA is ligated.

#### *Photothrombotic distal MCA occlusion*

The use of a photochemical reaction to produce focal cortical ischemia in the rat brain was first described in 1985 (Watson *et al.*, 1985). In this model, vascular thrombosis is induced by transcranial illumination with a filtered light source in combination with intravenous injection of a photosensitive dye. Electron microscopy and light microscopy studies showed intravascular thrombotic material, red blood cell stasis, and platelet aggregates adhering to luminal surfaces inside vessels and intravascular thrombosis that is responsible for the occurrence of ischemia leading to infarction. Increased permeability through disruption of the BBB by the photochemical reaction is also involved in this type of model. The method involves mounting the rat in a stereotaxic head-holder, and making a 1 to 1.5-cm vertical incision between the right eye and ear. With the aid of an operating microscope, a burr hole is made with a high-speed drill. Care should be taken not to injure the dura matter. The distal segment of the right MCA is thus exposed. A krypton laser operating at 568 nm (Innova 301, Coherent Inc, or 643-Y-A01, Melles Griot Inc) is used to irradiate the distal MCA at a power of 20 mW for four minutes. The laser beam is focused with a 30-cm focal length convex lens and positioned with a mirror onto the distal MCA. The photosensitizing dye, normally rose bengal or erythrosin B (15–25 mg/mL in 0.9% saline), is administered intravenously at a body dose of 20 mg/kg over 90 seconds, starting simultaneously with four minutes of laser irradiation.

#### HEMORRHAGIC STROKE MODEL

Several animal models of intracerebral hemorrhage (ICH) have been developed in mice, rats, rabbits, cats, and nonhuman primates. A widely used method that produces ICH by injection of bacterial collagenase into the basal ganglia was first introduced in the rat and was subsequently studied in the mouse (Rosenberg *et al.*, 1990; Clark *et al.*, 1998). This enzyme digests the collagen present in the basal lamina of blood vessels and causes bleeding into the surrounding brain tissue. However, another study demonstrated that bacterial collagenase causes a significant inflammatory reaction and likely

differs from the mechanism that produces ICH in humans (Del Bigio *et al.*, 1996). A second model uses the infusion of autologous blood into the brain parenchyma. This model was designed to mimic the natural events that occur with spontaneous ICH in humans. However, it produces hematomas of varying size because of ventricular rupture and the backflow of infused blood along the needle track, which leads to intraventricular and/or subarachnoid leakage of blood. Recently, a double injection ICH model has been developed in which a small amount of blood is infused into the striatum at a slow rate to allow blood clotting along the needle track; the remaining blood is then infused to generate the hematoma. This method creates a reproducible hematoma volume suitable for study of the pathophysiology and treatment of ICH (Belayev *et al.*, 2003). A widely used experimental procedure for ICH in mice is as follows. The animal is placed in a stereotaxic frame. A 30-gauge stainless steel cannula is introduced through a burr hole into the left striatum (2 mm lateral to midline, 1 mm anterior to bregma, depth 4 mm below the surface of the skull) and the mouse receives an injection of either whole blood (taken from a donor mouse) or CSF (10–15  $\mu$ l) over several minutes, and the injection cannula is slowly withdrawn 10 minutes after the injection.

#### IN VITRO MODELS TO STUDY STROKE INJURY

Brain slices, particularly the hippocampal slice and primary neuronal/glial cultures from cortex, hippocampus, and cerebellum of embryonic or perinatal rats and mice, have become widely used models for studying ischemia-like damage. In brain slices, ischemia-like conditions are induced by replacing the normal O<sub>2</sub>/CO<sub>2</sub> equilibrated medium with N<sub>2</sub>/CO<sub>2</sub> equilibrated medium; typically the cultures are maintained in an incubator containing a N<sub>2</sub>/CO<sub>2</sub> atmosphere. When glucose is maintained in the anoxic buffer, the insult is termed hypoxia, and when glucose is omitted, the insult is termed *in vitro* ischemia or oxygen/glucose deprivation. Glucose deprivation alone can also induce neuronal death with some features similar to those observed in *in vivo* ischemia models. Hypoxia also can be induced by treatment with cyanide (NaCN or KCN) or by incubating in an anoxic atmosphere. Chemical hypoxia results in more free radical generation than does anoxia. *In vitro* models differ from *in vivo* stroke models in several aspects. Typically, a long duration of the anoxic or hypoxic insult is required to kill neurons *in vitro*. ATP depletion is less severe and the release of glutamate is delayed compared to ischemia *in vivo*. The absence of blood vessels and flow *in vitro* eliminates important components of the damage process present *in vivo*, including infiltration of inflammatory cells. In addition, the composition and responsiveness of glial cells *in vitro* differs from that in the intact brain.

**Figure 79.3** Representative coronal brain section from a mouse that had been subjected to MCA occlusion-reperfusion. This mouse had one hour MCA occlusion and 72 hours reperfusion. The dark staining indicates healthy brain tissue and the pale indicates damaged tissue.

### Measurement of Stroke-Induced Damage

The measurement of dynamic changes in ischemic brain has attracted growing attention. Ischemic brain injury in both focal and global ischemia models evolves as a sequence of cellular and molecular events (Dirnagl *et al.*, 1999). In this section we describe methods for analyzing brain injury and dynamic changes in the brain during ischemia and reperfusion.

#### QUANTIFICATION OF CEREBRAL INFARCTION

The size of the brain infarct in focal cerebral ischemia increases in size during the period of reperfusion (see Figure 79.3).

This has been shown in animal models of stroke and in human stroke patients. The infarct volume is normally analyzed after 24 hours in transient focal ischemia models and after six hours in permanent focal ischemia models. The brain is removed, and coronal sections are cut (2 mm-thick slices in rats or 1–2 mm thick slices in mice) through the entire rostro-caudal extent of the cerebral cortex. The slices are immersed in a 2% solution of 2,3,5-triphenyltetrazolium chloride (TTC). An edema index is calculated by dividing the total volume of the hemisphere ipsilateral to the MCA occlusion by the total volume of the contralateral hemisphere. An infarction index, the actual infarcted lesion size adjusted for edema, is then calculated for each animal.

#### NEUROLOGICAL ASSESSMENT

The functional consequences of focal ischemic stroke injury are evaluated using a 5-point scale neurological deficit score (0, no deficit; 1, failure to extend right paw; 2, circling to the right; 3, falling to the right; and 4, unable to walk spontaneously) (Bederson *et al.*, 1986). More recently, a 14-point neurological scoring system was developed (Li *et al.*, 2000). This new scoring method

includes the results of motor, reflex, and balance tests; a point is awarded for the inability to perform the test or for the lack of a tested reflex.

#### CEREBRAL BLOOD FLOW ANALYSIS

Regional microvascular tissue perfusion (cerebral blood flow) normally is monitored before, during, and after focal ischemia using laser Doppler flowmetry. The values during ischemia are calculated as a percentage of preocclusion levels. The region of measurement is set at 1 mm rostral and 1 mm dorsal to the cross-over point of the left MCA and rhinal fissure, which is in the ischemic penumbra of the ischemic lesion.

#### BLOOD-BRAIN BARRIER FUNCTION

Albumin leakage, a quantitative index of endothelial barrier dysfunction, can be applied to the brain for determination of BBB function. Albumin extravasation in the brain can be quantified either by fluorescence imaging of the leakage of fluorescein isothiocyanate-labeled albumin or sulforhodamine (Texas Red)-labeled albumin from cerebral venules or from the clearance of the same fluorochromes from blood to the artificial CSF perfusing the brain surface. With the imaging approach, fluorescently tagged albumin is administered intravenously to the animals 15 minutes before the baseline observation period, and fluorescence intensity (excitation wavelength, 420–490 nm; emission wavelength, 520 nm) is detected using a silicon-intensified target camera. The fluorescence intensities within a specified segment of a cerebral venule (Iv) within the cranial window and in a contiguous area of perivenular interstitium (Ii) are measured at various times after administration of fluorescent-albumin using a computer-assisted digital imaging processor (NIH Image 1.61 on a Macintosh computer). Vascular albumin leakage is determined from the difference in fluorescence intensity between the outside and inside of the venular segment. An index of albumin leakage is determined from the Ii-to-Iv ratio (after subtraction of baseline intensity measured before labeled albumin injection) at specific time points during the course of the experiment.

#### BRAIN EDEMA MEASUREMENT

The brains are immediately removed and divided into contralateral and ipsilateral hemispheres. The tissue samples are weighed on an electronic analytical balance to the nearest 0.1 mg to obtain the wet weight. The tissue is then dried at 100°C for 24 hours to determine the dry weight. Brain water content (%) is calculated as  $\{(wet\ weight - dry\ weight) / wet\ weight\} \times 100$ .

#### PHYSIOLOGICAL VARIABLES

Blood pressure, rectal temperature, and blood gases are measured during the operation in rats and mice. Normally there are no significant differences in these variables monitored at pre-, intra-, and postischemic periods in most studies. However, measuring these parameters is

important for interpretation of outcomes among animals, as well as for evaluation of adhering leukocytes using intravital video microscopy. An estimate of shear rate in cerebral venules is obtained by fluorescence microscopy based on image analysis determinations of the maximal velocity of fluorescently labeled red blood cells or platelets within the venules under study. Such estimates of pseudo-shear rate in venules are obtained using measurements of venular diameter ( $D_v$ ) and the maximal velocity of flowing platelets ( $V_{plt}$ ) according to the formula: pseudo-shear rate =  $(V_{plt}/1.6)/D_v \times 8$ .

#### ASSESSMENT OF LEUKOCYTE AND PLATELET ADHESION

Adhesion of leukocytes and platelets following ischemia and reperfusion can be monitored *in vivo* using intravital video microscopy. The head of the animal is immobilized and a hole drilled through the skull using a high-speed micro drill (1 mm posterior from bregma and 4 mm lateral from the midline). The dura matter is not cut because the fluorescently labeled blood cells are easily observed and intracranial pressure is well maintained with the dura matter intact. Artificial cerebrospinal is placed on the exposed brain tissue. For focal ischemia models, the observation area includes the infarcted region following MCAO. For global ischemia models the observation area includes the entire cerebral cortex. Platelets are isolated from a donor animal using a series of centrifugation steps and labeled *ex vivo* with carboxyfluorescein diacetate succinimidyl ester. Once the platelet data is collected, endogenous leukocytes are labeled *in vivo* by infusing rhodamine-6G (100  $\mu$ l; 0.02%) over five minutes and allowed to circulate an additional five minutes before observation. An upright Nikon microscope equipped with a SIT camera (C2400-08; Hamamatsu Photonics) and a mercury lamp is used to observe the cerebral microcirculation. The images are received by a CCD video camera and recorded on a video recorder equipped with a time-date generator (WJ-810; Panasonic).

#### QUANTIFICATION OF CELL ACTIVATION AND ADHESION MOLECULES EXPRESSION

The dual radio-labeled monoclonal antibody (mAb) technique is used to quantify the expression of different endothelial cell adhesion molecules, including P-selectin, ICAM-1, and VCAM-1, in the microvasculature of the brain. This method determines the relative accumulation, in any regional vascular bed, of a binding mAb to a specific endothelial surface epitope (e.g., P-selectin) and an isotype-matched nonbinding mAb, the latter of which is used to compensate for nonspecific accumulation of the binding mAb. Different endothelial cellular adhesion molecules (P-selectin, E-selectin, VCAM-1, ICAM-1, MAdCAM-1, PECAM-1) in the brain can be analyzed following ischemic stroke. However, adhesion molecules specifically expressed by immune cells such as LFA-1 are analyzed at least 24 hours after reperfusion. Activation

of microglial cells following ischemia or reperfusion normally is analyzed using CD11b (Mac-1) antibody.

#### MAGNETIC RESONANCE IMAGING (MRI)

With different MRI techniques, *in vivo* diagnostic and prognostic information can be obtained on edema formation, hemodynamics, tissue structure, neuronal activation, cell migration, gene expression, and more. In addition, MRI can be combined with other imaging modalities such as positron emission tomography or optical imaging to obtain complementary or supplementary information. Advances in MR technology, such as magnets with higher field strength, more powerful gradient systems, and increasing availability of targeted MR contrast agents, allow MRI research in animal models of ischemic and hemorrhagic stroke with higher sensitivity, faster acquisition, and improved specificity (Dijkhuizen and Nicolay, 2003).

#### MEASUREMENT OF PROTEIN AND mRNA LEVELS IN THE ISCHEMIC BRAIN

Identification and quantification of specific proteins and mRNAs *in situ* and in brain tissue samples can provide valuable information to elucidate the signaling pathways and molecular mechanisms involved in ischemic brain damage and recovery from stroke. Proteins can be identified *en masse* by proteomic methods, and individual proteins can be quantified by immunoblot or enzyme-linked immunosorbent assays. mRNAs are detected and quantified by polymerase chain reaction (PCR)-based gene array methods and by real-time PCR (Harrison and Bond, 2005).

#### Current Therapeutics and Preclinical Studies

A basic question in translating results of animal experiments to clinical use is whether or not the pathophysiological processes in animal models correlate with those in human disease. Differences may arise for the following reasons: differences in anatomy and physiology, differences in pathophysiological response to injury, or differences between injury mechanisms in animal models and those in human disease. Therapeutic manipulations generally work best when administered before and immediately after the insult. Experiments with animal models often begin with a pretreatment protocol. If the therapy works, it is tested at different intervals from injury onset. Most effective therapies work best within 15 to 30 minutes; rarely are they effective more than three hours after onset of injury. The most important step in limiting ischemia is the quick restoration of blood flow that occurs either naturally or with the aid of thrombolytic drugs such as rtPA. The intravenous recombinant tissue plasminogen activator (rtPA) is the first and only approved agent for the treatment of acute stroke. tPA is

a serine protease that catalyzes the activation of the zymogen plasminogen by converting it to the broad-specificity, active protease plasmin. In 1996, rtPA was approved for use in acute stroke. The NINDS trial using rtPA showed a highly significant improvement in outcome in treated patients. However, based on examination of the outcomes of rtPA-treated patients, the benefit of rtPA is not as robust as originally expected (Frey, 2005). It has been reported that tPA can exacerbate excitotoxic neuronal death (Tsirka, 1997), suggesting an adverse effect of this drug that may in part counteract its clot-busting action.

Another treatment that shows promise is hypothermia, which may decrease metabolic demand and extend neuron survival. Additional therapeutic approaches target the processes involved in calcium overload, glutamate excitotoxicity, oxygen radical production, apoptosis, and inflammation.

#### CALCIUM-STABILIZING AGENTS

Cell death cascades in ischemic stroke are mediated, in part, by excessive calcium influx resulting from activation of glutamate receptors and voltage-dependent calcium channels (VDCC). In addition, the function of  $\text{Ca}^{2+}$ -ATPases is compromised, resulting in prolonged elevation of the intracellular calcium concentration. Drugs that block glutamate receptors (MK-801, for example) or VDCC (nimodipine and flunarazine, for example) have proven effective in rodent models of stroke. At least 14 clinical trials of nimodipine in ischemic stroke were conducted beginning in the mid 1980s. Nine trials found no effect, one trial found short-term worsened outcome with treatment, and four trials found positive outcomes (Danton and Dietrich, 2004). Clinical trials with flunarazine found no statistically significant improvement in outcome. Despite this discouraging analysis, dantrolene, which blocks ryanodine receptors, recently has been discussed for clinical trials as the result of beneficial effects in rodent stroke models (Zhang *et al.*, 1993).

#### ANTI-EXCITOTOXIC AGENTS

Several compounds that interfere with glutamate receptor activation have been developed and tested against experimental animal models of stroke as well as against human clinical trials. The noncompetitive NMDA antagonist MK-801 (dizocilpine) improved outcome in models of focal ischemia, producing up to 75% reductions in infarct volume. Both MK-801 and dextromorphan, another noncompetitive NMDA receptor antagonist, exhibited protective effects in experimental studies, but clinical trials were terminated early because of phencyclidine-like psychotic side effects and lack of efficacy against stroke injury (Kermer *et al.*, 1999). Some other noncompetitive (aptiganel, ceresine) or competitive (selfotel, eliprodil) NMDA receptor antagonists were shown to be very effective in animal stroke models, but with no

significant effects in clinical trials (Danton and Dietrich, 2004). Non-NMDA antagonists also were being developed and studied against stroke conditions. Zonampanel (YM-872) is an AMPA antagonist and currently is being tested in human phase 2 clinical trials. In addition, another AMPA antagonist SPD-502, as well as metabotropic glutamate receptor modulators, are being developed and tested against stroke injury in animals and humans (Danton and Dietrich, 2004; Legos and Barone, 2003). However, the development of anti-excitotoxic agents against stroke has been disappointing.

#### ANTIOXIDANTS

Free radical production is enhanced in both the ischemic core and penumbral following stroke injury, and this is believed to cause much of the damage seen in the core as well as penumbra. There are many agents that either block free radical production or inhibit its activation that have been shown to be very effective in experimental models. Uric acid is a well-known natural antioxidant present in fluids and tissues. Administration of uric acid resulted in a highly significant reduction in ischemic damage and improved behavioral outcome (Yu *et al.*, 1998). Edaravone, Tetramethylpyrazine, alpha-phenyl-N-tert-butyl-nitron, FR210575, and NXY-59 are other free radical inhibitors that were effective against experimental stroke injury. EGb-761 is a free radical scavenger derived from a concentrated extract of Ginkgo that is currently in a phase 2 clinical trial (Legos *et al.*, 2002). Clinical trials with free radical scavengers have had limited success after acute ischemic stroke, but have had more success in the treatment of subarachnoid hemorrhage. Patients administered nicaraven after subarachnoid hemorrhage had a reduced rate of delayed ischemic neurologic deficits. NXY-59 was well tolerated in patients with stroke and currently is being studied for efficacy by AstraZeneca Pharmaceuticals.

#### ANTI-APOPTOTIC AGENTS

Accumulating evidence strongly suggests that apoptosis contributes to neuronal cell death in stroke injury. Caspases, a family of cysteine-aspartate proteases that include at least 14 members divided into three groups (I, II, and III), are essential players in apoptotic death. Many groups have studied the effects of caspase inhibition on cerebral ischemia-induced neurodegeneration by using the broad spectrum caspase inhibitor z-VAD, either in the fluoromethylketone (fmk) or dichlorobenzoyloxopentanoic acid (dcb) form and z-DVED-fmk. Both inhibitors were neuroprotective in mouse models of transient cerebral ischemia, and z-VAD was neuroprotective also in transient and permanent models in the rat (Hara *et al.*, 1997). Ac-YVAD-cmk (Ac-Tyr-Val-Ala-Asp-cmk), a caspase group I (caspase-1-like) inhibitor also was shown to be neuroprotective in a mouse transient model of cerebral ischemia (Hara *et al.*, 1997). Peptide-based caspase inhibitors also have been shown to prevent

neuronal loss in animal models of stroke. A protein identified as having anti-apoptotic activity in many different cell types, including neurons, is Bcl-2. Bcl-2 is one of a family of related proteins, some of which have anti-apoptotic properties (e.g., Bcl-xL, Mcl-1), whereas others are pro-apoptotic (e.g., Bax, Bid, and Bad) (Mattson *et al.*, 2000). The efficacy of anti-apoptotic agents in human stroke patients has not been tested.

#### ANTI-INFLAMMATORY APPROACHES

Inflammation in stroke is characterized by the accumulation of leukocytes and activation of resident microglial cells. Inflammatory cells can contribute to stroke pathology through two basic mechanisms: they form aggregates in the venules after reperfusion or enter infarcted tissue and exacerbate cell death through production of free radicals and cytokines. Cell adhesion molecules such as selectins, integrins, and ICAMs permit endothelial-inflammatory cell interactions. Treatment with anti-selectin antibodies successfully decreased infarct volume up to 70% after transient focal ischemia. The anti-ICAM-1 antibody also has shown to decrease infarct size after transient but not permanent focal ischemia. However, a recent clinical trial using murine anti-ICAM-1 antibody enlimomab worsened neurologic score and mortality in patients and a follow-up study using the murine anti-rat ICAM-1 antibody in rats also found an increase in infarct volume and no efficacy. It is believed that immune activation in response to the foreign mouse protein probably accounted for the clinical and follow-up experimental results (Furuya *et al.*, 2001). Recently a phase 2 trial using anti-CD11b/CD18 agent UK-279276 has been completed, and demonstrated that this compound is safe and well tolerated. Another integrin antagonist LDP-01 is currently in phase 2 trials for stroke patients. Mitogen activated protein kinases (MAPK) have been linked to inflammatory cytokine production and cell death in ischemic stroke injury. SB-239063 is a MAPK inhibitor that reduced infarct size and improved neurological outcome following focal stroke in rodents. VX-745 is another orally active MAPK inhibitor tested in a clinical trial against stroke; the trial was stopped due to adverse effects of this drug.

MMPs are enzymes that break down components of the extracellular matrix and enhance BBB breakdown after stroke, promote hemorrhage, and increase inflammation. MMP inhibitors such as BB-94 and KB-R7785 decreased infarct volume in mice after permanent focal ischemia (Jiang *et al.*, 2001). MMP inhibitors have been evaluated in patients for their anti-angiogenic properties and are well tolerated. Although chemokines can have pro- or anti-inflammatory actions, the overall effect of chemokine up-regulation in ischemia-reperfusion injury is detrimental. NR58-3.14.3, a novel broad-spectrum inhibitor of chemokine function significantly reduced the lesion volume by up to 50%, which was associated with a

marked functional improvement (Beech *et al.*, 2001). Several other anti-inflammatory cytokine approaches were tested in experimental stroke models, including various antibodies that target inflammatory proteins. However, there have been no successful clinical trials of such anti-inflammatory agents reported so far. As mentioned earlier, microglial activation following stroke insult plays a role in promoting inflammatory processes, but therapeutic approaches that specifically target microglia are lacking.

#### Conclusion

Ischemic and hemorrhagic stroke brain injury result from the interaction of complex pathophysiological processes. The molecular biology of stroke injury is a rapidly growing field that may lead to the identification of novel stroke therapies. Mechanisms of cell damage are determined by testing effects of different manipulations on the extent of cell death in animal and brain cell and slice culture models. Several different models of stroke have been developed. The three main classes of *in vivo* animal models are global ischemia, focal ischemia, and hypoxia/ischemia. Technological advances and experimental discoveries have begun to define the cellular and molecular mechanisms involved in stroke injury. Exploration of these targets led to the development of numerous agents that target various injury pathways. Despite numerous agents that can prevent the cascade of events leading to ischemic neuronal death in animal models, there is no neuroprotective agent that has been shown to conclusively improve stroke outcome in humans. The inconsistency between animal results and clinical trials may be due to several factors, including the heterogeneity of human stroke, morphological and functional differences between the brain of humans and animals, the relatively long post-stroke delay in administration of the drugs in clinical trials, and the better experimental control of physiological variables such as temperature, blood pressure, and differences in evaluating efficacy in animal models. The window of therapeutic opportunity in animal models is not necessarily predictive of the time window in humans, but the determination of relative windows is useful. In animal models, the time of the stroke or ischemic onset is known precisely and the administration of drug is at precise times, whereas in humans this may not be the case. There are numbers of important issues that remain unresolved regarding the translation of experimental developments to the clinical setting. Novel interventions will be required to overcome hurdles associated with bench-to-bedside translation. Finally, it is important to note that risk factors for stroke have been established (overeating, hypertension, sedentary lifestyle, and smoking). A vigorous effort to reduce these risk factors would therefore have a major impact in reducing the incidence of stroke.

# Werner Syndrome as a Model of Human Aging

Raymond J. Monnat, Jr.

*This chapter reviews clinical and basic science aspects of Werner syndrome (WS), a heritable human disease that displays features suggestive of premature aging. The resemblance of changes in WS to those observed in normal aging has long suggested WS may be a useful model in which to study the biology of aging and to identify mechanistic pathways responsible for age-associated diseases that are prevalent in WS patients and in normal aging such as atherosclerosis, neoplasia, diabetes mellitus, and osteoporosis. This chapter summarizes our understanding of the WS clinical phenotype. Current understanding of in vivo functions of the Werner syndrome protein is summarized, together with a discussion of how the loss of WRN function may promote disease pathogenesis in WS patients and in normal individuals. Subsections provide an historical overview of WS and WS research; a description of WS as a clinical disease entity, together with diagnostic criteria for WS; a discussion of the relationship of WS to normal aging; a summary of our current understanding of the WRN gene and the mutational basis for WS; a discussion of in vivo functions of the WS protein in human somatic cells, and how loss-of-function may be linked to disease pathogenesis; and an introduction to the more promising animal models of WS. A selection of the most useful additional resources on WS clinical medicine and biology are included to aid those interested in learning more about this fascinating and instructive human disease.*

## Introduction

Werner syndrome (WS) is an uncommon, autosomal recessive human disease that displays clinical features suggestive of premature aging. The initial description of WS was by Otto Werner, a German medical student, in 1904 (Werner, 1985). Werner saw a family in the north of Germany consisting of four siblings, ages 31 to 40, who shared common features including short stature, premature graying of the hair, bilateral cataracts, skin changes (hyperkeratosis, scleroderma-like changes and ulceration) that were most severe on the feet and ankles, atrophy of the extremities, and, in females, an early

cessation of menstruation. He noted that one of the siblings, a 36-year-old male, gave “the impression of extreme senility.” Werner published these observations as part of his doctoral thesis, though he did not further study these or similar patients during the remainder of his career. He practiced general medicine in Eddelak, a small village on the North Sea near the Danish border, where he died in 1936 (Pehmoeller, 2001).

The eponym *Werner’s syndrome* was first used in 1934 by Oppenheimer and Kugel in reporting findings in a patient (Oppenheimer and Kugel, 1934). Their paper, together with the more comprehensive study by Thannhauser (1945) of five additional cases, provided an accurate clinical description of WS that distinguished it from Rothmund (now Rothmund-Thomson) syndrome. The subsequent diagnosis of Werner syndrome in three affected, American-born sisters in a Japanese-American sibship seen in Seattle in the early 1960s led to further, detailed clinical and pathological characterization of Werner syndrome. Part of this characterization included a formal genetic analysis that firmly established an autosomal recessive mode of inheritance. These observations, together with a critical analysis of 122 additional cases, were published in 1966 (Epstein *et al.*, 1966). This landmark paper remains readily accessible and a key source of information for investigators interested in WS (see Recommended Resources).

The modern clinical and biological investigation of WS has been an international effort. This reflects both the worldwide occurrence of WS (Goto, 1997) and early collaborative efforts by investigators in Japan (where WS is prevalent), the United States, and Western Europe to better define and understand the WS clinical phenotype and its underlying biology. The first major gathering of investigators to discuss this work was in Kobe, Japan, in 1982. This United States–Japan Cooperative Seminar on Werner’s Syndrome and Human Aging was sponsored by the U.S. National Science Foundation and the Japan Society for the Promotion of Science. The proceedings of this workshop were subsequently published and represent an important first summarization of modern work to better define and understand WS (Salk *et al.*, 1985). The published proceedings also include an important

selection of published primary sources of information on WS (e.g., Epstein *et al.*, 1966; Salk, 1982; Thannhauser, 1945) together with an edited translation of Otto Werner's thesis (Werner, 1985).

Several subsequent small workshops were sponsored by the U.S.–Japan Cooperative Cancer Research Program during the 1990s and led to further discussion of and interest in WS. These were part of a long-standing joint venture of the U.S. National Cancer Institute and the Japan Society for the Promotion of Science. Meetings held in 1994, 1996, and 1997 brought together investigators interested in WS as a cancer predisposition syndrome (1994), in clinical and biological aspects of WS (1996), and in the relationship of WS to other pediatric cancer syndromes (1997). The focus for these meetings broadened with a U.S.–Japan Workshop on Cancer in Human RecQ Helicase Gene Disorders (February 2002), the Keystone Symposia on DNA Helicases, Cancer and Aging (March 2002 and 2005), and a U.S. NIH-sponsored International Workshop on Werner Syndrome held in May 2003. Regrettably, the results of only one of these very productive workshops were captured in a meeting report (Bohr, 2003). The broader focus of these more recent meetings reflects the recognition that WS, Bloom syndrome, and Rothmund-Thomson syndrome are all human genetic instability/cancer predisposition disorders that result from mutations in different members of the five-member human RecQ helicase protein family (see later; Bachrati and Hickson, 2003; Opresko, Cheng *et al.*, 2004).

Attempts were made in the 1980s and early 1990s to isolate or map the affected gene in WS. These approaches took advantage of potentially useful cellular phenotypes for complementation such as a severe *in vitro* cell proliferation defect and chromosomal instability, and the fact that WS is an autosomal recessive disease that likely resulted from a single gene defect. Attempts at functional complementation to identify the *WRN* gene were not successful for at least two important reasons: the scarcity and poor growth properties of primary cells from WS patients that were used as complementation hosts, and the large size of the *WRN* gene and the *WRN* open reading frame (see later). In contrast, linkage mapping using the then-new technique of homozygosity mapping was successful, and led in 1992 to assignment of the *WRN* locus to the proximal short arm of chromosome 8 in a region defined by five anonymous DNA markers (Goto *et al.*, 1992). This initial linkage assignment, together with rapid maturation of methods for positional cloning in the early 1990s, led in 1996 to identification of the *WRN* locus and of unambiguous pathogenic mutations in the *WRN* gene of WS patients (Yu *et al.*, 1996).

Successful positional cloning of the *WRN* gene with delineation of WS-associated *WRN* mutations and predictions of potential activities encoded in the *WRN* protein provided a powerful stimulus for subsequent work on WS. There was an immediate effort in several

laboratories to confirm predicted biochemical activities, and then identify *in vivo* functions, of *WRN*. There was also renewed speculation on how the loss of *WRN* function could generate WS cellular and clinical phenotypes. Recent work has also begun to focus on genetic variation in the *WRN* gene, and the association of *WRN* mutations and polymorphisms with disease risk and disease pathogenesis in the general population. Each of these areas of investigation is discussed in greater detail below.

## Werner Syndrome as a Clinical Disease Entity

The key clinical features of Werner syndrome were readily recognized by Otto Werner in the first patients he identified and described in 1904. These clinical signs or findings, outlined in Table 80.1, were subsequently confirmed and further elaborated by Oppenheimer and Kugel (1934), Thannhauser (1945), and Epstein *et al.*

TABLE 80.1  
Diagnostic criteria for Werner syndrome

### Consistent findings

- **clinical findings** (onset > age 10)
  - ◆ short stature
  - ◆ bilateral cataracts
  - ◆ premature graying and loss of scalp hair/eyebrows
  - ◆ scleroderma-like skin changes
- **history**
  - ◆ parental consanguinity (3rd cousin or closer)
  - ◆ affected sib
- **laboratory**
  - ◆ elevated 24 hr urinary hyaluronic acid secretion

### Additional findings

- **clinical findings**
  - ◆ flat feet
  - ◆ voice changes
  - ◆ hypogonadism
- **history or laboratory findings**
  - ◆ diabetes mellitus
  - ◆ osteoporosis
  - ◆ soft-tissue/tendon calcification
  - ◆ premature atherosclerosis, myocardial infarction, stroke
  - ◆ neoplasia

### Diagnostic likelihood of Werner syndrome

- **definite:** all of consistent clinical and history findings
- **probable:** short stature, bilateral cataracts and scleroderma-like skin changes, any two other clinical, history or laboratory findings
- **possible:** bilateral cataracts or scleroderma-like skin changes, any four other additional clinical, history or laboratory findings
- **exclusion:** onset of clinical or laboratory findings ≤ age 10

(1966) in their analyses of WS patients and pedigrees. Among the most consistent and earliest of the features of WS to be observed are short stature, bilateral cataracts, the early graying and loss of hair, and scleroderma-like skin changes. All four features have been observed in all or nearly all patients (Epstein *et al.*, 1966; Goto, 1997; Tollefsbol and Cohen, 1984). They appear *de novo*, and are not the secondary consequence of another systemic disease process, or the result of a primary endocrine deficiency or dysfunction syndrome. Each of these features or clinical signs of WS are discussed briefly, next, together with less consistently observed changes. This constellation of changes and the clinical appearance and progression of these changes have been used to develop criteria for the clinical diagnosis of WS.

### SHORT STATURE

The short stature of WS patients results from a failure to undergo an adolescent or pubertal growth spurt. Short stature, together with progressive thinning and atrophy of the limbs and a stocky trunk, give patients a Cushingoid appearance that is readily apparent in full body clinical photographs (see, for example, patient photos in Figure 2 of Goto, 2001).

### GRAYING AND LOSS OF HAIR

Early graying and loss of hair are, together with short stature, among the earliest and most consistent changes observed in WS patients. Hair graying and loss start late in the second decade of life, and first affect the scalp and eyebrows. The loss of hair pigmentation is progressive and may lead over the course of a decade or more to complete loss of pigmentation. The premature graying and loss of hair also extend to other areas of the body, although these changes usually start later and may not be as extensive as the changes observed in the scalp and eyebrows.

### CATARACTS

Bilateral ocular cataracts are a consistent feature of WS and first appear or are reported in many patients by the second or third decades of life. The cataracts consist of

posterior cortical and subcapsular opacification. Vacuoles and small punctate opacifications in other parts of the lens have also been noted, though are not a consistent part of the lens changes. This type of cataract, often referred to as juvenile, can be readily distinguished from the more common opacification of the lens nucleus observed in the senile cataracts of normal aged individuals. Vision is otherwise unimpaired, and thus can be restored following cataract removal.

### SCLERODERMA-LIKE SKIN CHANGES

Skin changes were first clearly described in the patient series reported by Thannhauser, who distinguished changes in WS patients from those commonly seen in scleroderma patients or in patients with Rothmund-Thomson syndrome (Thannhauser, 1945). The histologic appearance of skin biopsies from WS patients reveals an interesting mix of atrophic and proliferative changes. There is epidermal atrophy that extends to include skin appendages (e.g., hair follicles, sweat and sebaceous glands), in conjunction with focal hyperkeratosis and basal hypermelanosis. Dermal subcutaneous connective tissue atrophy is common, and often is found in conjunction with dermal fibrosis. Muscle, adipose, and connective tissue underlying the skin is often atrophic. This constellation of changes gives the skin a tight, white, and shiny or contracted appearance, with a loss of normal elasticity.

These cutaneous changes often are first seen and may be most prominent in the face and extremities. Skin changes in the face lead to a progressive sharpening of facial features to give patients what is often described as a pinched, beaked, or bird-like appearance (see the patient photo panel in Figure 3 of Goto, 2001). The lower extremities, especially the feet, are often markedly affected by these changes, leading to foot deformation, ulceration of nonpressure-bearing portions of the foot and ankles, and calcification of soft tissue and tendons (Hatamochi, 2001; Figure 80.1). Laryngeal changes consisting of a mix of proliferative and atrophic changes are likely responsible for the thin, high-pitched voice noted of many

**Figure 80.1** Skin and soft tissue changes in Werner syndrome patients. **A.** Scleroderma-like skin changes, hyper-pigmentation and ulceration (arrow) of the lateral border of the left foot in a male Japanese WS patient age 37. **B.** Localized calcification of the Achilles tendon (arrow) and plantar tendon insertion site calcification in a Japanese female WS patient age 54. Both photos were previously published (Hatamochi, 2001) and are used here with kind permission of Dr. Atsushi Hatamochi, Professor of Dermatology, Dokkyo University School of Medicine, and the Japanese Scientific Societies Press.

patients, although the associated laryngeal pathology has not been well studied.

#### OTHER PROMINENT CLINICAL FEATURES OF WERNER SYNDROME

Several less consistent clinical findings have been noted in a portion of WS patients. These additional findings (see Table 80.1) have been mentioned in many independent reports of WS, and thus are likely to be part—albeit a more variable part—of the WS phenotype. Most notable among these changes are clinically important disease states that we commonly associate with aging: atherosclerosis and its cardiovascular and cerebral sequella; a mix of nonepithelial and epithelial neoplasms (see later); osteoporosis that is characteristically most severe in the distal phalanges; diabetes mellitus; and hypogonadism affecting both males and females. Each of these disease states in part can be explained by proliferative and atrophic changes at the tissue level (see later). A few pertinent negatives also need to be mentioned. Among these, the most notable are that development, structure, and function of the central and peripheral nervous systems are normal, and WS patients are invariably of normal or higher-than-normal intelligence. Also, few or no indications of primary endocrine defects or abnormalities have been reported in WS patients beyond secondary changes that accompany the development of diabetes mellitus or with gonadal atrophy and the loss of reproductive function.

#### CANCER IN WERNER SYNDROME

WS patients are at increased risk of developing cancer (Goto *et al.*, 1996; Monnat, 2001; Monnat, 2002). The elevated risk of neoplasia in WS patients is of particular biological interest. As discussed later, neoplasia may be an expression of important mechanistic links between WRN function *in vivo*, genome stability assurance, and the limitation of cell proliferation defects. The elevated risk of neoplasia in WS is selective in that only a small subset of neoplasms are clearly elevated in incidence as compared with general population controls (see Table 80.2). The following neoplasms, in order of decreasing frequency, have been observed most often in WS patients and occur at higher or much higher frequency than in normal population controls: soft tissue sarcomas, thyroid carcinoma, meningioma, malignant melanoma, malignant or preneoplastic hematologic disease, and osteosarcoma. Many other neoplasms, including common adult epithelial malignancies, have been observed in WS patients. However, it is not clear whether the risk of developing these neoplasms is significantly elevated. Of note, the histopathologic spectrum of neoplasms observed in WS overlaps with, though is distinct from, that observed in patients with Bloom syndrome and Rothmund-Thomson syndrome,

TABLE 80.2  
Neoplasia in Werner syndrome

Frequent (2/3 of neoplasms)	Less common (1/3 of neoplasms)
<b>Soft tissue sarcomas</b>	<b>Non-melanoma skin cancer</b>
malignant fibrous histiocytoma	<b>Hepatobiliary carcinomas</b>
leiomyosarcoma	hepatocellular
fibrosarcoma	cholangiocarcinoma
malignant schwannoma	gallbladder
synovial sarcoma	<b>Genito-urinary</b>
rhabdomyosarcoma	bladder carcinoma
<b>Thyroid carcinoma</b>	uterine/ovarian carcinoma
follicular	renal cell carcinoma
papillary	prostate carcinoma

two other RecQ helicase deficiency syndromes, (Monnat, 2001).

Several pathologic and clinical aspects of neoplasia in patients indicate that WS is a classical cancer predisposition syndrome. WS patients develop neoplasms at a comparatively early age and often display unusual sites of presentation (e.g., osteosarcoma of the patella) or less common histopathologic subtypes (e.g., follicular, as opposed to the more common papillary, type of thyroid carcinoma) than do population controls. The elevated risk of melanoma in WS provides a striking example of unusual histology. The melanoma seen in WS patients is exclusively acral lentiginous melanoma (ALM), a comparatively rare melanoma subtype that arises on the palms and soles, or in mucosa of the nasal cavity or esophagus. The risk of ALM is most clearly elevated in Japanese WS patients. This suggests the existence of patient- and population-specific modifiers for ALM in the absence of WRN function. A final expression of elevated cancer risk and predisposition in WS is the occurrence of

## 80. Werner Syndrome as a Model of Human Aging

multiple tumors: there are numerous reports of multiple, concurrent, or sequential neoplasms of different histology; for example, thyroid carcinoma and osteosarcoma, with up to five neoplasms having been reported in individual patients. Estimates of the increased risk of neoplasia in WS patients range from ~30-fold elevated overall lifetime risk across all tumor types to ~1000-fold elevated risk for acral lentiginous melanoma (Goto *et al.*, 1996; Monnat, 2001; Monnat, 2002).

### CLINICAL PROGRESSION OF WS

One aspect of WS that is not well conveyed by Table 80.1 is the progressive nature of the WS clinical

phenotype: a complex constellation of changes that may develop over two or three decades, after having been first noticed beginning in the second decade of life. A sense of the progressive nature of the WS clinical phenotype and visible changes can be gleaned from pairs of patient photos taken in early adulthood, and later in mid-life when the clinical phenotype of WS is often well-developed (see Figure 80.2).

These two patients and many other WS patients appear remarkably normal until the time of puberty, after which the most prominent of the features outlined in Table 80.1 become apparent over the subsequent 10 to 20 years. A simple animation from one of these patient

**Figure 80.2** Clinical progression and features of Werner syndrome. **A, B.** Photographs of a Werner syndrome patient reported by Epstein *et al.* (1966) as Case 1, at ages 15 (**A**) and 48 (**B**). **C, D.** Photographs of a second patient at ages ~13 (**C**) and 56 (**D**). Note in both instances the rounded face, sharp features, graying, thinning, and loss of scalp and eyebrow hair and, in **D**, the thin, atrophic forearms and elbow ulceration. Panels **A** and **B** are used with kind permission of Drs. George Martin and Nancy Hanson of the International Registry of Werner Syndrome, and Lippincott Williams & Wilkins (**B**). The patient photographs in panels **C** and **D** were previously published in Martin (2005), and are used here courtesy of the patient's spouse with informed consent of the patient and of Drs. George Martin and Nancy Hanson, and Elsevier Press.

photo pairs can be viewed on the Web to get a sense of clinical progression of the changes in external appearance (see Recommended Resources).

The progression of clinical changes in WS can usefully be thought of as having three distinct phases. The first of these comprises the absence of an adolescent growth spurt followed over the subsequent decade by the appearance of graying and loss of hair, the development of skin changes, and of cataracts. A second wave of changes, often first seen late in the third or in the fourth decades of life, include skin ulceration, hypogonadism, and reproductive failure, together with a progressive worsening of the primary changes. A third phase may follow with the development of clinically important disease processes such as atherosclerosis, osteoporosis, diabetes mellitus, and cancer. These diseases occur proportionately earlier in WS patients than in otherwise normal individuals of comparable age, and are an important cause of premature morbidity and mortality. The three leading causes of death in WS patients are atherosclerotic cardiovascular disease, neoplasia, and, in a minority of cases, infection. The mean age at death in a Japanese clinical series was ~47 years, though well-documented patients have lived into the seventh decade of life (Goto, 1997).

#### DIAGNOSTIC CRITERIA AND DIFFERENTIAL DIAGNOSIS

The complex, progressive, and variable nature of the WS clinical phenotype makes the clinical diagnosis of WS challenging. This is especially true in young adults, where there are often few convincing signs or changes and where there may be no family history of WS to raise clinical suspicion. There are no universally accepted criteria for the diagnosis of WS. However, a useful set of diagnostic criteria and a scoring system have been developed by investigators at the International Registry for Werner Syndrome (Table 80.1, bottom panel; see also Recommended Resources). These criteria, together with molecular approaches to identify common *WRN* mutations or the loss of WRN protein expression (see later), can be used in most instances to confirm or exclude a diagnosis of WS in suspected affected individuals. The ability to couple clinical and molecular diagnostic approaches, as noted later, now allows the unambiguous identification of affected or at-risk homozygous mutant individuals, and of heterozygous carriers in families regardless of age or clinical findings.

The availability of a consistent set of clinical diagnostic criteria and of molecular diagnostic criteria for WS have provided sharper definition of WS as a disease entity, and provide a way to distinguish WS from other human diseases and syndromes that may mimic WS. Two groups of patients who may be confused with, or not easily distinguished from, typical or classic WS include patients who fulfill the clinical diagnostic criteria for WS as outlined in Table 80.1, though lack mutations in the *WRN*

gene; and patients who resemble WS patients though fail to fulfill the diagnostic criteria outlined in Table 80.1. This second group is often ascertained as potential variant or atypical WS. Both of these groups of patients are rare, and from the experience of the International Registry of Werner Syndrome together represent no more than a small fraction of suspected WS patients.

Despite their rarity, these WS look-alikes are of considerable clinical and biological interest as they are likely to be highly enriched for rare mutations in proteins that act with—or act on—WRN to modify or target its function *in vivo*. There are strong theoretical grounds for proposing the existence of these individuals, in light of the growing number of proteins that may act with WRN (see later). There are experimental hints, for example, of at least one additional complementation group for WS in addition to the group represented by inactivating mutations in the *WRN* gene (Prince *et al.*, 1999). These WS phenocopies or partial phenocopies represent an important area for additional clinical and molecular diagnostic work.

A portion of the second group of patients just mentioned, with what has been termed atypical Werner syndrome, share some clinical features of WS (see Table 80.1), though lack mutations in the *WRN* gene. A small number of these patients were recently found to carry germline mutations that alter splicing of the *LMNA* or lamin A/C gene (Chen *et al.*, 2003). A subset of different *LMNA* mutations that alter the splicing of *LMNA* mRNA have been found in patients with Hutchinson-Gilford progeria (HGPS), a rare, heritable, severe, and rapidly progressive disease that is often referred to simply as progeria or childhood progeria. Of note, other mutations that alter splicing or the properties of *LMNA* or lamin A/C have been associated with at least eight other clinically distinguishable diseases that have been collectively termed the laminopathies. This fascinating group of diseases affect predominantly nerve, muscle, connective tissue, or adipocytes (Broers *et al.*, 2005). HGPS and WS show little clinical overlap, and are unlikely to share any deep mechanistic similarities. Thus the existence of atypical WS as a distinct clinical entity has been controversial. It would appear to make the best sense at present to consider atypical WS patients with *LMNA* mutations that affect RNA splicing as having an atypical form of HGPS, rather than a variant form of WS (Hegele, 2003).

#### ADDITIONAL WORK NEEDED TO BETTER CHARACTERIZE WS

Our present understanding of clinical and pathologic features of WS is far from complete. This reflects both the comparative rarity of WS (see later) and the way in which patient data have been accumulated during the diagnosis or treatment of individual patients or their relatives rather than as part of a research protocol.

As a result, there is important work needed on all aspects of WS clinical medicine, pathology, and molecular and cellular function. A few of the more important areas that should receive emphasis to improve our understanding of WS are outlined here.

#### *Systematic phenotyping*

One way to improve our understanding of WS as a disease entity is to use our current understanding of clinical and pathologic features of WS to identify areas where systematic—or more quantitative—data need to be collected. For example, the clinical diagnosis of WS can often be made with confidence if the patient history and physical exam are systematic, and draw on aspects of history and clinical signs and symptoms already known to be associated with WS (see Table 80.1). Medical information forms available from the International Registry of Werner Syndrome Web site (see Recommended Resources) have been constructed with this end in mind, and can be used to collect key pieces of data to aid diagnosis during the history and physical examination of suspected WS patients. Table 80.1 also highlights those areas where we need to identify appropriate normal population control data for comparison with data collected from WS patients and their family members.

#### *Longitudinal and cohort analyses*

A second area where much productive work remains to be done is in the longitudinal analysis of WS in individual patients and their families. Few longitudinal data now exist, though will be essential to better understand the clinical expression and clinical progression of WS and of associated diseases (see Table 80.1). Careful family or pedigree studies linked to molecular data could also serve as the starting point for identification of important genetic or environmental factors that may modify either the clinical expression of WS or the development of associated diseases. Coupled clinical and molecular analyses that are longitudinal, within pedigrees, would also help resolve the question of whether there is a weakly penetrant haploinsufficiency or heterozygote phenotype in carriers of single mutant *WRN* alleles (Moser, Bigbee *et al.*, 2000). This is a point of considerable importance for, as noted later, heterozygote or haploinsufficiency phenotypes that may have clinical importance have been identified in cells and cell lines from *WRN* heterozygotes.

#### *Patient-centered support to facilitate care and research*

The ability to identify, follow, and support individual patients and their families would be immeasurably improved by a Werner patient-centered support group that provided consistent, accurate, general information on WS, developed guidelines for the clinical care of WS patients, and served to identify referral physicians knowledgeable about and skilled in the care of WS patients. An excellent example of this type of support

group is the Fanconi Anemia Research Fund (FARF). The FARF was founded to support patients and families with Fanconi anemia, a rare, heritable form of bone marrow failure that is also a predisposition to leukemia and squamous cell carcinoma. The FARF provides an example of how to create a support system that serves patients and their families by providing information and advice on patient care, while facilitating further study of biological and clinical aspects of a rare, heritable disease by linking patients and their families to investigators and clinicians (see Recommended Resources).

#### *Tumor specimens*

Tumor studies of WS point to a fourth area where more work is needed. Careful pathologic analysis of even small series of tumors from WS patients already has been shown to be productive and revealing. For example, the analysis of a small number of osteosarcomas arising in Japanese WS patients revealed important clinical and pathologic differences between OS in WS patients as compared with the general population, and provided a first estimate of the relative risk of developing OS in WS (Goto *et al.*, 1996; Ishikawa *et al.*, 2000). Thus the collection of additional WS tumor specimens, together with information on the response to and the success of treatment and the presence of atypical or precursor lesions, has a very high priority. These materials, even if conventionally prepared for histopathology, often can be used for a growing range of immunocytochemical and molecular analyses including mutation typing of the *WRN* gene or of other loci of interest.

#### *Tissue resources to facilitate research*

The diagnosis and treatment of tumors or other lesions requiring surgical intervention, together with the rare opportunity to autopsy WS patients, represent our best opportunities to preserve tumor and normal tissue specimens from patients and to provide material appropriate for analyses that demand viable cells or fresh tissue for procedures such as RNA-based microarray analyses. Skin samples from autopsy can be readily cryopreserved as a source of primary dermal fibroblast cultures. Similar samples served as the source of primary fibroblast strains and their SV40 large T-antigen or telomerase catalytic subunit-immortalized cell line derivatives that have proven remarkably useful for analyses of WS cell proliferation, cytogenetic and DNA damage response abnormalities. Biopsy and autopsy specimens may also serve as a useful source for additional cell strains or cell lines.

## **The Relationship of WS to Normal Aging**

Published accounts of WS from Otto Werner have commented on the similarities between WS and what might be expected in premature aging. This idea is supported by the striking clinical appearance and progression of

changes observed in WS patients (see Figure 80.2). The consistent appearance of features of advanced chronological age in patients in the fourth and fifth decades of life led, not surprisingly, to the idea that WS is a premature or accelerated aging syndrome and that there *must* be deep mechanistic links between WS and normal aging. Despite these apparent similarities, careful clinical and/or pathologic examination of WS patients has consistently pointed out differences in the nature or degree of change observed in WS as compared with normal aging.

Quantitative differences between WS and normal aging include the greater extent or severity of the loss of hair or hair color; of the extent of calcification of heart valve leaflets; of atherosclerosis and of osteoporosis; and of the loss of reproductive function. Qualitative differences between WS and normal aging include the unusual type of cataract observed in WS patients as opposed to normal aged individuals; the unusual changes observed in skin and subcutaneous connective tissue of the face and extremities, together with nontrophic ulceration; the unusual spectrum of neoplasms; the location and extent of soft tissue calcification; and the autosomal recessive nature of WS (Epstein *et al.*, 1966).

In light of these differences, there has been substantial discussion of the value of studying WS, related diseases, or related animal models as ways to gain insight into mechanistic aspects of aging or of age-associated disease pathogenesis. An oft-cited disadvantage of studying diseases such as WS is that they may represent at best a phenocopy of what we are *really* interested in understanding, and thus mechanistic or pathophysiologic blind alleys as regards the mechanisms underlying normal aging or disease pathogenesis (Miller, 2004). A more optimistic view is that a subset of the disorders that affect the apparent rate of aging or the appearance of age-associated diseases *will* have mechanistic overlap with normal aging. Thus these diseases may provide a useful way to bring data on many aspects of human biology, genetics, and medicine to a focus to formulate and test specific hypotheses about age-dependent disease pathogenesis. These diseases or syndromes may also provide useful instances in which to test ideas about more general mechanisms that contribute to human aging (Kipling *et al.*, 2004; Martin, 2005).

This issue was discussed in some detail by Epstein *et al.* (1966) in their clinical, pathologic, and genetic characterization of WS. Their conclusions on this point are worth revisiting. They stated that the many observed differences between normal aging and WS led to the conclusion that WS was neither a precocious or accelerated form of aging, but “may be better considered a ‘caricature’ of aging, exaggerating, although not necessarily by the same mechanisms, some of the clinical and pathologic changes which connote aging” (Epstein *et al.*, 1966). This conclusion is still largely sound after 40 years of additional work on WS, despite the large number of

references to WS in the popular and scientific presses as a premature aging syndrome.

## The WRN Gene and Disease-Associated Mutations

The chromosome 8p12 *WRN* gene was identified in 1996 by positional cloning and predicted to encode a 162 kDa member of the human RecQ helicase family (Yu *et al.*, 1996). The human RecQ helicase family consists of five proteins that may possess 3' to 5' helicase and ATPase activities. WRN is unique among the human RecQ proteins in possessing an additional 3' to 5' exonuclease activity (Fry, 2002; Bachrati and Hickson, 2003; Opresko, Cheng *et al.*, 2004; Figure 80.3). Two stable RNAs are expressed from the *WRN* locus in human cells, and the shorter of these, of 5.8 kb, is expressed ubiquitously at varying levels in many cell types, tissues, and organs (Yu *et al.*, 1996). The 162 kDa WRN protein can be detected by Western blot analysis in cell lines and tissue samples from normal individuals, and from heterozygous carriers of single mutant copies of the *WRN* gene (Goto *et al.*, 1999; Kawabe *et al.*, 2000; Moser, Kamath-Loeb *et al.*, 2000). No systematic study of the level of expression of WRN protein as a function of human cell type or of development has as yet been published.

Thus far, a total of 25 different mutations in the *WRN* gene have been reported in WS patients. These published examples have been assembled in the form of a Web-accessible Locus-Specific Mutational Database that contains detailed information for each published mutation (Moser *et al.*, 1999; see Recommended Resources). All of these *WRN* mutations, regardless of molecular type, confer a common biochemical phenotype—they truncate the WRN open reading frame, and lead to the loss of WRN protein from patient cells (Goto *et al.*, 1999; Moser, Kamath-Loeb *et al.*, 2000). This biochemical phenotype of WS patient mutations is thus consistent with the autosomal recessive inheritance pattern of WS. The absence of missense mutations that selectively inactivate the WRN helicase or exonuclease activity from this series of WS patient mutations is notable, and suggests that both activities need to be lost to promote WS pathogenesis. This point has been further addressed experimentally (see later; Swanson *et al.*, 2004). At least 17 additional *WRN* mutations have been identified in WS patients that resemble those already described. These will be added to the *WRN* Mutational Database as they are published.

The availability of mutation typing has allowed reinvestigation of the prevalence of WS, and of the frequency of mutations and heterozygous carriers in defined populations. Previous methods to address these questions have included case counting in defined populations, and comparisons of the frequency of consanguinity in WS pedigrees with population estimates of consanguinity. Prevalence estimates by these methods have varied

## 80. Werner Syndrome as a Model of Human Aging

**Figure 80.3** The human Werner syndrome protein WRN and a summary of mutations identified in the *WRN* gene of Werner syndrome patients. The central box indicates the *WRN* open reading frame with amino acid residue numbering indicated on top, and cDNA bp coordinates below, the left end of the open reading frame. The positions of five protein motifs are indicated by shaded boxes and labels: exonuclease and RecQ helicase domains, RecQ consensus (RQC) domain, the helicase and RNaseD-C-terminal (HRDC) domain, and the C-terminal nuclear localization signal (NLS). The location and molecular nature of mutations identified in Werner patients are indicated by symbols below the open reading frame to indicate the corresponding mutation location in the *WRN* cDNA sequence. All of the depicted mutations, stop codons (TER), frameshift mutations that alter the open reading frame (FS/TER), and mutations that alter splicing and the reading frame (Splice FS/TER) lead to truncation of the *WRN* open reading frame and loss of a C-terminal nuclear localization signal. The resulting proteins are unstable mislocalized and/or lost from patient cells. These data have been compiled and are available in the *WRN* Mutation and Polymorphism Database developed and maintained at the University of Washington (see Recommended Resources). See the color plate section.

over a 50-fold range ( $1/22,000$  to  $1/10^6$ ), with corresponding allele frequencies ranging from 0.0067 to 0.001. More recent estimates of allele frequency that make use of molecular diagnostic criteria are consistent with these allele frequency estimates. These wide-ranging estimates reflect uncertainties in several of the population estimates used to calculate each value, rather than inherent unreliability of the methods, and the comparatively small numbers of normal population controls who have been studied by molecular methods to determine allele frequencies (Schellenberg *et al.*, 2001).

The *WRN* locus resembles many other human genes in displaying a large number of genetic variants. A small subset of these are mutant alleles segregating in the human population. However, most of the genetic variation identified thus far in the human *WRN* gene consists of single nucleotide polymorphisms or sequence variants of uncertain functional importance. The number of these variants is surprisingly large: 375 *WRN* sequence variants were detected during the recent resequencing of *WRN* exons, promoter region and downstream untranslated region at the University of Washington as part of the NIEHS-funded Environmental Genome Project. Of note, these variants were detected in a small number of different DNA samples, the 90 contained in the EGP's Polymorphism Discovery Resource (see Recommended Resources for additional information). A few of the more common polymorphic sites in the *WRN* open reading frame are shown in Figure 80.3 by asterisks. At least one of these common polymorphic variants has been shown to have a substantial impact on catalytic function of the *WRN* protein (Kamath-Loeb *et al.*, 2004). Several additional common sequence variants are also being

examined for association with clinically important diseases prevalent in WS patients (e.g. atherosclerotic cardiovascular disease; see, e.g., Castro *et al.*, 2000; Ye *et al.*, 1997), or for possible associations with enhanced longevity (Castro *et al.*, 1999).

Another line of investigation of the potential of *WRN* sequence variants to modify human disease risk has come from the study of *WRN* heterozygotes. Heterozygous carriers of WS-associated mutant *WRN* alleles are likely to be present worldwide at frequencies ranging up to 1:100 in selected populations (Schellenberg *et al.*, 2001). Estimates of the prevalence or frequency of carriers of single, clearly pathogenic mutant *WRN* alleles in the United States are  $\sim 1:250$ , which places the number of carriers of mutant alleles in the U.S. population at  $>10^6$ . These frequency estimates suggest it will be important to determine whether the WS clinical phenotype is even weakly penetrant in heterozygous carriers.

There are some suggestions that *WRN* heterozygosity may be manifest at the cellular—and perhaps organismal—level. These data include the identification of genetic instability *in vivo* in mutation-typed heterozygous carriers of several *WRN* mutations (Moser, Bigbee *et al.*, 2000). Moreover, lymphoblastoid cell lines from otherwise healthy *WRN* heterozygotes display an intermediate sensitivity to killing by DNA damaging agents that selectively kill *WRN*-deficient cells (Ogburn *et al.*, 1997; Okada *et al.*, 1998). These two results indicate that *WRN* heterozygote effects may play an important role in cancer risk or the outcome of cancer therapy.

The clonal growth of many tumors may provide a way to identify inherited or somatically acquired *WRN*

mutations or *WRN* gene silencing events that play a role in cancer pathogenesis or progression. The first place to look for this type of mutational enrichment will be in sporadic tumors of the histopathologic types most commonly observed in WS patients (see Table 80.2). Tumors or normal tissue in a tumor patient that displayed an aberrant or exaggerated response to chemotherapy might also be further investigated to identify heritable or acquired compromise of the *WRN* functional pathway. The most productive place to look for this type of response would be in patients receiving camptothecin, mitomycin-C or cis-Pt, as these agents selectively kill cells that are *WRN*-deficient or haploinsufficient (Ogburn *et al.*, 1997; Okada *et al.*, 1998; Poot *et al.*, 2001).

### **WRN Protein Function in Human Cells**

The identification of *WRN* as a RecQ helicase, and later as an exonuclease, were made initially on the basis of protein sequence analyses (Mian, 1997; Mushegian *et al.*, 1997; Yu *et al.*, 1996). These suggestions were subsequently verified by work from several laboratories (reviewed in Fry, 2002; Bachrati and Hickson, 2003; Opresko, Cheng *et al.*, 2004). Helicases are motor proteins that use the chemical energy obtained from nucleotide triphosphate hydrolysis to break hydrogen bonds in DNA or RNA. The disruption of hydrogen bonding and base pairing is essential for the expression, repair, and replication of DNA, and helicases together with additional proteins provide a way to do this in a controlled fashion. Exonucleases, in contrast to helicases, degrade DNA (or RNA) by hydrolyzing the phosphodiester bonds between adjacent nucleotide bases. Exonucleases facilitate many DNA metabolic processes such as repair or recombination by making single-stranded DNA ends of defined polarity available as substrates. They also play key roles in insuring the fidelity of DNA replication by acting as proofreading exonucleases, and in cellular nucleotide metabolism by insuring the turnover and salvage of DNA precursors.

The predicted helicase and exonuclease activities of *WRN* have been confirmed and further characterized by several groups using recombinant *WRN* protein and short oligonucleotide substrates of defined sequence and structure. These analyses indicate that *WRN* can bind, unwind, or degrade several types of 3- and 4-way DNA junctions and gapped, branched, or unpaired DNA regions, and that exonuclease and helicase activities often are coordinated in acting on these DNA substrates. Subsequent protein interaction studies of *WRN* indicated physical and/or functional cross-talk between *WRN* and general nucleic acid metabolic proteins such as RPA, together with more specialized proteins involved in DNA synthesis, on similar nucleic acid substrates (reviewed in Fry, 2002; Bachrati and Hickson, 2003; Opresko, Cheng *et al.*, 2004). Knowledge of these properties of *WRN* and results from prior work on *in vivo* functions of RecQ homologs

in *E. coli* and in budding and fission yeast suggested potential roles for *WRN* in recombination, replication, or repair.

Many of the types of DNA substrates that *WRN* can act upon *in vitro* resemble intermediates that are common to and generated during DNA replication, recombination, or repair *in vivo*, or may be present at telomeres. DNA replication and recombination are often thought of as discrete and rather distinct aspects of nucleic acid metabolism. Both processes are now recognized to be tightly linked and interdependent upon one another in many or all organisms. In human and other mammalian cells, the close functional interrelationship between DNA replication and homology-dependent recombinational repair (HR repair) is indicated by the importance of HR repair of DNA breaks, the critical role played by HR repair in mammalian development, and the critical role for HR proteins and HR function in the rescue of stalled replication forks (Cox *et al.*, 2000; Thompson and Schild, 2001). Consistent with these observations, abnormalities in DNA replication have been noted in WS cells for many years, and there are more recent data indicating an important role for *WRN* protein in insuring the completion of late stages of homologous recombination (Prince *et al.*, 2001; Saintigny *et al.*, 2002).

Several lines of evidence argue that telomeres are physiologic substrates for *WRN* function *in vivo*. *WRN* protein can be found at telomeres, and associates with key telomeric proteins such as TRF1 and TRF2. Moreover, TRF1 and TRF2 can modulate *WRN* biochemical activities on telomeric substrates *in vitro* (Opresko, Otterlei *et al.*, 2004). The T-loop structure of telomeres resembles the D-loop intermediate involved in recombination and replication, which is one of the branched DNA structures that may be a preferred *in vivo* substrate for *WRN*. Moreover, upon replication, telomeres are transiently converted into another postulated substrate for *WRN*, a single-ended DNA double-strand break. A final line of evidence for *WRN* function at telomeres comes from the observation that telomerase expression can extend the lifespan and modify the DNA damage responses of primary WS fibroblasts (Hisama *et al.*, 2000; Wyllie *et al.*, 2000), and that WS-like changes have been observed in mouse models in which telomerase function and *Wrn* function have been simultaneously ablated (see the section, "Animal Models").

If *WRN* plays a role in DNA replication and recombination, in telomere maintenance, or in HR repair in human cells, how does the loss of *WRN* function lead to characteristic molecular and cellular abnormalities in WS patients? A model for *WRN* function that reflects the close connection between replication and recombination is shown in Figure 80.4.

In this simplest version of *WRN* function *in vivo*, *WRN* acts on DNA molecules that are generated during the HR repair of DNA damage, from potential recombination substrates that are generated during stalled or

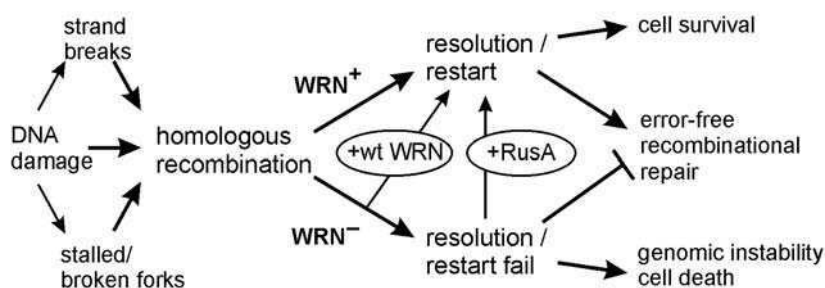

## 80. Werner Syndrome as a Model of Human Aging

disrupted DNA replication, or from intermediates or products of telomere maintenance. Successful resolution of these substrates suppresses genomic instability and insures high cell viability. In the absence of WRN function, these processes either stall or fail and leave cells with potentially toxic DNA intermediates that can trigger both DNA damage and apoptotic response pathways. Thus a loss of WRN function may lead in many cell lineages to apoptosis or mitotic death, while leading to gene rearrangement, mutation, or loss in surviving cells.

Experimental evidence supporting this model has been recently reviewed (Monnat and Saintigny, 2004).

For example, the predictions of genomic instability and reduced cell viability following the loss of WRN function are reflected in the characteristic chromosomal rearrangements in primary lymphocyte and fibroblast cultures from WS patients (Hoehn *et al.*, 1975; Melcher *et al.*, 2000; Figure 80.5), and in the reduced proliferation of primary WS fibroblasts in culture (Martin *et al.*, 1970).

The most surprising aspect of the model depicted in Figure 80.4 is that WS disease pathogenesis may be driven by a recombination *defect*. This conclusion is the opposite of what has been widely assumed—that WS is

**Figure 80.4** Model of Werner protein function in human cells. A requirement for WRN function can be initiated by DNA damage that leads to DNA strand breaks or that stalls or disrupts DNA replication. Damage to chromosomal DNA, replication forks, or telomeres can initiate homologous recombination repair (HR repair) that in the presence of WRN is successfully resolved to insure high cell viability and genetic stability ( $WRN^+$  arrow). In the absence of WRN ( $WRN^-$  arrow), HR resolution and/or replication restart fail, leading to mitotic arrest, cell death, and genetic instability. Two of the experimental tests of this model are shown by the ovals: re-expressing WRN protein ( $+wt\ WRN$ ) improves both cell survival and the recovery of viable mitotic recombinants, as does expression of the bacterial resolvase protein RusA ( $+RusA$ ).

**Figure 80.5** Variiegated translocation mosaicism in primary fibroblasts from a Werner syndrome patient. The figure is a spectral (or SKY) karyotype of the chromosomal complement of a skin fibroblast from a male WS patient (reported in Melcher *et al.*, 2000). Note the many stable chromosomal changes including reciprocal translocations (e.g., involving chromosomes 1 and 8), together with translocations that are not obviously reciprocal in nature and may be accompanied by deletions (e.g., the translocation of material from chromosome 1 to chromosomes 7 and 17). This original spectral karyotype was kindly provided by Dr. Holger Hoehn, University of Würzburg, Würzburg, Germany. See the color plate section.

a hyper-recombination syndrome—and thus of particular conceptual value.

The model depicted in Figure 80.4 provides a useful way to integrate molecular, biochemical, and cytologic data on WS, and begins to explain mechanistic links among recombination, cell viability, and mutagenesis in WS cells. It also provides a useful way to further explore mechanistic aspects of WRN function. One example of this is illustrated by recent work to determine whether one or both of the WRN catalytic activities must be lost in order to generate the HR repair and cell survival defects characteristically seen in cells from WS patients. These experiments used single amino acid substitutions to disrupt the WRN exonuclease or helicase activities, together with the reexpression of mutant protein in WS cell lines. We found that both the WRN exonuclease and helicase activities needed to be lost to reveal the WRN recombination defect. However, and in contrast to WRN-deficient cells, the expression of either single missense mutant supported high cell viability after DNA crosslink damage (Swanson *et al.*, 2004).

These results indicate that the spectrum of *WRN* mutations identified in WS patients reflects the need to lose *both* WRN catalytic activities from cells in order to generate the cellular and clinical defects characteristic of WS. Our results also raise the intriguing possibility that *WRN* missense mutations that selectively affect helicase or exonuclease activity may be segregating in the human population, and could be associated with disease phenotypes in addition to WS that resulted from a selective loss of WRN-mediated HR repair.

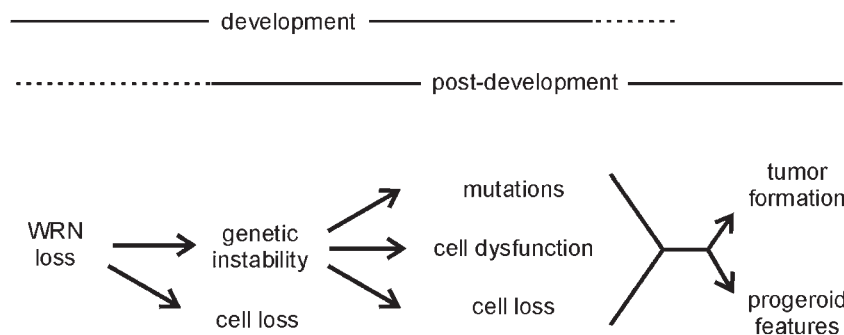

### WRN Function and Disease Pathogenesis in Cell Lineages

The elucidation of molecular aspects of WRN function, and of how the loss of WRN function generates WS

cellular phenotypes, together begin to suggest how the WS clinical phenotype may originate and progress. The postulated role for WRN in insuring successful, high-fidelity DNA replication, HR repair, and telomere maintenance, as outlined earlier (see Figure 80.4), indicates that a loss of function will be accompanied by genomic instability and reduced cell viability in many cell lineages during and after development. These two cellular consequences are likely to be intermediate phenotypes that lead to mutation accumulation and cell loss, that together drive the development of cell type-, cell lineage-, or tissue-specific defects in WS patients.

This idea of pathogenesis is shown in Figure 80.6. Further rounds of mutation accumulation, cell dysfunction, and cell loss can occur in continuously or conditionally replicating cell lineages, with the eventual compromise of tissue or organ structure and function and, in some tissues, the emergence of mutation-dependent neoplastic proliferation. This model of clinical progression indicates that the appearance of the first features of WS during adolescence is a reflection of the progressive accumulation of cellular defects during development and over the first decade of life, rather than something that is driven by the endocrine and physiologic changes that accompany puberty. Thus puberty reveals, rather than generates, the WS phenotype in affected individuals.

This view is consistent with the clinical and mechanistic view of WS as outlined earlier, and emphasizes the importance of genomic instability and replicative senescence in the generation of the WS phenotype. If this picture is accurate, however, why are dividing cell lineages not *selectively* affected during adult life by the loss of WRN function? And why are some organs such as the CNS spared the consequences of loss of WRN function? One likely explanation is the following. All cell lineages are generated by mitotic division during development and thus have the potential to be affected by mutation

**Figure 80.6** Model for pathogenesis of disease in the absence of WRN function. WRN loss as a result of inherited germline mutations (see Figure 80.3) leads from the beginning of development to genetic instability and cell loss in many or all cell lineages. These changes, following the completion of development, can be perpetuated or amplified in specific cell lineages or tissues where division potential is retained. How the intermediate consequences or phenotypes of the absence of WRN function, i.e., mutation accumulation, cell dysfunction and cell loss, affect specific lineages or tissues to lead to the emergence of either neoplastic, atrophic, or progeroid outcomes is heavily conditioned by normal lineage biology (see text for additional discussion). Two different time lines above the figure indicate the progressive nature of cell and cell lineage defects, and their origins during development.

accumulation or cell loss in the absence of WRN function. Continuously dividing lineages during adult life such as skin, gut, and bone marrow may be tolerant of the loss of WRN function by virtue of mutation expansion-limiting lineage architecture, normally stringent cell editing by a combination of apoptosis and terminal differentiation, and large reserves of stem cells or lineage repopulating cells.

Conversely, in the absence of WRN function, those cell lineages or tissues that are largely postmitotic following the completion of development (e.g., many CNS cell lineages) may take advantage of normal developmental regulatory mechanisms such as compensatory cell proliferation and cell editing by programmed cell death to compensate for increased cell loss or dysfunction to insure the completion of development with normal structure and function. Key variables that determine the eventual outcome are the number of cell divisions required to generate a mature lineage; how much cell editing via apoptotic cell death occurs during and after development; and what functional redundancy is present to compensate for cell loss or dysfunction.

The fibroblast lineage and other mesenchymal or mesodermally derived cell lineages may be selectively affected by the loss of WRN function for several of these reasons, including the persistence of conditional cell division throughout life; the ability to accumulate genetic variation, and perhaps genetic damage, in conjunction with a comparative resistance to damage-induced apoptosis; and the absence of a compartmentalized tissue architecture that could effectively suppress the proliferative defects that result in neoplasia. In the absence of WRN function this combination of features may predispose mesenchymal lineages to the progressive accumulation of mutant and dysfunctional or senescent cells, together with progressive disruption of trophic or regulatory interactions with adjacent epithelial or stromal cells (reviewed in Campisi, 2005).

This line of pathogenetic reasoning leads to two important conclusions. First, we need to know more about the normal biology of specific human cell lineages before we will be able to understand and predict *in vivo* consequences of a loss or absence of WRN function. A second important conclusion is that we clearly need experimentally tractable animal models in which to study cell lineage-specific functions of WRN.

### Animal Models of WS

Animal models are clearly important if we are to study WRN function and WS pathogenesis at the levels of cell lineage and the whole organism. The only mammalian models of WS that have been developed thus far have been in the mouse. Three different types of mouse model have been published: a complete knockout or null of murine *Wrn* leading to a loss of Wrn protein expression in all tissues (Lombard *et al.*, 2000); an in-frame deletion of

the helicase domain of murine *Wrn*, leading to a truncated protein that retains exonuclease activity though lacks helicase activity (Lebel and Leder, 1998); and transgenic expression of a human K577M WRN variant protein that lacks helicase activity against a background of normal murine *Wrn* expression (Wang *et al.*, 2000).

Of these three models, the only one that faithfully recapitulates the genetic and biochemical defect observed in WS patients is the knockout that does not express Wrn protein. However, despite having faithfully recapitulated the biochemical defect observed in WS patients, the *Wrn* knockout mouse model does not have an obvious aging, genetic instability, or cancer phenotype. Several reasons have been suggested to explain the apparent absence of an obvious organismal phenotype in *Wrn* knockout mice: that mice simply do not live long enough to develop the changes first observed in WS patients beginning in the second and third decades of life; that mice may have different, or more robust, ways to compensate for the loss of *Wrn* function; or that humans may represent for reasons of lack of redundancy, long life span or environmental exposures, the equivalent of a sensitized background for revealing WRN function at the cell and organismal levels. Three caveats in interpreting these results and arguments are that the phenotyping of the *Wrn* knockout mouse model has been very modest to date; there has not as yet been a careful aging cohort study taken to completion; and knockout mice have not been systematically challenged with DNA damaging agents such as cross-linkers that may reveal defects in the murine *Wrn* functional pathway that parallel those observed in human cells.

One obvious way to test these ideas and further develop the murine model of WS is to generate sensitized mouse genetic backgrounds by altering the genetic constitution of *Wrn* knockout mice to place additional stress on the replication, HR repair or telomere maintenance pathways where *Wrn* is likely to function. One example of this approach was taken by two collaborating groups that made use of a murine telomerase RNA template-deficient (or *Terc*-deficient) mouse in conjunction with the loss of *Wrn* (Chang *et al.*, 2004), or of *Wrn* and *Blm* (Du *et al.*, 2004), function to reveal the progressive appearance of changes observed in WS patients.

Changes observed in these double or triple mutants include the graying and loss of hair, osteoporosis, diabetes mellitus, and cataracts. These changes appear to depend on critically short telomeres as a primary driver of the phenotype in the absence of *Wrn* and *Blm*. This provides an explanation as to why changes are observed in only a portion of mice, and in those affected only in late-generation *Terc*-deficiency where telomere erosion is substantial. These results are encouraging and have begun to provide mouse models in which to investigate *Wrn* function while identifying telomeres as a potential substrate for *Wrn* function *in vivo*.

## Conclusion

Werner syndrome is one of a growing number of human diseases that have revealed the importance of genetic instability, replicative senescence, and cell death as intermediate phenotypes that can shape the risk of human disease or modify disease pathogenesis. WS is further distinguished as one of the growing number of human cancer predispositions that appear to result from a defect in homologous recombination function. One prominent role for WRN function *in vivo* is as part of one or more resolution complexes that act on common nucleic acid substrates that are generated during DNA replication or recombination, or that are part of the structure or metabolism of telomeres. This resolution function of WRN insures the successful completion of replication, recombination, or telomere maintenance, and thus high cell viability and genetic stability in all human cell lineages during development. WRN may also play comparable roles in cell lineages that retain the ability to divide during adult life.

Much work remains to be done to improve our understanding of WS as a biological and clinical human disease state. WRN function clearly modulates normal biology and physiology, and thus disease risk or pathogenesis in many human tissues or cell lineages. There are also tantalizing suggestions that the importance of WRN function in human biology will extend well beyond the small number of individuals affected with classic WS, as a modulator of both neoplastic and non-neoplastic disease risk in the general population. These hints suggest that additional work on the biology and medicine of WS will be challenging though richly rewarding.

## ACKNOWLEDGMENTS

I thank past and present members of my laboratory and members of the University of Washington NCI-funded Werner Syndrome Program for contributing ideas, hard work,

and enthusiasm to our attempts to understand WS. I would like to extend a special thanks to my senior colleagues and WS pioneers Drs. George M. Martin and Arno Motulsky, and to WS colleagues worldwide for their help and encouragement. Alden Hackmann provided graphics support, and Dr. Ali Ozgenc provided a thoughtful reading of the finished manuscript. Work in my laboratory on WS has been supported by grants from the U.S. National Institutes of Health including the NIA and NCI, and by a grant from the Nippon Boehringer Ingelheim Virtual Research Institute on Aging. There are no conflicts of interest to disclose in this work.

# Models of Sarcopenia

Alfred L. Fisher

*Sarcopenia refers to the loss of muscle mass during normal aging. The medical importance of sarcopenia lies in the significant loss of muscle strength that accompanies the loss of muscle mass. Clinical studies have linked the loss of strength to decreases in mobility and functioning seen in older people, and have suggested that the extent of strength loss could serve as a risk factor for mortality. Sarcopenia has been observed in multiple mammalian species besides humans and even in simple non-vertebrate animals, like the nematode *Caenorhabditis elegans*. This observation suggests that the development of sarcopenia may be an unfortunate but normal part of the aging of the neuromuscular system. Although the exact cause of sarcopenia is currently unknown, there is evidence from studies in people and experimental animals to support a number of theories, such as loss of motor neurons, declines in specific catabolic hormones, increases in inflammatory cytokines, and inadequate protein intake. Given the medical importance of sarcopenia, there is a pressing need to understand this condition further with the hope of developing effective treatments. This chapter will provide an introduction to sarcopenia and the current methods used to study sarcopenia both in people and experimental systems.*

## Introduction

The term *sarcopenia* describes the loss of muscle mass and muscle strength that occurs with normal aging (see Figure 81.1).

Sarcopenia is not a uniquely human condition as comparable changes have been seen in people, mice, rats, dogs, and even lower animals such as the nematode worm *Caenorhabditis elegans*, and hence sarcopenia may represent the aging of the neuromuscular system in animals (Fisher, 2004).

The medical importance of sarcopenia lies in the reductions of strength that accompany the loss of muscle mass (see Figure 81.2).

Muscle strength reaches a peak in the late 20s to early 30s before beginning a slow, continuous decline. For much of adulthood the declines in muscle strength are of little consequence except for elite athletes and those involved in intense physical labor. However, starting in the late 50s, the loss of muscle mass and strength appears

to accelerate (Lexell, 1995; Vandervoort, 2002). However, the loss of strength varies between individuals resulting in significant differences between individuals of the same age. Consequently, by the 60s the loss of muscle strength begins to impact individuals to varying degrees. The declines in strength have been linked to impairments in mobility and functioning seen in older people. The decline in strength also appears to act as a risk factor for mortality (Fisher, 2004).

At a simple level, the loss of muscle strength impairs the ability to lift and carry objects, such as groceries or laundry. For example, data from the Framingham cohort indicate that 45% of women aged 65 to 74 years and 65% of women aged 75 to 84 years are unable to lift 4.5 kg. (Fisher, 2004). The loss of strength also has a significant impact on lower extremity strength and on lower extremity function as measured by gait speed, rising from a chair, or climbing stairs (Evans, 1997; Greenlund and Nair, 2003). Besides the direct impact of impaired lower extremity function on mobility in daily life, poor lower extremity function is strongly associated with both falls and need for nursing home placement (Guralnik *et al.*, 1995; Rantanen, 2003). Besides the impairment in functioning, the loss of strength also serves as a risk factor for future mortality as multiple studies have demonstrated weaker individuals to have higher mortality than stronger individuals even after correction for comorbid illnesses (Metter *et al.*, 2002; Rantanen, 2003; Rantanen, *et al.*, 2003). The reason for this association between strength and mortality is not known, but could involve sarcopenia and the loss of strength serving as a marker for the aging of the entire body, with individuals with worse sarcopenia being biologically older than the individuals with more preserved muscles (Fisher, 2004).

The cause of sarcopenia is unknown, but there is evidence from human and experimental animals for multiple theories, including loss of motor neurons, oxidative stress, declines in catabolic hormones, increases in inflammatory cytokines, and inadequate nutrition.

Electromyography and anatomic studies have demonstrated a loss of up to 50% in the numbers of motor neurons in the spinal cord with resulting reduction in the numbers of functioning motor units (Lexell, 1995; Vandervoort, 2002). As some of the changes seen in aging

muscle are reminiscent of changes seen following denervation, this suggests that the chronic denervation and reinnervation occurring due to the loss of motor neurons may be a cause of sarcopenia during aging (Lexell, 1995; Vandervoort, 2002).

During aging, metabolically active tissues such as muscle are at risk of damage from reactive oxidative species either from atmospheric oxygen or internally generated radicals from mitochondrial metabolism (Carmeli *et al.*, 2002). The oxygen radicals are highly reactive and can damage DNA, proteins, and lipids in the muscle cell, eventually leading to cell death or dysfunction. Studies in aging muscle have shown increases in markers of oxidative damage to proteins and lipids with age. Additionally, lower levels of oxidative damage have been seen in animals treated with caloric restriction, which

is an intervention that slows organismal aging (Carmeli *et al.*, 2002).

The levels of muscle catabolic hormones, such as growth hormone and testosterone, decline significantly during aging. For growth hormone, during aging there is an approximately 14% per decade decline in secretion (Horani and Morley, 2004). This decline is due to reductions in both the frequency and amplitude of pulses of secreted growth hormone from the pituitary. Associated with the decrease in growth hormone production is an accompanying decrease in IGF-1 (insulin-like growth factor) production, which is made by the liver in response to growth hormone. IGF-1 acts on several tissues including muscle, where IGF-1 simultaneously promotes muscle hypertrophy and inhibits muscle atrophy (McKinnell and Rudnicki, 2004). In men, testosterone declines at a rate of approximately 100 ng/dL per decade during adulthood (Horani and Morley, 2004). Testosterone has anabolic actions on muscle and also appears to increase the production of muscle stem cells. Unfortunately, human studies investigating the effects of testosterone or growth hormone replacement on sarcopenia have produced at best modest results, though none of the studies were long-term (Blackman *et al.*, 2002; Horani and Morley, 2004).

Aging is associated with increasing levels of inflammatory cytokines, such as TNF $\alpha$  (tumor necrosis factor) and IL-6 (interleukin) (Ferrucci *et al.*, 2002; Roubenoff, 2003a; Roubenoff *et al.*, 2003). The reason for the observed increases and the sites of cytokine production are not known. However, clinical studies have demonstrated an association between higher levels of

**Figure 81.1** Sarcopenia is a loss of muscle mass during aging. **A.** CT scan of the mid-thigh of a young active person shows subcutaneous fat (dark gray) and skeletal muscle (light gray). **B.** A CT scan of the mid-thigh of an older person demonstrates the dramatic loss of skeletal muscle mass and the accompanying increase in subcutaneous fat. inflammatory cytokines and lower strength and muscle mass. Animal studies have demonstrated that inflammatory cytokines, like  $\text{TNF}\alpha$ , act on muscles to promote muscle atrophy through the activation of the transcription factor  $\text{NF-}\kappa\text{B}$  (McKinnell and Rudnicki, 2004).  $\text{NF-}\kappa\text{B}$  produces muscle atrophy at least in part through the activation of specific ubiquitin ligases that degrade muscle proteins. It remains to be determined if the losses of muscle mass due to sarcopenia are secondary to the direct actions of inflammatory cytokines on muscle with the activation of  $\text{NF-}\kappa\text{B}$ .

In people, body weight increases until the late 50s to early 60s before declining in later life (Roubenoff, 2003a; Volpi *et al.*, 2004). Much of the weight loss is due to a reduction in caloric intake, which occurs at a time in life when the daily protein requirement may be increased compared to younger adults. Consequently, weight loss in late life has a significant impact on muscle mass through mild protein calorie malnutrition (Roubenoff, 2003a; Volpi *et al.*, 2004). Clinical studies have demonstrated that supplements containing essential amino acids can have a beneficial effect on muscle protein synthesis (Volpi *et al.*, 2004). Unfortunately, many commercially available supplements obtain most of their calories from either carbohydrate or nonessential amino acids, and as a result these supplements have shown minimal effects in clinical studies (Fiatarone *et al.*, 1994; Volpi *et al.*, 2004).

As the proportion of older people is expected to increase dramatically in both developed and developing countries in the coming decades, the medical, social, and financial impact of sarcopenia and its effect on function are of growing importance. There is a pressing need to better understand the biologic mechanisms involved in sarcopenia to promote the development of new therapeutic approaches. This chapter will provide an introduction to the basic biology of sarcopenia and to the study of sarcopenia in clinical research, experimental animals, and cell-based systems.

## Biology of Aging Muscle

### CHANGES IN MUSCLE STRUCTURE

During human aging there is a loss of both muscle mass and cross-sectional area that averages 25 to 40% between ages 20 to 80 years (Lexell, 1995). Consistent changes have been seen regardless of technique as measurements of total body potassium, creatinine excretion, CT scans, MRI scans, ultrasound images, and anatomic dissection (see later for details on techniques) have shown consistent and reproducible declines in muscle mass (Lexell, 1995). The loss in muscle mass is due to two factors: the loss of total muscle fiber number and the reduction in the size of specific fibers. Human muscle consists of type I slow-twitch and type II fast-twitch fibers. Type I fibers are involved in endurance activities and generate most of their

energy from aerobic metabolism. In contrast, type II fibers provide explosive muscle strength during periods of exercise or intense activity with energy being produced from anaerobic glycolysis. The numbers of both types of fibers in a given muscle decline with age, with losses of up to 60 to 70% of fibers seen (Lexell, 1995). Additionally, selective declines in type II fiber volume also occur during aging (Lexell, 1995). These two changes begin as early as the late 20s and appear to accelerate after age 50 (Lexell, 1995).

### GENE EXPRESSION CHANGES

Changes in muscle gene expression have been studied via the use of serial analysis of gene expression (SAGE) and both cDNA and oligonucleotide-based microarrays (Giresi *et al.*, 2005; Welle *et al.*, 2000). Both of these techniques examine changes in the transcript abundance of specific genes between groups and use statistical techniques to then identify significant differences. Human studies have examined changes in gene expression between young individuals and older individuals using muscle biopsy specimens (Giresi *et al.*, 2005; Welle *et al.*, 2000). Experimental animals, such as mice and rhesus monkeys, also have been used for comparisons. The inclusion of these animals has allowed the comparison of normal aged animals with similarly aged animals with slowed aging due to dietary restriction (Kayo *et al.*, 2001; Welle *et al.*, 2001).

Numerous gene expression differences have been seen. Several studies have noted a decrease in old age of genes involved in biochemical pathways involved in energy generation such as oxidative phosphorylation and glycolysis (Giresi *et al.*, 2005; Kayo *et al.*, 2001; Welle *et al.*, 2000). Genes involved in heat shock responses, inflammation, and DNA damage repair also tend to be increased (Kayo *et al.*, 2001; Welle *et al.*, 2001). Changes in extracellular matrix gene expression have been noted, with specific changes in collagen gene expression (Kayo *et al.*, 2001; Welle *et al.*, 2001). These studies have provided new avenues for future investigation.

### CHANGES IN CONTRACTILE PROTEINS

Changes in muscle protein synthesis and turnover could account for at least part of the loss of muscle mass and strength during aging. Although studies have suggested that there are no changes in overall muscle synthesis, there seem to be selective changes in specific muscle proteins (Greenlund and Nair, 2003; Volpi *et al.*, 2004). For example, the rates of myosin heavy chain isoform (MHC) IIa and IIx synthesis have been shown to decrease in older subjects, which is a change probably due to a decline in mRNA levels (Greenlund and Nair, 2003). The exact cause of this change is unknown but could reflect the loss of type II muscle fibers during aging (Lexell, 1995). Furthermore, proteomic studies have demonstrated declines in myosin light chain and actin protein levels (Piec *et al.*, 2005). There is also a decline in

protein turnover in aging muscle due to declines in proteasome function that leads to the accumulation of proteins with damage such as oxidation. These damaged proteins may show impaired contractile function.

### METABOLIC CHANGES

Both enzymatic, proteomic, and gene expression studies (see earlier) have suggested declines in glycolytic and glycogenolytic enzymatic activities, as well as decreases in enzymes involved in citric acid cycle and oxidative phosphorylation (Carmeli *et al.*, 2002; Giresi *et al.*, 2005; Piec *et al.*, 2005). Accompanying the decreases in the mitochondrial enzymes involved in citric acid cycle and electron transport is an overall decrease in mitochondrial protein synthesis. The net effect of the decline in mitochondrial enzyme levels is an age-related decline in the mitochondrial ATP production rate and a decline in ATP stores (Short *et al.*, 2005). The decline in mitochondrial function correlates with the decline in maximal aerobic capacity ( $\text{VO}_2 \text{ max}$ ) during exercise.

An area of uncertainty is the extent to which the observed metabolic changes relate to the aging of muscle versus the physical inactivity frequently seen in older people (Russ and Kent-Braun, 2004). Carefully conducted studies that correct for the activity level of the young and older participants have suggested that the metabolic changes during aging are fairly minimal with regard to *in vitro* or *in vivo* oxidative capacity of muscle. Additionally, physical activity has been shown to be associated with higher levels of mitochondrial proteins involved in electron transport and the citric acid cycle (Russ and Kent-Braun 2004; Greenlund and Nair, 2003).

### SATELLITE CELL CHANGES

Vertebrate muscles contain satellite cells that are quiescent myoblasts that have the ability to proliferate, differentiate, and fuse together to form new muscle fibers. The satellite cells are found between muscle fibers and its surrounding basal lamina (Carlson 1995). One theory of sarcopenia is that either the depletion or impairment of satellite cells with age produces the loss of muscle fibers once the remaining satellite cells are unable to repair normal muscle damage (Edstrom and Ulfhake, 2005). Animal studies support this theory as both declines in satellite cell number and replicative potential decline with aging. Interestingly, the slow-twitch type I muscle fibers, which are better preserved in aging muscle, have a greater number of satellite cells than the fast-twitch type II fibers (Carlson, 1995).

### Human Studies

Although sarcopenia appears to be a universal phenomenon during aging, ultimately the importance is its impact on older people. Consequently, human studies have and will continue to play important roles in elucidating the

consequences of sarcopenia on strength, functioning, and mortality. Additionally, these clinical studies have provided insights into the role nutrition, endocrine changes, lifestyle factors, and comorbid disease could play in the development of sarcopenia. These insights often have provided starting points for subsequent cell culture and animal experiments. Also, the characterization of the clinical effects of sarcopenia provides a framework to ultimately test the effects of treatments developed through human studies or model systems. As a result of the importance of human studies, we will begin with a review of methods used in patient-oriented sarcopenia research.

### METHODS OF MUSCLE MEASUREMENT

Multiple methods of measuring the effects of sarcopenia are used in clinical studies. The use of multiple methods reflects the lack of a standard definition of sarcopenia, the development of new techniques during the last 25 years that improve upon older techniques, and the lack of a technique that is clearly superior to the others. Beyond the purely technical aspects of measuring sarcopenia is the unresolved question of what is the most important level of measurement. Specifically, is motor performance, muscle strength, muscle mass, or muscle cross-sectional area actually the most relevant for study? Though motor performance is likely the most important from a clinical perspective, it is probably the least amenable to clinical study given potential confounding by cognition, medications, comorbid illnesses, and motivation. Fortunately, muscle mass and muscle cross-sectional area show relatively good linkage so measurement of one provides information about the other. This leaves the debate to muscle mass versus strength as the most relevant measure. Studies have shown that declines in muscle cross-sectional area account for much, but clearly not all, of the declines in strength (Goodpaster *et al.*, 2001). This suggests simply measuring muscle mass or cross-sectional area is a valid approach, but misses some of the details that assessing strength instead would provide.

#### *<sup>40</sup>K measurement*

Potassium is the predominant intracellular cation, and approximately 60% of total body potassium is concentrated in skeletal muscle (Heymsfield *et al.*, 1995). Consequently, whole-body counting for naturally occurring <sup>40</sup>K can be used to quantify total body potassium and hence estimate muscle mass. This method was expanded by the inclusion of total body nitrogen, as measured by prompt- $\gamma$  neutron activation analysis, and equations developed that allowed approximation of skeletal and nonskeletal muscle mass. This technique has been largely supplanted by newer techniques that more directly measure skeletal and more specifically appendicular muscle mass (see Table 81.1).

## 81. Models of Sarcopenia

TABLE 81.1  
Comparison of muscle mass measurement techniques

Technique	Advantages	Disadvantages
<sup>40</sup> K Measurement	Well validated	Indirect measurement of muscle mass
Measurement of Muscle Metabolites	Sensitive to small changes	Requires special diet High coefficient of variability
Anthropometric Measurements	No specialized equipment Inexpensive Portable	Insensitive Poor Accuracy
Four Compartment Models	Well studied	Overestimates Muscle Mass Laborious
DEXA	Less expensive equipment Accurate Reproducible	Overestimates Muscle Mass Needs trained operator Radiation Exposure
Ultrasound	Accurate Portable	Needs trained operator
CT scan	Less expensive equipment Very Accurate Reproducible	Expensive Equipment Needs trained operator Radiation Exposure
MRI	Sensitive to small changes Very Accurate No Radiation Exposure Reproducible	Expensive Equipment Needs trained operator
Bioelectric Impedance	Sensitive to small changes Accurate Portable Less expensive equipment	Less Well Studied

### *Measurement of muscle metabolites*

Muscle produces creatinine and 3-methylhistidine, which are excreted in the urine, allowing measurement via timed urine collection (Heymsfield *et al.*, 1995; Lukaski, 1997). Creatinine is largely derived from creatine in muscle by nonenzymatic hydrolysis. Human studies indicate that one gram of creatinine is derived from 18 to 20 kilograms of muscle. However, the ratio can change depending on age, physical activity, sex, metabolic state, and contribution of creatinine from nonskeletal muscle sources (Lukaski, 1997). 3-methylhistidine is produced in skeletal muscle via the posttranslational modification of specific histidine residues in myofibrils. During routine muscle protein turnover, the liberated 3-methylhistidine is neither metabolized or recycled into new proteins, but instead excreted in the urine. Additionally, small but significant amounts of 3-methylhistidine also are derived from nonskeletal muscle, resulting in about 75% of 3-methylhistidine being of muscle origin. Both creatine and 3-methylhistidine also can be ingested in the diet, making accurate collections dependent on following a meat and creatine-free diet. The need to follow a special

diet and to collect a timed urine collection for measurement has greatly limited the development and application of this technique (see Table 81.1) (Lukaski, 1997).

However, the use of creatinine excretion has been found to be helpful for demonstrating the loss of muscle mass during aging in a comparison study with DEXA (Proctor *et al.*, 1999). When used in a carefully controlled clinical research center setting using a defined meat-free diet, comparison with DEXA results in subjects of increasing age suggested that creatinine excretion was more sensitive than DEXA for demonstrating declines in muscle mass. Creatinine excretion also demonstrated the highest variability in a test-retest comparison with a coefficient of variation of 17.7%. Together these results suggest that creatinine excretion can be a useful technique that still shows significant variability of results even when used in a carefully controlled setting (Proctor *et al.*, 1999). This may limit its use in a community-based setting.

### *Anthropometric measurements*

Anthropometric measurements use extremity circumference measurements and skin-fold thickness measurements

to estimate regional and whole-body muscle mass (Heymsfield *et al.*, 1995; Lukaski, 1997). This technique has the advantage of not requiring any specialized training or equipment to make accurate measurements (see Table 81.1). For example, the measurement process can easily be included in an initial screening exam for a clinical trial and can be performed reliably in both medical and home settings. A variety of equations for estimation of total muscle cross-sectional area for the upper arm and thigh have been developed with derivation and validation provided from data collected by CT or MRI (Heymsfield *et al.*, 1995; Lukaski, 1997). In addition, similar equations for the estimation of the cross-sectional area of specific muscle groups, such as the quadriceps and hamstrings, have been developed and validated using MRI as a reference (Housh *et al.*, 1995). With young subjects, the equations have a small but significant error compared with the reference, but in older subjects the equations are significantly less accurate and can overestimate muscle mass by up to 41.5% (Baumgartner *et al.*, 1992; Housh *et al.*, 1995). Additionally, concerns have been raised as to whether anthropometric measurements show sufficient sensitivity to measure small but important differences in muscle cross-sectional area that would occur after interventions such as physical training (Housh *et al.*, 1995). Consequently, although anthropometric measurements are easy to obtain and do not require specialized equipment or training for measurement, concerns about the accuracy of measurement, especially in older patients, limit the use of this technique in sarcopenia research.

#### *Four-compartment models*

Fat-free body mass can be used to estimate skeletal muscle mass since skeletal muscle comprises roughly 49% of fat-free body mass (Heymsfield *et al.*, 1995). One way of measuring fat-free body mass is through a four-compartment body mass model (see Table 81.1). The four-compartment model breaks body mass into fat mass, fat-free mass (consisting of muscle and connective tissue), body water, and mineral mass (consisting of bone) (Lohman and Going, 1993). Multiple techniques have been developed to measure each component, but often underwater weighing, deuterium dilution, and DEXA (see next) are used (Heymsfield *et al.*, 1995; Lohman and Going, 1993). The performance of measurements using fat-free mass has been examined in cross-sectional studies with evidence that use of the fat-free mass may overestimate muscle mass compared to other techniques, perhaps due to increases in connective tissue or total body water (Kyle *et al.*, 2001; Proctor *et al.*, 1999). The four-compartment model also suffers from being somewhat laborious as multiple measurements requiring specialized equipment are needed for each subject.

#### *DEXA*

Dual-energy X-ray absorptiometry uses an X-ray source to produce photons of two different energies, which are attenuated as they pass through the tissues of the subject. The X-ray beam is attenuated depending upon the composition of the intervening tissue, with bone producing the strongest attenuation and fat the least attenuation (Heymsfield *et al.*, 1995). Data derived from DEXA measurements can be used in two main ways. First, the measurements can be used as part of a four-component model to determine fat-free mass (Heymsfield *et al.*, 1995). From this, muscle mass can be estimated as 49% of the fat-free mass. This approach may suffer from the same overestimation of muscle mass as noted for four-component models due to possible changes in the fat-free mass composition (Proctor *et al.*, 1999). Alternatively, DEXA measurements can be focused on the extremities that comprise approximately 75% of total muscle mass (Heymsfield *et al.*, 1995). Measuring extremities also carries the advantage that the lean mass of the extremities largely consists of skeletal muscle and this muscle is most important for daily activities including ambulation (see Table 81.1) (Heymsfield *et al.*, 1995). DEXA measurements of extremity muscle mass have shown good correlation with those measured by CT scanning, though there does appear to be a slight overestimation of muscle mass (Visser *et al.*, 1999; Heymsfield *et al.*, 1995).

DEXA is widely used in sarcopenia research. The technique has been shown to have excellent reproducibility and interobserver variability (Visser *et al.*, 1999). The main drawbacks to the technique are the need for specialized costly equipment, though much less expensive than CT or MRI, as well as an experienced operator. There is also a small radiation exposure associated with DEXA measurements.

#### *Ultrasound*

Ultrasound uses sound waves to image and measure tissues. The obtained data can be used with anthropometric equations in an analogous fashion to skin-fold and circumference data (Heymsfield *et al.*, 1995). More recently, improved ultrasound equipment has allowed the technique to be used directly for measurement of muscle cross-sectional area in a fashion analogous to CT or MRI (see Table 81.1) (Reeves *et al.*, 2004). The cross-sectional areas measured by ultrasound compare favorably to those obtained from MRI and show consistent test-retest reproducibility (Reeves *et al.*, 2004). Ultrasound offers the advantage of lower cost when compared with MRI and CT as well as portability.

#### *CT scan*

Computerized tomography (CT) scanning uses collimated X-ray beams and computer manipulation to provide high-resolution images of subjects. CT provides accurate measurements of muscle cross-sectional area and muscle

volume (Heymsfield *et al.*, 1995; Lukaski, 1997). The muscle volume can readily be converted to muscle weight as the density of muscle at body temperature is 1.04 grams per cubic centimeter (Heymsfield *et al.*, 1995). CT scanning can be used to assess either total body or extremity muscle mass (see Table 81.1). The muscle masses obtained by CT have been validated through work using cadaver limbs for comparison with good agreement between CT results and anatomic dissection (Heymsfield *et al.*, 1995). The technique has adequate sensitivity to detect even changes in muscle area seen in response to resistive exercise, which are on the order of 8 to 9% (Fiatarone *et al.*, 1990). Additionally, studies in older subjects have noted that there are changes in muscle composition with aging that can be detected via CT and are correlated with declines in strength independent of decreases in muscle mass (Goodpaster *et al.*, 2001). Consequently, CT scanning has become widely used in clinical sarcopenia research.

The drawbacks of CT are the expense of CT equipment and the need for a trained operator to produce accurate scans. The size of the equipment requires that subjects be able to come to the hospital where the CT scanner is housed. Also, due to the radiation exposure involved in CT scanning, there has been a trend toward the use of CT only on extremities (Heymsfield *et al.*, 1995).

#### MRI

Magnetic resonance imaging (MRI) involves the use of radio-frequency energy and magnetic fields to provide high-resolution three-dimensional images of subjects. Similar to CT scanning, MRI provides accurate measurements of muscle area and muscle volume (Heymsfield *et al.*, 1995; Lukaski, 1997). MRI also demonstrates adequate sensitivity to detect small changes in muscle mass in response to resistive exercise (Ross *et al.*, 1995). As a result, MRI is also commonly used in clinical sarcopenia research. It additionally carries the advantage of not involving radiation exposure (see Table 81.1).

The drawbacks of MRI are the size and expense of the required equipment. A trained operator is also required to operate the scanner. Additional limitation, especially in research involving older subjects, is that the strong magnetic field involved limits the use of MRI in subjects who have pacemakers, certain surgical clips, and certain metallic implants.

#### Bioelectric impedance

Bioelectric impedance (BI) involves measuring the conductance of an electric current in the limb of a subject to estimate muscle mass. The technique relies upon the differing electric conducting properties of muscle, fat, and bone with muscle being the best conductor and bone the worst. Comparison of bioelectric impedance with measurements made by either CT scan or DEXA has

shown good correlation with these techniques (see Table 81.1). BI requires the use of specialized equipment, but the required equipment is lower in cost and much more portable when compared to techniques like CT and MRI. It is not known if BI demonstrates sufficient sensitivity to measure small changes in muscle mass such as in response to resistive training. BI also has been less extensively studied and used in human sarcopenia studies.

#### STRENGTH ASSESSMENT

In many ways strength assessment represents the gold standard of sarcopenia research as it is the loss of strength and the consequences of this loss of strength that make sarcopenia an important topic of study. Most sarcopenia studies include measures of strength to test the effects of declines in muscle mass, effects of changes in muscle composition, or effects of specific treatments on muscle strength.

Strength is often assessed via measurement of the force of static or dynamic muscle contractions. Static muscle contractions are muscle contractions where the force is exerted on a stationary object and the involved joints do not move during the contraction. Isometric contractions are the most widely used means of measuring static muscle strength due to the safety and ease of isometric testing as well as the lower cost of equipment (Hunter *et al.*, 1998). A variety of reliable and portable equipment, such as handgrip dynamometers, are available for testing.

Despite the ease of static testing, dynamic strength testing may be more relevant as most daily activities, such as walking, climbing stairs, and doing housework, are dynamic tasks (Hunter *et al.*, 1998). A dynamic muscle contraction is a muscle contraction where the involved joints move while under a resistive load. Dynamic strength can be measured either via the one repetition maximum (1RM) approach or with a isokinetic dynamometer. The 1RM approach involves finding the heaviest weight that can be lifted through a complete range of motion. This can be accomplished easily by using commonly available gym weight machines (Hunter *et al.*, 1998). Concerns have been raised about the safety of this approach especially in older subjects, but in carefully supervised settings, 1RM testing has been performed safely (Fiatarone *et al.*, 1994; Fiatarone *et al.*, 1990). Isokinetic dynamometers allow strength to be measured while the limb or joint moves at a defined speed. Most dynamometers are amenable to computer monitoring, so force data can be measured over the entire range of movement. Use of a dynamometer also has a safety advantage over the 1RM method as both the speed of movement and range of motion can be controlled (Hunter *et al.*, 1998). A significant limitation of dynamometers is the cost of the equipment.

An important concern during strength testing is to be sure that differences in strength observed is due

to differences in muscle contractile properties instead of differences in muscle activation. When older subjects, or inactive younger subjects, are first tested for strength, there is often incomplete recruitment or suboptimal firing of motor units (Hunter *et al.*, 1998). Consequently, repeated testing less than a week later can show a significant improvement due to improvements in muscle motor unit activation as opposed to muscle hypertrophy (Hunter *et al.*, 1998). This issue can be addressed by providing a practice session first and then performing the actual strength testing at a later second session. These retest measures have been shown to be reliable for both younger and older people (Hunter *et al.*, 1998). A more rigorous approach is to use pulses of electrical stimulation during an isometric contraction that is believed to be maximal. The stimulation can either be delivered via electrodes over the motor nerve or the muscle itself. If the isometric contraction is maximal, then delivering the stimulus should not increase the force of contraction, but submaximal contractions are augmented by the pulses. The benefit of this approach is to provide feedback to both the observer and subject regarding the degree of muscle activation. Electrical stimulation also has been utilized in the study of dynamic muscle contractions through the use of tetanic stimuli (Hunter *et al.*, 1998).

#### MUSCLE BIOPSY

The use of percutaneous muscle biopsy represents one of the few ways in which the effects of aging on human muscles can be studied at the biochemical, molecular, or cellular level. A single biopsy can yield 25 to 75 milligrams of tissue, which can then be analyzed in multiple ways including via microscopy or biochemical assays (Coggan, 1995).

Muscle biopsy involves the use of a biopsy needle, such as the one developed by Bergström, which consists of a closed hollow cylinder with a pointed tip (Coggan, 1995). A cylindrical cutting blade fits inside the first cylinder and is responsible for obtaining the biopsy. An opening a few centimeters from the tip in the outer cylinder serves as the location where the actual biopsy is taken since tissue can bulge into the center of the cylinder through the opening when the blade is removed. Reinsertion of the blade then cuts the protruding tissue and obtains the biopsy.

Technically, biopsies are performed on patients by first injecting local anesthetic into the skin and fascia over the muscle of interest. The vastus lateralis is the most commonly used muscle, but the biceps, tibialis anterior, and gastrocnemius have also been used (Coggan, 1995). Following anesthesia, a scalpel is used to make a small incision in the skin and the needle is then inserted into the muscle belly. During the insertion of the needle, the cutting blade is placed inside to occlude the opening in the needle. Once placed, the blade is removed and then reinserted to obtain the biopsy. After removal of the

needle, a solid rod is inserted into the center of the blade cylinder to eject the obtained tissue. Post biopsy, pressure is held at the side for 30 minutes to minimize bleeding, and the incision is closed with a suture or tape dressing like a Steri-strip. The biopsy samples are either fixed and embedded if the ultimate goal is either light or electron microscopy, or frozen if the ultimate goal is biochemical or functional analysis.

The risks of biopsy include infection and intramuscular hematoma, which are both low when the biopsy is performed in sterile fashion and pressure is held for adequate time (Coggan, 1995). For most patients the biopsy produces only mild discomfort, consisting of a pressure or cramp-like sensation when the needle is inserted into the muscle and a few days of muscle soreness after the biopsy.

The biopsy samples have a wide variety of uses, which include analysis of morphology, assessment of metabolism, analysis of gene or protein expression, culture of satellite cells, and evaluation of contractile properties of muscle fibers (Coggan, 1995; Peterson, 1995). Morphologic analysis can include examination of the numbers and size of type I and type II fibers or the examination of specific cellular organelles like the contractile apparatus by either light or electron microscopy. Metabolic assessment can involve the measurement of specific enzyme activities, the measurement of glucose, triglyceride, and protein levels, the measurement of intermediate metabolite levels, or the measurement of cellular energy stores like ATP or phosphocreatine. Gene or protein expression can be analyzed at the single gene or protein levels through use of Northern or Western blotting. Biopsy samples would also be amenable to modern genomic or proteome techniques like microarray or 2D gel electrophoresis to identify differentially expressed genes (Roth *et al.*, 2002; van den Heuvel *et al.*, 2003). Biopsy samples also can serve as a source for human satellite cell myoblasts for use in cell culture experiments, as discussed in a later section (Peterson, 1995). Finally, the contractile properties of single fibers from biopsy samples can be functionally assessed by the measurement of maximal force or shortening velocity (Coggan, 1995).

An important limitation of muscle biopsy is the observed sample-to-sample variation seen even in biopsies taken from the same muscle in the same patient (Coggan, 1995). The variation is probably due to differences between the areas of the muscle sampled by individual biopsies. For example, 10 to 20% variation has been observed in measures of fiber type or muscle fiber area. Ways to overcome this limitation are either to take two or more biopsies at the same time to obtain a more accurate measurement for an individual, or, if the goal of a study is to compare two or more groups at a population level, then increasing the number of subjects would also be an effective way to cope with the variability of individual biopsies.

## CLINICAL COHORTS

A major hurdle involved in patient-oriented research in general is the effort and expense involved in recruiting a well-characterized cohort. Consequently, existing cohorts can be a fast and convenient way to test a new hypothesis as patient data, blood samples, and DNA are already collected and allow retrospective study.

### *Health ABC Study*

The Health ABC Study was specifically designed to investigate connections between changes in body composition and strength, functioning, and mortality. The study involves 3,075 nondisabled men and women aged 70 to 79 years of age (mean 73.6 years) who reside in Pittsburgh, PA or Memphis, TN, who were recruited primarily from a random sample of Medicare-eligible adults (Goodpaster *et al.*, 2001). Overall the cohort is 48.5% male and 58.3% white. Exclusion criteria were use of assistive devices for ambulation, self-reported difficulties with activities of daily living, self-reported difficulty walking a quarter-mile or climbing 10 stairs, self-reported life-threatening cancer, plans to leave the study area within three years, or participation in clinical trials involving medications or diet/exercise modifications. Muscle mass was measured for all participants with the use of dual-energy X-ray absorptiometry (DEXA), and muscle area was measured by axial CT scans of the mid-thigh. For 2,627 participants isokinetic strength of the knee extensors was measured by determining the maximum torque produced with an isokinetic dynamometer.

### *Women's Health and Aging Study*

The Women's Health and Aging Study I was designed to study the impact of chronic and new illnesses on the health and functioning of a group of moderately to severely disabled older women (Kasper *et al.*, 1999). The study involves 1,002 women divided into three groups based upon age, with 398 women aged 65 to 74 years, 306 women aged 75 to 84 years, and 298 women older than 85 years of age. An important inclusion criteria is that participants had to demonstrate impairments in two domains of function including upper extremity (i.e., raising arms over head, using fingers to grasp/handle, or lifting/carrying objects weighing 10 pounds), mobility/exercise tolerance (i.e., walking a quarter-mile, walking up 10 steps without resting, getting in and out of bed or chairs, or doing heavy housework), higher functioning (i.e., using the telephone, doing light housework, preparing meals, or shopping for personal items), or basic self-care (i.e., bathing or showering, dressing, eating, or using the toilet). Exclusions included a Folstein Mini-Mental Status Exam (MMSE) score less than 18 or inability to participate in an interview. For participants, muscle area was estimated by use of anthropometric measures

(Cappola *et al.*, 2001). Muscle strength was measured in terms of grip strength using a JAMAR hand-held dynamometer, knee extensor (quadriceps) using a Nicholas Manual Muscle Tester dynamometer, and hip flexor (iliopsoas) using a Nicholas Manual Muscle Tester dynamometer. Testing was performed by a trained nurse using a standardized protocol. Performance data was also collected on participants, including time required to complete a four-meter walking course and to stand from a chair with arms folded five times. Blood samples were collected from most participants.

A later companion study, the Women's Health and Aging Study II, was designed to study women aged 70 to 79 years who represented the least disabled women in the community (Fried *et al.*, 2000). Recruitment was carried out in a similar fashion to WHAS I from a random sample drawn from the Baltimore area, except that women needed to have a MMSE score greater than 24 and could have impairment in at most one domain of functioning as defined earlier. A total of 436 women were enrolled. Similar data was collected on participants with regard to muscle area, strength, and physical performance as for the WHAS I study (Cappola *et al.*, 2001).

### *Framingham Heart Study*

The Framingham Heart Study began in 1948 with 5,209 men and women who reside in the Framingham, MA area and are examined biennially. The study originally was designed to study clinical risk factors for heart disease, but information on body composition have been collected as well (Roubenoff *et al.*, 2003). Specifically, fat-free body mass was measured via the use of bioelectric impedance. It is important to note that neither muscle area via MRI or CT nor muscle strength were measured in participants.

### *Longitudinal Aging Study Amsterdam*

The Longitudinal Aging Study Amsterdam is a prospective study of a random sample of people 55 to 85 years old drawn from 11 municipalities in three geographic areas in the west, northeast, and south of the Netherlands (Visser *et al.*, 2003). Initially 3,107 participants were enrolled. Data was collected in three interviews and medical exams occurring in 1992 to 1993, 1995 to 1996, and 1998 to 1999. Morning fasting blood samples were collected as part of the study. Grip strength was tested on almost all participants by means of a grip strength dynamometer, and muscle mass was measured via dual-energy X-ray absorptiometry (DEXA) on a subset of patients.

### *The MINOS Study*

The MINOS Study was started in 1995 as a prospective study of osteoporosis and its determinants in men (Szulc *et al.*, 2000). The participants are 840 men between 45 and 85 years of age who live in Montceau les Mines, France, which is a town of 21,000 inhabitants near Lyon.

Muscle mass was measured by DEXA, and blood samples were collected from participants.

### GENETIC EPIDEMIOLOGY

Studies of muscle biology, including mechanisms of development, atrophy, and hypertrophy, from cell and animal models have provided information about a large number of genes that may have an additional role in sarcopenia during aging. One way to study the roles of such genes in sarcopenia is to use genetic epidemiology (Mehrian-Shai and Reichardt, 2004). Genetic epidemiology studies the association of naturally occurring alleles of genes with the extent or rate of sarcopenia in a clinical cohort. Each allele is assessed as a risk factor or protective factor for the development of sarcopenia in the context of other risk factors as part of a multivariate model. A frequently used technique is to identify single-nucleotide polymorphisms (SNPs) in genes of interest, which are naturally occurring variants where a single base-pair is altered. Advances in genotyping techniques have made the use of multiple SNPs per gene and larger population sizes feasible from a technical and financial perspective. The SNPs are treated as alleles for the purpose of analysis. The functional role of important SNPs can later be evaluated in biochemical, cell, or animal models.

### Cell Culture Models

Although intact muscles cannot be grown in culture for sufficient time to develop an *ex vivo* model of sarcopenia, there is a role for cell culture in sarcopenia research (Peterson, 1995). Vertebrate muscles contain satellite cells that are quiescent myoblasts with the ability to proliferate, differentiate, and fuse together to form new muscle fibers. These new muscle fibers are able to replace damaged fibers in muscles. One theory of sarcopenia is that either the depletion or impairment of satellite cells with age produces the loss of muscle fibers once the remaining satellite cells are unable to repair normal muscle damage (Edstrom and Ulfhake, 2005).

Satellite cells can be isolated either from human donors or experimental animals and grown in culture (Peterson, 1995). The *ex vivo* culture of satellite cells is valuable for four reasons. First, isolated cells can be studied for replicative potential. In both humans and rats, the doubling capacity of satellite cells has been shown to decrease dramatically from youth to middle age with even further declines seen in old age. Second, satellite cell differentiation and fusion can be studied in culture. Cells isolated from older donors show impairments in the ability to differentiate and fuse to form myotubes compared to cells from young donors. Unfortunately, satellite cells in culture complete only the early steps in differentiation and fusion, as indicated by the failure to transition from the expression of fetal and neonatal myosin heavy chain isoforms to the adult isoforms. This

suggests that culture alone has a limited role in the study of the differentiation and fusion steps. However, the use of culture along with reimplantation into experimental animals may overcome this limitation, as discussed further, later. Third, cultures of satellite cells can be used to study changes in gene expression with age. Microarray experiments have been performed using satellite cells isolated from animals of increasing age to analyze global changes in gene expression (Beggs *et al.*, 2004). Finally, culture can be used as a means of modifying satellite cells from experimental animals via viral transfection, followed by reimplantation into either wild-type or transgenic animals. These modified satellite cells have been shown to be able to proliferate and differentiate *in vivo* and form chimeric muscles (Rando and Blau, 1994). The *ex vivo* modification allows both marking of the cells with a marker like  $\beta$ -galactosidase along with genetic modification with the over-expression of normal or mutated proteins or the reduction in gene expression via RNA inhibition (RNAi). The value of this procedure is the ability to study the *in vivo* role of genes identified through experiments such as microarray.

### Animal Models

Human studies can provide insights into the clinical consequences and risk factors for sarcopenia and can suggest mechanisms involved in sarcopenia, but they have important limitations. Experimental animals often have significantly shorter life spans than people, so longitudinal studies can be performed over days, weeks, or months instead of the decades involved in human studies. Also, animals can have controlled environments and an essentially identical genetic background between groups. These properties make animal studies faster and more carefully controlled than clinical studies (Cartee, 1995).

Most experimental animals are amenable to types of experiments that are not possible with people. An important insight into the biology of aging and aging associated changes has been provided by dietary restriction. This intervention involves limiting daily caloric intake and results in an up to 50% increase in overall lifespan, along with a slowing of phenotypic signs of aging. Remarkably, dietary restriction has comparable effects on a large number of laboratory animals. Dietary restriction is extremely difficult for people to follow, but is easily instituted in a laboratory setting where access to food can be readily controlled. The genetics of experimental animals can be readily manipulated either via genetic crosses or the construction of transgenic animals. Transgenic animals that either lack specific genes, carry mutated versions of specific genes, or misexpress specific genes can be constructed and used for study. Experimental preclinical medications are easily tested in animals, and animal studies provide a critical precursor to eventual clinical study of successful therapies.

This section will review the use of the two most commonly used animal models: mice and rats. A limitation of these animals is the two- to three-year life span seen under laboratory conditions. Consequently, there is a need for an animal with a shorter life span. As a result the section will end with a discussion of the nematode *Caenorhabditis elegans*, which has a two- to three-week life span and develops significant sarcopenia during normal aging.

## RODENTS

The effects of aging on muscle have been studied in both rats and mice. These animals offer the benefits of being small and easy to maintain in a laboratory environment, being familiar to many in the scientific community, having a growing number of identified genetic mutations, and having easily implemented transgenic technology.

### *Age-related muscle changes*

Both rats and mice show a decline in muscle mass during aging (Cartee, 1995). In rats this decline in muscle mass is due to both declines in muscle fiber number and fiber cross-sectional area. The declines in fiber number are less pronounced, but the declines in fiber cross-sectional areas are comparable to those seen in humans (Cartee, 1995). As seen in humans, the decline in fiber cross-sectional area is due predominantly to atrophy of type II muscle fibers. Interestingly, several muscles in the rat do not experience declines in muscle mass: the adductor longus, epitrochlearis, and flexor digitorum longus. Both epitrochlearis and flexor digitorum longus have a comparable number of type II fibers compared to the gastrocnemius muscle, roughly 75%, that undergoes significant atrophy during aging. The reason for these differential susceptibilities to the effects of age on muscle is not known, but provides the advantage of having internal aged controls that can be used in studies. Mice also show declines in muscle mass, but this is due more to declines in cross-sectional area than declines in fiber number. However, the relative contributions of type I and type II fiber atrophy have not been well studied (Cartee, 1995).

### *Viral/transfection of muscles*

One approach to test the function of genes or mark specific cells for later histological study is to use transfection of foreign DNA transgenes. The transgene can consist of either specific genes of interest or marker genes like *E. coli* beta-galactosidase or GFP (green fluorescent protein) that can be easily detected on tissue sections. Transgenes are assembled in bacterial plasmids using standard recombinant DNA techniques, and the transgene consists of a promoter to direct expression in the muscle cell and a poly-adenylation sequence flanking the gene of interest or marker gene (see Figure 81.3).

Promoters can consist of muscle-specific promoters, such as the muscle creatinine kinase promoter; or strong viral promoters, such as the cytomegalovirus (CMV)

**Figure 81.3** Diagram of a transgene. Transgenes consist of a promoter sequence, a gene, and a polyadenylation sequence. The promoter controls the expression pattern of the gene and can either be a muscle-specific promoter or derived from a viral promoter. The gene can either be a mammalian gene of interest or a reporter gene, such as GFP or  $\beta$ -galactosidase, which serves to mark transfected cells. The polyadenylation sequence provides the proper modification of the end of the produced RNA transcript needed for expression in muscle cells.

promoter, which offer high expression levels but are not muscle specific. Marker genes can be obtained from commercial sources or freely available plasmids. Genes of interest can be obtained as cDNA from commercial clone libraries or be produced from cells by techniques such as polymerase chain reaction (PCR).

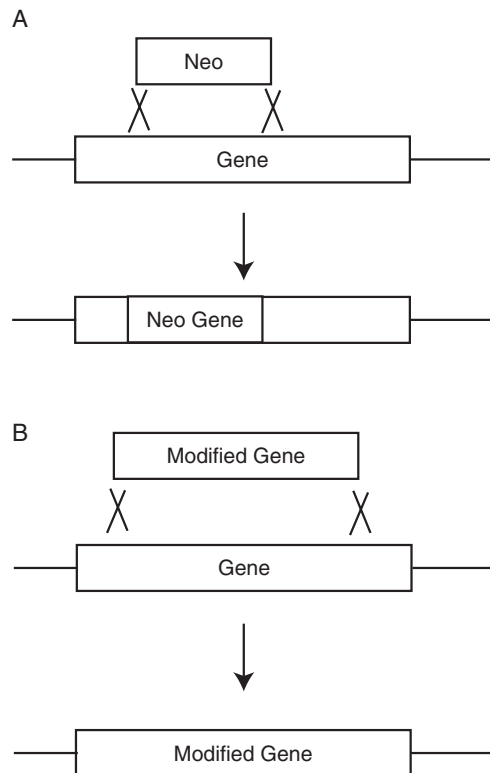

Transfection can be performed either in cell culture or in live animals. For cell culture, transfection can be performed by isolating satellite cells from mice and transfecting them *in vitro* using a retroviral vector (Rando and Blau, 1994). Transfected cells are identified and expanded in cell culture before being injected into recipient mice (Rando and Blau, 1994). These injected cells can differentiate and join existing muscles. This approach is well suited for studying the biology and function of satellite cells in mice.

For live animals, intact muscles can be transfected *in vivo* either with the use of electroporation or viral infection. Electroporation uses electric pulses to permeabilize muscle fibers and thus facilitate the entry of foreign DNA (Mir *et al.*, 1999). The DNA is maintained as nuclear extrachromosomal DNA, which is transcriptionally active for long periods of time. This approach uses transgenes easily produced by standard molecular biology techniques but does require the use of electroporation equipment to deliver the electric pulses. Viral infection uses specific viral vectors that can be packaged into viral particles in specialized packaging cell lines (Gregorevic *et al.*, 2004). Depending upon the viral vector, either transient or stable infection is possible. Transient infection produces transgene expression for a short period of time, which is dependent on the rate of viral clearance. Stable infection is durable due to integration of the transgene. The efficiency of infection is usually superior for viral vectors producing transient expression, but transient expression demonstrates decreasing efficiency with repeated use due to immunization of the animal.

### *Transgenic animals*

The genomic DNA of both rats and mice can be modified through the construction of transgenic animals. Transgenic technology allows genes to be deleted (also referred to as a “knock-out”) or modified (also referred to as a “knock-in”) (see Figure 81.4).

The modified genes can have either changes to the amino acid sequence of the protein or changes to the

**Figure 81.4** Examples of transgenic modifications. **A.** A “knock-out” consists of deleting the genomic copies of a gene of interest through homologous recombination. A targeting gene carrying a selectable marker, like neomycin resistance, is constructed with ends that have sequence homology to the genomic DNA. Inside the cell recombination between the ends of the targeting gene and the genomic DNA occurs with replacement of part of the gene with the targeting gene. This effectively destroys the function of the endogenous gene. **B.** A “knock-in” consists of replacing part of the genomic copy of a gene of interest with a modified version of the gene through homologous recombination. A targeting gene carrying the modified version of the gene is constructed with ends that have sequence homology to the genomic DNA. Inside the cell, recombination between the ends of the targeting gene and the genomic DNA occurs with replacement of part of the gene with the modified gene.

regulatory sequences responsible for when and where the gene is expressed. The power of transgenic technology lies in the ability to create animals, where all cells of the animal carry the manipulated DNA so an entire muscle, for example, experiences the effects of the manipulation. Transgenic animals stably transmit the modifications to offspring, providing an essentially unlimited source of animals for study. Additionally, different transgenic animals of the same species can be mated to test the genetic effects of combining two mutations together.

The construction of transgenic animals has been greatly facilitated by the development of transgenic core facilities at many academic institutions. These facilities provide the equipment and technical expertise needed to successfully produce animals, and these services usually are provided on a recharge basis. Consultation with the

staff of a core facility, if available, is highly recommended to provide guidance for the experimental strategy.

#### *Muscle atrophy research*

One challenge involved in studying losses in muscle mass due to aging is the long time required to see the final effects, which can be up to 24 to 27 months (Cartee, 1995). An alternate approach that has been developed is to study muscle atrophy that occurs after hind-limb immobilization, hind-limb suspension, or muscle denervation (Cartee, 1995). These interventions result in profound muscle atrophy over a period of several weeks. Both aging and these interventions demonstrate muscle atrophy, but there are significant differences between the two. The magnitude of muscle mass loss following immobilization, suspension, or denervation is often much greater than the changes seen during aging. Additionally, both type I and type II fibers are affected, whereas type II fibers are preferentially affected by aging. However, research into muscle atrophy has contributed greatly to the understanding of the mechanisms involved in the regulation of muscle mass (McKinnell and Rudnicki, 2004). These studies provide new insights that can now be explored in the context of age-related sarcopenia.

#### *C. elegans*

*C. elegans* is a microscopic organism that has emerged during the last decade to be a powerful genetic system in which to study molecular and biochemical events involved in organismal aging. Under laboratory conditions, worms develop from egg to adult in three days, then reproduce during a four- to five-day reproductive period. The usual total adult life span is 12 to 18 days. Worms develop sarcopenia starting in the postreproductive period at age seven days (Herndon *et al.*, 2002). However, sarcopenia does not develop in a stereotyped fashion in worms of a given age; instead, sarcopenia develops at different ages within a cohort of genetically identical worms grown in culture together. Sarcopenia consists of a reduction in muscle cell size due to loss of cytoplasm and myofibrils. The remaining myofibrils also show a progressive increase in disorganization with loss of the densely packed parallel fibers seen in young worms. In contrast, the nervous system of the worm remains largely intact during aging (Herndon *et al.*, 2002).

The sarcopenia observed with aging has important functional consequences for the affected worms. Beginning at the same time that structural changes occur in the muscles, affected worms show a progressive decline in mobility (Herndon *et al.*, 2002). Young worms demonstrate high levels of activity, which consist of sinusoidal swimming along the surface of an agar plate. The aging worms progress from this initial spontaneous well-coordinated swimming to poorly coordinated swimming only evoked by direct stimulation, which involves touching the worm with a thin platinum wire. Eventually, mobility declines to only minimal movement of the head

or tail evoked after similar direct stimulation. These declines in mobility appear irreversible during normal worm aging.

The development of sarcopenia in worms can be delayed by the *age-1* mutation, which also extends the worm lifespan by 60 to 100% (Herndon *et al.*, 2002). The *age-1* mutation affects a phosphatidylinositol-3-phosphate kinase (PI3 kinase), which acts along with the *daf-2* insulin/IGF-1 receptor and *daf-16* FOXO family DNA-binding protein to control aging and life span of the worm. The ability of a single mutation to alter the development of sarcopenia provides a ready intervention to study the mechanisms involved. Other potential applications of *C. elegans* in sarcopenia research involve exploiting the small size and short lifespan of worms to develop genetic or pharmacologic screens to find new genes and compounds that prevent or delay sarcopenia.

### Study of Interventions

There is a pressing need for new treatments for sarcopenia. Ideas generated by clinical studies or experiments in animals can serve as the basis for the design of new treatments. Experimental animals will need to serve as the initial test system with the goal of translating safe and effective treatments to clinical studies. Many of these treatments will ultimately be destined for trials in potentially frail older people. The age and comorbid illnesses in these subjects result in unique challenges (Ferrucci *et al.*, 2004).

### Conclusion

Sarcopenia is an unfortunate but normal aspect of the aging of the neuromuscular system of people and many other animal species. The loss of muscle strength that accompanies sarcopenia has important impacts on the health and functioning of people. Consequently there is a pressing need to better understand the clinical risk factors and cellular and molecular mechanisms involved to promote the development of new therapeutic approaches. Fortunately, the last several years have seen the development of new clinical and experimental resources to facilitate studies.

A current challenge in the field is to develop rigorous animal research in sarcopenia. Clinical research has provided support for a number of endocrine, nutritional, and inflammatory changes as being associated with the development of sarcopenia. As clinical studies based upon addressing some of these changes have shown only modest effects, there is a pressing need for animal research to prioritize the contribution that each change has on muscle mass and muscle strength. Further basic studies would then be able to elucidate the biochemical mechanisms underlying the effects with the ultimate goal of finding new targets for drug discovery. The development of the simple nematode *C. elegans* as a model system

provides a new opportunity to study the development of sarcopenia at a genetic level.

# Aging of Human Skin

Paolo U. Giacomoni

*Aging is defined as the accumulation of molecular damages. Skin accumulates damages because of the mitochondrial production of superoxide in the course of phosphorylative oxidation, and because of the exposure to external damaging agents, such as solar radiation, gravitational traction, infections, electric fields, psychological stress, cigarette smoke, specific foods, anoxia and other agents.*

*All the factors contributing to the acceleration of the rate of accumulation of damages share the capability to induce the synthesis of I-CAM 1 in endothelial cells. This has prompted the proposal of the micro-inflammatory model of skin aging. According to this model, endothelial synthesis of I-CAM 1 allows the diapedesis of circulating monocytes, which enter the dermis and digest the surrounding extra-cellular matrix. During this process, nearby cells can be damaged and will secrete molecular signals to provoke vasodilation and diapedesis of more monocytes, to maintain the inflammatory cycle.*

*This model predicts the sagging and the thinning of the skin with age, the appearance of wrinkles, and the loss of elastic and rheological properties. This model does not account for the appearance of age spots.*

## Introduction

With time, damages accumulate in organs and organisms, which lose some of the prerogatives characteristic of youth. Damages are chemical modifications to molecules in an organism. Molecular damages accumulating in cellular DNA are called somatic mutations. According to the gene where these mutations occur, the physiology of the cell or of the organ can change unremarkably or dramatically. It can even provoke the death of the cell, with minor consequences, or of the organism, which is a major consequence. Other biochemical damages can accumulate in cellular membranes or cell organelles, but the damages most relevant to the aging of an organism are the ones accumulating in the extra-cellular matrixes such as bones, blood vessels, dermis, or in postmitotic cells clustered in anatomical entities such as muscular fibers or fat tissues. Indeed, these damages are the ones more directly linked to the visible manifestations of the onset of the aging process.

The accumulation of damages consequent to the basal metabolism has been defined as *natural* or *intrinsic* aging (Giacomoni and Rein, 2004). The accumulation of damages provoked by the interaction with other environmental factors (exposure to humidity for the onset of osteoarthritis) or by the way of life (lack of exercise for the aging of skeletal muscle) can be defined as *accelerated* or *extrinsic* aging. Expressions such as *chronologic* aging or *premature* aging are to be avoided. Aging is the continuous accumulation of damages with time and is therefore a chronologic phenomenon *per se*. It can't be premature because it starts at the fertilization of the egg. So it is recommended to use the expressions natural aging or accelerated aging. It is also true that genes can play a role in the overall rate of aging and in the life span of the individual. Indeed, the same environmental factor will have different effects on two individuals with different genetic backgrounds. To give an example, exposed to the same dose of UV radiation, individuals with a defective Glutathion-S-Transferease (GST) gene are more likely to develop skin cancers than individuals with a wild-type GST gene.

Aging has been defined as the accumulation of molecular damages over time (Novoseltsev *et al.*, 2001; Giacomoni and D'Alessio, 1996b; Giacomoni, 1992). For a decade or so, biogerontologists have been discussing the necessity of aging. In particular the question has been asked about the selective advantage, if any, provided to a species by the fact that the individuals in the species undergo aging and therefore lose the capability to reproduce and to compete for food. Some scientists have elaborated a thought-provoking theory called disposable soma theory. According to this theory, the aging of the individuals represents a selective advantage for the species, and to ensure the aging of the individuals, specific genes called gerontogenes are turned on at a certain point in life. The function of gerontogenes is to trigger the process of aging, which eventually leads to the removal of the individual from competition.

In the last decade, though, gerontogenes were not found. Moreover it was observed that repair functions do not decrease with age (van Zeeland *et al.*, 2001; Giacomoni *et al.*, 2000) and no gene has been found that provokes the loss of functionality of cells or organs. Longevity in a species seems to be governed mainly by

the capability to withstand aggressions and remove damages. The other possibility to achieve longevity is to live at a reduced metabolic pace by limiting the caloric intake, one of the consequences of which is to delay the onset of reproductive maturity.

For higher organisms, in particular humans, we can now say that the rate of aging is dictated mostly by way of life. The effects of caloric restriction on the process of aging are a good example in favor of the effect of lifestyle on the onset of aging (Giacomoni and Rein, 2001; Everitt, 2003). A Gedanken Experiment shows that, even in a hypothetical life without interaction with the environment other than water, sugar as food, and oxygen to breath, superoxide is generated in the course of oxidative phosphorylation, which provokes damages to cell constituents such as mitochondrial DNA (Giacomoni, 1992).

So, notwithstanding theoretical suggestions relative to genetically programmed aging (de Magalhães 2003; Tan *et al.*, 2001), consensus has been building in the scientific community about the understanding that the aging of the individual does not provide selective advantages to the species. The presently accepted conclusion is that the aging of a cell or of an organ, far from being an unavoidable curse, is more the consequence of its interaction with the environment (McArdle *et al.*, 2002; Rattan, 2001).

## Skin and Skin Aging

Longevity and aging are two very different aspects of the life of an organism. Modifying longevity is not necessarily a relevant target in the scientific struggle against the undesirable effects of aging. If it were, dying young would be the best way not to grow old.

To study aging we need an organ accessible to analyses and such, that its aging does not bring prejudice to the survival of the organism (that is to say, one needs longevity to study aging).

Skin is one such organ. It is one of the largest organs in the human body. Its surface is smaller than that of intestinal epithelium, and its weight is smaller than that of the lungs, but with its two square meters and couple of kilograms, skin is respectable in size and mass. Human skin is vascularized, innervated, and immune-competent. It is able to secrete water and sebum. It supports the growth of muscle-associated hair, and human hair, at variance with other mammals, presents characteristics that differ according to the anatomical site where it grows. Indeed, the human hair growing on the scalp is morphologically and developmentally different from the human hair on the chest or on the pubis.

At variance with other mammals, human skin changes remarkably with aging. Hair on the scalp is lost or changes color, the epidermal surface undergoes discolorations, and the thickness of the dermis is reduced, particularly so in women. In the sites exposed to air

and sun, the skin becomes elastotic (i.e., it loses elasticity because of the deposition of elastin), the capillary vessels are pushed farther away from under the basement membrane, sagging is generalized, and wrinkles appear on expression zones, which are those anatomical sites located on the human face that allow feelings to be expressed without words.

Histologically, the dermal-epidermal junction is flattened, possibly because of the constant stretching of the skin exerted by the gravitational field. The consequence of this flattening is an increased surface and hence the necessity to maintain a particular neurological state so that neural cells continuously send impulses to induce tendons and muscles to contract. In this way the formation of wrinkles allows the cutaneous tissue to remain confined to its natural location. Another consequence of this flattening is to reduce the apparent average epidermal thickness, and this has led some scholars to the incorrect belief that the number of epidermal layers is reduced with aging. The thickness of the *stratum corneum* and the duplication time of keratinocytes do not seem to undergo major changes with age. The immune response seems to be modified with aging, skin seems to increase its susceptibility to pruritus, and wounds require a longer time to heal.

The aging of the skin is more the consequence of way of life than of predetermination. Factors of skin aging such as solar radiation, cigarette smoke, tractional forces, electromagnetic fields, infections, psychological stressors, air pollutants, anoxia, wounds, and traumas have been identified. The genotype will play a role in the process of skin aging, too, because the same environmental insult, such as the same dose of ultraviolet radiation, will have different results on two individuals with differently active genes for DNA repair (Giacomoni *et al.*, 2000; Heenen *et al.*, 2001).

## Macroscopic Effects of Skin Aging

Visible signs on the surface of the skin are the consequence of time and environmental insults that trigger a series of cellular and physiological responses because of which, in the long term, the physical properties of the skin are modified. The role of solar radiation in skin aging can be understood when the necks of sailors are compared with the necks of nuns: *Cutis rhomboidalis nuchae* is characterized by profound textural and pigmentary changes, which occur upon chronic exposure to sun. Another consequence of excessive exposure to solar radiation is nodular elastosis or Favre-Racouchot disease, consisting of the appearance of cysts and comedons on the exposed parts of the skin. Other consequences of exposure to solar radiation are Millian's type citrine skin, teleangectasia, sagging, solar lentigo, and so on (for reviews on photo-aging, see Lyon and Fitzpatrick (1993) and Wlaschek *et al.* (2001)).

The skin of humans differs from the skin of other mammals, even rodents or mini-pigs. Yet for invasive laboratory studies, these two species have been selected, and now we know more about the effect of UV on the skin of hairless mice or of albino mini-pigs than on the skin of humans.

The physiological effects of ultraviolet radiation on skin has been analyzed by Bissett and coworkers (Bissett *et al.*, 1989). Cohorts of laboratory rodents were exposed to quasi-monochromatic radiation at different wavelengths in the ultraviolet range. They observed that the sagging of skin is provoked by radiation at 365 nm. The ultra-structural details of the continuous exposure of mini-pig skin to artificial ultraviolet radiation have been described by Fourtanier and Berrebi (1989), who found that after 24 months of exposure to artificial UV radiation, the fibers of collagen are no longer oriented. They are entangled, instead, and this might explain the loss of elasticity, the loss of resilience, and the sagging of photo-aged skin. These findings, together with the observation that neutrophils infiltrates are to be found in the skin after moderate exposure to UV-B (Hawk *et al.*, 1988) prompted the proposal that post UV-repair is analogous to wound healing (Giacomoni and D'Alessio, 1996a). Indeed wound-healing and post-UV-repair seem to share common features, in particular the mechanisms of tissue modifications, which include massive cell migration, proliferation, phenotypic differentiation, and enhanced biosynthetic activities. Macrophages and fibroblasts express embryonic fibronectin during cutaneous wound-healing, thus providing an extra-cellular matrix that facilitates wound repair. They are able to promote cell migration so that subpopulations of fibroblasts able to secrete migration-stimulating factors (MSF) might undergo transient and local expansion during wound healing. The process of disassembly of the extra-cellular matrix (ECM) operates via collagenases, proteoglycanases, and other lytic enzymes of macrophage origin. The last phase of wound healing involves a systematic dissolution of the granulation tissue, which is accompanied by a gradual loss of cells and vasculature and by exhaustive restructuring of the ECM. Newly synthesized ECM molecules do not fit, per se, into an ordered structure but can modulate the original geometric framework, which is essential for cell-matrix interaction. In fact, the disordered structure, which is observed upon chronic UV irradiation, might well be the consequence of one particular disposition of newly synthesized molecules. This is to say that to improve skin repair and fight skin aging, we should not try and accelerate the synthesis of collagen, because the turnover of collagen in human skin is of the order of 15 years or more (Verzeijl *et al.*, 2000). To improve skin repair we might well have larger chances of success by trying and looking for treatments able to help in maintaining newly synthesized macromolecules in an orderly structure. This, at least in laboratory rodents, seems to be, possible by specifically

inhibiting the maturation of TGF- $\beta$  (Shah *et al.*, 1992). It might be interesting to notice that TGF- $\beta$  is an agent often used in cosmetic products to stimulate the synthesis of collagen. The results by Shah *et al.* (1992) might be overly interesting if the "quantity" of collagen production were in conflict with the "order" of the structure of the macromolecular fibers.

### The Micro-inflammatory Model of Skin Aging

The research leading to the conception of the micro-inflammatory model of skin aging (Giacomoni and D'Alessio, 1996b) was prompted by the understanding of the relevant role played by actors of the inflammatory response in wound-healing and in post-UV-repair. In the course of such research, it was noticed that all the commonly accepted accelerators of the aging process shared a common feature the capability to induce the synthesis of ICAM-1 in the endothelium. This meant that all the factors recognized as being able to accelerate skin aging had the capability to trigger a self-maintained inflammatory response.

Indeed, upon synthesis of ICAM-1 in the endothelium, circulating monocytes secrete hydrogen peroxide to perform diapedesis across the endothelium lining the vascular wall. Once in the dermis, the macrophages secrete lytic enzymes and reactive oxygen species (ROS) to fray a path in the dermis.

In the majority of instances, macrophages respond to chemotactic signals to reach and destroy infectious agents, or to remove damaged skin cells. In some instances, as in the case of anoxia-generated diapedesis, macrophages in the dermis release collagenases and ROS so as to damage the smooth muscle surrounding veins. When anoxia is repetitive, as in the case of the veins in the legs of workers obliged to long-lasting stasis, this provokes such damage to smooth muscles that the vein becomes varicous.

In these conditions, it is highly likely that nearby resident cells, such as fibroblasts or keratinocytes, are damaged by the free radicals. When this happens, the damage can trigger the cascade of arachidonic acid and secretion of prostaglandines and leukotrienes, which diffuse to interact with resident mast cells. Upon binding of these mediators to specific receptors, the resident mast cells release histamine and TNF- $\alpha$ , which in turn stimulate the release of P-selectins and the neo-synthesis of ICAM-1 in endothelial cells. The cycle therefore is closed, and the micro-inflammatory status is maintained.

### Discussion

Does this model account for all the factors of skin aging and for all the phenomenological characteristics of

aged skin? Some of the accepted factors of skin aging are direct cell- or tissue-damaging factors. When damage to cells or tissue is generated (e.g., by UV-radiation, smoke-related free radicals, infectious agents, or wounds and traumas), thousands of damages are provoked to the ECM, resident cells, and vessel walls by the free radicals and lytic enzymes, which are released in the course of the inflammatory response, consequent to the diffusion of cytokines produced via the arachidonic acid cascade. What about the other factors of aging that are not directly damaging agents? Traction and gravitational forces provoke the activation of phospholipase A2, an enzyme involved in the arachidonic acid cascade. Anoxia induces ICAM-1 synthesis and diapedesis of macrophages, which start digesting the ECM around veins or other blood vessels. Glucose binds to proteins in a non-enzymatic glycation process, and glycated proteins are inducers of ICAM-1 synthesis. Electromagnetic fields associated with computers provoke the release of histamine, IL-1 and IL-6. (A summary of the results of scientists at the Karolinska Institute of Stockholm on this subject is given by Giacomoni and Rein, 2001.) Neuropeptides regulate the expression of cell-adhesion molecules on both leukocytes and endothelial cells in a coordinated effort to control neurogenic inflammation. These phenomena trigger a cycle of self-maintained inflammatory response, which comprises the induction of the neo-synthesis of ICAM-1, and are summarized in Giacomoni and Rein (2001).

This micro-inflammatory model of skin aging emphasizes the aging of the connective tissue and of the extra-cellular matrix. Macroscopic consequences of this model are verified by the experience. The recognition that post-UV-repair and wound-healing share the ECM remodeling as a common feature has allowed us to understand why blood vessels are deeper down in aged skin than they are in young skin. The sagging of the dermis is the consequence of a modified ECM and is accompanied by an overall increase of the surface of the skin, particularly of the face.

It can be noted at this point that muscular and neurological actions are involved in the formation of wrinkles to maintain the skin with increased surface to cover a skull. This was first observed by neurophysiologists who noticed that in the case of hemiplegia, the wrinkles were observed only on that part of the forehead that was not paralyzed (Prunieras, private communication). Surgeons also noticed that patients subjected to anesthesia did not display wrinkles (Marty, private communication).

The increase of skin surface and the reduction of body volume can be invoked to explain the observation that the thickness of the epidermis is diminished with aging. This is more the consequence of the stretching of the skin than of a modification of the turnover rate of the keratinocytes. Indeed, the turnover of the keratinocytes does not change much with aging; this is witnessed

by the fact that the thickness of the *stratum corneum* does not change with aging (Gilchrest, 1993).

On the other hand, the micro-inflammatory model of skin aging does not provide detailed explanations for the appearance of other visible signs of aging associated with the surface of the skin, such as discoloration and dryness.

It is known that a permanent state of irritation (i.e., with constantly high levels of mediators of irritation such as IL-1) stimulates the production of melanin by the melanocytes. In this case the micro-inflammatory model of skin aging predicts that with time, the skin should undergo a progressive homogeneous darkening. What the model fails to predict is the appearance on specific skin regions, of the so-called age spots, dark regions of less than 0.25 cm<sup>2</sup> in sun-exposed areas, the color of which has been suggested to be the consequence of the accumulation of melanin and/or lipofuscin. Recent studies have demonstrated a role for the growth factor, insulin-like growth factor I (IGF), in the appearance of the signs of aging.

It can be noted at this point that elderly men with low serum IGF levels (Bonafe *et al.*, 2003) are more likely to be healthy (van den Beld *et al.*, 2003). Furthermore, long-lived individuals have lower levels of the IGF receptor (Bonafe *et al.*, 2003). Higher levels of IGF appear to be pro-inflammatory. It has been long known that IGF induces histamine release from basophils in inflammatory bronchial asthma (Morita *et al.*, 1993). More recent evidence indicates IGF plays an important regulatory role in inflammatory processes. Shortly after injury, acutely inflamed human wounds show increases in IGF-1 protein concentrations, believed to arise from blood sources (Wagner *et al.*, 2003). Similarly, IGF is up-regulated following tendon injury, where its expression is increased during the early inflammatory phase (Molloy *et al.*, 2003). In this animal model, IGF is believed to mediate the proliferation and migration of fibroblasts. The actions of IGF and other growth factors in promoting aging and inflammatory processes are further regulated by neuropeptides. Neuropeptides are now being considered in the aging process. A recent study in normal children demonstrated age-dependent changes in serum levels of several neuropeptides, as well as IGF (O'Dorisio *et al.*, 2002). Of particular interest here is that the physiological actions of neuropeptides are synergistic with IGF. Although this has mostly been demonstrated using cultured neurons (Jones *et al.*, 2003), recent studies with epithelial wound healing demonstrate a similar effect with substance P and IGF (Nagano *et al.*, 2003; Nakamura *et al.*, 2003). These results demonstrate the complexity of the regulatory mechanisms involving neuropeptides in the process of skin aging. Although not yet proven, these mechanisms are also thought to affect the activation of melanocytes, which is possibly linked to the age-associated skin discoloration.

Skin dryness is a more complex state of affairs, because the model does not provide suggestions to predict the accumulation of water or the synthesis of lipids in the *stratum corneum*. This parameter depends so closely from yearly cycles (seasons) and meteorological conditions (temperature, relative humidity) that the individual and local variability provide a “noise” able to mask the trends dictated by aging (if any). Hormonal imbalance and the loss of capability to retain water in the dermis, which occur at the onset of menopause, are not predicted by the micro-inflammatory model of skin aging, and correctly so because the onset of menopause is more a development- than an aging-related phenomenon. This being said, we could add that the moisturization of the skin is difficult to assess both instrumentally and via self-description. When the assessment of skin moisturization is conducted by self-description, the words used by different subjects do not mean the same thing to everyone. It is now felt, for instance, that the word “moisturization” is used to describe a state of suppleness, flexibility, and softness, more than an actual state of hydration. Instruments to assess the hydration of the skin measure either the gradient of the concentration of water vapor in the proximity of the skin surface, or the conductivity of the surface of the skin. In both cases the correspondence between the state of the skin and the experimental results is not unequivocal. Indeed, a high value of the gradient of concentration of water vapor (called trans-epidermal water loss, or TEWL) can be the consequence of a well-hydrated skin or of a lack of surface lipids. Similarly, high conductivity can be the consequence of high water content or of low water content concomitant with high electrolyte content in the surface of the skin. So when we measure macroscopic properties of the skin such as TEWL versus age, we observe that at young age the TEWL is low, then it increases during young adulthood and maturity, and it decreases again in old age (Giacomoni *et al.*, 2002). From these measurements it is impossible to conclude that young skin is hydrated and has a good barrier, whereas old skin is dry and has a poor barrier. In the absence of data that can be unequivocally interpreted, the comparison of the predictions with the experimental results is a useless endeavor.

## Conclusion

The micro-inflammatory model of skin aging provides a sound mechanistic paradigm to understand the aging of the dermis and of the extra-cellular matrix in general. The model also recognizes new factors of aging, insofar as it may “predict” whether a particular aggression will be able to trigger the synthesis of ICAM-1 in the endothelium. It also allows us to consider interventions to reduce the rate of aging, and in this respect it can be considered a successful model. It has also been applied to describe the aging of other organs of the human body, such as joints (Pincus, 2001) and the brain

(Wilson *et al.*, 2002), and for the understanding of the onset of age-associated diseases such as osteoarthritis and senile dementia. The micro-inflammatory model of skin aging, on the other hand, fails to predict the appearance of age-related modifications of the surface of the skin.

As of today, mainly because of the lack of appropriate experimental devices able to provide unequivocal data, the micro-inflammatory model of skin aging cannot be applied to predicting changes in the production of those molecules that are essential for maintaining the hydro-dynamic equilibrium of the surface of the skin and that seem to be impaired with aging. The micro-inflammatory model fails to predict the appearance of age spots. This might be the consequence of our ignorance relative to the ontogenesis of these spots. We do surmise a role for resident neural-crest melanocytes, which respond to neuropeptides (Kausar *et al.*, 2003); this has been suggested in the overall process of skin aging (Giacomoni and Rein, 2001).

The micro-inflammatory model of skin aging has prompted the use of anti-oxidant and anti-inflammatory agents in creams and ointments aimed at reducing the rate of aging of the connective tissue via the topical applications of such ingredients. The rationale behind these experiments was that anti-oxidants and anti-inflammatory agents are expected to reduce the rate of accumulation of damages provoked in the course of a micro-inflammation subsequent to the synthesis of ICAM-1. As of today, positive preliminary results are now and then communicated to dermatology or cosmetic congresses, but published evidence is yet to be found.

# Models of Hypertension in Aging

Jane F. Reckelhoff, Radu Iliescu, Licy Yanes, and Lourdes A. Fortepiani

*All forms of hypertension studied to date are caused by a defect in the handling of sodium and water by the kidney. There is a shift to the right in the pressure-natriuresis relationship (higher blood pressure) in which a hypertensive individual must increase blood pressure in order to excrete a normal sodium load. There are sex differences in blood pressure control in humans and animals, with males having higher blood pressure than females. However, blood pressure increases in some women after menopause. The mechanisms that play a role in hypertension, and have been studied extensively, include the renin-angiotensin-aldosterone system, endothelin, oxidative stress, the sympathetic nervous system, androgen/estrogen ratio, and obesity.*

*Rats and mice are commonly used for the study of hypertension and aging. There are both genetic and nongenetic models of hypertension in which the animals exhibit increases in blood pressure spontaneously or are genetically predisposed to increase blood pressure in response to a high-salt diet. Some of these models have been used for aging studies. The nongenetic models of hypertension are produced in normotensive rats by maneuvers that will increase their blood pressure. Many of these maneuvers could be performed in aging animals. There are also transgenic rat and mouse models that may be suitable for aging studies, but to date have not been used in aging studies. Therefore, their suitability remains to be determined experimentally.*

## Introduction

The study of aging in hypertension is limited mainly to rats and mice since these animals have relatively short life spans, are inexpensive to purchase and maintain, and can be easily manipulated. This chapter will focus on genetic and nongenetic models of hypertension in rats and transgenic models of hypertension in rats and mice. There are few studies of aging in hypertensive animals. Therefore, in this chapter the most common hypertensive models used will be discussed along with other models that could be used but have not been in the past.

## ETIOLOGY OF HYPERTENSION

### *Abnormal pressure-natriuresis in hypertension*

Substantial evidence supports the theory that some form of renal dysfunction plays a role in the development

and maintenance of hypertension. A common defect that has been characterized in all forms of hypertension studied to date is a shift in the pressure-natriuresis relationship (Guyton *et al.*, 1972; Hall *et al.*, 1990). The pressure-natriuresis relationship refers to the fact that increased arterial pressure elicits a marked increase in sodium excretion. According to the renal body fluid feedback concept, a long-term increase in arterial pressure or hypertension occurs as a result of a reduction in renal excretory function or a rightward shift in the pressure-natriuresis relationship. In kidneys from normotensive individuals, when sodium intake is increased, the blood pressure will increase transiently to increase sodium excretion. When the sodium load has been excreted, the blood pressure returns to normal levels. However, in a hypertensive individual, in order to excrete a normal amount of sodium, the blood pressure must be maintained in an elevated state, thereby causing a shift in the pressure-natriuresis relationship to the right (higher pressure).

### *Hypertension "follows the kidney"*

Providing the strongest support for the theory that renal dysfunction in the excretion of sodium and water is the etiology of hypertension are observations that "hypertension follows the kidney." Of particular relevance to human hypertension is the study by Curtis *et al.* (1983), which demonstrated that blood pressure returns to normal in hypertensive patients who receive kidneys from normotensive donors. The results indicate that a defect within the kidney may play a crucial role in the pathogenesis of hypertension. In animal studies, when the kidney from a spontaneously hypertensive rat (SHR) is transplanted into a normotensive rat, the blood pressure in the previously normotensive rat increases (Harrap *et al.*, 1992). Similarly, when kidneys from Dahl salt-sensitive (DS) rats were transplanted into Dahl salt-resistant (DR) rats, the blood pressure became salt sensitive in the DR rats (Rettig, 1993). When kidneys from DR were transplanted into DS rats, the rats became resistant to increases in blood pressure with increased salt consumption. Similar findings were also made when SHRSP kidneys were transplanted into WKY and vice versa (Rettig, 1993). These data strongly support the notion that a defect in the kidney in sodium and water handling causes hypertension.

*Sex differences in blood pressure*

**Sex differences in blood pressure regulation in humans.** Men are generally at greater risk for cardiovascular and renal disease than are age-matched, premenopausal women (Reckelhoff, 2001). One factor that may contribute to these sex differences is the differences in blood pressure in men and women. Recent studies using the technique of 24-hour ambulatory blood pressure monitoring have shown that blood pressure is higher in men than in women at similar ages. For example, Wiinber and colleagues studied 352 normotensive (for age) Danish men and women, aged 20 to 79 years, and found that blood pressure increased with aging in both men and women, but that men had higher 24-hour mean blood pressure, by approximately 6 to 10 mm Hg, than did women, until the age of 70 to 79 years, when blood pressure was similar for men and women (Reckelhoff, 2001). Khoury and colleagues performed ambulatory blood pressure monitoring on 131 men and women, aged 50 to 60 years, and found that men had higher blood pressure than did women (Reckelhoff, 2001). In addition, NHANES III, the Third National Health and Nutrition Evaluation Survey, showed that in general, men had higher blood pressure than women through middle age (Reckelhoff, 2001). Furthermore, the incidence of uncontrolled hypertension is also greater in men than women.

**Sex differences in blood pressure regulation in animals.** The gender-associated differences in blood pressure observed in humans have also been documented in various animal models (Reckelhoff, 2001). In hypertensive rat models, many investigators have found that males have higher blood pressure than do females. For example, male spontaneously hypertensive rats have higher blood pressure than do females of similar ages. Similar gender differences in development of hypertension also are found in Dahl salt-sensitive rats, deoxycorticosterone acetate (DOCA) salt-hypertensive rats, and the New Zealand genetically hypertensive rat. Therefore, as found in humans and hypertensive rat models, males have higher blood pressure than age-matched females.

The data showing that males have higher blood pressure than females also are supported by studies of Harrap and colleagues (1992), who reported that when the kidney from male SHR was transplanted into female SHR, this maneuver did not result in a significant rise in blood pressure such that female SHR with male kidneys had similarly elevated blood pressure as female SHR with female kidneys. When the kidney from female SHR was transplanted into male SHR, blood pressure was not attenuated in the male with female kidneys compared to blood pressure in a male SHR with male kidneys. These data indicate that the 25 to 30 mm Hg higher blood pressure in the male SHR compared to the female is not due to an intrinsic defect of the male

kidney but due to some external factor in the male, which further increases blood pressure perhaps due to a reduction in pressure-natriuresis. We hypothesize that androgens are the factor in males by which the pressure-natriuresis relationship is blunted and higher blood pressure results (Reckelhoff, 2001).

*Postmenopausal hypertension*

Although blood pressure typically is lower in women than age-matched men, after menopause (which occurs at approximately 51.4 years of age), systolic blood pressure increases in women such that the prevalence of hypertension in postmenopausal women is similar to, or higher than, in men (Reckelhoff and Fortepiani, 2004). Furthermore, the increase in blood pressure in postmenopausal women does not occur as soon as the ovary becomes senescent, but rather occurs over a number of years. Data from NHANES III confirmed that by 60 to 69 years of age, non-Hispanic black and Hispanic women developed higher blood pressure than men of similar ethnic background. However, the mechanisms responsible for the hypertension in these populations are complicated by comorbid conditions of obesity and type II diabetes, both of which lead to increases in blood pressure. However, in the non-Hispanic white population, in which the incidence of obesity and type II diabetes with aging were not as high, blood pressure also increased after menopause, although at a later age. So by 60 to 69 years of age, non-Hispanic white women had similar blood pressure as men, and by 70 to 79 years of age, this population of women had higher blood pressure than did men.

**POSSIBLE MECHANISMS RESPONSIBLE FOR HYPERTENSION**

Various humoral and cardiovascular systems play a role in controlling blood pressure. Among them are the renin-angiotensin-aldosterone system, endothelin, oxidative stress, obesity, and the sympathetic nervous system. Aging is associated with changes in most of these systems, and this could impact the roles they may play in mediating hypertension. The following will be a concise overview of the humoral factors that could affect blood pressure in aging individuals and that are subsequently investigated in models of age-related increases in blood pressure.

*The renin-angiotensin-aldosterone system (RAAS)*

The key system for controlling blood pressure and body fluid volume (i.e., pressure-natriuresis) is the RAAS (Hall *et al.*, 1999). For example, under normal conditions, any perturbation that increases arterial pressure will also provoke an increase in sodium and water excretion via pressure-natriuresis as described earlier. This will lead to decreases in extracellular fluid volume, venous return and cardiac output and blood pressure return to normal.

Long-term pressure-natriuresis is modulated by the RAS. Angiotensin II (Ang II) increases proximal sodium reabsorption by the kidney by stimulating epithelial transport. In the event of abnormal Ang II levels for the level of volume in the body, the blood pressure will increase with abnormal sodium and water reabsorption, leading to blunting of the pressure-natriuresis relationship. Similarly, if total body fluid volume levels are perceived incorrectly and thus Ang II levels do not respond appropriately, increases in blood pressure also will occur (Reckelhoff and Romero, 2003).

The biological activity of Ang II is mediated by two types of receptors, AT1 and AT2. The AT1 receptor is thought to mediate the vasoconstrictor effects of Ang II and Ang II-mediated sodium reabsorption in the proximal tubule and thus the increase in blood pressure (Sandberg and Ji, 2000). The AT2 receptor on the other hand is thought to activate NO production perhaps by increasing intracellular calcium to activate NO synthase.

Whether RAS activity changes with age in men and women is somewhat controversial. James and colleagues (1986) reported from serial analyses that plasma renin activity (PRA) was higher in men than in age-matched women, that PRA was higher in postmenopausal women than in premenopausal ones, and that in white men, PRA did not decrease with age. Blood pressure becomes more salt sensitive with aging in both men and women (Weinberger and Fineberg, 1991), which suggests that RAS activity and Ang II do not respond appropriately in the presence of salt in aging individuals.

Another function of Ang II that is mediated by the AT1 receptor is to stimulate the production of aldosterone, which is responsible for increasing sodium reabsorption in the distal nephron. In addition, several investigators have hypothesized that aldosterone may play an important role in renal injury (Brown, 2005). An increase in glomerular injury and loss of nephron function will also contribute to increases in blood pressure.

Ang II has also been shown to cause oxidative stress by increasing the expression of the NADPH oxidase subunits (Mollnau *et al.*, 2002). As discussed later, oxidative stress is capable of increasing blood pressure, and thus Ang II may increase in blood pressure via an oxidative stress-mediated mechanism.

#### *Endothelin*

Endothelin is a potent vasoconstrictor that when infused chronically leads to increases in blood pressure (Wilkins *et al.*, 1995). Endothelin has been shown to be up-regulated during Ang II infusion (Alexander *et al.*, 2001). Therefore, if aging is associated with activation of the RAS, then the increased synthesis of endothelin could play a role in the Ang II mediated increase in blood pressure with aging. In postmenopausal women, plasma endothelin levels have been shown to be increased, but the data are not consistent as to whether endothelin increases in tissues with aging in men and/or women.

Endothelin also could play a role in increasing blood pressure by contributing to oxidative stress. Endothelin has been shown to stimulate oxidative stress by causing up-regulation of the subunits of NAD(P)H oxidase and stimulating production of superoxide (Duerrschmidt *et al.*, 2000).

#### *Oxidative stress*

Both supraphysiological and physiological doses of Ang II can cause oxidative stress (Reckelhoff and Romero, 2003). For example, Rajagopalan and colleagues found that pharmacological doses of Ang II (Ang II; 0.7 mg/kg/d s.c. by minipump) increased blood pressure and superoxide levels in aortic segments of rats, whereas infusion of norepinephrine, which resulted in a similar increase in blood pressure as Ang II, had no effect on superoxide levels (Reckelhoff and Romero, 2003). These data suggested that infusion of Ang II at pharmacological doses was capable of inducing oxidative stress independent of elevated blood pressure. In addition, these investigators found that increased superoxide levels could be normalized with losartan, the Ang II receptor antagonist, or with liposomes containing superoxide dismutase. In further experiments they also reported that the Ang II increases superoxide production via increased NAD(P)H oxidase activity.

Superoxide is known to interact with nitric oxide (NO) to cause quenching of NO and to produce peroxynitrite, one of the most potent oxidative compounds known (Pryor and Squadrito, 1995). Thermodynamically speaking, the reaction of NO and superoxide is preferential since the rate of reaction is more rapid than the reaction rate of superoxide and its scavenger, superoxide dismutase (Pryor and Squadrito, 1995). The interaction between superoxide and NO causes a reduction in the biological activity (vasodilation) of NO leading to vasoconstriction, which could impact hypertension. Although peroxynitrite itself is a vasodilator, tachyphylaxis occurs at low peroxynitrite concentrations, and not only prevents further response to its own vasodilator actions, but also causes long-lasting impairment of the response to other vasodilators (Reckelhoff and Romero, 2003).

#### *Androgens/estrogens*

In experimental settings, many *in vitro*, estradiol has been shown to have a variety of effects that should be cardiovascular protective. However, despite the potential of estradiol to combat cardiovascular disease, large clinical trials on the effect of hormone replacement therapy (HRT) in post-menopausal women do not support these findings (The Writing Group for the PEPI Trial, 1995; Burry, 2002). Furthermore, HRT doesn't always result in a reduction in blood pressure in postmenopausal women, and even if it does so, the reduction is not dramatic. Proponents of the beneficial role of estradiol in cardiovascular disease cite the use of

progesterone in HRT as possibly negating the positive effects of estradiol. However, in women who have experienced surgical menopause, estrogen replacement therapy (ERT) was also not successful in reducing blood pressure (Powledge, 2004). Thus reductions in estradiol that occur at menopause do not fully explain the progressive increases in blood pressure in postmenopausal women, and estrogen replacement is not used as an antihypertensive in their treatment.

There are various ways that androgens could impact blood pressure. Testosterone has been shown to stimulate production of angiotensinogen, the substrate for renin, in the kidney (Reckelhoff, 2001). This would activate the renin-angiotensin system. Androgen supplementation in female-to-male transsexuals is associated with increased plasma endothelin (van Kesteren *et al.*, 1998). Thus androgens could mediate an increase in blood pressure in postmenopausal women or rats by activating the renin-angiotensin system, which would subsequently increase endothelin synthesis and oxidative stress.

#### *Obesity*

Many, but not all, men and women gain weight with aging. Weight gain has been shown to be associated with increases in blood pressure in human and animal studies. Furthermore, obesity is associated with increased incidence of type II diabetes, which is also a strong mediator of cardiovascular disease and hypertension. In a study in which body mass index was similar for pre- and postmenopausal women, postmenopausal women experienced significantly higher blood pressure, waist circumference, and waist-to-hip ratio, compared with premenopausal women, which suggests that even without a change in BMI with age, body fat distribution changes following menopause. It is well known that abdominal fat accumulation, as opposed to lower body fat accumulation, is a risk factor for cardiovascular disease. Obesity is also accompanied by an increase in sympathetic activity (Esler *et al.*, 2001), particularly in the kidney, which would lead to an increase in renin release and contribute to hypertension.

#### *Sympathetic nervous system*

Aging in both men and women is associated with increased sympathetic activity (Seals and Esler, 2000). For example, Ng and colleagues have demonstrated that tibial and peroneal muscle postganglionic sympathetic nerve activity (MSNA), as measured by microneurography, doubles between ages 25 and 65 years and the increase is consistent for women as well as men (Ng *et al.*, 1993). In addition, the total body norepinephrine spillover rate has been shown to be elevated in older compared with younger individuals. On the other hand, age-related changes in norepinephrine spillover, and thus sympathetic activation, are organ-specific. For example, cardiac and hepatomesenteric, but not renal, norepinephrine spillover rates are increased with age. However, in obese

individuals, total body norepinephrine spillover rates are usually normal, but renal norepinephrine spillover is increased. Thus with the combination of aging and obesity, there may be a greater activation of the sympathetic nervous system. A greater increase in renal sympathetic activity in aging individuals could stimulate renin release from intracellular stores in the kidney leading to increased production of Ang II and hypertension by all the ways just described.

## **Models of Hypertension**

There are a considerable number of models of hypertension that can be produced in various animals. The following discussion will focus on the most common models of hypertension in rats (and mice for transgenic models), since this is an animal model that is easily adaptable to studies of aging.

### **GENETIC MODELS OF HYPERTENSION**

#### *Spontaneously hypertensive rat (SHR)*

**Males.** The SHR is a commonly used model of hypertension (Reckelhoff, 2001). These animals develop increases in blood pressure beginning at six to seven weeks of age and reach a stable level of hypertension by 17 to 19 weeks of age. Inhibitors of the renin-angiotensin system reduce blood pressure in SHR, suggesting a role for the RAS in mediating the hypertension.

Removal of the renal nerves also reduces blood pressure in SHR, suggesting that the sympathetic nervous system is important in mediating the hypertension. Because increased sympathetic activity can stimulate renin release from the kidney, it is possible that the up-regulated RAS in SHR may be due to increased sympathetic activation.

In addition to the RAS and sympathetic nervous system in mediating the hypertension in SHR, treatment with antioxidants also reduces blood pressure, suggesting a role for oxidative stress in the hypertension of SHR. For example, treatment with tempol, a superoxide scavenger, reduces blood pressure as does apocynin, an inhibitor of the assembly of the subunits of NADPH oxidase. However, treatment with allopurinol protects against some of the end organ injury in SHR but fails to reduce blood pressure, suggesting that the oxidative stress in SHR that plays a role in their hypertension is mediated via NADPH oxidase, but not xanthine oxidase.

With aging, renal function decreases with reductions in GFR and renal plasma flow and increases in renal vascular resistance. Modest levels of proteinuria are also present in aging animals. In SHR at nine months of age, studies by Tolbert and colleagues (2000) showed no injury despite mean arterial blood pressure of 160 to 180 mm Hg for at least five months. These investigators attributed the protection against renal injury to increased afferent arteriolar resistance. Glomerular sclerosis is

present, although at modest levels at 18 months of age with less than 10% of glomeruli expressing any level of sclerosis (Fortepiani *et al.*, 2003).

A variation of the SHR is the SHR stroke-prone (SHRSP) rat. These animals develop malignant hypertension and die within several weeks due to stroke. They would not be conducive for aging studies.

**Female SHR: A model of postmenopausal hypertension.** The elucidation of mechanisms responsible for postmenopausal hypertension has been stunted by lack of an animal model (Reckelhoff and Fortepiani, 2004). Most of the studies in postmenopausal women have been correlative. Sheep, rabbits, nonhuman primates, rats, and mice have been used as models of various menopausal changes. However, to our knowledge, there have been few studies in which a naturally occurring animal model of postmenopausal hypertension has been described. The female SHR is an exception to this.

Throughout their reproductive lives, female SHR have mean arterial pressures that are 25 to 30 mm Hg lower than male SHR, although they are quite hypertensive compared to normotensive rats (Reckelhoff and Fortepiani, 2004). When female SHR stop estrous cycling at 10 to 12 months of age, the blood pressure begins to increase such that by 16 months of age, the mean arterial pressure is similar or even higher than in males of similar ages. This makes the aging female SHR a good model for the study of postmenopausal hypertension. Most models of postmenopausal changes are performed in young animals that have been ovariectomized, which removes the factor of "aging" from the studies. However, if female SHR are ovariectomized at a young age, there is no increase in their blood pressure as they age. If females are ovariectomized at nine months of age or after cessation of estrous cycling, their blood pressure either does not increase or actually falls compared to intact females. These data suggest that there is some factor produced by the ovary that impacts the blood pressure in the aging intact female SHR. However, this makes the aged, ovariectomized female SHR a poor model of postmenopausal hypertension.

The aging female SHRs are protected against target organ damage compared to males. Despite similar or higher blood pressure in aging females compared to males, they exhibit less renal injury (glomerular sclerosis) or protein excretion than age-matched males. Left ventricular hypertrophy is greater in the female SHR, however, but this may be an important compensatory mechanism due to the hypertension that is absent in the males.

The mechanisms responsible for the hypertension in the aging female SHR are related to the endothelin system, which is not the case in aging male SHRs. Blockade of the endothelin ET<sub>A</sub> receptor reduces blood pressure in aging female SHRs, but not aging males nor in young females (Yanes *et al.*, 2004). In contrast the RAS seems to play a more important role in maintenance of

the hypertension in the aging male SHR than females. Treatment of aging male and female SHRs with an angiotensin AT1 receptor antagonist causes a greater reduction in blood pressure in males than females. In addition, angiotensinogen protein expression in kidneys of males is several fold higher than in females. The data suggest that the RAS is up-regulated in aging male SHRs, but not females (Yanes and Reckelhoff, unpublished data).

**Advantages and disadvantages of use.** The aging SHR is a good model in which to study the effects of chronic hypertension in aging, and in the case of females, to study a model of postmenopausal hypertension. One disadvantage of the model is that they fail to gain a considerable amount of weight, as other rats do. The females are typically 300 and 350 g at 18 months, whereas the males are typically 400 to 450 g at that age. Therefore, for investigators studying aging, metabolic syndrome, and hypertension, these animals would not be appropriate.

Similarly, because the renal vasculature is protected against age-related injury, the SHR is not an appropriate model in which to study chronic renal injury. There are several normotensive rat models that develop considerably more glomerular sclerosis with normal aging than do the SHR.

#### *Dahl salt-sensitive rats*

**Males.** There are a significant number of individuals who are hypertensive who have low plasma renin activity, but whose blood pressure increases further when they ingest salt. Certain populations, such as African-Americans and the elderly, are more susceptible to development of salt-sensitive hypertension. The Dahl salt-sensitive rat is a commonly used model of salt-sensitive hypertension. Typical rat chow is 1% salt, and diets of 0.1 to 0.4% are considered low-salt diets. Dahl salt-sensitive rats (DS) exhibit an increase in blood pressure when placed on 1% salt or higher. Many investigators use 2 to 8% salt diets in order to invoke the hypertension. Along with the hypertension, the rats develop significant renal injury, heart failure, and inflammation within three to six weeks of being placed on high-salt diet.

The determination of an appropriate control for the DS is controversial. There is a Dahl salt-resistant rat (DR) that is used by some investigators as a control. These rats do not exhibit an increase in blood pressure when placed on high-salt diet. However, genetic studies have shown that the DR is no more similar to the DS than is another normotensive strain, such as the Brown Norway rat or the Sprague Dawley rat. These normotensive rats also fail to develop an increase in blood pressure when placed on a high-salt diet.

The mechanisms responsible for the salt-sensitive hypertension in DS rats include reductions in nitric oxide (NO) and increased oxidative stress. Sanders and colleagues (1996) reported several years ago that

treatment of DS rats with L-arginine, the precursor for NO, protects against salt-sensitive hypertension (Sanders, 1996). Manning and colleagues also reported that giving tempol, the superoxide scavenger, attenuates the development of hypertension in DS rats, but has no effect on blood pressure in DR on a high-salt diet, suggesting a role for oxidative stress in the hypertension (Meng *et al.*, 2003). Taken together these data suggest that superoxide may be responsible for the reduction in NO availability in DS rats since superoxide is capable of scavenging NO leading to vasoconstriction and production of another potent oxidant, peroxynitrite, which has been shown to up-regulate vasoconstrictors and down-regulate vasodilators due to its ability to nitrotyrosinate proteins.

Endothelin also plays a role in the development of salt-sensitive hypertension in DS rats, since DS rats given endothelin ET<sub>A</sub> receptor antagonists are resistant to increases in blood pressure when placed on high-salt diet (Kassab *et al.*, 1998). It is also possible that increased endothelin activity in the DS rat could be responsible for the increase in oxidative stress found in this rat model.

Because a high-salt diet is associated with reductions in renin release and thereby reductions in angiotensin II, the role that the RAS plays in mediating salt-sensitive hypertension is controversial. Navar and colleagues have measured angiotensin II in kidneys of DS and have found that when placed on a high-salt diet, the intrarenal angiotensin II levels do not change as the plasma renin activity does, suggesting an inappropriate level of angiotensin II for the level of salt and volume. Therefore, it is possible that the intrarenal RAS could play a role in the hypertension in DS rats on a high-salt diet. However, calcium channel blockers have been shown to attenuate the hypertension in DS rats on a high-salt diet better than either angiotensin converting enzyme inhibitors or AT1 receptor antagonists.

There is a paucity of aging studies in the DS rat. Mainly, investigators use these rats to study age-related changes in the brain. However, many so-called aging studies are in rats aged 20 weeks or less. The work of Hinojosa-Laborde and colleagues is an exception, as discussed next.

**Female DS rats—Model of postmenopausal hypertension.** Hinojosa-Laborde and colleagues were the first to maintain DS rats on a low-salt (0.3%) diet as they aged and followed changes in blood pressure (Maric *et al.*, 2004). Just like many other rat strains that exhibit sex differences in hypertension, the DS females on low-salt diets have slightly higher blood pressure than do males when they are young. Ovariectomy of the females causes a significant increase in blood pressure even when rats are kept on low-salt diets. With aging, however, the blood pressure in all groups of rats increases even on low-salt diets. Eventually males develop higher blood pressure than do females. However, ovariectomized females remain more hypertensive than the other sexes.

Estradiol treatment of the ovariectomized females reduces their blood pressure to the levels found in intact females. Thus, the aging DS rat is a good model in which to study postmenopausal hypertension.

**Advantages and disadvantages of use.** The use of the DS rat as a model of salt-sensitive hypertension and/or renal injury is attractive since the hypertension develops rapidly and the renal injury is present by three to four weeks. However, the fact that aging DS rats develop increases in blood pressure even when kept on low-salt diets may make them a difficult aging animal model with which to work. The ovariectomized rats do not live past 14 months of age, and the intact females do not live more than 15 to 16 months of age (personal communication, Dr. C. Hinojosa-Laborde). Whether males live longer is not clear from Dr. Hinojosa-Laborde's work, since she mainly focuses on aging females, but this is doubtful. The fact that the rats die at an early age may explain why there is a paucity of data in aging DS rats.

## NONGENETIC MODELS OF HYPERTENSION

In addition to the common genetic models of hypertension discussed earlier, there are also nongenetic models in which the hypertension is caused by infusion of a drug or by dietary manipulations or by placing a clip on the renal artery. The following is a list of such models.

### *DOCA and salt model in aging animals*

This model of hypertension is a model of mineralocorticoid hypertension developed by implanting the rats with deoxycorticosterone acetate (DOCA) pellets (typically 100 mg) and treating them with salt water (1%). This is another model of salt-sensitive hypertension. The hypertension develops rapidly, usually within a week of the DOCA being implanted. The systems that mediate the hypertension include oxidative stress since antioxidants reduce the blood pressure (Elhaimour *et al.*, 2002). Agonists of serotonin receptor 5HT1A and antagonists of serotonin receptor 5HT2B reduce the blood pressure in DOCA-salt treated rats, implicating serotonin in the hypertension (Shingala and Balaraman 2005). In addition, blockade of the endothelin ET<sub>A</sub> receptor also protects against the increase in blood pressure (Callera *et al.*, 2003). Blockade of the renin-angiotensin system (RAS), however, does not reduce blood pressure, as might be expected due to the reduction in renin release with the high-salt diet.

### *Infusion of low-dose Ang II in aging animals*

The infusion of a low dose (i.e., subpressor doses) of angiotensin II leads to hypertension that develops over approximately three to four days. The hypertension then is maintained at a stable level until approximately two weeks later, when another increase in blood pressure develops that plateaus within a few days (Hennington *et al.*, 1998). The exact mechanism by which the second increase in blood pressure occurs is not clear.

In normotensive rats, angiotensin II induced hypertension can be produced by infusing Ang II at as little as 5 ng/kg/min when the endogenous RAS is blocked with converting enzyme inhibitors. If the endogenous system is not blocked, a higher dose of Ang II (50–80 ng/kg/min) is required. However, as the endogenous system is blocked by negative feedback caused by the Ang II infusion, the amount of Ang II necessary to maintain the hypertension progressively falls to that required to cause hypertension in endogenously blocked RAS rats. Similar findings have been made in mice, although mice require significantly more Ang II to cause a sustained increase in their blood pressure (600–1000 ng/kg/min).

The mechanisms responsible for the increase in blood pressure with low-dose Ang II are oxidative stress and endothelin activation (Reckelhoff and Romero, 2003). Treatment of animals with antioxidants attenuates the hypertensive response to Ang II. In addition, nonspecific blockade or specific blockade of the endothelin ET<sub>A</sub> receptor attenuates the hypertensive response to Ang II. It is likely that endothelin may stimulate oxidative stress since Ortiz and colleagues reported that treatment of Ang II infused rats with the superoxide scavenger, tempol, reduced blood pressure and oxidative stress, but failed to reduce plasma endothelin (Reckelhoff and Romero, 2003).

Studies in humans and animals have shown that aging may be associated with increased sensitivity of the cardiovascular and renal systems to Ang II. Acute infusion of Ang II is a common maneuver in aging humans, but chronic infusion of Ang II is performed only in animals.

#### *Dietary-induced hypertension*

**Fat-fed rats—Obesity-induced hypertension.** There is an epidemic in obesity that is occurring throughout the developed countries of the world. The mechanisms responsible for metabolic syndrome and the target organ injury associated with the complications of metabolic syndrome, such as type II diabetes, sleep apnea, end stage renal disease, and heart failure, are a major research focus today. Not all models of obesity are associated with elevated blood pressure. Why this is the case is also not clear at the present time.

The model of obesity-induced hypertension has been produced in dogs for years by feeding them a high-fat diet. However, only recently has a model of obesity and hypertension due to a high-fat diet been obtained in rats. Dobrian and colleagues have succeeded in producing a model of obesity in Sprague Dawley rats by feeding them 32% Kcal fat and 0.8% NaCl for 10 weeks (Dobrian *et al.*, 2001). After 10 weeks, half the rats develop obesity (the so-called obese prone (OP) rats) whereas the other half do not (the so-called obese resistant (OR) rats). Typically, the OP rats weigh approximately 660 g compared to 540 g in OR rats. Control Sprague Dawley rats untreated with high-fat diets of similar ages exhibit similar weight as the OR rats. The OP rats

develop mild hypertension and increased leptin levels. They also have increased plasma renin activity, an index of stimulated RAS. In addition, the rats have increased F2-isoprostanes, an index of oxidative stress, and renal injury. There have been no aging studies published with this model.

**Fructose-fed rat—Model of insulin resistance and hypertension without obesity.** The fructose-fed rat develops insulin resistance, increased triglycerides and glucose, and hypertension when approximately 60% of their diets contain fructose (Girard *et al.*, 2005). Rats typically are treated for six to nine weeks before developing hypertension. The rats develop end organ damage of various types, and there is a sex difference in the development of hypertension, with only males becoming hypertensive despite the females becoming insulin resistant. This is a model that could lend itself to aging studies since aging normotensive rats could be given fructose with the expectation that they would become mildly hypertensive and insulin resistant within a few weeks.

#### *Renovascular hypertension (2 kidney, 1 clip, or Goldblatt model)*

The typical method for producing renovascular hypertension is by placing a silver clip on the renal artery of one kidney in rats and as they grow, the clip will cause a renal stenosis (Pipinos *et al.*, 1998). The contralateral kidney becomes hypertrophied. The pressure in the clipped kidney is low due to the clip, whereas the pressure in the contralateral kidney is high due to the hypertension that develops. In the early phases, the blood pressure increases due to the release of renin from the clipped kidney. Oxidative stress also plays a role in the hypertension. Endothelin has been shown to be involved in the cardiac damage associated with renovascular hypertension, but not in the renal injury.

The Goldblatt model of hypertension is difficult to use since the hypertension is inconsistently produced. Even with rats of the same weight, the same size clip will cause moderate hypertension in some rats, but malignant hypertension in others (personal communication, Dr. William Beierwaltes). Whether this model could be reproduced in aging rats is not clear since the clips usually are placed in young animals, and as they grow, the renal vasoconstriction is produced. It is also not clear what the survival time would be for rats with 2-kidney, 1-clip maneuver that developed hypertension and were allowed to age.

#### *The model of reduced renal mass (5/6 ablation model)*

The model of renal ablation typically is produced by the removal of the right kidney and either the ligation of two of the three renal arteries on the left in the rat or the removal of the poles of the left kidney. Within days to a few weeks, this model develops hypertension and severe glomerulosclerosis. The renin-angiotensin system

has been shown to play a role, but oxidative stress is likely to be involved as well (Sandberg and Ji, 2000). The endothelin system and reductions in NO are also involved. In addition, there is a component of the immune system involved in the hypertension in rats in the renal artery ligation model, but not in the model in which the renal tissue is removed. The model of renal ablation is one that could be reproduced in aging rats. There is only one aging study to our knowledge using this model, and the rats were studied 28 weeks after ablation was performed at approximately 34 to 36 weeks of age.

## TRANSGENIC MODELS OF HYPERTENSION

The use of transgenic animal models to study the role that specific genes play in causing hypertension has been a focus of much research. However, to our knowledge there are no studies in which the mice were allowed to age. With the exception of a few models that are severely hypertensive and will not survive more than a few weeks or months, the lack of data in aging hypertensive transgenics likely reflects the specific interest of the investigators who developed the strains; that is, the animals were developed to answer a question not involving aging. Following we describe the most common transgenic hypertensive strains.

### *Models transgenic for genes of the renin-angiotensin system*

*TGR(mREN2)27.* TGR(mREN2)27 is the first rat model of hypertension caused by a defined genetic defect. The TGR(mREN2)27 harbors the murine *Ren-2* gene on the genetic background of the SD rat. These transgenic rats develop fulminant hypertension at an early age despite low levels of renin in plasma and kidney. High expression of the renin transgene in extrarenal tissues is associated with increased local formation of angiotensin II, which suggests that activated extrarenal RAS might be responsible for the hypertensive phenotype. In heterozygous animals, hypertension is evident at four to five weeks of age, reaching maximum values at eight to nine weeks (systolic BP: 240 mmHg in males and 200 mmHg in females). The phase of established hypertension is followed by a decrease in blood pressure by 20 to 30 mmHg in male and 40 to 60 mmHg in female TGR(mREN2)27 between 20 and 24 weeks of age. At 42 weeks of age, the male TGR(mREN2)27 are hypertensive, whereas blood pressure levels in female transgenic rats are not different from those found in age-matched SD rats (Lee *et al.*, 1996).

*TGR(hAOGEN-hREN).* The TGR(hAOGEN-hREN) is a model of high human renin hypertension in the rat. This strain resulted from a cross between transgenic rats harboring human angiotensinogen gene and human renin gene, respectively. The offspring from this cross harbor both transgenes and have all the necessary components of the human renin angiotensin system to generate angiotensin II. The TGR(hAOGEN-hREN) rats have severe hypertension and hypertensive end-organ

damage and die after about eight weeks, unless treated with converting enzyme inhibitors. Although useful for pharmacological investigation of the human renin angiotensin system, this rat model is not well suited for aging studies, due to their short survival (Bohlender *et al.*, 1997).

*Mice transgenic for both human renin and angiotensinogen genes.* Sigmund *et al.* developed transgenic mice expressing both human renin and angiotensinogen genes that are markedly hypertensive and exhibit high plasma concentrations of angiotensin II (Sigmund *et al.*, 1992). These animals also display hypertensive end-organ damage and endothelial dysfunction. Transgenic mice harboring an artificial chromosome encoding human renin together with the next upstream and downstream genes in order to ensure appropriate regulation of the renin transgene display a modest increase in blood pressure when crossed with human angiotensinogen-expressing mice. These data show that even small amounts of renin could cleave increased amounts of angiotensinogen producing hypertension. To our knowledge, no aging studies have been performed using these animals.

*Models transgenic for genes of the endothelin system.* Elevated plasma endothelin concentrations have been associated with several cardiovascular diseases, including hypertension. A mouse model overexpressing endothelin-1 gene under the control of its own promoter has been characterized. These transgenic mice exhibit two-fold increases in endothelin-1 concentration in plasma, aorta, heart, kidney, and intestine. Although the blood pressure and kidney morphology and function are normal in young (8 weeks old) transgenic mice, with aging (12–14 months old) they develop renal injury with glomerulosclerosis and interstitial fibrosis (Hoher *et al.*, 1997). In addition, Shindo *et al.* showed that salt-sensitive hypertension develops with aging in these mice, perhaps secondary to nephron loss (Shindo *et al.*, 2002). This model therefore might be useful for the study of the permissive role of the aging process on the endothelin-induced renal pathology and hypertension. However, there are currently no data using aging ET-1 overexpression mice.

### *Other transgenic models*

*The follitropin receptor knockout mouse (FORKO)—Model of postmenopausal hypertension.* A genetic model of estrogen deficiency recently has been characterized for the study of menopausal hypertension. The FORKO mice exhibit a reduced production of estrogen due to the genetic inactivation of FSH receptors (Dierich *et al.*, 1998). These mice have ovarian insufficiency, low estrogen levels with functionally active estrogen receptors, and increased testosterone levels. They also show osteoporosis, hypercholesterolemia, and weight gain consistent with the postmenopausal pathology in women. The FORKO mice have significantly elevated systolic and diastolic blood pressure at 14 to 16 weeks of age,

as measured by telemetry (Javeshghani *et al.*, 2003). Hypertension in this model is paralleled by vascular remodeling and altered contractile responses to angiotensin II. The mechanisms of altered blood pressure regulation in the FORKO mice are not clear and might involve both estrogen deficiency and increased testosterone levels. There are no aging studies in these animals as yet.

*Glial cell-line-derived neurotrophic factor heterozygotes (GDNF)—Model of reduced renal glomeruli.* It has been hypothesized that low nephron number is a risk factor for the development of cardiovascular disease including hypertension. The GDNF has been shown to play a major role in kidney development (Treanor *et al.*, 1996). Although homozygous null mutants for GDNF show bilateral renal agenesis and die shortly after birth, the heterozygous mice are fertile and viable but have a 30% reduction in the nephron endowment at 30 days of age, as compared to the wild-type controls (Pichel *et al.*, 1996). The study of Cullen-McEwen *et al.* (2003) shows that at 14 months of age, the GDNF heterozygous mice have elevated blood pressure but preserved renal function as measured by GFR and RBF. These mice also display glomerular hypertrophy, probably due to the compensatory hyperfiltration. Therefore, the GDNF heterozygous mouse may be a useful tool to study the lifelong consequences of reduced nephron number on the development of hypertension.

## Conclusion

There are several animal models of hypertension that would be conducive for aging studies. These include genetic models and nongenetic models of hypertension and transgenic models that exhibit hypertension. However, some of the genetically hypertensive models, such as the SHRSP and the Dahl salt-sensitive rats, have limited life spans that make them inappropriate for aging studies. Transgenic rats and mice are novel models in which to study specific systems known to be responsible for hypertension. However, there are very few aging studies in hypertensive transgenic animals, and whether these transgenics prove to be good models of aging and hypertension remains to be determined experimentally.

# Glossary

**5-alpha reductase:** Enzyme catalyzing the production of dihydrotestosterone from testosterone. Two types of this enzyme are known. Type II is found in high concentrations in prostatic stroma.

**8-OHdG:** 8-hydroxydeoxyguanosine, an oxidized nucleoside of DNA.

**24-hour rhythm:** The periodical pattern of sleep (rest) at night and wakefulness (activity) in the daytime.

**25th percentile survival point:** When lifespan is compared in respect to aging, the 25th or 10th percentile survival point is a better index than the 50th percentile survival point or mean lifespan, because experientially the median or mean value of lifespan is known to often fluctuate from the effects of experimental intervention for diseases or specific causes of death in a strain of rodents.

**ABR:** Auditory brainstem response; physiological recordings.

**Ach:** Acetylcholine; cochlear efferent neurotransmitter.

**Activation-induced cell death:** T-cell apoptosis as opposed to growth, under certain conditions, caused by stimuli that would otherwise result in cell division.

**Activity theory:** Proposes that individuals who age successfully maintain regular activities, roles, and social pursuits into old age.

**Advance directive:** Directions given by an individual intended to guide future decisions about medical treatment in case of incapacitation.

**Advance directive for research:** A legal document executed by a decisionally capable person that authorizes their enrollment in research studies for the time the person lacks decision-making capacity.

**Ageism:** Process of systematic stereotyping and discrimination against people because they are old.

**AGE:** Advanced glycosylation end-product, or the potentially harmful compounds produced through glycosylative and glycoxidative reactions. AGEs have been hypothesized to be responsible for damage to cells and tissues and to contribute to aging-related diseases.

**Aggrecan:** A large aggregating glycosaminoglycan, mainly found in articular cartilage.

**Aging:** In models of systems failure, aging is defined as a phenomenon of increasing risk of failure with age of a system.

**Agreeableness:** The personality trait of being warm, generous, and helpful.

**ALCAR:** Acetyl-carnitine; an anti-apoptotic drug.

**Allate/Deallate:** Queens and males with wings are called allates. After the mating flight, the queens remove their wings and are called deallate females.

**Allele:** One or two or more alternate forms of a gene that have the same locus on homologous chromosomes and are responsible for alternative traits; some alleles are dominant over others.

**Allocentric:** Spatial references made on the basis of external cues or landmarks in the surrounding environment.

**Allogeneic cells:** Cells recognized as non-self, due to their expression of "foreign" transplantation antigens.

**Allostasis:** The ability of a system to dynamically adopt varying states in order to accommodate changing demands. It is a dynamic regulatory process that allows organisms to respond to the challenges of their

## Glossary

environment (“stability through change”). An example would be a rise in epinephrine release in response to exercise, stress, or perceived danger. This should be followed by a fall of epinephrine release during relaxation.

**Allostatic Load:** Cumulative changes that reflect either continued operation of the allostatic state or overactivation of allostatic responses.

**Alpha ( $\alpha$ ) level:** See Significance level.

**AMD:** Age-related macular degeneration; a dangerous illness of the human retina.

**AMP kinase or AMP-activated protein kinase (AMPK):** AMPK is stimulated by elevated AMP/ATP ratios; thus AMPK plays a role in monitoring cellular energy status and eliciting cellular response when ATP levels are diminished.

**Amygdala:** A rounded lobule on the undersurface of each cerebellar hemisphere, continuous medially with the uvula of the cerebellar vermis.

**Amyloid:** A term originally referring to starch-like histological staining properties, now used to refer to insoluble fibrils of proteins folded into cross- $\beta$ -sheet secondary structure.

**Analytic epidemiology:** The study of the determinants of disease or reasons for high or low frequency of disease in specific groups.

**Andropause:** The decline in T levels with aging when associated with symptoms and signs of androgen deficiency.

**Aneuploidy:** Any imbalance in the normal number of chromosomes, or in the number of chromosome sets (normal, 2 sets).

**Angiogenesis:** The process in which new blood vessels are formed via endothelial capillary sprouting from existing vascular beds.

**ANN:** Advanced or artificial neural network bioinformatics pattern-detection computer programs, which can be iteratively trained to associate complex patterns with a given state or diagnosis.

**Annual fish:** Fish present in hot ponds of South America and Africa, having an average lifespan of one year.

**ANOVA:** Analysis of variance.

**Antagonistic pleiotropy:** An aging theory, which argues that genes that confer benefits early in life may be selected for, even if those genes cause increased senescence later in life.

**Anthropomorphic:** The attribution of human characteristics, traits, and emotions to nonhuman animals.

**Antioxidant:** substance that inhibits oxidation and protects against the effects of free radicals.

**AP:** Antero-posterior.

**Apneic episode:** Cessation of breathing for 10 or more seconds during sleep.

**Apoptosis:** Programmed cell death.

**Aromatase:** Enzyme catalyzing the irreversible aromatization of testosterone to estradiol.

**Artificial enteral feeding:** All techniques permitting partial or total nutritional support in subjects incapable of spontaneously absorbing a sufficient nutritional input.

**Assent:** Authorization that only partially meets the standards of informed consent because it is given by a person whose capacity to understand and judge is somewhat impaired, but who is able to express a preference or choice.

**Astrocyte:** A small, star-shaped cell of the nervous system that provides nutrients, support, and insulation for neurons.

**A-T:** Ataxia–telangiectasia.

**Atherosclerotic:** The process of arteriosclerosis in which deposits of yellowing plaques (atheromas) containing cholesterol, other lipoid material, and lipophages are formed within the intima of large and medium-sized arteries.

**ATM:** A human DNA damage responsive kinase that acts early in the response to DSBs to activate the checkpoint that pauses the cell cycle. Cells lacking ATM will synthesize DNA in S-phase after being exposed to ionizing radiation that causes DSBs, while cells with ATM will not. ATM is an ortholog of budding yeast *TEL1* and plays a role in telomere function in human cells. ATM stands for ataxia telangiectasia mutated from the human disease that identified the gene.

**ATP:** Adenosine triphosphate; the nucleotide known in biochemistry as the “molecular currency” of intracellular energy transfer.

**ATR:** A paralog of human ATM that also plays a role in the response to DSBs. The name stands for ATM-Related. ATR is the human ortholog of budding yeast *MEC1* by homology, but the response to DSBs in yeast are controlled mostly by *MEC1* while in humans ATM seems to have a larger role. Thus, the sequence homology predicts general functions but not the division of functions between ATM and ATR or *TEL1* and *MEC1*.

**Auditory hair cells:** The sensory cells of the auditory system.

## Glossary

**Auditory scene analysis:** The analysis of multiple sound sources into auditory perception of individual sources (such as human voices or music) using cues such as spatial and frequency separation, harmonic relations, common onset, and offset.

**Autonomy:** Self-rule; capability of self-determination by comprehending information and making considered judgments based on personal goals or preferences.

**Aves:** The vertebrate order consisting of all bird species.

**A $\beta$ :**  $\beta$ -amyloid peptide, a 39 to 42 amino acid peptide cleaved from its membrane-bound precursor protein  $\beta$ APP ( $\beta$ -amyloid precursor protein that is deposited in the brains of subjects with Alzheimer's disease).

**B cell:** Lymphocyte that produces antibodies and is responsible for humoral immunity.

**BAL:** Broncho-alveolar lavage; procedure performed during a bronchoscopy (bronchial fibroscopy) permitting sampling of cells and microorganisms in the peripheral lung. The bronchoscope is wedged in a segmental or subsegmental bronchus and saline solution is injected and then aspirated (successive aliquots of 20 to 50 ml). Samples obtained are less contaminated by upper airways than bronchial or tracheal aspirates and more representative (in terms of cell populations and microorganisms) of the periphery of the lung in pathological situations such as pneumonia.

**Base Excision Repair (BER):** A DNA repair pathway in which an altered base is removed by a DNA glycosylase enzyme, followed by excision of the resulting sugar phosphate. The small gap left in the DNA helix is filled in by the sequential action of DNA polymerase and DNA ligase.

**Basic reproductive number (R0):** The number of secondary infections which would, on average, arise from introduction of a single primary infection into a wholly susceptible population.

**BBN:** Broadband or wideband noise.

**Belmont Report:** Influential report of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, which, in turn, was established by the U.S. Congress (1974 National Research Act); the report describes the following three broad prima facie ethical principles that provide a basis on which specific rules for conducting human subjects research may be established, appraised and interpreted: respect for persons, beneficence and justice.

**Beneficence:** The prima facie ethical principle that requires investigators to act to secure the well being of human research subjects, maximize benefits and minimize harms; inhumane treatment of human research subjects research is never morally justified.

**Benign prostatic hyperplasia (BPH):** Pathological proliferation of fibrostromal and epithelial tissue of prostate with high prevalence in aged men; associated with low urinary tract syndrome.

**$\beta$ -cell:** Highly specialized cells found in the islets of Langerhans in the pancreas that produce and secrete insulin into the bloodstream.

**$\beta$ -cell dysfunction:** Decrease in the secreted insulin amount.

**Beta level:** The probability of committing a type II error.

**Beta-amyloid:** An amyloid derived from a larger precursor protein, which is a component of plaques that develop with age and are more numerous in Alzheimer's disease.

**$\beta$ -galactosidase:** an enzyme.

**Bias:** a flaw in either the study design or data analysis that leads to an erroneous result.

**Big Five:** In psychology, five generally accepted personality traits that typify human behavior: conscientiousness, agreeableness, neuroticism, openness, and extroversion.

**Binaural processing:** The integration of acoustic information received across left and right ears.

**Biomarker:** A physical attribute that may be a biological state or trait that contributes to the distinction between classes or types of individual. Most often used to distinguish disease states from health, but may be used to identify individuals at increased risk of disease.

**Biomarkers of aging:** Molecular, physiological or functional variables selected for their reliable correlations with the declines in healthy function characteristic of aging.

**Biomarker of aging rate:** A gene expression or other phenotypic change that correlates with the rate at which an individual is aging. A biomarker of aging rate will also be a biomarker of longevity.

**Biomarker of longevity:** A gene expression or other phenotypic change that correlates with the life span of an individual.

**Bistable percept:** The phenomenon of alterations between distinct interpretations (i.e., perception) of the same physical stimulation.

**Blastocyst:** The late stage of preimplantation embryo development that implants into the uterine epithelium in primates, comprising two primordial tissues: ICM and trophectoderm.

**Blood-brain barrier:** An elaborate network of supportive brain cells, called *glia*, that surrounds blood vessels and protects neurons from the toxic effects of direct exposure to blood.

**BMI:** Body mass index.

**Bone morphogenetic proteins (BMPs):** Phylogenetically conserved signaling molecules that belong to the transforming growth factor (TGF)-beta superfamily, and are involved in body patterning and morphogenesis.

**Bootstrapping:** a computationally intensive, nonparametric technique for making probability-based estimates and inferences about a population characteristic based on a sample drawn from that population.

**Bottom-up processing:** See Primitive segregation.

**Boundary conditions:** Terms that specify the state of the model population at time zero, and the distribution at age zero of the model population into specified subgroups and into the various infection states in the model (susceptibility, infection, immunity etc).

**bT:** Bioavailable T (testosterone).

**Budding:** The founding of a new colony when a polygynous colony splits with some workers and queens leaving to start a new colony.

**Budding yeast:** The yeast *Saccharomyces cerevisiae* divides by asymmetric budding to produce a larger Mother cell and a smaller Daughter cell.

**CA strand:** The 5' strand of the chromosome end, bearing the telomere repeat sequence CCCTAA in humans and C<sub>1-3</sub>A in budding yeast.

**CA1:** a region of the hippocampus proper containing the cell bodies of pyramidal neurons, which receive the primary input from CA3 pyramidal neurons.

**CA3:** a region of the hippocampus proper containing the cell bodies of pyramidal neurons, which receive the primary input from dentate gyrus granule cells.

**Caloric restriction (CR):** Dietary treatment in which the individual is given a nutritionally balanced diet which includes all vitamins, minerals, and trace elements; however, the diet aliquot per day is some percentage below the *ad libitum* intake, usually 30% for moderate restriction. For experimental purpose in insects CR can also bring about by intermittent feeding.

**CAP:** Community-acquired pneumonia.

**Capacity:** Individual's ability to understand and make decisions within a specific area of life.

**Cardiac ventricular ejection fraction:** Pntage of the ventricular blood volume that is propelled into the aorta at each ventricular contraction.

**Cardiomyocyte:** A cardiac muscle cell. These cells are post-mitotic, terminally differentiated cells responsible for the mechanical pump function of the heart.

**Carotid artery:** An artery, located on either side of the neck, that supplies the brain with blood.

**Cartilage:** A type of dense connective tissue that comprises three main types of cartilage: hyaline, elastic, and fibrocartilage.

**Case control study (syn.: case-referent study):** a study which compares cases and controls with regard to the presence or absence of some element in their past experience.

**Caste:** designation of a set of individuals in a colony that are distinct in regard to morphology and behavior.

**Categorical data:** a collection of observations that can be categorized by classification or on an ordered scale.

**CCA:** Common carotid artery.

**CCAo:** Common carotid artery occlusion.

**CD28<sup>-</sup>:** CD28-negative (i.e., cells that do not express CD28).

**CD28<sup>+</sup>:** CD28-positive (i.e., cells that express the CD28 molecule).

**CD28:** costimulatory molecule on T cells.

**CDC13:** a budding yeast protein that is part of the telomerase holoenzyme and is a protein that binds to and protects telomeres. Cells expressing the *est4* allele of *CDC13* (*cdc13-2*) behave as if they have no telomerase activity, but in vitro telomerase activity can be isolated from these cells. Yeast *EST1* protein is thought to serve as a bridge between the telomerase enzyme and the *CDC13/EST4* protein bound to the telomere end. The orthologs in humans and fission yeast are considered to be the telomere proteins *POT1* and *pot1*<sup>+</sup>, based in part upon protein structural similarities.

**Centenarian:** A person 100 years old or older.

**Central hearing loss:** Problems in acoustic processing associated with deterioration, maturation, or damage to the brain.

**Central sleep apnea:** Lack of effort to breathe.

**Cerebral blood flow:** The flow of blood through the arteries that lead to the brain, called the cerebrovascular system.

**cES:** Chicken embryonic stem cells derived from Stage X embryos, which are pre-blastula embryos collected from unincubated eggs consisting of about 40 000 cells.

**Chicken embryo fibroblast (CEF):** A fibroblast cell usually derived from 7–11 day-old (E7-11) chicken embryos. A cell from which connective tissue develops.

**CHF:** Congestive heart failure.

**CHIMP Act:** H.R. 3514, signed into law on December 20, 2000. Provides a nonprofit, long-term retirement

## Glossary

sanctuary system for chimpanzees that have been used in biomedical research.

**Chiroptera:** Order of Mammalia including all bat species, which is further subdivided into two suborders, the Megachiroptera and the Microchiroptera.

**Cholecystokinin (CCK):** Hormone released when food enters the small bowel; stimulates contraction of the gall bladder and mediates feeling of satiety.

**Chondrocyte:** The only cells found in cartilage.

**Chronobiology:** Description and research of time structure of animals and plants, populations and ecosystems. Periodic repeating physiological rhythms and oscillations on different levels of organisation steps proved to be a constitutive function of life.

**Chronological life span:** The length of time that a quiescent yeast cell retains the ability to re-initiate vegetative growth upon return to appropriate growth conditions.

**Cingulate cortex:** Large area of the limbic system involved in memory and emotional processing, found on the medial surface of each cerebral hemisphere dorsal to the corpus callosum.

**Circadian periodicity:** Rhythmic variation during the 24-hour period.

**Claustral colony founding:** The founding of a new colony by a single queen that raises its first brood without any outside help.

**Cloning efficiency:** That fraction of cells potentially able to generate clones that actually do so in practice.

**CLP:** Cecal ligation and puncture. A common method to induce sepsis in laboratory animals.

**CNS:** Central nervous system.

**Cochlea:** The coiled organ in the inner ear that converts mechanical energy (vibrations) into nerve impulses that are sent to the brain.

**Coculture model:** Two or more primary cell lines cultured together, separated by a microporous membrane to enable diffusion of soluble growth factors from one cell line to another.

**Cohort study (syn.: follow-up study: longitudinal study):** A study that starts with a group of people which are all free of disease, but vary in exposure to a factor, which may be related to development of the disease.

**Collagen:** Main structural protein of skin, bones, tendons, cartilage, and connective tissue.

**Comet assay:** Means of determining the level of DNA damage using electrophoretic techniques, so-called because samples take on the appearance of a comet, with DNA fragments in the tail.

**Comorbidity:** Disease(s) that exist in a study population in addition to the index condition that is the subject of study.

**Compartmental model:** A model, often depicted using a flow diagram, in which the population is divided into categories or reservoirs corresponding to each stage of susceptibility, infection and immunity represented in the model with population flows between stages representing transitions from one stage to another.

**Compensation law of mortality:** The observation that higher death rates at young ages in disadvantaged populations are compensated by lower pace of mortality acceleration with age, so that the relative differences in mortality between populations tend to decrease with age (also known as mortality convergence in later life).

**Competence-Press model:** The most widely acknowledged theory of the ecology of aging introduced by Lawton and Nahemow. Lawton and Nahemow have argued that older adults with lower competence are expected to be particularly prone to what they have coined as "environmental press."

**Competency:** Determination, typically in a court of law, that a person meets the basic criteria to make his/her own decisions in all areas of life.

**Compliance:** Pressure necessary to induce a change in volume (expressed in cmH<sub>2</sub>O/L); it is, in fact, a measurement of the elasticity of either the lung, the chest wall, or the respiratory system. Compliance of the respiratory system is influenced by changes in elastic recoil of either the lung or the chest wall, and by lung volume.

**Concept abstraction:** The ability to categorize or sort objects based on a common dimension.

**Concurrent sound segregation:** The separation of acoustic energy at a single point in time. Involves a fine-grained analysis of spectral and temporal information.

**Conditional survival curves for neoplastic causes of death:** Estimated survival curves if non-neoplastic fatal lesions are eliminated. If postmortem examinations are properly performed and a cause of death is reasonably determined in each spontaneously dying animal, conditional survival curves can be used to evaluate the potential effect on lifespan of a specific category of death.

**Confidentiality:** Duty to keep secret and prevent from discovery information revealed by a client within a professional relationship.

**Confounding:** Distortion of the estimated effect of an exposure on an outcome caused by the presence of an extraneous factor associated both with the exposure and the outcome.

## Glossary

**Congo Red:** A histological dye that stains amyloid fibrils a characteristic yellowish–green with birefringence. This staining is one of the characteristics that defines amyloid.

**Conscientiousness:** The personality trait of being organized, disciplined, and an effective worker.

**Contact matrix:** A matrix specifying the proportion of potentially infective contacts that individuals in each behavioral, age or other subgroup of a heterogeneous model population has with each of the other subgroups in the population and which would provide the conditions for transmission should the contact be with an infectious individual.

**Continuity theory:** Proposes that people who age successfully carry forward the activities and lifestyles of their middle years into old age.

**Continuous data:** Data that form one or more whole intervals.

**COPD:** Chronic obstructive pulmonary disease.

**CR:** Carotid restriction.

**Cortisol release:** A stress-related hormone, cortisol is increasingly released from the adrenal cortex as levels of stress increase. An excess of cortisol can cause stress-related physiological conditions, including an interruption of circadian rhythms.

**Costimulation:** T cell signaling via monomorphic surface receptors required in addition to signaling via the antigen receptor for cell activation.

**CpG:** Nucleic acids with a high content of cytosine and guanine.

**Cross-sectional study (syn.: disease frequency survey; prevalence study):** A cross-sectional study samples a population at a given point in time for disease conditions or characteristics.

**CRP:** C-reactive protein.

**CS:** Contralateral suppression of OAEs by the auditory efferent system.

**CT:** Computerized tomography imaging, which uses multiple X-ray images and computer processing to produce three-dimensional images.

**C.U.:** International conventional units used for the quantitative analysis of images.

**Culture arrest:** A condition observed in senescence wherein cells cease proliferating.

**Cytokines:** Chemical messenger molecules by which cells communicate with one another.

**D-loop:** DNA recombination and replication intermediate in which one DNA strand has invaded and displaced the

equivalent strand of a second DNA molecule of same or similar sequence.

**DAF-16: DAF-2:** Dauer larva formation; forkhead transcription factors.

**DAG:** Diacyl glycerol.

**Dahl salt-sensitive rats:** A strain of rats that was developed by Louis Dahl that increases its blood pressure when given a high-salt diet.

**Danio rerio:** scientific name for zebrafish.

**Dauer larva:** In *Caenorhabditis elegans*, dauer larvae are arrested, long-lived, environmentally resistant forms of the third stage larva (L3), which have a morphology, physiology and behavior distinct from other larval stages. The choice between development into “normal,” non-dauer L3s and dauer larvae is modulated by food availability, dauer pheromone concentration and temperature.

**dB SPL:** Decibels in sound pressure level.

**DC:** Dyskeratosis congenital.

**Decision-making capacity:** A potential research subject’s ability to understand, make and express a reasoned and meaningful choice about whether to participate in a research study.

**Declaration of Helsinki:** The World Medical Association’s code of ethics for research involving human subjects that, in addition to the topics addressed by the Nuremberg Code, also addresses research involving patients, proxy consent, the use of control groups and placebos and nontherapeutic research.

**Dementia:** Profound loss of cognitive function. Depending on the brain area affected, dementia manifests as changes in personality, ability to process speech, emotional stability, and the ability to reason.

**Descriptive epidemiology:** The study of the burden of disease within a population by person, place, and time.

**Deterministic model:** A model for which the results are completely determined by the model structure, model parameters, and the boundary conditions.

**Developmental tasks:** Developmental tasks result from three different sources: biology, society, and internal experience of the individual. Developmental tasks are helpful in determining the course and sequence of how and when individuals are expected to make specific developmental progress or at what time in life they should engage in or disengage from developmental goals.

**DHAP:** Dihydroxyacetone phosphate.

**DHEA:** Dehydrotestosterone.

**DHEA-S:** Dehydrotestosterone sulfate.

## Glossary

**DHT:** Dihydrotestosterone.

**Diapause:** Kind of dormancy of insects and different other invertebrates. It is characterized by a temporal interruption of development or gonadal function and goes together with a drastic reduction of energy metabolism. The inducing abiotic factor is a change of photoperiod to short day conditions. New findings indicate that the aging process arrests during this situation.

**Diet-induced thermogenesis:** Increase in metabolic rate that occurs with eating. It is a component of total energy expenditure that represents energy from food that is not used.

**DIGE:** Differential in-gel electrophoresis.

**Diphyodont:** Having two successive sets of teeth.

**Disability:** Any temporary or long-term reduction of a person's activity as a result of an acute or chronic condition.

**Discrimination learning:** An associative learning problem where one must attend to stimulus features and acquire an association between the stimulus features and a reward.

**Disengagement Theory:** Suggested by Cumming and Henry, older individuals are seen as limiting their social life spaces in response to societal pressures and in order to prepare for the final phase of their lives.

**Dissector:** A stereological procedure for counting objects in tissue sections. The dissector may be defined as a three-dimensional stereological probe composed of pairs of sections: the reference section and a serial section called the look-up section. The volume of the dissector is determined by the area of the sections and the distance between them. Objects are considered to be in the dissector and counted if they can be identified in the look-up section, but not in the reference one. In order to detect all the objects to be counted, the distance between reference and look-up sections must be less than the shortest dimension of the objects. With specific reference to synaptic counts, adjacent sections can be used and they must be located randomly within a given neural region.

**Distribution-free methods:** See Nonparametric methods.

**Distributive justice:** Fairness in the distribution among persons of the risks, harms and benefits incurred by their society.

**Diutinus:** The Latin word *diutinus* means enduring or long-lived.

**DLCO:** Diffusion capacity of the lung for carbon monoxide.

**DNA:** Deoxyribonucleic acid or deoxyribose nucleic acid; a nucleic acid that contains the genetic instructions specifying the biological development.

**DNA damage:** Changes in the DNA chemical structure induced by a variety of different chemical, physical, and biological agents.

**DNA repair:** The complex of enzymatic systems to remove DNA damage and to restore the original situation.

**DNA replication:** The process of copying the entire complement of genetic information.

**DNA transcription:** The process of copying the genetic information encoded in a gene into mRNA.

**DNP:** 2,4-dinitrophenyl.

**DPOAE:** Distortion product otoacoustic emission; cochlear physiological recordings.

**DSBs:** Double-strand breaks in DNA.

**DT40:** A transformed chicken B-cell derived from an Avian Leukosis Virus (ALV)-induced bursal lymphoma (tumor) of a female chicken.

**Dynamic susceptibility contrast: MRI:** a method of combining high resolution magnetic resonance images with paramagnetic intravascular susceptibility contrast agents to derive measures of hemodynamic changes such as blood flow and volume in the brain.

**Dyspareunia:** Painful intercourse.

**E:** Embryonic day.

**E<sub>2</sub>:** Estradiol.

**Ecdysone:** A steroid hormone in insects that stimulates molting and metamorphosis.

**Echocardiography:** The use of ultrasonic imaging to assess cardiac structure and function.

**Echolocation:** Sophisticated sensory system in microchiropteran bats based on the emission of ultrasonic calls and the interpretation of returning echoes. Bats use echolocation for navigation and location and identification of prey items.

**Ecological equation:** (Behavior = P, E, P X E). This equation has been most essential for the ecology of aging; that is, the consideration of the impact of the interaction between the aging individual and the environment on a variety of outcomes such as emotional well-being and behavioral functioning has been added to the isolated consideration of the person (P) and his/her environment (E).

**Ectothermic organisms (poikilothermic organisms):** Animals with missing or only partial developed ability to maintain body temperature in a constant range. They often rely on incident solar radiation as heat source.

**Edema:** The swelling of a cell that results from the influx of large amounts of water or fluid into the cell.

## Glossary

**EEG:** Electroencephalography.

**Effective reproductive number ( $R$ ):** The number of secondary infections arising on average from each new infection in population; at the time of first introduction into a wholly susceptible population  $R$  has the same value as  $R_0$ .

**EGB 761:** A drug extracted from Ginkgo Biloba.

**Egocentric:** Spatial references made on the basis of the observer's position in the environment.

**Elastic recoil of the lung:** Pressure tending to restore the lung to its resting volume (i.e., deflated) resulting from distention of the alveoli and the parenchymal interstitial network; increases with increasing lung volume.

**Elastin:** A protein in connective tissue that provides elasticity in various tissues such as ligaments, tendons, or skin.

**Elastosis:** The loss of elasticity of skin, possibly due to deposition of elastin.

**Electrocardiography (ECG):** The practice of recording the electrical discharges of the heart.

**Electron transport chain (respiratory chain):** The series of electron carriers in the inner mitochondrial membrane that pass electrons from reduced coenzymes (NADH, FADH<sub>2</sub>) to molecular oxygen via sequential redox reactions coupled to vectorial transduction of protons across the membrane.

**Electroporation:** A technique by which polar molecules are introduced into a host cell through the cell membrane. An electric pulse temporarily disturbs the phospholipid bilayer, allowing molecules such as DNA to pass into the cell.

**Embolic stroke:** A stroke caused by an embolus.

**Embryonic cell nuclear transfer (ECNT):** A technology involving fusion of a blastomere with an enucleated oocyte, so that the blastomere nucleus becomes the embryo nucleus; this is one (limited) form of cloning.

**Embryonic stem cells:** Primordial cells derived from the blastocyst ICM, that are capable of producing all the organ and tissue types of the fetus; possibly, only trophoctoderm cannot be derived from ES cells but this is not certain.

**Endocochlear potential:** Physiological voltage in scala media of the cochlea, generally around +90 mV.

**Endocrine system:** System of glands that secretes hormones to maintain homeostasis in a variety of systems. Examples include thyroid, adrenal, and pituitary systems. Two important bioactive endocrine molecules discussed in this book include DHEA-S from the adrenal gland and IGF-1, the first messenger molecular from the pituitary-produced growth hormone.

**Endocrinopathy:** A disorder in which there is a disturbance (increase or decrease) in one or more hormones; for example, growth hormone deficiency, hyperthyroidism.

**Endothelial dysfunction:** Dysfunction of the layer of epithelial cells that lines the cavities of the heart, the blood, and lymph vessels, and the serous cavities of the body, originating from the mesoderm.

**Endothelin:** A potent vasoconstrictor that plays a role in blood pressure control.

**Endothermic organisms (homeothermic organisms):** Animals (especially birds and mammals) with the ability to maintain the body core temperature within narrow limits independent from external fluctuations. The maintenance of temperature is reached by thermoreceptors in the skin and temperature sensitive neurons in the central nervous system which act upon temperature processing hypothalamic centers.

**Endurance exercise:** A form of exercise performed at well below the maximum aerobic capacity and for more prolonged periods than would be possible for aerobic exercise.

**End-replication problem:** The inability of DNA polymerase to replicate the 5' end of a linear chromosome causes loss of telomeric (TTAGGG) repeats upon successive divisions.

**eNOS:** Endothelial nitric oxide synthetase.

**Enteroinular axis:** Represents the enteral hormone (incretins) secretion to the ingestion of glucose to potentiate insulin secretion.

**Entorhinal cortex:** A region of the medial temporal lobe which has bidirectional connections with the hippocampal formation and which is vulnerable to age-related decline.

**Environmental enrichment:** The provision of stimulating, novel items and enriching experiences to captive primates.

**Epidemiology:** The study of the distribution and determinants of health-related states in specific populations, and the application of this study to control of health problems.

**Epigenetic:** A theory holding that development is a gradual process of increasing complexity. This contrasts with *preformationism*, which contends that the organism is already present in the gamete. Epigenesis encompasses all aspects of an individual's development as determined by genes and internal and external environments. Many genes require specific environmental circumstances in order to be expressed. Many genes are never expressed. In these terms, epigenesis is the influence of the environment (e.g., nutrients) on genes.

## Glossary

**Epiphyseal growth plate:** Cartilaginous region at the interface between the shaft (diaphysis) and the two ends (epiphyses) of a growing long bone.

**ERCs:** Extrachromosomal rDNA circles formed in yeast by intrachromosomal recombination between the tandem ribosomal RNA genes in the budding yeast *RDN1* locus. Because each repeat has an origin of DNA replication, these circles can replicate independently from the chromosome and accumulate in the mother cell over successive cellular divisions.

**Erythroid:** Red blood cell-related.

**ESRS:** Electron spin resonance spectroscopy; allows us to measure the quantity of melanin contained in retinal tissues.

**ESI:** Electrospray ionization.

**EST1:** a budding yeast protein that is part of the telomerase holoenzyme. Cells lacking *EST1* behave as if they have no telomerase activity, but in vitro telomerase activity can be isolated from these cells. Yeast *EST1* protein is thought to serve as a bridge between the telomerase enzyme and the *CDC13/EST4* protein bound to the telomere end. *EST1* orthologs exist in humans and fission yeast and play a role in telomere length regulation.

**EST2:** the budding yeast telomerase reverse transcriptase or yTRT or yTERT. With telomerase RNA, this protein catalyzes the synthesis of yeast telomere repeats. Orthologs are known in many organisms including humans and fission yeast (*trt1*<sup>+</sup>).

**EST3:** a budding yeast protein that is part of the telomerase holoenzyme. Cells lacking *EST3* behave as if they have no telomerase activity, but in vitro telomerase activity can be isolated from these cells.

**EST4:** See *CDC13*.

**ET-1:** Endothelin-1.

**ETC:** Electron transfer chain.

**Euglycemia:** Normal blood glucose level.

**Eusocial insects:** State building insects with one (rarely more) egg-laying and long-living queen and workers having reduced or functionless gonads. They are several-fold independently evolved in bees, wasps, ants and termites.

**Executive functions:** A term used to describe a number of cognitive functions including the ability to alter behavior in the face of changing environmental conditions. Believed to be mediated by the prefrontal cortex.

**Executive functions:** Higher order cognitive processes often controlled by the front part of the brain and includes functions such as categorical abstraction,

set maintenance and manipulation, set shifting, and inhibitory control.

**Exposure:** The generic term used to describe the effective presence of any agent or factor that is thought to cause disease, such as toxic chemicals, dietary habits, activity levels, microorganisms.

**Extra-cellular matrix:** The scaffold of macromolecules that constitutes the biological substance that surrounds cells in tissues. In tissues such as dermis, the extra-cellular matrix is constituted by the so-called ground substance (water-binding proteoglycans and polysaccharides such as hyaluronic acid, heparin, heparin sulfate, keratan sulfate, etc.) surrounding collagen fibers. Proteins in the extra-cellular matrix, such as the collagens and elastin, are not water soluble, which makes their quantitative analysis extremely difficult.

**Extrachromosomal rDNA circles (ERCs):** Self-replicating, circular DNA molecules that contain one or more complete copies of the 9.1 kb ribosomal DNA repeat unit. ERCs are formed by homologous recombination, are symmetrically segregated to the mother cell during cell division, accumulate with age in the mother cell nucleus, and are thought to cause replicative senescence in yeast.

**Extroversion:** The personality trait of being outward-looking and gregarious.

**F1:** Frequency of the first tone of the DPOAE stimulus.

**F2:** Frequency of the second tone of the DPOAE stimulus.

**F1 hybrid:** progeny of a cross between two different inbred stocks of mice.

**FA:** Fanconi anemia.

**Factor analysis:** A statistical procedure that works to discover simple patterns in relationships among variables.

**Failure rate (also known as hazard rate):** Risk or frequency of a system's failure. Mathematically it is defined as the relative rate of reliability (survival) function decline.

**Failure:** The event when a required function is terminated. Failures are often classified into two groups: (1) degradation failures, where the system or component no longer functions properly, and (2) catastrophic or fatal failures—the end of system's or component's life.

**FAT:** FRAP, ATM and TRRAP related.

**FATC:** FRAP, ATM and TRRAP C-terminal related.

**Fat free mass (FFM):** The component of body composition that is not fat; it varies between individuals and relates mainly to the mass of skeletal muscle.

**Fatigue:** A feeling of tiredness or weariness.

## Glossary

- FEF<sub>25-75</sub>**: Forced expiratory flow rate from 25 to 75% of the vital capacity.
- FEV<sub>1</sub>**: Volume expired in one second during a forced expiratory maneuver after a maximal inspiration.
- FFA**: Free fatty acids.
- FFT**: Fast Fourier transform.
- Fission (or coherence) boundary**: The level of frequency separation in a tone pattern that leads to the perception of a single stream of sound.
- Fission yeast**: The yeast *Schizosaccharomyces pombe*, which divides by symmetric division to produce two daughter cells of equal size called sisters.
- Flow diagram**: A diagram consisting of boxes (compartments) and arrows (flows) depicting the essential features of the dynamics of a particular infection in a population.
- Fluoro-angiography**: E.v. injection of a fluorescent contrast for the visualization of the retinal vessels of the ocular fundus.
- Follicle stimulating hormone (FSH)**: One of the pituitary gland gonadotropins.
- Follitropin receptor knockout mouse (FORKO)**: A transgenic mouse in which the follitropin (FSH) receptor is absent; this is a model for postmenopausal hypertension.
- Folstein Mini-Mental State Exam**: A bedside neuropsychologic test used to assess cognitive functioning of people. The test is commonly used as a screening test for dementia.
- Force of infection**: The annual per capita incidence of infection in the population amongst those susceptible to the infection, as distinct from the incidence in the whole population.
- Forced molting**: A method used by the poultry industry in which egg-laying chicken hens are temporarily starved or calorically restricted to induce feather loss and increase egg production.
- 4-HNE**: 4-hydroxy-2-nonenal.
- Four-way cross**: A stock produced by a mating between two different F1 hybrid parents.
- FOXO**: Forkhead box transcription factors.
- Frail**: Clinical term used to describe an older adult, or chronically ill younger adult who is weak, fatigued, and at high risk for poor health outcomes.
- Frailty**: Biological syndrome of decreased reserve and resistance to stressors, resulting from cumulative declines across multiple physiological systems. Causes vulnerability to problems such as unintentional weight loss, weakness, exhaustion, slow walking speed, and low physical activity.
- FRC**: Functional residual capacity.
- FRC**: Functional residual capacity; lung volume after expiration during quiet tidal breathing.
- Free radical theory of aging**: The original theory was published by Denham Harman in 1956. This theory proposes that aging is a consequence of damage to cellular components caused by free radicals produced during normal metabolism.
- Free radicals**: Molecules with one or more electrons unpaired in their most external orbitals. Due to this they are very reactive molecules, and can damage other molecules by reacting with them.
- Fruc-6-P**: Fructose-6-phosphate.
- fT**: Free testosterone.
- Fundamental frequency**: The lowest frequency of a periodic signal.
- Functional brain imaging**: Techniques that can visualize correlates of regional energy metabolism, either glucose or oxygen uptake. These techniques include functional magnetic resonance imaging (fMRI), positron emission tomography (PET), or single photon emission tomography (SPECT).
- Fusion (or segregation) boundary**: The level of frequency separation in a tone pattern, which leads to the perception of two streams of sound.
- FVC**: Total volume of air expired during a forced expiratory maneuver.
- GAL4**: A transcription factor from yeast that is functional in *Drosophila*.
- Gap detection**: Auditory behavioral and neurophysiological temporal processing task.
- GAPDH**: Glyceraldehyde phosphate dehydrogenase.
- Gastrulation**: The process whereby the three primitive germ layers are established in the embryo.
- Gedanken Experiment**: A purely intellectual experiment, the virtue of which is to allow one to predict what is expected to happen when all the hypotheses are verified. In the case of skin aging, the interest of the Gedanken Experiment described in the text is to show that aging is expected to occur even in the absence of gerontogenes.
- Gene**: The segment of DNA encoding a polypeptide chain; it includes regions immediately preceding and following the coding sequence as well as intervening sequences (introns) between individual coding sequences.

## Glossary

**Gene expression biomarker:** A gene expression change (or lack thereof) that correlates with a particular process.

**Gene expression profile:** A collection of gene expression responses (often several thousand) that correspond to a particular experimental parameter, such as age.

**Genome:** The full DNA sequence of an organism. The human genome consists of approximately 6 billion base pairs of DNA distributed among 46 DNA-protein complexes termed chromosomes.

**Genomics:** The study of an organism's genome.

**Genotype:** The alleles present at one or more specific loci.

**Geriatrics:** A branch of medicine dealing with the problems and diseases of old age.

**Gerontogenes:** Putative genes postulated by theories supporting the "necessity" of aging. To explain aging, this theory invokes the existence of specific genes that would be "turned on" a defined number of years after birth, and would induce or allow the accumulation of damages provoking the loss of the capability of the individual to compete for food and to reproduce. As of today, gerontogenes have not been found.

**Gerontology:** A branch of study dealing with aging and the problems of the aged.

**GFAP:** Glial fibrillary acidic protein; a protein specific to the astrocytes and other glia cells that can be stained by means of immuno-histochemical methods.

**GFAT:** Glutamine:fructose-6-phosphate amidotransferase.

**Ghrelin:** A hormone released from the stomach that acts a signal to eat. Levels are decreased in the elderly and in obese subjects.

**GlcNAc:** O-linked N-acetylglucosamine (hexosamine pathway).

**Glial cell-line-derived neurotrophic factor (GDNF) knock-out mice:** A transgenic mouse strain in which the gene for the GDNF is absent. The kidneys in homozygotes do not develop and they die early. The heterozygotes are a model of reduced renal glomeruli that develop hypertension with aging and high salt intake.

**Glucose tolerance test:** A test to evaluate the rate of glucose disposal in the body after glucose administration. Blood glucose level stays at higher if the metabolic process is impaired, as in cases of diabetes and/or aging.

**Glucose transporter:** A family of membrane proteins that allows the energy-independent transport of glucose across the cell membrane. An isoform of glucose transporter proteins (GLUT4) is important for regulating glucose disposal in the body, because GLUT4 is translocated into

the membranes of muscle and fat cells in response to the insulin signaling.

**Glut -1:** Glucose transporter 1.

**Glycation end products:** Nonenzymatic protein modifications.

**Glycolytic oscillator:** Periodic rhythm of glycolyse, first studied on intact yeast cells and later on cell free extracts of different organisms indicating a biochemical clock independent of spatial cell structure. The mechanism is based on complex interactions of glycolytic enzymes and ligands in which phosphofruktokinase plays the key role.

**Glycosaminoglycan:** Glycosaminoglycans are long unbranched polysaccharides, made of repeating disaccharides that may be sulphated. GAGs form an important component of connective tissues. Glycosaminoglycans include, for instance, chondroitin sulphate and dermatan sulphate.

**Glycosylated hemoglobin:** A test that measures the amount of glucose-bound hemoglobin, which provides information regarding how well a patient's diabetes is being controlled. As the blood glucose level increases, the proportion of hemoglobin molecules that bind glucose increases with time.

**Glycosylation:** A nonenzymatic series of reactions in which proteins or other molecules combine with reducing sugars in molecules, cells and tissues to produce compounds that may contribute to aging-related disease or loss of function.

**Glycooxidation:** A synergistic combination of glycosylative and oxidative reactions that produce metabolic end-products implicated in aging-related disease or loss of function.

**GNB:** Gram-negative bacteria.

**Gompertz curves:** Mathematical description of the exponential change in age-specific death rate ( $q_x$ ) with age was first described by Benjamin Gompertz in 1825, as follows:  $\ln q_x = \ln q_0 + x$ , where  $q_0 = y$  intercept and  $x =$  slope constant. Plotting this for adult mortality usually yields a linearly increasing straight line. Changes in observed longevity are brought about by changes in the intercept and/or the slope (see MRDT). This transformation enables the complexities of a survival curve to be understood in terms of a straight line describing the mortality kinetics.

**Gompertz law of mortality:** The law of exponential increase in death (failure) rates with age. It was first suggested by the British actuary Benjamin Gompertz in 1825 for use in the life insurance business. This law was found to be applicable not only to humans but also to fruit flies, nematodes, the human lice, flour beetles,

## Glossary

mice, rats, dogs, horses, mountain sheep, baboons and many other biological species. According to the Gompertz law, the logarithm of death rates is increasing linearly with age.

**Gompertz model:** A class of statistical models in which the hazard rate for death rate rises geometrically with increasing age of the organism (at least after an initial period of high risk of mortality at birth and infancy and a much lower risk in late childhood and adolescence).

**Gompertz–Makeham law:** An extension of the Gompertz law of mortality when the additional, age-independent component of mortality (failure) is taken into account. This law was suggested by the British actuary William Makeham in 1867.

**Gonadotropin releasing hormone (GnRH):** The primary hypothalamic hormone that regulated the reproductive axis.

**Granulosa:** Layer of specialized epithelial cells in the ovarian follicle which support the oocyte or developing egg.

**GRP or Glucose related proteins:** Members of a family of proteins secreted in response to stressors which appear to play a role in cell protection.

**GSH:** Glutathione.

**Gynogenetic diploids:** The diploids generated by early pressure treatment after fertilizing the eggs with UV treated sperm.

**Haplo-diploid:** Sex is determined by the male being haploid (one chromosome set) and the female being diploid (two chromosome sets)

**Haploinsufficiency:** Impaired cell structure and/or function resulting from half the normal amount of a gene product.

**Hayflick limit:** The barrier to further cellular proliferation represented by culture arrest of senescent cells.

**HDL and LDL cholesterol:** Lipids become soluble and are transported into the blood as lipoproteins. Depending on the protein components of lipoproteins, cholesterol are designated as high-density-lipoprotein (HDL)-cholesterol, low-density-lipoprotein (LDL)-cholesterol, and so on. Epidemiological studies indicate that people with increased plasma concentrations of HDL-cholesterol, and thus decreased LDL-cholesterol, show a reducing risk for cardiovascular diseases.

**Hearing thresholds:** The minimal intensity level required for auditory stimulus detection.

**Helicase:** An enzyme which separates DNA strands in preparation for replication.

**Hematopoiesis:** Formation of blood cells.

**Hematopoietic stem cell:** A pluripotent stem cell found in the bone marrow. These cells have the ability to differentiate into any of several types of blood cells and potentially other cells types, such as neuronal or cardiac.

**Hemorrhagic stroke:** Sudden bleeding into or around the brain.

**Herd immunity:** The level of immunity in the whole population to an infection, whether this arises from past infection, vaccination or maternal antibody.

**Heteroplasmy:** A condition in which cells have mitochondria from more than one source; normally, only maternal (oocyte) mitochondria are found in cells due to elimination of paternal (sperm) mitochondria during fertilization or early embryo development.

**Heterothermic:** Designation for organisms that can adjust body temperature and metabolic rate in response to environmental conditions and physiological cues (e.g. hibernation, torpor).

**Heterozygous:** Having two different alleles at a specified genetic locus.

**HGPS:** Hutchinson–Gilford progeria syndrome.

**HI:** Hypoxia-ischemia.

**HINT:** Hearing in noise test; speech recognition is measured in the presence of speech-weighted noise from different spatial locations.

**Hippocampal formation:** A brain circuit in the temporal lobes that plays a vital role in memory function. The circuit is made up of different hippocampal sub-regions including the entorhinal cortex and the dentate gyrus.

**Hippocampus:** A part of the medial temporal lobe system involved in memory storage and that is strongly affected by age-related decline.

**Histone deacetylase:** An enzyme that removes an acetyl group from histones, which allows histones to bind DNA and inhibit gene transcription.

**HIV:** Human immunodeficiency virus.

**Hive body:** A rectangular box with frames of wax comb hung in parallel on the inside. One honeybee hive consists of one or more such boxes.

**Homeostasis:** The ability or tendency of an organism or a cell to maintain internal equilibrium by adjusting its physiological processes.

**Homeothermic:** Said of organisms that regulate their body temperature within narrow limits.

**Homocysteine:** A sulfur-containing, amino-acid derivative formed during methionine metabolism. Hyperhomocysteinemia is a risk factor for premature vascular disease.

## Glossary

- Homologous trait:** A trait shared between organisms due to common descent or ancestry.
- Homozygous:** having the same allele at a specified genetic locus.
- Hormesis:** The beneficial effects of low doses of potentially harmful substances.
- Hormone replacement therapy (HRT):** Steroid hormones given to women or primates as a replacement for estrogens and progesterone decline during aging.
- HP:** Hydrogen peroxide.
- HP1:** Heterochromatin protein 1.
- HSE:** Region of DNA that responds to heat shock.
- Hsfs:** Heat shock transcription factors.
- Hsp:** Heat shock protein.
- Hyaluronan:** A glycosaminoglycan distributed widely throughout connective tissue and one of the main components of the extracellular matrix.
- Hydroxyproline:** A major component of the collagen protein that helps provide stability to the triple-helical structure of collagen.
- Hyperinsulinaemic glucose clamp:** This technique involves a fixed dose of insulin being administered and then normal glucose concentrations being maintained by the infusion of glucose given. Reflects insulin sensitivity and is an inverse measure of insulin resistance.
- Hyperkeratosis:** Thickening of the outermost keratinizing or cornified layer of skin, often in conjunction with increased proliferation of underlying keratinocytes.
- Hypersomnia:** Too much sleep.
- Hypertrophy:** Overgrowth or enlargement; hypertrophy of glial cells is generally associated with degenerative events in the brain.
- Hypogonadism:** A condition resulting from or characterized by abnormally decreased functional activity of the gonads, with retardation of growth and sexual development. Secondary hypogonadism is acquired in life and defined as a laboratory testosterone value of 300–325 ng/dL, depending on the study discussed.
- Hyposomnia:** Too little sleep.
- Hypothalamic–pituitary–gonadal axis (HPG axis):** the major components of the reproductive axis.
- Hypothesis:** A formal statement or prediction of the scientific question of interest.
- Hypoventilation:** Alveolar ventilation below metabolic needs (i.e., CO<sub>2</sub> production). Major cause of acute or chronic hypercapnia.
- Hypoxia:** A state of decreased oxygen delivery to a cell so that the oxygen falls below normal levels.
- IBTP:** (4-iodobutyl)triphenylphosphonium.
- ICAT:** Isotope-coded affinity tag.
- ICU:** Intensive care unit.
- IFN-g:** Interferon gamma; an important cytokine that promotes Th1 (cell mediated) immunity.
- IGF-1:** Insulin-like growth factor-1; a single-chain polypeptide of 70 amino acids. It is a trophic factor that circulates at high levels in the blood-stream and mediates many, if not most, of the effects of growth hormone.
- IHC:** Inner hair cells; convert sound to the code of the nervous system in the cochlea.
- iL3:** In the parasitic nematode *parayloides ratti*, larvae moult through two larval stages into infective third-stage larvae (iL3s), which infect new hosts by skin penetration. iL3s are nonfeeding and environmentally resilient and can survive for months in this developmentally arrested state until contact with a suitable host. They (and the iL3s of other parasitic nematodes) are considered as analogous to the dauer stage of *Caenorhabditis elegans*.
- IMAC:** Immobilized metal affinity chromatography.
- Imaginal discs:** Undifferentiated cells that will develop into adult tissue and organs in the blastoderm (the layer of cells that surrounds internal mass of egg yolk in an insect embryo).
- Immune senescence:** Waning of immune responses with advancing age.
- Immunosenescence:** That age-associated dysregulated state of immunity associated with increased susceptibility to infection.
- Impaired glucose tolerance (IGT):** A glucose level over > 140mg/dL (7.8mmol/L), but less than 200 mg/dL (11.1 mmol/L) two hours after a 75g oral glucose tolerance test (OGTT).
- Imprinting:** First applied to the acquisition of behaviors when exposed to specific stimuli during development. Genomic imprinting plays a critical role in the fetal growth and development. Imprinting is regulated by DNA methylation and chromatin structure.
- Inbred:** Referring to strains resulting from a minimum of 10 generations of brother–sister matings, in which 99% or more of the genome is homozygous.
- Inbreeding depression:** A reduction in fitness and vigor of individuals as a result of increased homozygosity through inbreeding in a normally outbreeding population.

## Glossary

**Incidence:** The number of new events, such as new cases of a disease during a given period of time in a specified population.

**Infarct:** An area of tissue that is dead or dying because of a loss of blood supply.

**Inflam-aging:** Physiological status of the immune system in the elderly in which a pro-inflammatory profile predominates.

**Information bias:** A flaw in measuring exposure or outcome data.

**Informed consent:** A central feature of ethical research involving human subjects that consists of (a) adequate information regarding the research and its potential risks and benefits and subject understanding of the information, (b) subject decision-making capacity, and (c) subject voluntariness to participate.

**Infralimbic cortex:** A cortical region in rats located along the medial surface of the cerebral cortex that, together with prelimbic cortex in rodents, has been suggested as analogous to the dorsolateral prefrontal cortex in humans. This region has been demonstrated to be important for extradimensional set shifting in rats. May be referred to as the medial frontal cortex.

**Inhibitory control:** The ability to maintain attention to relevant task features and inhibit interfering information or previously learned responses.

**Initiating sleep:** Falling asleep.

**Inner Cell Mass (ICM):** The part of the blastocyst that forms the fetus after implantation; also the cells from which Embryonic Stem cells are derived.

**Insomnia:** Inability to sleep.

**Institutional Review Board:** Committee comprised of scientists and nonscientists charged by an organization with reviewing, approving, and monitoring human subjects research in order to protect those subjects.

**Insulin resistance:** Altered glucose disposal and hepatic glucose production.

**Interleukin-2:** A potent autocrine and paracrine T cell growth factor.

**Interleukin-6 (IL-6):** An inflammatory cytokine that is released in response to infection, trauma, and strenuous exercise from immune system cells, adipocytes, and endothelial cells. Acute elevations are necessary for propagating inflammatory responses. Chronic elevation of this cytokine may have pathophysiologic consequences on a number of physiologic systems, including bone, muscle, cardiovascular tissue, and the immune system.

**Interstitial:** Pertaining to or situated between parts or in the interspaces of a tissue.

**Inflammation:** Activation of multiple molecular pathways that are a response to infections and/or trauma. There is increasing evidence that these same pathways are activated in chronic disease and that chronic elevations in inflammatory mediators may contribute to poor health outcomes, including frailty, in older adults.

**Intervertebral disc:** Lies in between adjacent vertebrae in the spine.

**Intracytoplasmic sperm injection (ICSI):** Direct injection of spermatozoa into the oocyte cytoplasm, bypassing the need for prefertilization changes in spermatozoa (capacitation) and even the need for sperm motility. This ART approach is very popular with spermatozoa from infertile men with spermatozoa that are immotile or too few in numbers to achieve fertilization.

**Ionotropic:** A type of receptor that is directly linked to and facilitates the passage of ions into a neuron through an ion channel.

**IPF:** Idiopathic pulmonary fibrosis.

**IR:** Ionizing radiation.

**Ischemia:** A loss of blood flow to tissue, caused by an obstruction of the blood vessel, usually in the form of plaque stenosis or a blood clot.

**Ischemic cardiomyopathy:** Disease of cardiac muscle due to decreased blood supply to the tissue.

**Ischemic penumbra:** Areas of damaged, but still living brain cells arranged in a patchwork pattern around areas of dead brain cells.

**Ischemic stroke:** Ischemia in the tissues of the brain.

**Isogenic:** mice in an isogenic stock are each genetically identical to one another.

**IVAS (Initial Virtual Age of a System):** A parameter in theoretical models of systems failure describing the load of initial damage. This parameter has the dimension of time, and corresponds to the age by which an initially ideal system would have accumulated as many defects as a real system already has at the starting age (at  $x = 0$ ).

**JH (juvenile hormones):** A family of acyclic sesquiterpenoids synthesized by the corpora allata, a small set of paired glands in immediate proximity to the insect brain.

**Joint capsule:** A sac-like envelope that forms a sleeve around joints and encloses its cavity.

**Justice:** The prima facie ethical principle that refers to the equitable distribution of the benefits and burdens of research.

**Juvenile hormone (JH):** Isoprenoid-resp. terpenoidhormone of the corpora allata (CA) of insects. During larval development it acts together with the steroid hormone

## Glossary

ecdysone and prevents adult moulting. In adults it has several pleiotropic functions in the context of reproduction. It is also involved in diapause regulation.

**Kainate receptor:** Type of ionotropic glutamate receptor.

**Knock-in:** Replacement of a gene by mutant version of the same gene or by another gene usually through homologous recombination.

**L1:** Sound intensity of the first tone of the DPOAE stimulus.

**L2:** Sound intensity of the second tone of the DPOAE stimulus.

**Lacunar infarcts:** Class of infarcts related to hypertension found in the basal ganglia and pons that are less than 1.5 cm in diameter. These infarcts are typically multiple and represent small areas of infarction. Lacunar infarcts are frequently hemorrhagic.

**Laminopathy:** One of a family of heritable diseases arising from mutations that alter the structure or expression of the lamin A/C gene that encodes a key protein of the inner nuclear envelope. The laminopathies preferentially affect nerve, muscle, adipocytes, and connective tissue for as-yet unknown reasons.

**Late-life mortality deceleration law:** The observation that the pace of mortality growth with age decelerates from an expected exponential curve at extreme old ages, so that mortality rates level-off and, therefore, aging apparently fades away.

**Latency period:** Delay between exposure to a disease-causing agent and the appearance of manifestation of the disease.

**Left anterior descending (LAD):** The left anterior descending branch of the left coronary system.

**Leptin:** A hormone that is exclusively the product of adipose tissue. It has a variety of effects on the endocrine and immune systems but its major role is to decrease food intake at times when the organism is calorie replete.

**Leukocyte:** White blood cell.

**Life-course epidemiology:** Study of the long-term effects on later health or disease risk of physical or social exposures during gestation, childhood, adolescence, young adulthood, and later adult life.

**Life expectancy:** The probable life span of an individual.

**Lifespan:** The period of time in which the life events of a species typically occur.

**Lifespan extension curves:** survivorship curves that indicate the number of survivors plotted against advancing age.

**Ligament:** A short band of tough fibrous connective tissue composed mainly of long, stringy collagen fibers. Ligaments connect bones to other bones to form a joint.

**Limiting dilution:** Sequential dilution of cell suspensions plated into culture wells, until none of the wells yields growing cultures.

**Link protein:** Stabilizes the interaction of the hyaluronan-binding region of aggrecan and hyaluronan.

**Lipofuscin:** The accumulation of fluorescent age-pigment, largely consisting of chemically highly complex aggregates of peroxidated lipid and protein.

**Lipid rafts:** Membrane microdomains, specially enriched in cholesterol and sphingolipids and proteins, that are mainly involved in receptor signaling.

**Lipopolysaccharide (LPS):** A structural component of the outer leaflet of the outer membrane of Gram-negative bacteria. LPS has been recognized as a microbial toxin, namely endotoxin.

**LOC:** Lateral olivocochlear auditory efferent system.

**Long-Evans rat:** An outbred rat strain commonly used for cognitive aging research.

**Longevity:** The period of time an organism is expected to live under ideal circumstances.

**Longevity assurance genes:** genes that regulate lifespan.

**Longitudinal study:** In general a study which repeated observations on experimental units. It has advantages over cross-sectional studies because in cross-sectional data, only a single response is available for each of the experimental units. Longitudinal studies in contrast can show the change of age effects over time within individuals.

**Loudness recruitment:** An attempt to compensate for peripheral hearing loss by the internal amplification of acoustic energy, often leading to painful levels of perceived intensity.

**Low urinary tract syndrome (LUTS):** A complex of symptoms related to the low urinary tract including voiding symptoms (poor urinary flow, prolong urination, incomplete emptying) and storage symptoms (urge incontinence, nocturia, frequent urination).

**LPS:** Lipopolysaccharide; the major component of the outer cell membrane of gram negative bacteria.

**LRTI:** Lower respiratory tract infection.

**Luteinizing hormone (LH):** One of the pituitary gland gonadotropins.

**Macronutrient:** Differs from the term micronutrients because its positive contributions to body function are

## Glossary

detectable only when present as a large proportion of the diet.

**Macrovascular:** Large vessels.

**MaDMaT:** Mass-deficient mass tag.

**Magnetic resonance imaging (MRI):** An imaging method that uses magnetic fields, radio frequencies, and a computer to produce a detailed picture of the inside of the body.

**Maintaining sleep:** Sleep without waking.

**MALDI:** matrix-assisted laser desorption/ionization.

**MAPK:** Mitogen-activated protein kinases.

**Matrix and Bone gamma-carboxyglutamic acid proteins (MGP and BGP, respectively):** Vitamin K-dependent proteins that are involved in skeletogenesis and bone maintenance.

**Maximal mouth inspiratory pressure (PIMAX):** Pressure measured through a mouthpiece during a maximal inspiratory effort, performed either at residual volume or at functional residual capacity (FRC).

**MBP:** Membrane-bound proteins; can be stained with immuno-chemical methods.

**MCA:** Middle cerebral artery.

**MCAo:** Middle cerebral artery occlusion.

**Meaning of home:** Emphasizes the simultaneous consideration of ties inside of the aging persons to his or her physical and social environment.

**MECI:** a budding yeast protein that is a DNA damage checkpoint kinase that helps pause the cell cycle in response to DSBs, and is a paralog of *TELI* and an ortholog of ATR in humans and *rad3<sup>+</sup>* in fission yeast. *MECI* protein is required for the telomere length checkpoint.

**Mechano growth factor:** Splice variant of the insulin-like growth factor that responds to mechanical stimulation.

**Meconium:** The substance excreted by insects soon after their eclosion.

**Medial frontal cortex:** A cortical area located on the medial surface of the cerebral hemisphere of the rat and which is vulnerable to age-related decline. This region is strongly implicated in attentional set shifting. It consists of the infralimbic and prelimbic cortices.

**Medial temporal lobe system:** A brain system comprised of structures on the medial surface of the temporal lobe, including hippocampus, which are critical for emotion, memory and sensory processing.

**Menopause hormone therapy (MHT):** Hormones including estrogen, progestins, and testosterone used to control menopause symptoms.

**Metabolic syndrome:** A cluster of cardiovascular risk factors (abdominal obesity, dyslipidemia, increased glucose, hypertension) that precedes diabetes and is strongly associated with obesity and aging.

**Metabotropic:** A type of receptor linked to intracellular signal transduction cascades.

**Methacholine-induced bronchoconstriction:** Measurement of airway reactivity to inhaled methacholine (cholinergic agent). Spirometry (measurement of FEV<sub>1</sub> and FVC) is repeated after inhalation of increasing doses of methacholine until FEV<sub>1</sub> drops by 20% from initial value, defining the PD<sub>20</sub>, index of airway reactivity. Low PD<sub>20</sub> values are suggestive of asthma.

**MHC I:** Major histocompatibility complex I; the receptor that presents peptide antigens derived from sources inside the cell to T cells.

**MHC II:** Major histocompatibility complex II; the receptor that presents peptide antigens derived from sources outside the cell to T cells.

**Microarray:** A molecular biology technique that uses glass slides spotted with oligonucleotides or DNA fragments complementary to a large number of genes to quantitate the relative abundance of messenger RNA transcripts between two groups of samples.

**Micronutrient:** A single compound (e.g., a specific amino acid) derived from dietary foodstuffs that contributes positively to body growth or maintenance when present in a small proportion of the diet.

**Microsatellite:** Small regions of chromosomes that help localize genes.

**Microvascular:** Small vessels.

**Migrant studies:** Studies taking advantage of migration to one country by those from other countries with different physical and biological environment, cultural background and/or genetic make-up, and different morbidity or mortality experience.

**Minimal risk study:** The risk and magnitude of harm of the research study to the subject are no greater than what the subject would encounter in daily life or during the performance of routine physical or psychological examinations or tests.

**Minimal risk:** Risk of harm no greater than that experienced in everyday living.

**Minims:** The first group of sterile worker offspring in a new colony. They are smaller than the workers of a mature colony.

## Glossary

**Mismatch repair:** DNA repair system scanning newly replicated DNA in order to deal with replicative and recombinational errors leading to mispaired bases (mismatches) by excising the mutated strand in either direction from the mismatch.

**Mistuned harmonic:** A component of a periodic signal that does not share an integer relationship with the fundamental frequency.

**Mitochondria:** Unique organelles that supply most of the cell's energy via oxidative phosphorylation and possess their own primitive genome, replication of which is under control of the nucleus.

**Mitochondrial electron transport chain:** It is located in the inner mitochondrial membrane and it is the place where oxygen is reduced to water to obtain ATP. It consists in a variable number and type of protein complexes and associated electron transporters. In mammals it is formed by four electron transport complexes and the ATP synthase: complex I or NADH:ubiquinone oxidoreductase, complex II or succinate dehydrogenase, complex III or ubiquinone: cytochrome c oxidoreductase, complex IV or cytochrome c oxidase, and complex V or ATP synthase.

**Mitochondrial heteroplasmy:** The presence of two or more genetically distinguishable mitochondrial populations within a cell.

**Mitochondrial metabolic competence (MMC):** The mitochondrial efficiency in providing adequate amounts of high energy intermediates; for example, adenosinetriphosphate. MMC can be tested in different experimental conditions by quantitative estimations of the activity of enzymes of the mitochondrial respiratory chain evidenced by preferential cytochemical methods.

**Mnemonic:** Of or relating to memory.

**MO:** Antisense-morpholino oligonucleotide.

**MOC:** Medial olivocochlear auditory efferent system.

**Monogyny:** The condition when a colony is headed by a single fertile queen.

**Morpholino:** A specialized antisense oligonucleotide used to silence gene expression.

**Morris water maze:** First described by Richard Morris in 1984, a swimming task designed for rodents that can be used to measure the integrity of the medial temporal lobe system.

**Mosaicism:** Different cells (blastomeres) in the preimplantation embryo having different numbers of chromosomes; this condition arises after fertilization by mitotic nondisjunction of chromosomes.

**MRDT (mortality rate doubling time):** The time required for the mortality rate to double.

**MRSA:** Methicillin-resistant staphylococcus aureus.

**MRX:** A complex of proteins encoded by the *MRE11*, *RAD50* and *XRS* genes in yeast that has a role in checkpoint activation in response to DSBs, and has nuclease and helicase activities in vitro. In humans, the *XRS2* encoded subunit is substituted by the *NBS1* encoded subunit to form the MRN complex.

**MS:** Mass spectrometry.

**MS<sup>n</sup>:** Multidimensional mass spectrometry.

**mtDNA:** Mitochondrial DNA.

**Mucociliary clearance:** Refers to all items contributing to elimination of inhaled or aspirated particles in the airways: cough, production of mucus, regular movement of ciliae of bronchial epithelium.

**MudPIT:** Multidimensional protein identification technology.

**Multiphoton laser scanning microscopy (MPSLM):** An advanced form of confocal microscopy that uses infrared light instead of short-wavelength (high energy) light to excite fluorescent molecules introduced into the cell to measure various aspects of cell function. Because MPSLM does not damage cells, subcellular structures and organization can be monitored for long periods of time so that cell structure and function can be directly correlated within the same cell.

**MuLV:** Murine leukemia virus.

**Multipotent:** Stem cells that can differentiate into only a limited number of cell types.

**Mutation:** Change in the sequence of DNA in a genome that can involve a single base pair position (point mutation) or a rearrangement (deletions, insertions, recombinations).

**Mutation accumulation theory:** A theory of biological aging that proposes that biological senescence is due to the accumulation of harmful, mutant genes in later, post-reproductive years when natural selection is a declining force.

**Mya:** Million years ago.

**Myeloid:** White blood cell-related.

**Myocardial infarction:** Cardiac injury characterized by necrosis and scar formation.

**Myocardial ischemia:** Cardiac hypoxia, primarily due to impaired vascular supply to cardiac tissue.

**NADPH:** Nicotinamide adenine dinucleotide phosphate reduced.

## Glossary

- NADPH oxidase:** An enzyme that produces superoxide.
- Natural selection:** Proposed by C. Darwin and A.R. Wallace, a process in nature that results in increased survival rates of organisms having favorable traits.
- Necropsy:** Post-mortem examination.
- Nematode:** Unsegmented worms with elongated rounded body pointed at both ends; mostly free-living (*e.g. Caenorhabditis elegans*) but some are parasitic (*e.g. parayloides ratti*).
- Neuroanatomic:** Of or relating to neural tissue or the nervous system.
- Neurofibrillary tangles:** Insoluble fibrils of hyperphosphorylated tau protein with a characteristic twisted structure that, along with amyloid plaques, are the histological hallmarks of AD. These structures fluoresce when stained with Thioflavine S or Thioflavin T and may be extracellular (dead neurons) or intracellular (damaged neurons). These accumulate in the brain with age and in larger amounts in Alzheimer's disease.
- Neurogenesis:** Formation of nervous tissue.
- Neuron:** The main functional cell of the brain and nervous system, consisting of a cell body, an axon, and dendrites.
- Neuroprotective agents:** Medications that protect the brain from secondary injury caused by stroke.
- Neuroticism:** A personality trait in individuals who worry and are emotionally unstable.
- Neurotransmitter:** A substance that is released from the axon terminal of a presynaptic neuron on excitation, and that travels across the synaptic cleft to either excite or inhibit the target cell.
- NFkB:** Nuclear factor kappa B. A signal transduction factor that controls the transcription of many immune response genes.
- NGT:** Naso-gastric tube; tube inserted through either nostril, with its distal end placed in the stomach.
- NHAP:** Nursing-home-acquired pneumonia.
- Night terror:** Waking with intense fear and unresponsiveness to other people.
- Nightmare:** An unpleasant and/or frightening dream that usually awakens a person.
- Nocturia:** A need to wake at night one or more times to void.
- Nocturnal polyuria syndrome (NPS):** Nocturia and nocturnal polyuria due to a lack of diurnal rhythm in the antidiuretic hormone (ADH) system.
- Nonagenarian:** A person age 90 years and older.
- Nominal data:** Categorical data based on classifications.
- Noncognitive behaviors:** A range of diverse behaviors that do not explicitly involve learning or memory but could be related to cognitive status.
- Nonparametric method:** A statistical method for obtaining estimates and drawing inferences based on a function of the sample observations, the probability distribution of which does not depend on a complete specification of the probability distribution of the population from which the sample was drawn. Consequently, such a method will be valid under relatively general assumptions about the underlying population. Many nonparametric methods have been based on the ranks of the observed data.
- Normoglycemia:** Normal blood glucose levels with no changes greater than two standard deviations from the mean.
- NP:** Nosocomial pneumonia.
- Nucleotide excision repair:** When a small region of the strand surrounding the damage is removed from the DNA helix as an oligonucleotide, and the small gap left in the DNA helix is filled in by the sequential action of DNA polymerase and DNA ligase. Nucleotide excision repair recognizes a wide range of substrates, including damage caused by UV irradiation (pyrimidine dimers and 6-4 photoproducts) and chemicals (intrastrand cross-links and bulky adducts).
- Nude rat:** Hypothymic (nude) rats have only a remnant thymic stump and are dysfunctional with respect to T-cell maturation.
- Numeric density of mitochondria (Nvm):** A morphometric parameter defining the number of mitochondria/ $\mu\text{m}^3$  of cytoplasm. Nvm has been calculated by applying different morphometric procedures. It is reported to undergo significant changes in several physiological and experimental conditions.
- Numeric density of synapses (Nvs):** This morphometric parameter can be estimated by using the recently introduced dissector counting procedure, and provides information on the number of synapses/ $\mu\text{m}^3$  of neuropil. Studies conducted prior to the introduction of the dissector can be considered still reliable results if referred to local differences within an individual or if used to make synapses-to-neuron ratios.
- Nuremberg Code:** List of rules for "permissible medical experiments" involving human subjects included in the 1947 verdict of the presiding judges of the Nuremberg War Crimes Physicians Trial of Nazi physicians for "crimes against humanity" that consisted of experiments on concentration camp prisoners and others without their involuntary consent. The Nuremberg Code is the first internationally recognized code of ethics for research

## Glossary

involving human subjects and included requirements that (a) subject voluntary consent be obtained, (b) study benefits outweigh the risks, (c) the study should be conducted to avoid unnecessary harm and should not be done if there is an a priori belief death or injury will occur, and (d) the subject has the right to withdraw from the study at any time.

**Nursery colony:** In many colonial species of bats, pregnant females will roost and raise their offspring together. This behavior may provide necessary social interaction for developing young and certainly allows for thermo-regulation by clustering.

**NYHA:** New York Heart Association.

**O<sub>2</sub>:** Oxygen.

**OAE:** Otoacoustic emissions; reflect the physiological responses of OHCs.

**Object recognition:** The ability to classify and register the identity of objects based on a set of stimulus features or dimensions.

**Obstructive sleep apnea (OSA):** Apnea caused by a closure of the air passage despite efforts to breathe.

**OGT:** O-GlcNAc transferase.

**OHC:** Outer hair cell system of the cochlea.

**Omega-3 fatty acids:** Long chain polyunsaturated fatty acids found primarily in cold water marine fish that possess potent anti-inflammatory properties.

**Oocyte or egg:** The female gamete, from immature stages (germinal vesicle or GV) to completion of fertilization at syngamy (fusion of male and female genomes).

**Oogenesis:** Formation of new oocytes.

**Openness to experience:** A personality trait defined by a willingness to welcome new experiences.

**Oral glucose tolerance test:** Measure of glycemia after 75g oral glucose ingestion every 30 minutes up to two hours.

**Orlistat:** A drug used in the treatment of obesity. It is a gastrointestinal lipase inhibitor that acts by decreasing the amount of fat absorbed from the gut.

**Ortholog:** Genes that have similar function in different species.

**Orthostatic hypotension:** A drop in blood pressure that is precipitated by changes in body position, such as when rising from a chair or bed.

**Osteocalcin:** A major noncollagenous protein of the bone matrix synthesized by osteoblasts. During bone formation, osteocalcin is incorporated into the bone matrix. Serum levels of osteocalcin are used as a specific marker of bone formation.

**Osteopontin (OPN):** A secreted adhesive glycoprotein expressed in bone, kidney, and epithelial lining tissues, found in plasma. It is involved in a number of physiologic and pathologic events including angiogenesis, apoptosis, inflammation, wound healing, and tumor metastasis.

**Osteoprotegerin:** A cytokine produced by osteoblasts and vascular tissue; a potent inhibitor of osteoclast formation.

**Ovarian senescence:** A late stage of ovarian function when the ovary begins to fail, both in the production of fertilizable oocytes and from the endocrine standpoint: estrogen production declines, Follicle Stimulating Hormone (FSH) production by the pituitary gland increases, and loss of fertility ensues.

**Oxidative phosphorylation (OXPHOS):** The production of ATP using energy derived from the redox reactions of the electron transport chain.

**Oxidative stress:** Accumulation of free radicals that damage components of cell membranes, proteins and lipids and the presence of lower than normal levels of antioxidants.

**P:** Postnatal day.

**PaCO<sub>2</sub>:** Partial pressure of carbon dioxide in systemic arterial blood.

**PAI-1:** Plasminogen activator inhibitor-1.

**PaO<sub>2</sub>:** Partial pressure of oxygen in systemic arterial blood.

**Parametric method:** A procedure for testing hypotheses about parameters in a population described by a specified distributional form (e.g. a normal distribution).

**PARP:** Poly (ADP-ribose) polymerase.

**Pathogenesis:** The origination and development of a disease.

**PEF:** Peak expiratory flow; maximal expiratory flow obtained during a forced expiratory maneuver after a maximal inspiration.

**PEG:** Percutaneous endoscopic gastrostomy; tube placed through the abdominal wall allowing direct administration of nutritional supplementation into the stomach.

**P-elements:** Transposable elements that are widely used to make mutations and manipulate the genome.

**Peripheral hearing loss:** Problems in acoustic processing associated with deterioration, maturation, or damage to the ear.

**Person-environment fit:** Misfits between an older person's objective competencies or subjective needs and the potential of the environment to support or fulfill these

## Glossary

objectives; subjective personal characteristics are detrimental to using one's full developmental potential.

**Personality trait:** A characteristic or quality used to describe differences in the behavior of others. In psychology, the *Big Five* (personality traits) dominate.

**PG:** Proteoglycans; complex molecules that show age-related changes. These molecules can be stained with special histochemical techniques.

**Phenotype:** The characteristics of an organism as determined by both genetic makeup and environmental influences.

**Phenotypic plasticity:** An environmentally induced change in phenotype.

**Phosphoinositide turnover:** a second messenger of muscarinic and metabotropic glutamate receptor activation. Activation of this signaling cascade results in a release of intracellular calcium from the endoplasmic reticulum and releases protein kinase C.

**Photothrombosis:** The use of a photosensitizing dye and an ion laser to induce a thrombus.

**Phylogeny:** The evolutionary development and history of a species or taxonomic group of species.

**Physogastric queen:** A condition in certain insects where the abdomen becomes distended by the growth of reproductive organs.

**PI3-K:** Phosphoinositide 3-kinase.

**PKC:** Protein kinase C.

**Place attachment:** Reflecting feelings about a geographic location and emotional binding of a person to physical places.

**Place cell:** A neuron which fires action potentials in a specific location as the rat explores an environment. Generally they are pyramidal cells of the CA1 and CA3 hippocampus.

**Place field:** the area of an environment in which a place cell is most active.

**Plasma renin activity:** A measure of the activity of the enzyme that is the rate limiting step in producing angiotensin II and converts angiotensinogen to angiotensin I.

**Pleiotropy:** The effect of a gene on several different traits.

**PMCAo:** Permanent middle cerebral artery occlusion.

**Poikilotherms:** Said of animals whose internal temperature changes depending on the environment.

**Polygyny:** The condition when a colony has more than one fertile queen.

**Polymorphism:** A nucleotide or amino acid sequence variant that is present at a frequency of  $\geq 1\%$  in a defined population. Existence of a gene in several allelic forms.

**Polyphyodont:** Developing several sets of teeth successively throughout life.

**Polysomnography:** A diagnostic test during which a number of physiologic variables are measured and recorded during sleep.

**Population:** The entire set of individuals of interest.

**Positron emission tomography (PET):** PET is one of the noninvasive techniques developed during the past decades to measure some parameters of cerebral energy metabolism, for example, cerebral blood flow (CBF) and the cerebral metabolic rate for glucose (CMRGlc) or oxygen (CMRO<sub>2</sub>). Specifically in emission tomography, the image is generated by differences in the distribution in the tissue of injected or inhaled isotopes that are constituents of important biological molecules. The radiation emitted by the isotopes can be detected, analyzed, and used by a computer to visualize the zones where a specific biological molecule is metabolized. In PET, the isotopes of elements that decay after minutes or hours normally are used and emit positrons (positive charged particles similar in mass to electrons).

**Postmenopausal hypertension:** The increase in blood pressure that occurs in women usually 5 to 10 years following cessation of menstrual cycling; also used in female rat studies to indicate when they stop estrous cycling.

**Postmitotic:** Cells that are in a nondividing state.

**Power:** A probability representing the power of a given statistical test to detect a true difference or association.

**PPAR:** Peroxisome proliferators-activated receptor.

**Pregnancy Rate:** Ratio of the number of conceptions that occur during a period to the mean number of women of reproductive age. This is also defined as the percentage of male subjects whose partners achieved a pregnancy over a period of time.

**Preimplantation embryos:** the stage of embryo development from fertilization to blastocyst.

**Prelimbic cortex:** A region of medial prefrontal cortex that together with infralimbic cortex in rodents has been suggested as analogous to the dorsolateral prefrontal cortex in humans. This region is implicated in attentional set shifting.

**Pre-patent period:** the time between infection and symptoms becoming apparent, which often differs from the latent period.

## Glossary

**Prepulse inhibition:** Reduction of startle response due to a sound presented just prior to the startle stimulus.

**Presbycusis:** Loss of hearing sensitivity for high frequencies traditionally associated with normal aging.

**Pressure-natriuresis relationship:** When sodium intake increases, the blood pressure increases until the sodium is excreted.

**Prevalence:** The proportion of people with a disease in a population at a given point in time.

**Prevention:** Actions aimed at eradicating, eliminating, or minimizing the impact of disease and disability. Usually broken down into *primary prevention* (protection of health by prevention of disease occurrence), *secondary prevention* (early detection and prompt intervention to minimize sequels of disease), and *tertiary prevention* (softening the impact of long-term disease and disability).

**Primate colonies:** Groups of captive, nonhuman primates kept and maintained in specialized facilities for the purpose of study.

**Primitive segregation:** Use basic stimulus properties to segregate the incoming sounds. Listeners may be innately tuned to these properties and thus they do not depend on specific experiences. These grouping mechanisms most likely utilize general properties of sound sources, such as frequency, intensity, phase, harmonicity, and temporal coherence.

**Procedural learning:** Skill acquisition.

**Progeria/progeroid:** Accelerated or premature appearance of the signs and symptoms of aging. A disorder characterized by premature aging.

**Progressive resistance training:** A form of exercise (weight training) that is particularly useful in building up skeletal muscle that may help to increase strength, metabolic rate, and well-being.

**Proliferation:** The expansion of a population of cells by repeated rounds of cell division.

**Proteopathy:** disease state that is characterized by accumulation of misfolded proteins which has toxic consequences. Amyloid diseases are examples of proteopathies.

**Proteasome:** Cellular enzymatic processing system of proteins either for presentation or disposal.

**Proxy:** The legally authorized decision-maker for a person for the time the person lacks decision-making capacity.

**Pulse oximetry:** Noninvasive (transcutaneous) measurement of saturation of hemoglobin by oxygen (SaO<sub>2</sub>).

**Pure-tone audiogram:** Basic clinical measurement of hearing sensitivity.

**p-value:** the probability of obtaining a test statistic that is as extreme or more extreme than the test statistic observed from the sample given that the null hypothesis is true.

**Q10 (temperature coefficient):** The ratio of the rate of a reaction at one temperature divided by the rate of the same reaction at a temperature 10°C less. The larger the Q10, the greater the effect the temperature has on the reaction.

**QAI:** Quantitative analysis of images; allow us to make a morphometric quantitative analysis of the studied structures.

**Quantitative trait loci (QTL):** Genetic (chromosomal) regions linked to a phenotype by mapping the phenotype against known genetic markers.

**Queen:** A female reproductive in an ant colony. Usually there is one or a group of related queens in a colony.

**rad3<sup>+</sup>:** The fission yeast ortholog of budding yeast *MEC1*. Mutants in *rad3<sup>+</sup>* alter telomere length in fission yeast to a greater extent than *MEC1* mutants in budding yeast.

**RAGE:** Receptor for AGE.

**RAP1:** The budding yeast gene that encodes the major double-stranded yeast telomere binding protein. The C-terminus of the *RAP1* protein interacts with a number of important proteins in yeast telomere length regulation, gene silencing and aging including the proteins encoded by *RIF1*, *RIF2*, *SIR2*, *SIR3* and *SIR4*. The human and fission yeast orthologs of *RAP1* are smaller proteins that lack the DNA binding domain, and instead associate with telomeres by binding to the Myb-domain telomere binding proteins TRF2 (human) and *taz1<sup>+</sup>* (fission yeast).

**Rate of living theory:** Introduced in 1928 by R. Pearl who observed the life prolonging effect of caloric restriction on domestic animals by reducing the metabolic rate and argued that metabolic rate determines longevity, and the slower the rate of metabolism, the longer an organism will live. A mechanism was later postulated proposing that oxygen radicals cause damage resulting in aging and death. Empirical evidence does not support Pearl's theory in general.

**Rate:** The ratio of the number of events in a group of individuals at risk for the event divided by the total time units contributed by the individuals at-risk of the event.

**Reactive oxygen species:** Products of the incomplete reduction of oxygen. There are different reactive oxygen species, including superoxide (O<sub>2</sub><sup>•-</sup>), a product of univalent reduction of oxygen, hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>), a product of bivalent reduction of oxygen, and hydroxyl radical (•HO), a product of trivalent reduction of oxygen.

**Receptor activator of NF- $\kappa$ B ligand (RANKL):** An essential molecule for osteoclast development, expressed on the surface of bone marrow stromal and osteoblast precursor cells, T- and B-cells. RANKL binds its cognate receptor, RANK, on osteoclast lineage cells, and can be neutralized by osteoprotegerin.

**RecQ helicases:** A family of five related human proteins that contain an evolutionarily conserved helicase consensus/ATPase domain. All members facilitate nucleic acid metabolism by using energy from the hydrolysis of ATP or other nucleotide triphosphates to disrupt hydrogen bonds in DNA or RNA. The human RecQ helicases appear to have arisen by gene duplication and divergence, and are part of a deeply rooted evolutionary lineage of similar helicases found in all kingdoms of life.

**Redundancy exhaustion:** The process when an initially redundant system degenerates into a system with no redundancy because of damage accumulation.

**Redundancy:** The use of more components than are needed to perform a function; this can enable a system to operate properly despite failed components.

**Region of interest planimetry:** A method of measuring in vivo tissue sections on digital images in a defined spatial region.

**Relative risk:** The ratio of the risk of disease or death among those exposed to a factor compared to those not exposed.

**Reliability:** The ability of a system (or its component) to operate properly according to a specified standard.

**Reliability function:  $S(x)$ :** the probability that a system (or component) will carry out its mission through time  $x$ . The reliability function (also called the survival function) evaluated at time  $x$  is just the probability  $P$  that the failure time  $X$ , is beyond time  $x$ .

**Reliability structure:** The arrangement of components that are important for system reliability. Reliability structure is graphically represented by a schema of logical connectivity (e.g. components connected in series, or in parallel).

**Reliability theory:** A general theory of system failure. Reliability theory is a body of ideas, mathematical models, and methods directed to predict, estimate, understand, and optimize the lifespan and failure distributions of systems and their components.

**REM:** Rapid-eye-movement.

**Renal ablation:** The removal of one kidney and either the poles of the other kidney or the ligation of two of the three branches of the renal artery going to the kidney in the rat, which produces hypertension, hyperfiltration, and renal injury. (Also known as 5/6 ablation.)

**Renin-angiotensin-aldosterone system (RAAS):** A hormone system that plays a role in sodium and potassium handling of the kidney and that causes vasoconstriction of the vasculature.

**Renovascular hypertension:** A maneuver that was first used by Goldblatt in which a silver clip is placed on the renal artery in a young rat and as the rat grows, the perfusion pressure to the kidney decreases, the contralateral kidney becomes hypertrophied, and hypertension develops. (Also known as 2-kidney, 1-clip, or Goldblatt hypertension.)

**Replicative life span:** The number of daughter cells produced by a mother cell prior to senescence.

**Replicative senescence:** Process leading to an irreversible cell cycle arrest, usually as a consequence of extensive proliferation.

**Reproductive cloning:** Using nuclear transfer to produce viable cloned individuals

**Reprogramming:** The termination of one gene expression program and the initiation of another.

**Research intermediary:** Person charged with detecting potential research subject vulnerability and concerns after the initial informed consent has taken place.

**Respect for persons:** The prima facie ethical principle that requires investigators to acknowledge that individual human subjects are autonomous agents with the right of self-determination; informed consent derives from this principle; the principle also requires that investigators protect subjects with diminished autonomy from exploitation and harm.

**Resting energy expenditure (REE):** Basal metabolic rate; equivalent to the amount of energy used up in the basal state, with no contribution from exercise or food intake.

**Restless legs syndrome (RLS):** A sleep disorder characterized by an irresistible urge to move the legs.

**Restless sleep:** Recurrent body movements, arousals, or brief awakenings in the course of sleep.

**Retroviral vectors:** The vectors derived from retroviral genome and used in insertional mutagenesis.

**Rhesus macaque (*Macaca mulatta*):** Old World monkey species that is well characterized in extensive laboratory investigations and an excellent biomedical model due to similarity to humans.

Rhesus macaque, the most popular species of old world monkey for biomedical research.

**RIF1 and RIF2:** Two genes encoding proteins that interact with the *RAP1* protein C-terminus to regulate telomere length.

## Glossary

**Risk:** The probability that an event (e.g. death) will occur within a stated period of time or by a certain age.

**RNA:** Ribonucleic acid; a nucleic acid consisting of a string of covalently-bound nucleotides. One of the main functions of RNA is to copy genetic information from DNA (via transcription) and then translate it into proteins (by translation).

**RNAi:** A naturally occurring, double-stranded, RNA-mediated mechanism for silencing of gene expression which can be exploited for loss-of-function experiments.

**ROI:** Reactive oxygen species.

**ROS:** reactive oxygen species.

**RR:** Respiratory rate.

**RSV:** Respiratory syncytial virus.

**RV:** Residual volume.

**SA- $\beta$ -gal:** Senescence associated  $\beta$ -galactosidase

**Sagging:** Flaccidity. Sagging skin is one of the most noticeable consequences of chronic exposure to ultraviolet A.

**SAMP:** Senescence accelerated-prone mice.

**Sample:** A subset of the population, usually random draws from the original population.

**SAMR:** Senescence accelerated-resistant mice.

**SaO<sub>2</sub>:** Oxygen saturation measured by pulse-oximetry.

**Sarcopenia:** Age-related decline in skeletal muscle mass and strength. Often happens in parallel to osteopenia or age-related bone loss.

**Saturation mutagenesis:** A mutagenesis method to randomly generate mutations to saturate the genome.

**Schema-driven segregation:** Using knowledge from past experience to group the acoustic input into meaningful mental representations. These schemata are thought to be learned and therefore are dependent on a listener's specific experiences.

**Scleroderma:** A rare, chronic, systemic, and progressive disease of unknown etiology, characterized by tissue fibrosis, small vessel vasculopathy, and autoimmunity. Also known as systemic sclerosis. Can affect skin, lungs, heart, gastrointestinal tract, kidneys, and musculoskeletal system.

**Secretases:** The proteases that cleave the A $\beta$  peptide out from the  $\beta$ APP precursor protein.  $\beta$ -Secretase (BACE) releases the amino terminus of the peptide while the  $\gamma$ -secretase (Presenilin 1,2) complex cuts at the carboxy terminus of the peptide.  $\alpha$ -Secretase cuts  $\beta$ APP in the middle of the A $\beta$  peptide sequence, preventing amyloid fibrils from forming.

**SELDI:** Surface enhanced laser desorption ionization; mass spectrometry system producing spectra of complex protein mixtures based on the mass/charge ratio and binding affinity to the chip surface. Differentially expressed patterns of proteins can be identified in these profiles by applying bioinformatics programs.

**Selection bias:** Error due to systematic differences in characteristics between those who participate in a study and those who do not.

**Selection: Optimization: and Compensation Theory (SOC):** Proposes that to age successfully, an individual must actively select from available options. They must also optimize their use of available resources and work to maintain a level of functioning, even in the face of actual or anticipated declines.

**Selective Theory:** This theory of behavioral aging argues that, with increased awareness of diminishing longevity in old age, a successful person will become increasingly selective and focused on acquiring emotional meaning in their remaining time.

**SEM:** Scanning electron microscopy; allows us to observe the surface morphology of organs and tissues.

**Semitone:** Corresponds to the interval between two adjacent musical notes on a chromatic scale (i.e., 1/12 octave). The frequency ratio is roughly 1.06 for all pairs of adjacent notes.

**Senescence:** Time-dependent changes seen in living organisms that have cumulative and deleterious effects.

**Senile plaques:** Extracellular condensed deposits of A $\beta$  fibrils and a hallmark of AD that give classic amyloid reactions with Congo Red and the Thioflavine dyes. These are often cross-linked and chemically modified. Diffuse plaques are comprised of A $\beta$  that is not in fibrils and do not stain with the classical amyloid dyes. These structures are less modified than the senile plaques.

**Sensorimotor:** Both sensory and motor. Within the context of aging research, it is important to distinguish these types of deficits those related to cognitive function.

**Sequential sound segregation:** The separation of acoustic energy over a series of time points. Involves a broad-based analysis of spectral and temporal information.

**Serotonergic system:** The system of nerve cells that uses serotonin as their neurotransmitter.

**Serial analysis of gene expression:** A molecular biology technique that measures the relative abundance of messenger RNA transcripts between two groups of samples.

**Set shifting task:** An attentional task that measures the integrity of the prefrontal-cortical system. Different versions can be used to assess function in humans, nonhuman primates or rodents.

**SHBG:** Sex hormone binding globulin.

**Sibutramine:** A drug used in the treatment of obesity. It decreases food intake by promoting satiety through inhibiting central reuptake of serotonin and noradrenalin.

**Significance level:** The probability, alpha ( $\alpha$ ), of committing a type I error for the test of a given hypothesis ( $100 \cdot \alpha$ )% of the time. Typically, this level is preset and thus represents the researcher's tolerance for incorrectly rejecting the null hypothesis.

**Silent mating type cassettes:** Both budding yeast and fission yeast have two mating types, and mating type is controlled by the gene present at the expressed mating type locus (the *MAT* locus in budding yeast). In addition to *MAT*, there are two other copies of *MAT* that are not expressed. In budding yeast, these loci are called *HML $\alpha$*  and *HMR $\alpha$* , and their expression is silenced by the action of the *SIR* proteins and a number of chromatin modifications.

**Single-cell recordings:** Extra-cellular registration of the action potentials of single neurons, often done while the animal is awake and behaving.

**SIR2-genes (Silent Information Regulator genes):** A gene family that is conserved from bacteria to humans. The gene product is a NAD<sup>+</sup> dependent histone deacetylase. It is involved in regulation of life span and acts in silencing, cell cycle progression, and chromosome stability. It is a member of a family of proteins called sirtuins, which also includes seven mammalian homologues among which are SIRT1 and SIRT3.

***SIR* proteins: *SIR1: SIR2: SIR3: SIR4:*** the four Silent Information Regulator proteins that control the expression of silenced loci at the silent mating type cassettes, telomeres and the rDNA array. Classically, gene silencing in budding yeast was the repression of gene expression at the silent mating type cassettes, which is controlled by these proteins. Of these proteins, *SIR2* protein is the one most universally conserved throughout evolution, although *SIR3* has some homology to the DNA replication protein encoded by *ORC1*.

**SIR2-genes:** A gene family which is conserved from bacteria to humans. The gene product is a NAD<sup>+</sup> dependent histone deacetylase. It is involved in regulation of lifespan and acts in silencing, cell cycle progression, and chromosome stability.

**siRNA:** Small, interfering RNA fragments used in RNAi experiments to silence gene expression.

**Skeletal muscle:** Allows joint movement by contraction and relaxation of its contractile proteins.

**Sleep apnea syndrome (SAS):** The propensity of cessation of breathing for 10 or more seconds during sleep.

**Sleep-disordered breathing:** Impaired breathing during sleep.

**Sleep efficiency:** The ratio of total sleep time to time in bed.

**Sleep/wake cycle or sleep/wake rhythm:** The periodical pattern of sleep and wakefulness.

**Snoring:** Often correlated with the severity of airway obstruction and apnea

**SOAE:** Spontaneous otoacoustic emission.

**Social Convoy model:** Among the most prominent theories of social aging and life-span development of social relationships in recent time, suggested by Antonucci. According to this model, an individual's social world is structured hierarchically. The metaphor of a social convoy is viewed as illustrating the life-long dynamic of social ties over the life course. As an individual grows old, his or her relationships and relationship partners change synchronously while he or she moves along the time continuum of his or her life course.

**Social Disengagement theory:** Proposed that the normal course of aging includes a mutual withdrawal between society and the aged person, ultimately ending in death.

**Social Integration theory:** As suggested by Rosow, the theory argues that loss of social roles in later life requires that individuals develop new age-specific and age-adequate social roles. According to the theory, older people, who live in age-segregated environments, are more likely to identify themselves with their age group and their neighborhood.

**Social lifespan:** Refers to Lewin's notion of a psychological life space and reflects the individual's decreasing social opportunities during the aging process.

**Social-physical agency:** Assumed in the Social-Physical Place Over Time model to represent a major motivation as people age; that is, actively changing one's social and physical environments according to one's personal goals and needs.

**Social-physical belonging:** Assumed in the Social-Physical Place Over Time model to represent a major motivation as people age; that is, developing strong emotional and cognitive ties to one's social and physical environments.

**Social-Physical Place Over Time model:** The major purpose of this model, suggested by Wahl and Lang, is to achieve a combined view of aging in social and physical environments.

**Sociality:** The nature of being social.

**Socio-emotional Selectivity Theory (SST):** This theory of behavioral aging predicts that, as individuals age,

## Glossary

they increasingly restrict social networks to fewer relationships with only their closest friends and family members.

**Socioemotional Selectivity Theory:** Carstensen argues that over the course of life, individuals become increasingly aware that time is a precious resource that is limited. As a consequence, when people perceive time as limited they are more eager to make the most efficient use of their time by focusing on aspects in their present lives that promise to entail meaningful experiences. According to the theory, such experience is expected to be associated with seeking emotional meaning rather than with seeking new information that will be useful in the more distant future.

**Somatic cell nuclear transfer (SCNT):** The process of transplanting nuclei from adult or fetal somatic cells to an oocyte to produce a developing cloned embryo.

**Sp1:** A nuclear transcription factor.

**Spatial learning and memory:** The ability to locate objects in space and use spatial information.

**Specific pathogen-free (SPF):** Health status of an animal colony, in which animals are tested routinely and shown to be free of antibodies to specific viruses.

**Sperm morphology:** Shape of the spermatozoon. This is most commonly defined as the percentage of normal sperm.

**Sperm motility:** Ability of the spermatozoon to move by flagellate swimming. This is most commonly assessed visually by light microscopy and defined as a percentage of motile sperm.

**SPIN:** Speech in noise test; speech recognition is measured in presence of multi talker babble.

**Spindle Chromosome Complex (SCC):** The complex of condensed chromosomes organized on a meiotic or mitotic spindle.

**Spontaneously hypertensive rats (SHR):** A rat strain that spontaneously develops hypertension as it matures.

**SRT:** Speech reception threshold; a measure of sensitivity to speech in quiet.

**Standardization (syn.: adjustment):** A set of techniques used to reduce the effects of confounding due to age or other factors when comparing two or more populations by making them comparable with respect to these specific confounding factors.

**Stochastic:** Random or by chance.

**Stochastic model:** A model which includes the effects of chance in the form of one or more random processes so that repeated model runs will produce a distribution of outcomes; the reasons underlying results obtained

are often less easy to interpret than with deterministic models.

**Striatum:** A region in the basal ganglia consisting of the caudate nucleus and the putamen and which has been implicated in some forms of executive function.

**Subarachnoid hemorrhage:** Bleeding within the meninges, or outer membranes of the brain into the clear fluid that surrounds the brain.

**Subfecundity:** Percent of couples remaining infertile at a defined time point. Most commonly, this is referred to as the time-to-pregnancy for couples.

**Subiculum:** Part of the hippocampal formation that sends hippocampal efferents to other cortical regions, including cingulate cortex.

**Successful aging:** Varyingly defined, used here as a combination of longevity and happiness.

**Supercentenarian:** A person 110 years old or older.

**Superovulation:** Recruitment of many ovarian follicles instead of just one or two in the natural menstrual cycle, by injecting daily doses of FSH followed by human Chorionic Gonadotropin (hCG), usually recombinant hormones in primate ART. Either oocytes are allowed to ovulate into the oviduct, in nonprimate species, or are aspirated by needle puncture prior to ovulation in primates.

**Survivors: type I:** A term used for a type of yeast cell that lacks telomerase activity and whose telomeres have shortened to the point that the telomere length checkpoint has been activated, cells in the culture have arrested and a subpopulation of cells have grown up that can now replicate their telomeres without telomerase using replication-based mechanisms. Type I survivors have amplified the subtelomeric repeat Y' so that it appears to be present at all telomere ends.

**Survivors: type II:** Similar to survivors, type I, except that instead of amplifying Y' elements, the telomeres of these yeast cells have long heterogeneous arrays of TG<sub>1-3</sub> repeats at their ends instead of Y' elements with short TG<sub>1-3</sub> repeats.

**Surface density of the synaptic contact zones (Sv):** A morphometric parameter reporting on the overall area of the synaptic contact zones/ $\mu\text{m}^3$  of neuropil. Sv is calculated by different methods and it is reported to constitute the structural basis, attained during experience-driven maturation, of acquired skills.

**Synaptic remodeling (supposed steps):** Synaptic junctional areas are in a very dynamic condition and their ultrastructural features can be modulated according to environmental stimuli. At present, it has been supposed that, as a consequence of repeated stimulations, the synaptic size may increase two- to three-fold, and

## Glossary

these megasynapses can perforate and split into smaller junctional areas that can undergo a new remodeling cycle.

**Synaptic ultrastructural homeostasis (SUH):** The inverse correlation between numeric density (Nv), average synaptic size (S), documented by many authors in different experimental paradigms, seems to aim at maintaining the synaptic surface density (Sv) constant under changing environmental stimulations. The term SUH serves to define the observed balanced changes between Nv and S, occurring in the physiological process of the functional remodeling of neural networks, in the maintenance of a constant Sv value. Accordingly, any derangement in SUH mechanisms may represent a potential unfavorable and subtle factor triggering synaptic pathology events.

**Synovium:** A thin, weak layer of tissue that lines the noncartilaginous surfaces within the joint space, sealing it from the surrounding tissue.

**System reliability theory:** A branch of reliability theory, which studies reliability of an entire system given reliability of its components and components' arrangement (reliability structure).

**T:** Testosterone.

**tBH:** t-butyl hydroperoxide.

**T cell:** T lymphocyte; The lymphocyte that matures in the thymus and regulates both the type and extent of an immune response by secreting cytokines.

**tau:** a protein normally in complex with, and conferring stability to, microtubules, the cytoskeletal framework along which cellular components are transported. Hyperphosphorylation of specific sites of tau prevents its association with microtubules, leading to misfolding and aggregation of the phospho-tau into neurofibrillary tangles.

**TCR:** T cell receptor; the antigen specific receptor on the T cell that binds to MHCs on other cells.

**TEL1:** A budding yeast protein first discovered as a regulator of yeast telomere length and later found to be an ortholog of human ATM, a DNA damage checkpoint kinase. The fission yeast ortholog is called *tell*<sup>+</sup>. Deletion of the *TEL1* gene causes cells to maintain telomeres at about 1/3 their normal length while simultaneous deletion of *TEL1* and *MEC1* causes cells to behave as if they have no telomerase, possibly because telomerase cannot access the 3' end of the chromosome.

**TEL2:** A budding yeast protein first discovered as a regulator of yeast telomere length. Unlike *TEL1* and many other genes in yeast telomere length regulation, deletion of the *TEL2* gene is lethal to yeast. The *C. elegans*

ortholog of *TEL2* suggests that this protein has a role in the DNA damage checkpoint response and in aging (the worm gene is called both *rad-5* and *clk-2*). The function of *TEL2* has yet to be defined.

**Telomerase:** The enzyme which synthesizes the TG strand of the telomere from an internal RNA template, composed of at least the telomerase reverse transcriptase protein subunit and the telomerase RNA. Often referred to as TERT or TRT for the protein subunit, with a single letter prefix such as "h" for human and "y" for yeast to designate the species of the protein being discussed. Other proteins may be part of the holoenzyme that allows the core telomerase subunit to access and elongate the telomere. See *EST* proteins.

**Telomere:** The chromosome end which in vertebrates is composed of many copies of the hexanucleotide repeat 5' TTAGGG 3' along with associated DNA binding proteins.

**Telomere length checkpoint:** The cell cycle checkpoint that halts cell cycle progression when telomere length becomes too short, usually due to lack of telomerase activity. This checkpoint can be avoided by expression of telomerase, or in human cells it can be bypassed by the expression of oncogenes such as SV40 T-antigen.

**Telomere repeats:** See CA strand and TG strand.

**Tendon:** A tough band of fibrous connective tissue, attached on one end to a muscle and on the other to a bone.

**TEOAE:** Transient otoacoustic emissions.

**TERC:** Telomerase RNA complex.

**Terminal restriction fragment (TRF) analysis:** In the context of telomere biology, the analysis by gel electrophoresis of telomere fragments obtained by digestion of genomic DNA with a restriction enzyme. The TRF includes the telomere repeat plus adjacent sequence up to the restriction site. TRFs are typically resolved as an overlapping smear, following Southern blotting using a telomere-probe, reflective of the species-specific diversity of sizes of telomere arrays.

**TERT:** Telomerase reverse.

**Tetrode:** Four electrodes twisted together to enable action potentials of many neurons to be distinguished through triangulation. The tetrode is particularly effective for densely packed layers of cells such as the CA1 hippocampus.

**TGF- $\beta$ :** Transforming growth factor  $\beta$ .

**TGF- $\beta$ 1:** Transforming growth factor beta-1.

**TGR (hAOGEN-hREN) rat:** A strain that was produced from a cross between transgenic rats harboring human

## Glossary

angiotensinogen gene and human renin gene, in which the renin-angiotensin system is activated, causing severe hypertension.

**TGR (mREN2)27 rat:** A transgenic rat that harbors the murine *Ren-2* gene (for renin) on the genetic background of the normotensive Sprague Dawley rat.

**TG strand:** The 3' strand of the chromosome end, bearing the telomere repeat sequence TTAGGG in humans and TG<sub>1-3</sub> in budding yeast.

**Th-1 cell:** The T lymphocyte subset that produces primarily cytokines, which propagates cell-mediated immunity.

**Th-2 cell:** The T lymphocyte subset that produces primarily cytokines, which propagates humoral (antibody-mediated) immunity.

**Thalamus:** Brain system that relays and integrates information between other parts of the brain to and from the cerebral cortex.

**Therapeutic cloning:** Using nuclear transfer to produce cloned embryos, from which can be derived embryonic stem cells, which can then be used for treating disease.

**Thermoneutral temperature:** Range of temperatures at which an animal does not have to actively regulate its body temperature by increasing metabolic rate.

**Thioflavin T: Thioflavine S:** Benzothiazole dyes that fluoresce in a classic amyloid reaction when bound to amyloid fibrils formed from many types of misfolded proteins, but not the normal proteins.

**Thrombotic stroke:** A stroke caused by thrombosis.

**TLC:** Total lung capacity.

**TLC1:** The gene encoding the budding yeast telomerase RNA.

**T-loop:** A telomere-specific structure formed from the 3' G-rich, single-stranded end of telomeric DNA by invasion of adjacent double-stranded telomeric DNA to form a D-loop, together with binding and stabilization by telomeric proteins. The T-loop protects chromosome ends from degradation or recognition as a single-ended DNA double-strand break.

**TLRs:** Toll-like receptors; recognition proteins that detect microbial lipids, proteins, sugars, and nucleic acid and trigger innate immune responses.

**TMA:** Tissue microarray.

**tmax:** Maximum lifespan, generally estimated from longevity records.

**TMCAo:** Transient middle cerebral artery occlusion.

**TOF:** Time of flight.

**Toluidine blue:** Basic staining for the observation of the morphological features of organs and tissue.

**Top-down processing:** See schema-driven segregation.

**Total energy expenditure:** Overall use of calories during a whole day comprising basal metabolic rate plus calories used in exertion and in association with eating.

**Totipotent:** With the potential to differentiate and generate a complete organism

can be derived embryonic stem cells, which can then be used for treating disease.

**t-PA:** See recombinant tissue plasminogen activator.

**TR:** Telomerase RNA.

**Trachea:** One of the internal respiratory tubes of insects and some other terrestrial arthropods.

**Tracheole:** A delicate tubule that extends from a trachea; the site of gas exchange between the tracheal system and the tissues.

**Transcription factor:** A protein, including an enzyme or coenzyme, a vitamin or other organic molecule which controls or affects the process of gene transcription, usually through the binding of a specific DNA sequence motif.

**Transcriptome:** The complete set of mRNAs of a given cell or cell type.

**Transformation:** In the context of the in vitro cellular phenotype, the process whereby a cell loses contact inhibition and anchorage dependence, acquires the ability to form colonies in semisolid media, exhibits decreased requirements for growth factors and overcomes the Hayflick Limit to become immortalized.

**Transforming growth factor- $\beta$ :** A growth factor that plays crucial roles in tissue development, cell differentiation, embryonic development, as well as numerous other signaling pathways.

**Transgene:** An artificial gene produced by recombinant DNA.

**Transgenic:** Animals, often mice, which have a foreign or modified gene implanted in their genetic material which is expressed under control of a promoter that specifies when and where that gene will be expressed.

**Transient ischemic attack (TIA):** A short-lived stroke that lasts from a few minutes up to 24 hours; often called a mini-stroke.

**Transmission dynamics of infection:** For the population as a whole, the evolution of incidence of infection and disease over time mediated by processes of demography, contact, transmission, infection and immunity etc.

## Glossary

**TRAP:** Telomerase Repeat Amplification Protocol also known as the TRAP assay. An assay which measures the presence of telomerase in a cell or tissue extract usually by primer extension wherein TTAGGG repeats are added to a synthetic oligonucleotide by the telomerase enzyme.

**Treg:** T regulatory cell; a T lymphocyte that expresses both the CD4 and CD25 receptors, and primarily produces the anti-inflammatory cytokine IL-10.

**Trophectoderm:** That part of the blastocyst that in primates makes intimate contact with the uterine epithelium as a prelude to implantation, and will form the fetal membranes.

**TUNEL:** Terminal transferase-dUTP nick-end labeling.

**Type 2 diabetes mellitus:** The diagnosis should be made on the basis of a fasting plasma glucose level of 126mg/dL (7.0 mmol/L) or greater on at least two occasions.

**Type I error:** The error of rejecting the null hypothesis when it is true.

**Type II error:** The error of accepting the null hypothesis when the alternative is true.

**Types I and II mortality:** Simplified representations of natural mortality in a population. Type I mortality is commonly used to represent mortality in industrialized developed countries; it provides a uniform age distribution as it involves no mortality until a limiting age is reached when all die. Type II is commonly used to represent mortality in developing countries with growing population; it involves a per capita natural mortality rate that does not change with age and provides a population age distribution that exponentially declines with increasing age.

**Ultrasound:** Imaging technique that uses sound waves to produce high-resolution two-dimensional images.

**Ultraviolet:** The range of electromagnetic radiation emitted by the sun and reaching earth, with wavelength between 280 and 400 nm. UV has been subdivided in UVA (315–400 nm) and UV B (280–315 nm), 315 nm being the cut-off wavelength of a specific glass. The intensity of UVB changes with latitude, altitude, meteorological conditions, and time of the day. UVA is much less dependent on these factors and is not filtered off by usual windows. Solar UV contains 20 to 50 times more UVA than UVB. UVB is directly absorbed by DNA, whereas UVA provokes only indirect, oxidative damages to macromolecules. Both UVA- and UVB-generated DNA damages are mutagenic.

**Universal:** A characteristic that is applicable everywhere, across cultures, or in all cases.

**Vagile:** Able to move around or disperse.

**Varicocele:** Dilation of the internal spermatic veins that drain the testicle. It is a very common condition present in 15% of the general male population and 40% of men evaluated for infertility.

**Vascular calcification:** A pathological process that involves active mineralization by chondrogenic and osteogenic cells in the vasculature.

**Vascular dementia:** A step-like deterioration in intellectual functions accompanied by focal neurological signs, as the result of multiple infarctions of the cerebral hemispheres.

**Vasomotor symptoms:** Hot flashes, night sweats.

**VEGF:** Vascular endothelial growth factor.

**Ventilatory response:** Defines the changes in ventilation induced by changes in either arterial oxygen pressure, carbon-dioxide pressure, or pH.

**Visceral fat:** Fat in the omental or abdominal dept. Fat in this region is particularly associated with features of the metabolic syndrome.

**Volume density of mitochondria (V<sub>v</sub>):** Defines the volume fraction of cytoplasm occupied by mitochondria. The V<sub>v</sub> value is given as mitochondrial  $\mu\text{m}^3/\text{cytoplasmic } \mu\text{m}^3$  and is reported to be constant throughout the individual's lifespan.

**Voxel-based morphometry (VBM):** Involves a voxel-wise comparison of the local concentration of grey or white matter between two groups of subjects to distinguish regional differences in brain atrophy.

**Weibull law:** The model predicting that failure rates are increasing as a power function of age. It was initially suggested by the Swedish engineer and mathematician Waloddi Weibull in 1939 to describe the strength of materials. According to the Weibull law, the logarithm of failure rates is increasing linearly with the logarithm of age.

**Worker:** The sterile female offspring of the queen that perform all of the tasks in the colony.

**Working memory maintenance:** The transferring, maintaining, and matching of information actively held in working memory.

**Working memory manipulation:** The reorganization or updating of information in a memory set.

**Working memory:** The temporary storage of information.

**X and Y' repeats:** Yeast middle repetitive DNA elements that are found at the telomere. X elements contain a conserved DNA sequence element but the sequences surrounding this core element are heterogeneous. The Y' element is more highly conserved, and is present in mostly 5.4 and 6.7 kb sizes. The X element is present at all

## Glossary

telomeres while the Y' element is present at some or all telomeres, depending upon the lab yeast strain. The Y' element is always closer to the chromosome end than the X element, and provides conserved sites adjacent to the TG<sub>1-3</sub>' repeats of many different telomeres.

**Years of life lost:** A measure of the relative impact of various diseases and lethal forces on society calculated as the sum, over all persons dying (or getting disabled) from a particular disease, of the years that these persons would have lived had they reached a specified age.
